In this study, Moran Index (I) in global and local version (Local Indicator of Spatial Association - LISA) has been calculated: it provides an overall measure of Spatial Autocorrelation [10]. Spatial autocorrelation is a property of spatial data that exists whenever there is a systematic pattern in the value recorded at different locations in an area [7]. Moran scatter plot [2] allows achieving a graphic representation of spatial relationships and enables us to investigate possible local agglomerations, LISA allows us to take into account local effects of the phenomenon [1, 11]. In other words, the global index gives a measurement of similarity/dissimilarity of units in relationship with the variable studied. Generally, global index assumes values between 1 and -1. The value 1 means positive autocorrelation: contiguous municipalities have the same density values; the value -1 means negative autocorrelation: contiguous municipalities have different density values. In absent of autocorrelation, the index assumes value -1/N-1.

The local index (LISA) shows the statistical significant units that gives an important contribute ($p<0.05$) at global index construction. Based on the results, the units are dived in four groups:

- HH: municipalities with density higher than average, contiguous to municipalities with density higher than average, too;
- LL: municipalities with density lower than average, contiguous to municipalities with density lower than average, too;
- AL and LA: municipalities with density higher than average, contiguous to municipalities with density lower than average; vice versa for LA.

The first two groups are homogenous geo-statistical configuration; the last two are “encalves”.

3 Results

The figure 1 shows the density of farms survived at last 17 years, defined “resilient”. The density is expressed in quintiles and darken colours highlights a higher concentration: Sud-Tyrrhenian and Adriatic lines, part of Veneto, Friuli-Venezia Giulia, Lazio, Liguria and Piemonte.

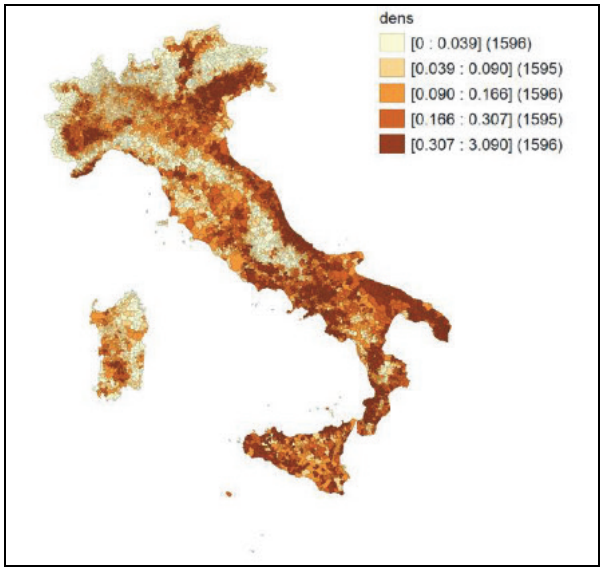

Figure 1: Density distribution of "resilient" farms for municipalities.

Spatial autocorrelation has been visualized adopting Moran scatter plot [4] and considering the density of resilient as abscissa and lagged density of residuals as ordinate. In the graph, Moran Index corresponds to direction coefficient of linear regression, which represents the scatter plot. Positive autocorrelation corresponds to spatial clusters in upper right and lower left quadrants. Lower right and upper left quadrants can classified as spatial outliers.

The Moran's index (figure 2) is 0.585. It's very significant ($p<0,001$): the positive sign and the intensity of this statistic reveal that the municipalities, with a similar density value, are located territorially close to each other.

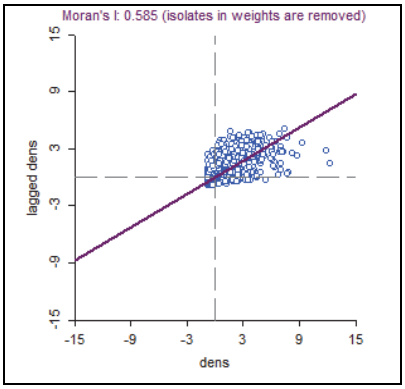

Figure 2: Moran scatter plot.

The scatter plot in figure 2 shows that most of the municipalities are in the first quadrant: municipalities with high density are close to other municipalities with similar density. In any case, the other municipalities are near the intersection of the Cartesian axes.

Figure 3 identifies several clusters of HH municipalities, located in almost all of Puglia; on the coast of Abruzzo and part of Molise; in Veneto and Trentino Alto Adige; in Campania, Calabria and Sicily. Small clusters are in Liguria, Piemonte, Emilia Romagna and Lazio. They are a kind of "hard core" of resilience. LL cluster are located mainly along Alps, Apennines and Sardegna. These areas can be considered as places where this type of structure has not established.

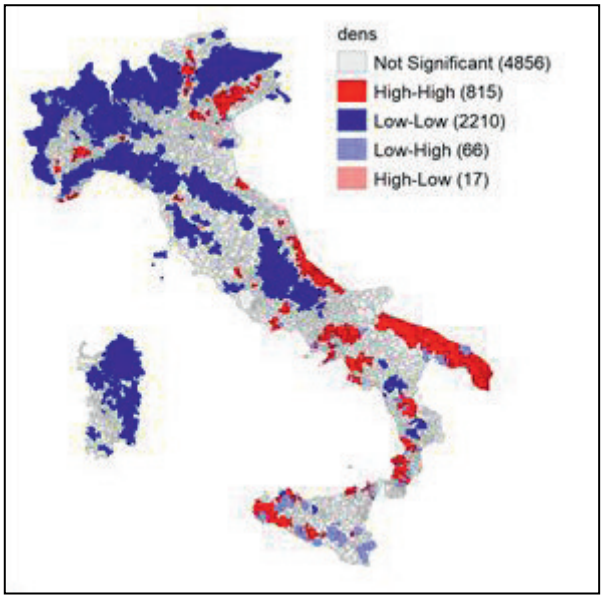

Figure 3: Local Indicator of Spatial Association - LISA

4 Conclusion

The micro data availability allows to explore the mechanisms that influence the farms resistance at the economic changes. A cohort of farms survived at the last 17 years was identified. The results show the importance of territory as a physical support where socio-economic information can be spread out. The results highlight the potential of spatial autocorrelation to prove the surviving spreads via some mechanisms of ‘contamination’ or spatial spill-overs.

There are some differences in the territorial distribution of this phenomenon, not only between north and south, but also between the Tyrrhenian and Adriatic lines where the number of farms survived at the last twenty years is grown.

We choose the Moran index, global and local variant, as a statistical measure of this event [13]. It registers units' autocorrelation with respect to the intensity of a statistical variable (farms surviving) in contiguous territorial units (municipalities). The value of the Moran index is very significant. This situation indicates the presence of a process of contagion that leads to the formation of territorial aggregations with higher than average levels of farms surviving. The LISA index highlights four main types of territorial aggregations, the two most common of which are displayed in blue (Low-Low aggregation) and red (High-High aggregation) where the creation of municipalities' cluster (territorial spill-over) is strongest. In particular, we can note the presence of a great spill-over effect in south of Italy, principally in Puglia region and Abruzzo coast, where the agricultural sector is linked to deep socio-cultural roots. The smaller presence of the spill-over effect in northern Italy probably depends on a greater farm liveliness in these areas, in fact, we can observe little clusters of HH just in North-Est.

Bayesian spatial modeling of extreme precipitation

Modellazione spaziale bayesiana per precipitazioni estreme

Federica Stolf

Abstract Maps of return levels provide information about the spatial variations of the risk of extreme precipitation and are expected to be useful for infrastructure planning. In this paper we analyze a collection of spatially distributed time series of precipitation in Georgia (USA): exploiting a spatial hierarchical Bayesian model we can produce maps of precipitation return levels with uncertainty measures. Inference about the parameters and spatio-temporal predictions are obtained via Markov Chain Monte Carlo (MCMC) simulation.

Abstract *Le mappe dei valori di ritorno forniscono informazioni importanti sulla variazione spaziale del rischio di precipitazioni estreme e sono utili per la pianificazione delle infrastrutture. In questo contributo analizziamo un insieme di serie storiche di precipitazioni con collocazione spaziale in Georgia (USA): tramite un modello spaziale gerarchico bayesiano possiamo produrre mappe dei valori di ritorno delle precipitazioni con le relative misure di incertezza. L'inferenza sui parametri e le previsioni spazio-temporali sono ottenute tramite simulazioni Markov Chain Monte Carlo (MCMC).*

Key words: Extreme value, Bayesian Hierarchical model, rainfall, Georgia.

1 Introduction

Extreme value theory finds wide application in environmental sciences. Extreme meteorological events such as high rainfall and windstorms arise due to physical processes and are spatial in extent. These events are usually characterized by limited predictability and can cause significant economical and social damages. We mention for example the catastrophic flood that impacted North Georgia, in partic-

Federica Stolf
Department of Statistical Sciences, University of Padova, Padova, Italy.
e-mail: federica.stolf@phd.unipd.it

ular the Atlanta metropolitan area, on September 2009 as a result of multiple days of prolonged rainfall. The flood is blamed for at least 10 deaths and $500 million in damage (National Weather Service). Although these extreme precipitation events are rare, understanding their frequency and intensity is important for public safety and long-term planning.

A rich statistical literature concerned with modeling extreme events is available and [2] provides a comprehensive introduction. Standard approaches utilize generalized extreme value (GEV) distributions [5] and Generalized Pareto Distribution (GPD) [6]. In [4] are identified three main classes of statistical models for spatial extremes: Bayesian hierarchical models, copula based models, and max-stable process models. Latent variable models arise naturally in the Bayesian framework and have been widely used in the context of extremes (see e.g. [3, 1]). A particular issue when dealing with extremes is that although vast amounts of data may be available rare events are necessarily unusual and so the quantity of directly relevant data is limited. One of the advantages of the Bayesian approach is the possibility to incorporate reliable information supplementary to the data in the form of prior distributions. In this paper we focus on the Bayesian method recently proposed in [9], a specification that does not make any asymptotic assumption and explicitly takes into account the spatial dependence of the data.

2 A hierarchical Bayesian Extreme Value Model

Let $x_{ij}(s)$ denote the magnitude of the i-th event within the j-th block for the site s, where $j = 1,\dots,J$ with J the number of blocks in the observed sample, $i = 1,\dots,n_j(s)$ with $n_j(s)$ the number of events observed within the j-th block for the site s and $s = 1,\dots,S$ with S the total number of stations. Traditional approaches, exploiting the asymptotic results stated in [6, 5], focus on the distribution of block maxima for each station $Y_j(s) = \max_i\{x_{ij}(s)\}$ only, discarding the 'ordinary values'. This approach has several limitations. First, the number of events per block may be often not large enough for the asymptotic argument to hold [7] and second the assumption of a constant parent distribution is unrealistic in many contexts. Based on these considerations a hierarchical Bayesian extreme value model that avoids the asymptotic argument and accounts for possible inter annual variability in the magnitude of the events was introduced in [10], building upon the results discussed in [8].

By considering some physical process such as rainfall, one can expect that nearby locations will exhibit similar behavior, and in the Bayesian framework the reduction in uncertainty gained from pooling over space is particularly useful. Thus, spatial modelling of extremes is expected to reduce the overall uncertainty in extreme values estimates, by borrowing strength across spatial locations. For these reasons starting from the approach proposed in [10], [9] include the spatial dependence of the data in the model, incorporating in the layers of the hierarchical model geographical features, to make predictions at unobserved sites. We adopt the latter model speci-

fication, where the events within a block, $x_{ij}(s)$, conditionally on unobserved latent processes are assumed to be conditionally independent with common parametric cdf $F(\cdot;\theta_j(s))$, with $\theta_j(s) \in \Theta$ unknown parameter vector. For technical details see [9].

3 Georgia rainfall data analysis

This study uses daily precipitation observations from the United States Historical Climatological Network (USHCN), a high-quality source of data sets freely available. We use all available stations in Georgia which contain more than 80 years of data from 1892 to 2021. The records characterized by non-blank quality flag were removed, as well as the years characterized by more than 30 daily missing observations. The number of stations included is 20. These data are particularly appropriate for studying heavy precipitation events because of their long-term records, indeed the records for most of the stations are longer than 100 years.

Data are analyzed applying the spatial hierarchical Bayesian model (sHMEV) of [9]. In particular, we consider as geographic covariates to be included in the model, in addition to latitude and longitude, also the elevation since there are some mountainous ranges in the northern part of the region. We fit the model only on the first 20 years of observations for each station and we use the remaining records to validate it.

Adopting a Bayesian methodology allows to make inference on any functional of the posterior distribution (like our target, the cumulative probability of block maxima) and uncertainty measures result naturally from the sampling procedure. A common measure of extreme events is the return level: the r-year return level is the quantile that has probability $1/r$ of being exceeded in a particular year. Figure 1 shows maps of the predictive pointwise posterior mean for the 25 and 100 year return levels, with pointwise 90% credible intervals width. To create these maps the study region was divided into a grid of points, and considering the posterior draws and the values of the covariates for each point is straightforward to obtain draws for the posterior distribution at any grid point. We observe higher return levels for the north mountain area and for the south area, in particular on the southeast of the region near the Atlantic Ocean. There are a few points in the mountainous area with rather high return values and great variability. This is due to the high values of elevation for those points, much greater than for the sites in the data, that lead to a more uncertain extrapolation.

In order to evaluate the performance of the model we compare it with standard alternative methods: Bayesian implementations of the classical generalized extreme valued distribution (GEV) and peak over threshold (POT) Poisson point process models. Since the focus is the right tail of the distribution of the block maxima, we evaluate the predictive accuracy in estimating the true distribution of block maxima on the test set. Figure 2 shows two representative examples. Specifically, the quantile versus return time plots obtained for the different methods for two sites, Waycross and Gainesville, are reported. The fist station is in south Georgia, while

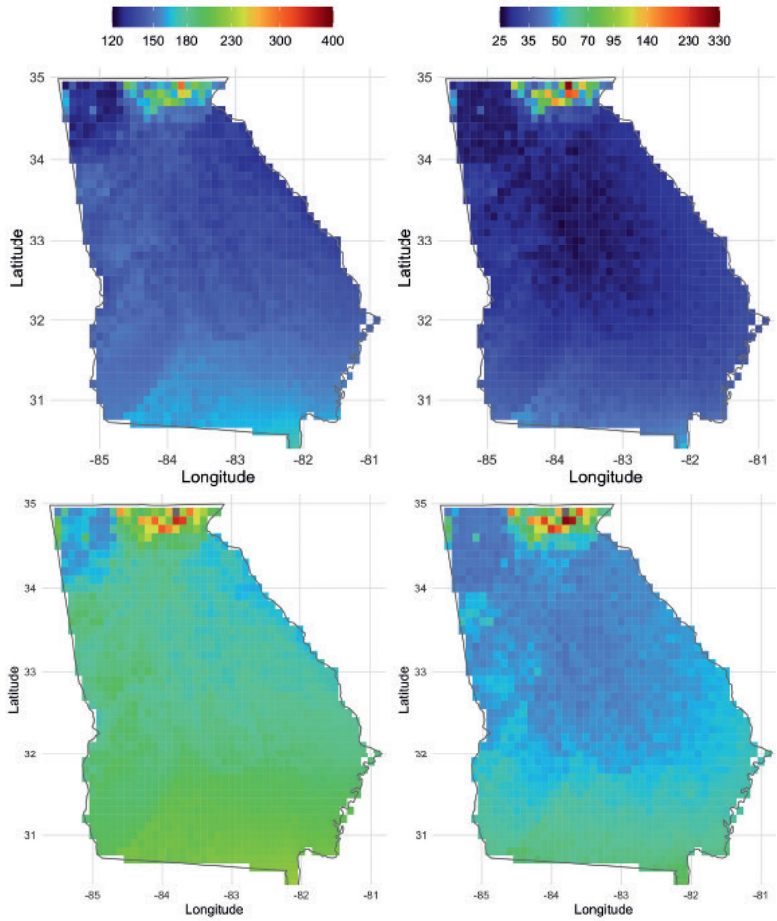

Fig. 1 Maps of the predictive pointwise 25 (top panel) and 100 (bottom panel) year return level estimates for rainfall (mm). Predictive pointwise posterior mean (left) and the width of the 90% pointwise credible intervals (right).

the second one is located north of Atlanta. For both stations the spatial hierarchical model presents an overall good agreement with the empirical frequencies associated to the annual maxima extracted from the entire record, and yields quantile estimates with narrower credibility intervals. POT and GEV appear to be more sensitive to the smallest observations in the training set and tend to underestimate the quantiles. This behavior is expected given the limited length of the records, as observed in [9, 10]. In this case the spatial hierarchical model, exploiting also information from the other sites (*borrowing strength*), manages to obtain more accurate and less variable estimations than the competitors.

This analysis shows the potentiality of the spatial hierarchical models framework for extreme precipitation, although a more detailed comparison via simulated and

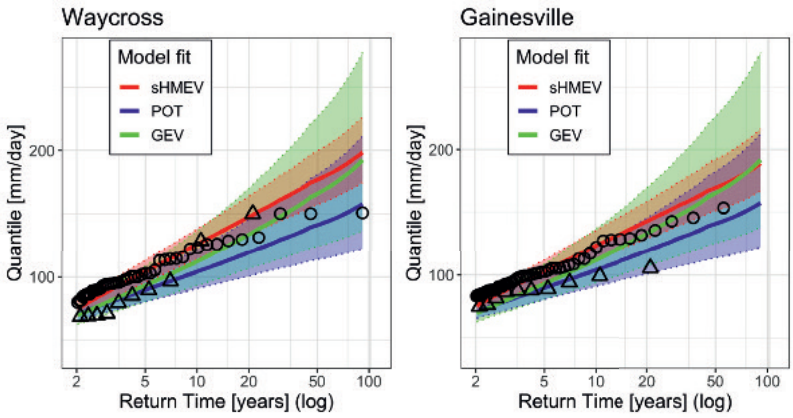

Fig. 2 Quantiles predicted for the stations of Waycross and Gainesville by the GEV (green), POT (blue), and spatial hierarchical Bayesian (red) models. Solid lines show the expected value of the quantile for a given return time, while dashed lines represent the bounds of 90% credibility intervals. Triangles represent the maxima on the training set, while the circles represent the maxima on the test set.

real data sets is needed. A major asset of latent variable models is flexibility: the approach discussed above can be generalized or extended to study different natural phenomena.

A proposal to adjust local Moran's I for measuring residential segregation

Una proposta di modifica dell'indice di Moran locale per misurare la segregazione residenziale

Antonio De Falco, Antonio Irpino

Abstract The study of the spatial distribution of social groups within urban areas has been gaining increasing attention in recent years due to the recent growth of both social inequalities and levels of urban segregation in European countries and cities. Over time, various measures have been proposed to analyze the phenomenon according to its main dimensions of analysis. Among these, detecting the concentration of social groups in specific areas is an essential indicator for revealing the presence of spatial clusters and the social geography of urban areas. The work aims to propose an implementation of the Local Moran's I to integrate some topological aspects of the territories to define a different structure of interaction between spatial units to calculate the index.

Abstract *Lo studio della distribuzione spaziale dei gruppi sociali all'interno delle aree urbane ha guadagnato una crescente attenzione negli ultimi anni a causa della recente crescita dei livelli di disuguaglianze sociali e di segregazione urbana nei paesi e nelle città europee. Nel corso del tempo sono state proposte diverse misure per analizzare il fenomeno secondo le sue principali dimensioni di analisi. Tra queste, il rilevamento della concentrazione di gruppi sociali in specifiche zone è un importante indicatore per rilevare la presenza di cluster spaziali e la geografia sociale delle aree urbane. Il lavoro propone un'implementazione dell'I di Moran locale capace di integrare alcuni aspetti topologici dei territori per definire una diversa struttura di interazione tra unità spaziali per il calcolo dell'indice*.

1 Introduction

Residential segregation is generally used to indicate the physical separation between two or more groups defined on relevant social characteristics such as socio-economic status or ethnicity that involve unequal distribution across the urban space. Although not problematic in an absolute sense, residential segregation can represent a severe threat to the social inclusion of disadvantaged groups: this is because the physical and social characteristics of the residential areas, along with an unequal spatial allocation of services and resources, contribute to defining the opportunity/constraint structure of social groups, feeding the r(e)production and transmission of social inequalities (Tammaru *et al.,* 2021).

Since the 1950s, the phenomenon has interested scholars with different disciplinary backgrounds, leading to the development of theoretical models and indices aiming to describe and identify patterns and processes underlying urban segregation. Several indices have been proposed and systematized according to the multidimensional conceptualization of the phenomenon suggested by Massey and Denton (1988). However, in recent times different re-conceptualizations and measures deemed more effective have delineated new analysis approaches (Reardon and O'Sullivan, 2004). Within this framework, the definition of indices that can incorporate the spatial dimension has a particular interest. In fact, they appear to be more effective in capturing different spatial patterns and the variability of the phenomenon across the space.

A proposed way to analyze segregation consists of using spatial clustering techniques based on spatial autocorrelation, such as Geary's C and Moran's I statistics. In particular, Anselin (1995) proposed a local approach to detect spatial clustering by introducing the local indicators of spatial association (LISA) derived by decomposing Moran and Geary indices into several local values for detecting local clusters and spatial outliers. However, critical steps arise when spatial correlation statistics for segregation analysis are used, such as the choice of neighborhoods and the type of spatial relationship among areal units, which significantly affects the results. Further, when summary statistics of the individuals describe spatial units, spatial autocorrelation indices may usually rely on compositional data, vectors whose components are the proportion or percentage of a constant-sum set (respectively 1 or 100). Because compositional data are constrained to be into a *simplex* inducing specific properties, standard statistics designed for unconstrained data – such as correlation coefficient –could lead to biases in the results (Aitchison, 1986).

Starting from this evidence, we propose a modified version of the local Moran's I calculation to investigate socio-economic phenomena and their spatial configuration, such as residential segregation, by introducing two major changes to deal with the issues mentioned above. Firstly, we suggest a different way for defining the structure of the spatial relationship between territorial units by introducing into the spatial weight matrix temporal-distance criteria which consider the spatial connectivity between areal units as a result of different travel time mode distributions (by walking, by car, by public transport, by bicycle). This approach allows us to consider topological features of the study area, trying to give a more realistic representation of

the existing degree of spatial interaction among territorial units than methods based on adjacency or geographical distance criteria. Secondly, since distributions express the variable used for Moran's I calculation, we propose to apply the compositional data analysis approach if the support is categorical (Aitchinson, 1986) or the distributional analysis of variables if the support is quantitative (Irpino and Verde, 2015).
We apply the proposed procedure to Population Census Data collected by the National Institute of Statistics (Istat), the primary statistical source of demographic and socio-economic information, available at high territorial detail.

2 Data and methods

The starting point is the Moran's index (Moran, 1948) of spatial autocorrelation, which is widely used to detect and quantify how a phenomenon of interest is related to itself in space. The existence of an association between the spatial distribution of values of the same variable is known as "spatial dependence." Moran's index can be considered an extension of Pearson's coefficient characterized by a matrix of spatial weights that defines the neighborhood relationships between spatial units, which is necessary to quantify spatial dependence.

The global Moran index measures the spatial autocorrelation in a study area; most often, in reality, spatial autocorrelation reports some level of spatial heterogeneity captured using a local Moran statistic derived from a decomposition of the global index. It can be defined as:

$$I_i = z_i \sum_{j,i \neq j}^{n} w_{ij} z_j \qquad (1)$$

where:

- z_i and z_j are the standardized values of the observed variable in the spatial units *i and j;*
- w_{ij} is the spatial weight matrix that defines the spatial relation between *i* and *j*.

It is worth noting that the Local Moran's index is sensitive to the definition of the relationships between the spatial units partitioning the study area. Since it was conceived for identifying local clusters and local spatial outliers, if the spatial weight matrix does not reflect the actual structure of spatial interactions, the index results may underestimate or overestimate the phenomenon of interest.

Usually, the spatial proximity between units is accounted for through their adjacency or a geographical distance. At the same time, a second step involves the assignment of weights to their proximity links (i.e., inverse distance or negative length of shared boundary), allowing the definition of a spatial weights matrix that is the basis for local Moran's I computation. However, in the study of socio-economic phenomena, relationship systems based on such criteria may not be adequate to catch

the complexity of factors that could influence the connection between territorial units and how and to what extent they interact.

If we focus on urban segregation, it might be helpful to integrate some topological aspects of urban areas, such as road networks and public transportation infrastructures affecting human mobility. Actually, human mobility patterns represent better the degree of connectivity of urban areas (Tóth *et al.*, 2021). In this perspective, a matrix of spatial weights is specified by adopting a criterion based on a temporal dissimilarity that is defined as a function of travel time distributions of people moving from one spatial unit to another. Other authors attempted to model spatial interaction according to road networks using time accessibility (Netrdová and Nosekor, 2020) and travel distances (Qin *et al.*, 2020), but, to our knowledge, there is no similar procedure for analysing socio-economic phenomena such as residential segregation.

In this work, we propose a time-spatial weight matrix, namely, an $n \times n$ positive symmetric matrix W with a generic element w_{ij}, where the weights for each pair of units, respectively i and j, are assigned by pre-set criteria describing the existing spatial connectivity structure among locations.

We consider a temporal similarity as follows:

$$w_{ij} = \frac{1}{t_{ij} + 1}; \qquad (2)$$

where:
t_{ij} is the needed time (in minutes) to get from point i to point j
+1 (minute) is the assumed minimum travel time

To specify the connectivity structure between areal units based on this formulation and incorporate it in local Moran's I calculation, we apply the following procedure using R on both census variables and geographical data released by Istat.

Firstly, we proceed by getting the centroids of spatial polygons and converting them into spatial points; after that, travel time distances can be obtained querying the Distance Matrix API, a Google service that provides travel distance and time between two points or two vectors of points allowing to calculate the travel time for each pair of centroids according to four route modes (bicycle, walking, car, and public transportation); next, we select the median time among the generated time distributions.

Once the time-spatial dissimilarity/distance matrix is created, we use an inverse distance function to define weights in the spatial weight matrix modeling neighborhood relationships: the greater the distance between territorial units, the lesser the connection between them, and vice versa. The result is stored as an instance of an "nb" object and then used as an argument in the global and local Moran's I calculation implemented in the *Spdep* package.

3 Preliminary results and further developments

The method described in the previous section has been applied to a sub-group of Istat Census Area (ACE) 2011, considering the incidence of high-medium skilled professions as a proxy of the middle-upper class. The preliminary results confirm the proposed procedure's validity and encourage applying the modified local Moran's I index to explore the spatial configuration of socio-economic phenomena such as residential segregation to a larger study area (i.e., municipalities or metropolitan areas).

Further analysis considering different ways to establish the spatial relationships between areal units is required to evaluate to what extent the Moran statistic based on dissimilarity distance is more effective in capturing spatial interaction and detecting the presence of autocorrelation in the study area. Additional developments concern the adoption of a strategy based on spatial interpolation techniques to define differently areal units on which the index is calculated to address Modifiable Areal Unit Problem (Openshaw, 1984) and give a more reliable representation of the variable of interest.

For the sake of brevity, we omit the detailed results here.

Accurate Directional Inference for Gaussian Graphical Models

Inferenza Direzionale Accurata per Modelli Grafici Gaussiani

Claudia Di Caterina, Nancy Reid and Nicola Sartori

Abstract Directional tests to compare incomplete undirected graphs are developed in the context of covariance selection for Gaussian graphical models. The exactness of the underlying saddlepoint approximation leads to exceptional accuracy of the proposed approach. This is verified by simulations in settings with high-dimensional parameter of interest, when the accuracy of standard asymptotic approximations to the likelihood ratio test and some of its higher-order modifications fails.

Abstract *Test direzionali per confrontare grafi non orientati incompleti sono sviluppati nell'ambito di selezione della covarianza per modelli grafici Gaussiani. L'esattezza dell'approssimazione saddlepoint coinvolta rende l'approccio proposto estremamente accurato. Ciò è illustrato da simulazioni in cui il parametro di interesse ha dimensione elevata, situazione in cui le approssimazioni asintotiche standard alla distribuzione del test di rapporto di verosimiglianza e di alcune sue modificazioni di ordine superiore falliscono.*

Key words: covariance selection, likelihood-ratio test, undirected graph.

1 Introduction

Undirected graphical models [3, 15] are probabilistic graphs describing complex multivariate distributions of variables (nodes) via the product of simpler sub-models for low-dimensional subsets of the graph (cliques). An important question is inferring the structure of large graphs, i.e. the underlying connections (edges) between

Nicola Sartori
Department of Statistical Sciences, University of Padova, Italy; e-mail: sartori@stat.unipd.it

the variables under study. This task is known in the literature by the name of covariance selection, especially if the assumed distribution is normal [9, Sect. 5.2].

Directional inference on a vector-valued parameter of interest was introduced by [6] in nonnormal linear regression models and then generalized in [13]. Substantial progress from both a methodological and computational perspective was made by [5], where the computation of the directional p-value by one-dimensional numerical integration proved especially accurate in several settings. The procedure was extended from linear exponential families to nonlinear parameters of interest in general continuous models by [7]. Besides its accuracy, the directional approach was found to coincide with exact results in several classical situations [10].

Here we show how to employ directional tests for covariance selection in Gaussian graphical models. The directional p-value derived by [5, Sect. 5.3] for testing the complete graph under the saturated model is computationally much simpler. We generalize that to situations where some previous information on the relationships among variables is available. Simulation studies confirm the exceptional performance of the directional approach, even in high-dimensional scenarios where the number of nodes is of the same order of magnitude as the sample size; the likelihood ratio statistic and its higher-order modifications [14] break down in these settings.

2 Likelihood quantities for Gaussian graphical models

Gaussian graphical models are useful for describing normal multivariate distributions. The nodes represent the variables and the lack of an edge between two nodes models conditional independence of the two variables, given the remaining ones. This corresponds to a zero entry in the concentration (inverse covariance) matrix, and covariance selection involves identifying these conditional independencies.

Let $y_1,\dots,y_n$ be a random sample from the normal distribution $N_q(\mu,\Omega^{-1})$, where the mean is $\mu\in\mathbb{R}^q$ and the $q\times q$ concentration matrix Ω is positive definite. For covariance selection the interest is not on the mean, so we focus on the restricted likelihood based on the marginal Wishart distribution of the ML estimator

$$\hat{\Omega}^{-1}=y^\top y/n-y^\top 1_n 1_n^\top y/n^2\,,$$

where y denotes the $n\times q$ matrix with ith row vector $y_i^\top$ and 1_n is a n-vector of ones. Exploiting the symmetry of Ω, we can express the corresponding log-likelihood in the standard exponential family form as

$$\ell(\omega;u)=\frac{n-1}{2}\log|\Omega|-\frac{n-1}{2}\omega^\top Ju\,, \tag{1}$$

where $\omega=\operatorname{vech}\Omega$, $u=n/(n-1)\operatorname{vech}\hat{\Omega}^{-1}$ and the matrix $J=G^\top G$ is diagonal with elements equal to either 1 or 2. If A is a $q\times q$ symmetric matrix, $\operatorname{vec}A$ is the $q^2\times 1$ vector which stacks the columns of A on top of one another, while $\operatorname{vech}A$ retains only the $q^*=q(q+1)/2$ entries in the lower triangle of A. The two vectors are

linked by the relationship $\mathrm{vec}A = G\,\mathrm{vech}A$, which also gives the $q^2 \times q^*$ duplication matrix G [1, Sect. 11.3].

Assume some off-diagonal elements in the concentration matrix are zero, and define the edge sets $k = \{(i,j) : \Omega_{ij} \neq 0, i \leq j\}$ and $h = \bar{k}$. As in [12], we can rearrange the elements of ω, u and the leading diagonal of J such that

$$\omega = \left(\omega_k, \omega_h\right)^{\mathrm{T}}, \quad u = \left(u_k, u_h\right)^{\mathrm{T}}, \quad J = \mathrm{diag}\{J_{kk}, J_{hh}\}. \tag{2}$$

Since $\omega_h = 0$, in the unsaturated model $\Omega = \Omega_k = \Omega(\omega_k)$ so that (1) becomes

$$\ell(\omega_k; u_k) = \frac{n-1}{2}\log|\Omega_k| - \frac{n-1}{2}\omega_k^{\top} J_{kk} u_k, \tag{3}$$

which is a function of the p-dimensional canonical parameter ω_k, with $p \geq q$. Differentiation of (3) with respect to ω_k leads to the score function

$$\ell_{\omega_k}(\omega_k) = \frac{n-1}{2} J_{kk}(\sigma_k - u_k),$$

where σ_k is the partition of $\sigma = \mathrm{vech}\,\Omega_k^{-1}$ obtained as in (2). Solving the score equation leads to $\hat{\sigma}_k = u_k$ and to the corresponding ML estimate $\hat{\omega}_k$, usually derived numerically [5, Sect. 5.3]. As the observed and expected information matrices are equal in canonical exponential families, from [12, Sect. 3] follows that

$$j_{\omega_k\omega_k}(\omega_k) = \frac{n-1}{4} J_{kk}\mathrm{Iss}(\Omega_k^{-1})_{kk} J_{kk}, \tag{4}$$

where $\mathrm{Iss}(\Omega_k^{-1})_{kk}$ is a $p \times p$ partition of the Isserlis matrix [8] of Ω_k^{-1}.

Note that we allow the sample size to be smaller than the number of nodes q, but large enough for the ML estimate $\hat{\omega}_k$ to exist. Particularly, n must be larger than the maximal clique size of the hypothesized graph or of its decomposable version [4, 9, Sect. 5.3.2].

3 Directional and likelihood-based tests for covariance selection

Consider the partition $\omega_k = (\psi, \lambda)^{\mathrm{T}}$ of the canonical parameter, where ψ is the component of interest having dimension $d \leq p - q$. The null hypothesis $H_0 : \psi = 0$ tests whether d additional off-diagonal entries $\Omega_{ij}, i < j$, are zero. Hence, the reduced model is nested in the unsaturated full model of Section 2.

The log-likelihood ratio statistic for testing H_0 results [9, Sect. 5.2.2]

$$w(\psi_0) = -(n-1)\log|\hat{\Omega}_k^{-1}\hat{\Omega}_0|, \tag{5}$$

where $\hat{\Omega}_k = \Omega(\hat{\omega}_k)$ is the ML estimate of Ω obtained from (3), and $\hat{\Omega}_0 = \Omega(\hat{\omega}_{k0})$ is its constrained ML estimate under H_0, given $\hat{\omega}_{k0} = (0, \hat{\lambda}_0)^{\mathrm{T}}$. The null asymptotic

distribution of (5) is χ^2_d, as is that of both higher-order modifications

$$w^*(\psi_0) = w(\psi_0)\left\{1 - \frac{\log\gamma(\psi_0)}{w(\psi_0)}\right\}^2 \quad \text{and} \quad w^{**}(\psi_0) = w(\psi_0) - 2\log\gamma(\psi_0) \quad (6)$$

introduced by [14], being the term $\gamma(\psi_0)$ in this case equal to

$$\gamma(\psi_0) = \frac{2\{(\hat\sigma_{k0}-\hat\sigma_k)^\top \mathrm{Iss}(\hat\Omega_0^{-1})^{-1}_{kk}(\hat\sigma_{k0}-\hat\sigma_k)\}^{d/2}}{\{-\log|\hat\Omega_k^{-1}\hat\Omega_0|\}^{d/2-1}(\hat\omega_k-\hat\omega_{k0})^\top J_{kk}(\hat\sigma_{k0}-\hat\sigma_k)}\left\{\frac{|\mathrm{Iss}(\hat\Omega_0^{-1})_{kk}|}{|\mathrm{Iss}(\hat\Omega_k^{-1})_{kk}|}\right\}^{1/2}.$$

Due to limited space, we refer to [5] for a thorough derivation of the general formula for the directional p-value when testing hypotheses on a parameter of interest which is linear in the canonical parameterization of an exponential family. We shall thus obtain the relevant quantities in the special context of this paper. First, we find

$$s_\psi = -\ell_{\omega_k}(\hat\omega_{k0}) = \frac{n-1}{2}J_{kk}(u_k - \hat\sigma_{k0}),$$

where $\hat\sigma_{k0}$ is the component of $\hat\sigma_0 = \mathrm{vech}\,\hat\Omega_0^{-1}$. Then, the so-called tilted log-likelihood function along the line $s(t) = (1-t)s_\psi$ follows from (3):

$$\ell\{\omega_k; s(t)\} = \frac{n-1}{2}\log|\Omega_k| - \frac{n-1}{2}\omega_k^\top J_{kk}\{\hat\sigma_{k0} + t(u_k - \hat\sigma_{k0})\}. \quad (7)$$

Maximization of (7) entails $\hat\Omega_k^{-1}(t) = t\hat\Omega_k^{-1} + (1-t)\hat\Omega_0^{-1}$, and by taking the inverse $\hat\omega_k(t)$ is obtained accordingly. The replacement of ω_k in (7) with $\hat\omega_k(t)$ and $\hat\omega_{k0}$, respectively, delivers after some manipulation the result

$$\exp[\ell\{\hat\omega_{k0}; s(t)\} - \ell\{\hat\omega_k(t); s(t)\}] \propto |\hat\Omega_k(t)|^{-\frac{n-1}{2}}.$$

By (4), we get $|j_{\omega_k\omega_k}\{\hat\omega_k(t); s(t)\}|^{-1/2} \propto |\mathrm{Iss}\{\hat\Omega_k^{-1}(t)\}_{kk}|^{-1/2}$ and consequently

$$\begin{aligned} h\{s(t);\psi_0\} &\propto \exp[\ell(\hat\varphi^0_\psi; s) - \ell\{\hat\varphi(s); s\}]\,|j_{\varphi\varphi}\{\hat\varphi(s); s\}|^{-1/2} \\ &\propto |\hat\Omega_k^{-1}(t)|^{\frac{n-1}{2}}|\mathrm{Iss}\{\hat\Omega_k^{-1}(t)\}_{kk}|^{-1/2}. \end{aligned} \quad (8)$$

The directional measure of deviation from H_0 in the direction indicated by the data [5] is computed as

$$p(\psi_0) = \frac{\int_1^{t_{\max}} t^{d-1}h\{s(t);\psi_0\}\,\mathrm{d}t}{\int_0^{t_{\max}} t^{d-1}h\{s(t);\psi_0\}\,\mathrm{d}t}. \quad (9)$$

The value $t_{\max}$ is the largest t such that $\hat\Omega_k(t)$ is positive definite, and is determined numerically. The saddlepoint approximation (8), when normalized, is the exact conditional distribution of $s(t)$ in the multivariate normal setting [2, p. 189]. Normalization occurs implicitly in the ratio (9), so the only approximation error involved in the calculation of the directional p-value $p(\psi_0)$ stems from the numerical integration.

4 Simulation studies

The performance of the directional approach is presented via Monte Carlo studies based on 100 000 replications, along with that of the test statistics $w(\psi_0)$, $w^*(\psi_0)$ and $w^{**}(\psi_0)$ expressed in Section 3.

To enable comparison with [5, Sect. 5.3], samples of size $n = 60$ are drawn from a q-variate Gaussian distribution under the hypothesis of first-order Markovian dependence (MD). For each $q \in \{11, 30, 50\}$, this null model is tested against higher MD orders for the concentration matrix. These unsaturated alternative models are chosen to check the sensitivity of the various methods to the number d of parameters of interest. Table 1 reports results obtained for $q = 30$. The empirical null distribution of the directional p-value is extremely accurate in all settings, almost unaffected by the size of d; on the contrary, its competitors break down as d increases.

A second simulation study considers q-variate Gaussian samples of size $n \in \{60, 90, 120\}$, with $q = 50$ and block diagonal concentration matrix with two main-diagonal blocks. The larger unsaturated model allows instead for some nonzero entries in the off-diagonal blocks, so that $d = 250$. Figure 1 shows the exceptional agreement with the uniform benchmark of the empirical directional p-values, as opposed to the classical likelihood-based alternatives that are found to be strongly influenced by the value of n.

Despite being intrinsically a conditional method, the directional p-value proves to enjoy extremely good marginal properties in this high-dimensional framework, particularly compared to the omnibus tests which quantify the observed departure from H_0 taking all directions of the parameter space into account. A future line of research could extend the same approach to graphical models for discrete data [11].

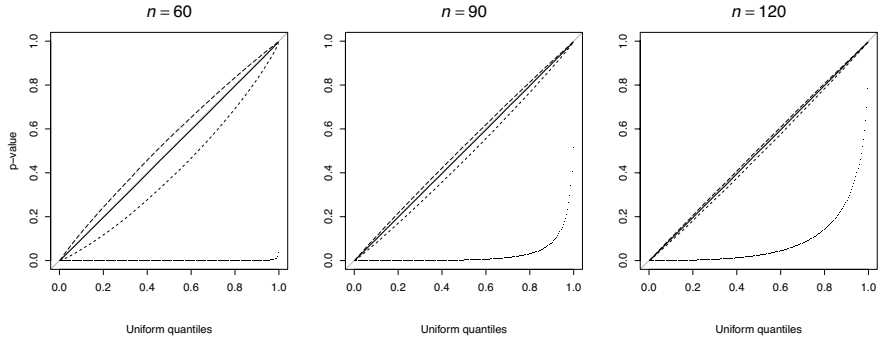

Fig. 1 Results from 100 000 Gaussian samples simulated with block diagonal concentration matrix and $q = 50$. The empirical p-values obtained via w (dot-dashed), w^* (dashed), w^{**} (long-dashed) and the directional test (solid) are compared with the uniform distribution given by the gray diagonal for $d = 250$ and several sample sizes: $n = 120$ (left), $n = 90$ (middle) and $n = 60$ (right).

Advances in Classification

Measures of interrater agreement based on the standard deviation

Misure di accordo tra valutatori basate sulla deviazione standard

Giuseppe Bove

Abstract Interrater agreement for measurements on quantitative (discrete or continuous) scales is usually evaluated by overall measures across subjects like the intraclass correlation coefficient. In this paper, a new index that allows to evaluate the agreement between two or more raters for each single case (subject or object) is presented, and a global measure for the whole group of cases is obtained as the arithmetic average of the single case values. Some advantages of the proposed indices are highlighted by an application related to the measurement of tumor sizes.

Abstract *L'accordo assoluto tra misurazioni su scala quantitativa (discreta o continua) è valutato generalmente con misure globali di accordo come il coefficiente di correlazione intraclasse. In questo lavoro viene presentato un nuovo indice che consente di valutare l'accordo tra due o più valutatori per ogni singolo caso (soggetto o oggetto), e di ottenere anche una misura globale dell'accordo tra i valutatori per l'intero gruppo di casi valutati. Alcuni vantaggi degli indici proposti sono evidenziati con un'applicazione relativa alla misurazione della dimensione dei tumori.*

Key words: interrater agreement, quantitative measurement, tumor measurement

1 Introduction

Agreement among measurements provided by two or more raters (humans or devices) is considered in applications regarding education, psychometrics, biomedical sciences, and other disciplines. For instance, the agreement among clinical diagnoses

[1] Giuseppe Bove, Dipartimento di Scienze della Formazione, Università Roma Tre; giuseppe.bove@uniroma3.it

provided by more physicians on a nominal scale is analysed for identifying the best treatment for the patient, or the agreement among ratings of educators who assess on a new ordinal rating scale the language proficiency of a corpus of argumentative (written or oral) texts is considered to test reliability of the new scale. Besides, agreement among quantitative measurements can be analysed, for instance, when radiologists measure the tumor size of lung cancer patients who could be considered in a clinical trial. In all these applications, the main interest is to analyse interrater absolute agreement, that is the extent raters assign the same (or very similar) values on the rating scale.

Many indices have been proposed to measure the agreement between ratings or measurements of two or more raters on a whole group of subjects (objects) (for a review see, for example, Shoukri (2011), Broemeling (2009), von Eye and Mun (2005)). Moreover, methods to detect subsets of raters who demonstrate a high level of interobserver agreement were considered, for instance, by Landis & Koch (1977). Less frequently agreement on a single subject has been considered (O'Connell & Dobson, 1984), in spite of the fact that having evaluations of the agreement on the single case is particularly useful, for example, in situations where the rating scale is being tested, and it is necessary to identify any changes to improve it, or to request the raters for a specific comparison on the single case in which agreement is poor. Recently, Bove *et al.* (2021) and Bove (2021) proposed subject-specific measures of absolute agreement for ratings provided on an ordinal and nominal scale, respectively. In the next sections, indices measuring the interrater agreement for quantitative measurements on a single subject based on the standard deviation are proposed. Furthermore, a global measure of agreement on the whole group of subjects obtained as the arithmetic average of the subject values of the indices will be also considered and applied to a data set concerning the agreement of radiologists measuring tumor size.

2 Method

There are several well-known methods that are employed to reveal the patterns of agreement between scores provided for a group of subjects (objects) by raters using a quantitative scale X. For quantitative discrete scales with a limited number of levels, weighted versions of kappa-type indices are available (e.g., Gwet (2014)). For quantitative continuous scales, the intraclass correlation coefficient is the traditional approach (e.g., McGraw and Wong (1996)), by which the agreement on the whole group of subjects can be evaluated using mean squares from an analysis of variance (ANOVA). Another very common and simple approach is based on the graphical method proposed by Bland and Altman (1986), according to which, for each pair of raters, differences in the paired scores versus the mean of the paired scores are plotted to determine if the fitted line is flat and if the observations are within two standard deviations of the mean.

A different approach based on a regression framework is considered in this section to propose subject-specific measures of absolute agreement between scores on a

quantitative scale. A global measure of agreement is also obtained as the average of the values of the subject-specific measure. We consider first the case of two raters and then the case of several raters.

Two raters

The scores of two raters (X_1, X_2) can be depicted in a scatter plot, the raters are in perfect agreement $(X_1 = X_2)$ if the regression goes through the origin with a slope of 1. Normally, the points in the scatter plot deviate from perfect agreement, so the level of agreement can be explored as the dispersion around the straight line $x_1 = x_2$. For subject *i* having the scores x_{i1}, x_{i2} $(i = 1,2, \dots, n)$, the distance l_i of the point (x_{i1}, x_{i2}) from the straight line $x_1 = x_2$ is

$$l_i = \sqrt{(\sum_{j=1}^{2} x_{ij}^2) - \frac{(\sum_{j=1}^{2} x_{ij})^2}{2}} = \sqrt{2s_i^2}$$

with s_i^2 the variance of the scores x_{i1}, x_{i2}. When min(X) and max(X) are known for the quantitative scale X, a subject-specific measure of absolute agreement g_i can be defined as

$$g_i = 1 - \frac{l_i}{\max(l_i)} = 1 - \frac{s_i}{(\max(X) - \min(X))/2}$$

with $g_i = 0$ for maximum disagreement and $g_i = 1$ for perfect agreement. When the minimum and maximum of X are unknown, a relative measure of agreement can be obtained (disregarding the constant $\sqrt{2}$) by the coefficient of variation $CV_i = \frac{s_i}{\bar{x}_i}$, with $\bar{x}_i$ the arithmetic average of the scores x_{i1}, x_{i2}, (or the absolute value if $\bar{x}_i < 0$).

Global measures of agreement are obtained by averaging the subject-specific values

$$g_{ave} = \frac{1}{n} \sum_{i=1}^{n} g_i \quad , \quad CV_{ave} = \frac{1}{n} \sum_{i=1}^{n} CV_i$$

for the two cases, respectively.

More raters

The scores of *k* raters $(X_1, X_2, \dots, X_k)$ are now represented in *k* dimensions, so the level of agreement can be explored as the dispersion around the straight line $x_1 = x_2 = \cdots \dots = x_k$. For subject *i* having the scores $x_{i1}, x_{i2} \dots, x_{ik}$ $(i = 1,2, \dots, n)$, the distance l_i of point $(x_{i1}, x_{i2} \dots, x_{ik})$ from the straight line $x_1 = x_2 = \cdots \dots = x_k$ is

$$l_i = \sqrt{(\sum_{j=1}^{k} x_{ij}^2) - \frac{(\sum_{j=1}^{k} x_{ij})^2}{k}} = \sqrt{k s_i^2}$$

with s_i^2 the variance of the scores $x_{i1}, x_{i2} \ldots, x_{ik}$. Formulas for g_i and g_{ave} remain the same.

Generalizations of the coefficient of variation CV_i and the average CV_{ave} are immediate for any k.

Some experiences with real applications suggest the following indications of thresholds for the interpretation of CV_i and CV_{ave} expressed in percentage: values less than or equal to 10% excellent agreement, values between 10% and 20% good agreement, values greater than 20% fair to poor agreement.

3 Application

A discussion of disagreement between radiologists is considered in Erasmus et al. (2003). The purpose of the study was to assess the consistency of measurements performed by readers evaluating lung tumors, this is a critical component of many cancer trials because measurements can be used, for instance, to warrant additional testing of an agent or to determine whether therapy should be continued.

Patients were selected with non-small-cell lung cancer and with 40 lung lesions whose size exceeded at least 1.5 cm. Measurements were performed independently by five thoracic radiologists using printed film by computed tomography. Each radiologist read each of 40 images measuring a) the longest diameter (unidimensional measurement) and b) the longest diameter and the perpendicular longest diameter (bidimensional measurement) of each lesion. Measurement was repeated on the same images 5–7 days later, that means each radiologist was looking at the same image (and the same tumor size) twice (Table 6.18 in Broemeling (2009) contains the data of the two replications of the unidimensional measurements). Variation between and within (the two replications of) the five radiologists measuring tumor size is examined in Erasmus et al. (2003) with different methods, in order to ascertain how to improve measurement consistency in terms of reduction of incorrect interpretation of tumor response.

In the following, we are only interested in analysing agreement applying the proposed indices CV_i and CV_{ave} to the unidimensional measurements of the five radiologists in the first and second replication. Some descriptive statistics regarding the first replication of the unidimensional measurement are provided in Table 1. The

similarity of the means in Table 1 reflects a pretty good level of agreement, with radiologist 2 reporting the smallest mean tumor size and the smallest standard deviation. The level of agreement is confirmed by the values of the intraclass correlation coefficient (random factorial design assumed) and the CV_{ave} provided in Table 2, where it can also be noted that at least half of the forty CV_i values are less or equal to 10% in both the repetitions.

Table 1: Descriptive statistics of tumor measurements (centimeters) of five radiologists on *n*=40 lung lesions (first replication)

Radiologist	*Mean*	*Median*	*Range*	*SD*
1	3.92	3.80	1.5 to 8	1.59
2	3.71	3.80	1.2 to 7.8	1.50
3	4.42	4.20	1.5 to 9	1.54
4	4.37	4.10	1.5 to 9	1.60
5	4.14	3.95	1.7 to 9	1.54
Total	**4.11**	**4.00**	**1.2 to 9**	**1.58**

On the other hand, some high CV_i values (not reported) are present in each repetition (e.g., images 14, 16, 30, 34), these images could be selected for a comparison between radiologists and to detect particular types of lesions (irregular edge and/or irregular contour) difficult to measure.

Table 2: Intraclass correlation values and descriptive statistics of the distributions of the coefficient of variation (percentage) in repetitions 1 and 2

Repetition	*Intraclass correlation*	CV_{ave}	CV_{min}	CV_{max}	$CVi \leq 10\%$	$10\% < CVi \leq 20\%$	$CVi > 20\%$
1	0.837	12.89	1.27	39.24	20	13	7
2	0.842	12.61	0	36.23	23	8	9

In Erasmus et al. (2003) the measurements referring to the same radiologist in the two replications (intraobserver) and the measurements referring to two different radiologists in the same repetition (interobsever) were compared for each tumor to detect the presence of misclassifications (differences in the measured size of tumors higher than a predefined cutoff). The level of intraobserver misclassifications was lower than the level of interobserver misclassifications, so it was adviced that the same reader should perform measurements for any one patient for the duration of the clinical cancer trial.

The indices CV_i and CV_{ave} were computed for each radiologist in the two replications and for each pair of radiologists in each replication. CV_{ave} values are provided in Table 3. It can be noted that off-diagonal values are higher than diagonal values in Table 3, and this confirms that intraobsever measurements have less dispersion than interobserver measurements.

Table 3: Pairwise intraobserver and interobserver CV_{ave} values (percentage) of five radiologists

Radiologist	1	2	3	4	5
1	4.26				
2	8.80	4.54			
3	9.30	13.03	3.47		
4	6.84	10.55	7.39	4.36	
5	6.06	9.69	7.84	5.26	4.20

4 Conclusions

This contribution provides new subject-specific measures of interrater agreement, extending to scores on quantitative scales the proposals for categorical data presented in Bove et al. (2021) and Bove (2021). The approach is mainly descriptive and it is based on a geometrical formalization. Preliminary results obtained in the application to the measurement of tumor sizes seem encouraging. Future developments may concern a study of the sampling properties of the proposed indices.

A comparison of accuracy measures for classification tasks

Confronto tra misure di accuratezza delle classificazioni

Amalia Vanacore[1] and Maria Sole Pellegrino[2]

Abstract Evaluating the ability of a classifier for making predictions on unseen data and increasing it by tweaking the learning algorithm are two of the main reasons motivating the evaluation of classifier predictive performance. While the commonly adopted performance measures are suitable for balanced data sets, in the case of data imbalances it is suggested to adopt a balanced performance measure. In this study the properties of the Balanced AC_1 — a recently introduced classifier accuracy measure — are investigated under different class imbalance conditions via a Monte Carlo simulation. The study results reveal the suitability of Balanced AC_1 with both balanced and imbalanced data sets.

Abstract *Valutare la capacità di un classificatore di processare nuovi dati e cercare di incrementare tale capacità migliorando l'algoritmo di apprendimento sono due delle principali ragioni per cui è necessario misurare le prestazioni di un classificatore. Mentre le misure di prestazione comunemente utilizzate sono adatte a dati ugualmente distribuiti tra le classi, in caso di dati sbilanciati è suggerito l'utilizzo di misure bilanciate. Attraverso uno studio in simulazione Monte Carlo, questo lavoro vuole investigare le proprietà del Balanced AC_1 — una misura di accuratezza del classificatore introdotta recentemente — in diverse condizioni di sbilanciamento dei dati. I risultati ottenuti rivelano l'adeguatezza del Balanced AC_1 sia con dati bilanciati che sbilanciati.*

Key words: Classifier predictive performance, Accuracy, Balanced AC_1, Monte Carlo Simulation

1 Introduction

Several measures have been proposed in the specialized literature for evaluating classifier predictive performance (see [5, 6] for an overview). The most commonly used are the measures determined on the basis of confusion matrix, a cross table that records how cases are distributed over predicted (on columns) and actual (on rows) classes in such a way that cells on the main diagonal count the correctly classified cases whereas off-diagonal cells the cases incorrectly assigned to the class. Each measure deals with a different performance aspect so that the appropriate classifier performance measure for the problem at hand is generally chosen according to the performance aspect to be investigated.

Sensitivity (or recall), precision, specificity and accuracy are four of the commonly used classifier performance measures based on confusion matrix. In the most popular classification task with 2 non-overlapping classes, sensitivity and precision focus on the performance on positive class, specificity focuses on the performance on negative class and accuracy focuses on overall effectiveness. Specifically, sensitivity counts the proportion of cases predicted as positive that are truly positive related to the total count of truly positive cases whereas precision counts the proportion of cases predicted as positive that are truly positive related to the total count of cases predicted as positive. Specificity, instead, counts the proportion of cases predicted as negative that are truly negative related to the total count of truly negative cases. Whereas accuracy, by far the most widespread performance measure, is defined as the number of both positive and negative successful predictions relative to the total number of classifications.

Despite its popularity, a main criticism raised against accuracy is that it fails to compensate the non-zero probability that some classifications match only by chance. To fill this gap, the Cohen's K coefficient [1], a κ-type coefficient introduced in social and behavioral sciences for measuring the degree of agreement between two raters, has been adopted in the last decades as an alternative measure of classifier accuracy. However, its adoption is still debated since the probability of classifications matching by chance is estimated through marginal frequencies in such a way that a reasonably high proportion of observed agreement is converted into a much smaller coefficient value when the marginal frequencies are unequal [2]. A variant of Cohen's K is the AC_1 proposed by Gwet [3] who formulates the chance agreement term as independent from trait prevalence; this allows the coefficient to be recognized as a reliable measure of classifier predictive performance [4].

Moreover, in the case of imbalanced data sets, common in many real world classification problems, it is suggested to adopt a balanced performance measure which averages the performance values estimated for each class and thus treats classes equally avoiding the dependency over the majority class. The recently introduced Balanced AC_1 [7] is an accuracy measure able to treat both classes equally while compensating the non-zero probability that some classifications match only by chance.

This research work aims at investigating, via a Monte Carlo simulation study, the statistical behavior of Balanced AC_1 for binary classification tasks with different

class imbalance conditions. The performance of Balanced AC_1 is compared against that of the commonly adopted accuracy measures. It is worth to note that our simulation study has been conceived to generate confusion matrices with known randomness rather than generating synthetic data from specific classification algorithms.
The remainder of the paper is organized as follows: in Section 2 the classifier accuracy measures under study are introduced; in Section 3 the Monte Carlo simulation algorithm and the main results are fully discussed; finally, conclusions are summarized in Section 4.

2 Classifier accuracy measures

Let n be the number of cases classified on $k = 2$ non-overlapping classes during a binary classification task. The provided classifications are arranged in a 2×2 confusion matrix reported in Table 1.

Table 1 2×2 confusion matrix

		Predicted		
		Positive (+)	Negative (−)	TOTAL
Actual	Positive (+)	*tp*	*fn*	AP
	Negative (−)	*fp*	*tn*	AN
	TOTAL	PP	PN	*n*

The widespread accuracy is formulated as follows:

$$\text{Accuracy} = \frac{tp + tn}{n} \tag{1}$$

Cohen's K coefficient [1] compensates the effect of classifications matching by chance by correcting the observed agreement (i.e. accuracy in Eq. 1) as reported in the following:

$$K = \frac{(tp + tn)/n - (\text{AP} \cdot \text{PP} + \text{AN} \cdot \text{PN})/n^2}{1 - (\text{AP} \cdot \text{PP} + \text{AN} \cdot \text{PN})/n^2} \tag{2}$$

Gwet's AC_1 coefficient [3] quantifies the probability of agreement between two series of evaluations *exclusively* on the cases not susceptible to agreement by chance. According to Gwet, the cases whose classification is not certain are difficult to classify and these are the only cases that could lead to chance agreement. This notion of chance agreement let the Gwet's AC_1 coefficient be formulated as follows:

$$AC_1 = \frac{(tp + tn)/n - 2\left[\frac{\text{AP}+\text{PP}}{2n}\left(1 - \frac{\text{AP}+\text{PP}}{2n}\right)\right]}{1 - 2\left[\frac{\text{AP}+\text{PP}}{2n}\left(1 - \frac{\text{AP}+\text{PP}}{2n}\right)\right]} \tag{3}$$

The balanced version of Accuracy suitable to deal with imbalanced data sets is given by:

$$\text{Balanced Accuracy} = \left(\frac{tp}{\text{AP}} + \frac{tn}{\text{AN}}\right) \cdot \frac{1}{2} \tag{4}$$

The Balanced AC_1 [7] is formulated as a relative measure that corrects the Balanced Accuracy with the balanced proportion of classifications matching by chance obtained by averaging the values estimated for each class:

$$\text{Balanced } AC_1 = \frac{\text{Balanced Accuracy} - p_{a|c}^{AC_1}}{1 - p_{a|c}^{AC_1}} \tag{5}$$

where $p_{a|c}^{AC_1}$ is estimated as follows:

$$p_{a|c}^{AC_1} = \frac{\left[\frac{tp}{\text{AP}} \cdot \left(\frac{tp}{\text{PP}}\left(1 - \frac{tp}{\text{PP}}\right) + \frac{fn}{\text{PN}}\left(1 - \frac{fn}{\text{PN}}\right)\right) + \frac{tn}{\text{AN}} \cdot \left(\frac{fp}{\text{PP}}\left(1 - \frac{fp}{\text{PP}}\right) + \frac{tn}{\text{PN}}\left(1 - \frac{tn}{\text{PN}}\right)\right)\right]}{2} \tag{6}$$

3 Monte Carlo simulation

To compare the biases of the coefficients under investigation, a Monte Carlo simulation study has been conducted in order to generate R confusion matrices of dimension 2×2. Each confusion matrix contains the cross-classifications of $n = 100$ cases into '+' and '−' classes under the assumption of a prevalence rate (Pr) of class '+'. Specifically, at the beginning of each experiment, classifier sensitivity $\alpha = 0.9$, classifier specificity $\beta = 0.6$ and classifier propensity of random classifications $\theta = 0.05$ have been set. Three different scenarios have been investigated, corresponding to balanced (i.e. Pr = 0.5), moderately imbalanced (i.e. Pr = 0.7) and highly imbalanced (i.e. Pr = 0.9) data sets. In order to simulate the data sets, the n cases are firstly randomly assigned to the actual class in such a way that the probability of belonging to class '+' is Pr; the cases with actual class '+' are then randomly assigned to the predicted '+' class with probability α, whereas the cases with actual class '−' are randomly assigned to the predicted class '+' with probability $1 - \beta$. A proportion of θ cases are then randomly classified into one of the two classes with the same probability 1/2 assuming that a non-random rating leads to a correct classification.
For each scenario, $R = 1000$ Monte Carlo data sets have been generated and cross-classified in 2×2 confusion matrices. For each Monte Carlo data set, Accuracy, K, AC_1, Balanced Accuracy and Balanced AC_1 have been assessed and the relative bias of each coefficient i ($i = 1, \ldots, 5$) assessed as follows:

$$\text{RelBias}_i = \frac{\frac{1}{R}\sum_{r=1}^{R} \hat{p}_{r|i} - \text{P}^*}{\text{P}^*} \tag{7}$$

being $\hat{p}_{r|i}$ the classifier performance estimated with coefficient i for r^{th} data set and P^* the 'true' value of classifier performance given by:

$$P^* = \frac{(\alpha+\beta)/2-\theta/2}{1-\theta/2} \tag{8}$$

The adopted α, β and θ parameters give a 'true' value of classifier performance equal to 0.7436.

Table 2 Mean value and relative bias of performance measures based on $R = 1000$ Monte Carlo replications

		Accuracy	K	AC_1	Balanced Accuracy	Balanced AC_1
Pr = 0.5	Mean	0.7382	0.4735	0.4903	0.7377	0.6969
	RelBias	- 0.73	- 36.31	- 34.07	- 0.79	- 6.28
Pr = 0.7	Mean	0.7960	0.4908	0.6579	0.7385	0.7022
	RelBias	7.05	- 33.99	- 11.53	- 0.68	- 5.56
Pr = 0.9	Mean	0.8529	0.3587	0.8075	0.7377	0.7146
	RelBias	14.73	- 51.76	8.60	- 0.79	- 3.91

Simulation results, reported in Table 2, reveal that the mean value of classifier accuracy changes with class imbalance for imbalanced measures: the accuracy estimates vary from 0.4735 to 0.7382 with balanced data set (i.e. Pr = 0.5) and from 0.3587 to 0.8529 with highly imbalanced data set (i.e. Pr = 0.9).
The lowest accuracy estimate is always given by Cohen's K whereas the highest estimate is provided by Accuracy, since this latter does not compensate the non-zero probability of chance classifications. Cohen's K shows low sensitivity to moderate changes of class prevalence from 0.5 to 0.7 but K value decreases in the presence of highly imbalanced data set; indeed, the probability of classifications matching by chance is estimated through marginal frequencies and it is not clear how the classifier performance over majority and minority classes is balanced. Due to the strong dependency on the performance over the majority class, Accuracy increases with class prevalence and the same behavior is observed for AC_1, although its chance agreement has been formulated with the aim of compensating class imbalance.
Vice-versa, the balanced measures (i.e. Balanced Accuracy and Balanced AC_1) are not sensitive to class prevalence, as confirmed by the relative bias always at the most equal to 6%.

4 Conclusions

The blindly adoption of performance measures could result in dangerously misleading conclusions if they are not suited for the problem at hand. Although κ-type coefficients are able to account for chance agreement, they do not treat classes equally being thus not recommended for imbalanced data sets; on the other hand, Balanced Accuracy treats classes equally but it does not account that some classifications could match only by chance. The Balanced AC_1 coefficient is a novel κ-type coefficient able to treat both classes equally while accounting for predicted classifications matching the actual class by chance alone.
This research study aims at investigating, via a Monte Carlo simulation, the statistical behavior of Balanced AC_1 under different class imbalance conditions. Simulation results reveal the coefficient stability with class imbalance and its similarity with true classifier performance, being thus recommended as a good classifier performance measure able to deal with imbalanced data sets, which are a rule in many real-word classification problems.

Iterative Threshold-based Naïve Bayes Classifier: an efficient Tb-NB improvement

Il classificatore Iterative Threshold-based Naïve Bayes: un efficace miglioramento di Tb-NB

Maurizio Romano, Gianpaolo Zammarchi, and Giulia Contu

Abstract While analyzing online reviews on Booking.com, we proposed an ad-hoc classification model (Threshold-based Naïve Bayes Classifier, Tb-NB) to evaluate Customer Satisfaction, starting from the reviews' content, and predicting them as positive/negative. The log-likelihood ratios attributed to each word included in a review are then used to estimate a numeric sentiment score. In this paper we propose an improved version of Tb-NB called "iterative" Tb-NB. It results in a second step of Tb-NB: starting from the output of Tb-NB and reclassifying reviews with a probabilistic approach, it refines iteratively the threshold value used to classify a given subset of reviews.

Abstract *Analizzando le recensioni online presenti su Booking.com, è stato proposto un classificatore ad hoc (Threshold-based Naïve Bayes Classifier, Tb-NB) per valutare la Customer Satisfaction che, partendo dal contenuto delle recensioni stesse, le classifica in positive/negative. La log-verosimiglianza attribuita ad ogni parola contenuta in una recensione è successivamente utilizzata per stimare un sentiment score numerico. In questo paper si propone una versione migliorata chiamata "iterative". La nuova versione si comporta come un secondo step: a partire dall'output di Tb-NB si riclassificano le recensioni con un approccio probabilistico, raffinando la regola-soglia di classificazione per un sottoinsieme di recensioni iterazione dopo iterazione.*

Key words: Threshold-based Naïve Bayes Classifier, Iterative Threshold-based Naïve Bayes Classifier, Customer Satisfaction, Sentiment Analysis, General Sentiment Decomposition

1 Introduction

Analyzing textual data has proved to be extremely useful in many field [7, 1, 4] but, likewise the language is complex so is the data [3]. In [2, 6] we have proposed Threshold-based Naïve Bayes Classifier (Tb-NB), a framework able to produce a good sentiment classifier with a particular focus on the model interpretability. In this paper we introduce an "iterative" step able to improve the performance of Tb-NB while reclassifying subsets of observations. Furthermore, we compare the performance of the new proposal with the previous one using the same Booking.com reviews data.

2 The data

For this study, with an ad hoc web scraping Python program, we have collected two datasets from Booking.com with a total of 127 features:

- Hotels dataset (86 features): Hotel (3), Review (8), Reviewer (2), Booking's score (11), Accommodation (32), Guest (8), Length of stay (6), Other info (4), Score components (12);
- Comments dataset (41 features): Hotel (2), Comment (6), Reviewer (2), Accommodation (16), Guest (4), Length of stay (3), Other info (2), Score components (6).

More in detail, the web-scraped data, is related to:

- 619 hotels located in Sardinia;
- 66,237 reviews, divided in 106,800 comments (in Italian or English): 44,509 negative + 62,291 positive;
- Period: Jan 3, 2015 – May 27, 2018.

3 Iterative Threshold-based Naïve Bayes Classifier

Considering a Natural Language text corpora as a set of reviews $\boldsymbol{r}$ s.t.:

$$r_i = comment_{pos_i} \cup comment_{neg_i}$$

where $comment_{pos}$ ($comment_{neg}$) are set of words (a.k.a. comments) composed by only positive (negative) sentences, and one of them can be equal to $\emptyset$, the basic features of the Threshold-based Naïve Bayes classifier applied to reviews' content are as follows. For a specific review r and for each word w ($w \in$ *Bag-of-Words*), we consider the log-odds ratio of w,

$$\begin{aligned} LOR(w) &= \log\left[\frac{P(c_{neg}|w)}{P(c_{pos}|w)}\right] \approx \\ &\approx \log\left[\frac{P(w|c_{neg})}{P(\bar{w}|c_{neg})}\cdot\frac{P(w|c_{pos})}{P(\bar{w}|c_{pos})}\cdot\frac{P(c_{neg})}{P(c_{pos})}\right] = \ldots = \\ &\approx pres_w + abs_w \end{aligned}$$

where $c_{pos}(c_{neg})$ are the proportions of observed positive (negative) comments whilst $pres_w$ and abs_w are the log-likelihood ratios of the events $(w \in r)$ and $(w \notin r)$, respectively.

While computing those values for all the w ($w \in$ *Bag-of-Words*) words, it is possible to obtain an output such that reported in Table 1, where we report c_{pos}, c_{neg}, $pres_w$ and abs_w for each word in the considered *Bag-of-Words*.

Table 1 Threshold-based Naïve Bayes output

	w_1	w_2	w_3	w_4	w_5	...
$P(w_i\|c_{neg})$	0.011	0.026	0.002	0.003	0.003	...
$P(w_i\|c_{pos})$	0.007	0.075	0.005	0.012	0.001	...
$pres_{w_i}$	0.411	-1.077	-1.006	-1.272	1.423	...
abs_{w_i}	-0.004	0.052	0.003	0.008	-0.002	...

We have then used cross-validation to estimate a parameter τ such that: c is classified as "negative" if $LOR(c) > \tau$ or as "positive" if $LOR(c) \leq \tau$.

We knew now that the Threshold-based Naïve Bayes Classifier has engaging performances with respect to other algorithms [6, 2]. However, still, there are some problems during the classification in Pos/Neg of text data that have a LOR-value close to the selected value of τ. In particular, we can observe this in Fig. 1: if the LOR-value is far from the estimated threshold, there are few chances to obtain an incorrect classification.

Considering that the LOR-value is a numeric sentiment value, it is obvious than if this value is close to the threshold even a word with an irrelevant sentiment value could be classified incorrectly.

To improve the performance of the Threshold-based Naïve Bayes Classifier for LOR-values located close to the threshold, we add a new step that refines the threshold while classifying only those comments that are close to the selected value of τ. Then, we classify again those comments with a new estimated value of τ.

The "augmented" Iterative Threshold-based Naïve Bayes works as follows:

1. a proportion of observations close to τ, and located in the uncertainness area, are marked for being reclassified.
2. A new decision rule is created for those observations only, estimating a new value of τ.
3. Observations in the uncertainness area are re-classified and Steps 1-3 are repeated until the proportion of cases in the uncertainness area reduces consistently.

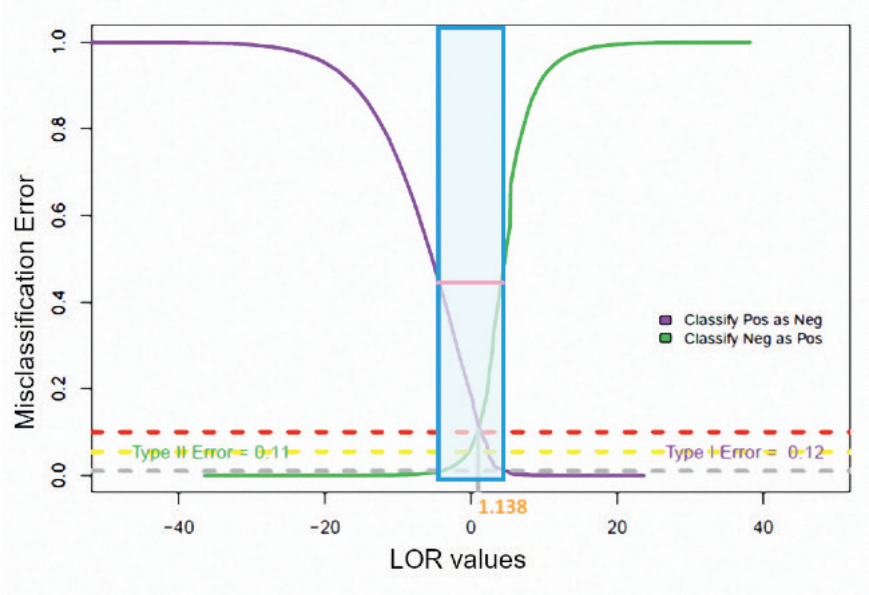

Fig. 1 Threshold-based Naïve Bayes uncertainness area

We can then transform that logic in an algorithm that better describes such a process:

---

1. Set $i = 0$
2. Map the distribution of LOR-values into two functions:

$$x = LOR(\pi_c)$$

$$f_{pos} : x \mapsto [0;1], f_{neg} : x \mapsto [0;1] \qquad \forall x \in (-\infty;+\infty)$$

   s.t. the input (x) is the LOR-value of a comment c and the output of f_{pos} (f_{neg}) is the probability that c is positive (negative).
3. Define max_{pos}, max_{neg} s.t.:

$$max_{pos} = \underset{x\in(-\infty;+\infty)}{\text{argmax}} \; f_{pos}(x)$$

$$max_{neg} = \underset{x\in(-\infty;+\infty)}{\text{argmax}} \; f_{neg}(x)$$

4. Compute the intersection point τ_i s.t.

$$\tau_i = \begin{cases} \underset{x \in (max_{pos}; max_{neg})}{\text{argmin}} \; (f_{neg}(x) - f_{pos}(x)) & \text{if } max_{pos} < max_{neg} \\ \underset{x \in (max_{neg}; max_{pos})}{\text{argmin}} \; (f_{neg}(x) - f_{pos}(x)) & \text{if } max_{pos} > max_{neg} \end{cases}$$

5. if $max_{pos} < max_{neg}$ update the decision rule:
   $LOR(\pi_c) > \tau_i \rightarrow$ c is classified as "Negative"
   $LOR(\pi_c) \leq \tau_i \rightarrow$ c is classified as "Positive"
6. otherwise, if $max_{pos} > max_{neg}$ update the decision rule:
   $LOR(\pi_c) > \tau_i \rightarrow$ c is classified as "Positive"
   $LOR(\pi_c) \leq \tau_i \rightarrow$ c is classified as "Negative"
7. Set $i = i + 1$
8. Repeat steps 1-7 with a proportion ω of comments located in the interval $\tau_i \pm \partial\omega$ until a stopping criterion is satisfied.

The proportion of observations marked for being re-classified is estimated while considering the uncertainness area around τ. Using a large value of ω leads to results that are similar to those obtained from Threshold-based Naïve Bayes classifier, whilst using a low value for ω might lead to consider few observations only, thus producing a decision rule which overfits the data. Our experiments suggest that, empirically, a good trade-off is reached by setting $\omega = 0.20$.

Whereas, the **stopping criterion** of the iterative Tb-NB depends on at least one of the following conditions:

1. the number of cases (positive and negative comments) used to produce a reliable distribution of LOR-values, and the associated function that map them, is too small;
2. there is no intersection point (other than zero) between $f_{pos}(x)$, *and* $f_{neg}(x)$ and $max_{pos} \neq max_{neg}$. The two distributions are well separated, thus the τ estimated by the standard Threshold-based Naïve Bayes Classifier at the previous step is the final value of τ;
3. $max_{pos} = max_{neg}$. We cannot distinguish the positive distribution from the negative one. Thus, there is not a geometric solution to this problem and the classification of those comments has to be done with the τ estimated by the Threshold-based Naïve Bayes Classifier.

Moreover, it is interesting to highlight how empirical results suggest that the stopping criterion usually is reached after no more than two iterations ($0 \leq i \leq 2$).

Furthermore, in Table 2 we have compared the performance of the proposed classifier (iTb-NB) with the previous version (Tb-NB) and that of other well known competitors, in particular: Logistic Regression (LOG), Random Forest (RF), standard Naïve Bayes (NB E1071 [5]), Naïve Bayes using kernel estimated densities (NB KlaR [8]), Decision Trees (CART), Linear Discriminant Analysis (LDA) and Support Vector Machine (SVM).

It is possible to notice that iTb-NB is the most accurate classifier with respect to four out of the five measures reported in the table.

Table 2 Performance metrics on raw data using 5-fold cross validation

Classifier	ACC	Sensitivity	Fall-out	F1	MCC
Tb-NB	0.911	**0.929**	0.117	0.926	0.813
iTb-NB	**0.925**	0.923	**0.072**	**0.939**	**0.829**
LOG	0.850	0.884	0.532	0.877	0.361

LDA	0.764	0.860	0.641	0.816	0.246
SVM	0.793	**0.929**	0.290	0.771	0.621
average	0.826	0.872	0.401	0.851	0.469

Notes: ACC = Accuracy; F1 = F1-score; MCC = Matthews Correlation Coefficient

4 Conclusions

We have proposed an improved, and "iterative", Threshold-based Naïve Bayes Classifier. Furthermore, we have compared the performance of the new proposal with the previous one using the same Booking.com reviews data. Reclassifying subsets of observations has then been proved as a way to reduce the misclassification rate and hence boosting the performance of Tb-NB whilst keeping the original interpretability of the results.

Reprogramming FairGANs with Variational Auto-Encoders: A New Transfer Learning Model

Auto-Encoders variazionali per la riprogrammazione di FairGANs: un approccio basato su Transfer Learning

Beatrice Nobile, Gabriele Santin, Bruno Lepri and Pierpaolo Brutti

Abstract Fairness-aware GANs (FairGANs) exploit the mechanisms of Generative Adversarial Networks (GANs) to impose fairness on the generated data, freeing them from both disparate impact and disparate treatment. Given the model's advantages and performance, we introduce a novel learning framework to transfer a pre-trained FairGAN to other tasks. This reprogramming process has the goal of maintaining the FairGAN's main targets of data utility, classification utility, and data fairness, while widening its applicability and ease of use. In this paper we present the technical extensions required to adapt the original architecture to this new framework (and in particular the use of Variational Auto-Encoders), and discuss the benefits, trade-offs, and limitations of the new model.

Abstract *Le FairGANs rappresentano una classe di modelli di recente introduzione che si sono dimostrati particolarmente efficaci nell'indurre imparzialità nei dati generati sfruttando i meccanismi propri delle Generative Adversarial Networks (GANs). Sulla base di queste premesse, nel presente lavoro introduciamo un nuovo schema di transfer learning per estendere l'applicabilità di una FairGAN pre-addestrata ad altri data-set e task, anche profondamente diversi da quelli visti in training. Questo processo di riprogrammazione ha lo scopo di mantenere i principali obiettivi di FairGAN ampliandone al tempo stesso il campo e la facilità d'uso. Qui presentiamo le estensioni tecniche necessarie per adattare l'architettura originale al nuovo framework (in particolare l'uso di Variational Auto-Encoder) e discutiamo i vantaggi, i compromessi e le limitazioni del nuovo modello.*

Key words: FairGAN, Reprogramming, Variational Auto Encoder, Fairness

1 Introduction

The research on Fairness in automated systems has recently advanced considerably, even if recent developments have made the field increasingly complex. The paper [6] lists as many as 23 possible biases in the data, and 6 different types of discrimination that may arise from it, but most importantly they also list 10 different definitions of fairness with no method that can address them all at the same time [8].

Within this complex landscape, FairGANs [10] offer a simple and actionable mechanism to address biases in the data. Rather than debiasing the data at hand, FairGANs use a GAN-like mechanism to generate new data that must be as similar as possible to the original, but with the additional feature that no evident correlation with the protected attribute is present. As such FairGANs can ensure that the system would be free of both *disparate treatment* and *disparate impact*, i.e., implicit and explicit discrimination in its decision making.

Since the need for retraining at each usage may be cumbersome at best and unfeasible in many cases where there is not enough data or computing power, this paper aims at creating a transfer learning model for FairGANs. This could lead to a wider adoption of such a method given an increased ease of usage, minimized resource demands, and the ability to re-use knowledge from high-quality data, potentially without loss of accuracy.

To achieve these goals, we make use of Adversarial Reprogramming techniques [3, 5]), which can retrain the model without the need for the original dataset, and only modifiying a reduced part of the model. The biggest issue in applying transfer learning for FairGANs with Adversarial Reprogramming is that the two architectures have been designed to work on different types of data. In fact, while FairGANs have to do with tabular data, Adversarial Reprogramming so far has only been applied to images and sequences [5, 7]. Therefore, the first contribution of this paper is designing a model that is able to perform Reprogramming on tabular data. To do so, we have used Variational Auto-Encoders [2] which allow for the necessary dimensional flexibility. The second contribution is understanding whether transfer learning is possible on FairGANs, or if instead direct training is absolutely necessary at each new task. Our findings suggest that balancing all three objectives of FairGANs, data utility and fairness and classification utility, is not trivial when performing transfer learning. Yet, even extreme cases have yielded positive results in most experiments, suggesting that it is indeed possible.

2 Materials and Methods

We recall the tools used in our model in Section 2.1, and introduce the complete solution in Section 2.2.

2.1 Background on GANs, FairGANs, and reprogramming

GANs were first introduced in 2014 [4]. Given an initial dataset $\mathscr{D} := \{x_i\}$ of certain objects, the idea is to train two neural networks, a generator G and a discriminator D, so that G is able to generate, from a random input seed $\bar{z}$, an object $\bar{x}$ that is as similar as possible to the true ones, while D is able to classify real and fake objects. The two networks are trained to minimize a minimax loss [4].

FairGANs [10] follow the same mechanism but applied now to an extended dataset $\mathscr{D} := \{(x_i, y_i, s_i)\}$, where x_i is a certain object, y_i is an associated binary label, and s_i is a binary value representing the membership of x_i in a protected class. In this case G is seeded with a random input $\bar{z}$ and a value $\bar{s} \in \{0,1\}$, and outputs a generated pair $(\bar{x}, \bar{y})$. A first discriminator D_1 tries to tell apart the triples $(\bar{x}, \bar{y}, \bar{s})$ from those found in $\mathscr{D}$, while a second discriminator D_2 tries to classify the pairs $(\bar{x}, \bar{y})$ generated with an input $\bar{s} = 0$ from those generated with an input $\bar{s} = 1$, of course without access to the actual value of $\bar{s}$. A modification of the minimax optimization problem forces G to fool both discriminators, thus learning to generate data that are realistic (*data utility*), and for which the protected attribute is hard to identify if not disclosed (*data fairness*). Once the training is completed, G can be used to generate a bias-free dataset, that can finally be used to train a classifier that predicts the binary label y for a previously unseen object x, without relying on s.

In order to perform transfer learning with a pre-trained FairGAN, we additionally use Adversarial Reprogramming techniques [3]. In general terms, given a model $f : X \to Y$ between sets X, Y and a target model $g : X' \to Y'$ between sets X', Y', the goal is to modify the input and output of f in order to mimic the response of g. A typical example is the modification of a pre-trained classifier that maps a set of images X to suitable labels Y, in order to obtain a new classifier g that works on a different set of images X' of possible different resolution, with other labels Y'. This goal is achieved by training two parametric functions $h_f : X' \to X$, $h_g : Y \to Y'$ so that the input-output modified model $h_g \circ f \circ h_f : X' \to Y'$ approximates g. This general technique has been applied to GANs in [5], where an existing generator-discriminator pair (G, D) is updated to generate objects of the same original dimension, but following a different distribution. An input modification function h_f is applied to obtain a new generator $G' := G \circ h_f : Z' \to X$, where Z' is a second set of input noise seeds. Since the GAN training step requires the join optimization of the generator and discriminator, the new discriminator D' is instead trained from scratch, therefore moving away from an adversarial attack paradigm towards one of transfer learning.

2.2 Reprogramming FairGANs

We assume to have a dataset $\mathscr{D} := \{(x, y, s)\} \subset X \times Y \times \{0,1\}$, where X are tabular data, and initially train a classifer $\overline{C} : X \to Y$, that will remain fixed. Additionally, we train a standard VAE $\overline{\text{Enc}}, \overline{\text{Dec}}$ on $X \times S$, i.e., $\overline{\text{Dec}}(\overline{\text{Enc}}((x,s))) := (G_x(x,s), G_s(x,s)) \approx (x,s)$ for all $(x,s) \in X \times S$. This will serve as the base for the

construction of the generator and allow us to tackle reprogramming with dimension expansion, which is a notoriously hard to solve problem [5].

We then consider a second target dataset $\mathscr{D}' := \{(x', y', s')\} \subset X' \times Y \times \{0,1\}$ with tabular input X'. We assume that the columns of X' are either a subset or a superset of those of X. Observe that a special setting of interest, which we will explore in the following, is the case when $X = X'$ or $Y = Y'$. Our goal is to adapt the classifier $\overline{C}$ to $\mathscr{D}'$ under two constraints: creating realistic data, and creating bias-free data.

To reprogram with the realism constraint only, we define a generator $G : (X', S') \to (X, S)$ defined as $G := \overline{\text{Dec}} \circ \text{Enc}$ which maps the new columns to the old ones. We also define a discriminator $D : X \to \{0,1\}$. Observe that the decoder part of the generator is kept fixed. Instead, we train Enc with two goals: we want to have $\overline{C}(G_x(x')) \approx y'$, i.e., the classification accuracy is preserved, and we want that D_1 can't distinguish $G(X' \times S')$ from $X' \times S'$. Observe that D_1 acts only on the columns of $G(X')$ that are in common with those of X', so that it can be trained by having access to X' only, and not to the original set X. That is, the discriminator should discriminate only those columns that represent the current data. This goal is realized by the optimization of Enc and D_1 by minimization of a loss composed by the usual GAN loss with ℓ_2 norm penalty, plus the cross entropy loss for classification. The balance between the two losses is controlled by a parameter $\gamma \geq 0$ (large γ means large importance to classification). In this way we realize a transfer of the classifier from $\mathscr{D}$ to $\mathscr{D}'$, in a way that preserves a realism condition on the generated data. Observe that even without the realism constraint, this *tabular reprogramming* is an unexplored field for adversarial reprogramming.

When adding a fairness constraint, we obtain the full *FairGAN reprogramming* model, which differs solely for the presence of additional discriminators. In this case, a second discriminator $D_2 : G(X' \times S') \to S'$ tries to distinguish between the generated columns that are generated with an original input with $s' = 0$ or $s' = 1$. This second discriminator is trained together with Enc and D_1, by adding to the loss a second GAN-discriminator loss term controlled by a second parameter $\delta \geq 0$, where $\delta = 0$ means that D_2 is deactivated. With this design, the reprogrammed FairGAN guarantees data fairness because the "fairness" discriminator D_2 forces the generator to produce data that is independent of the sensitive information.

3 Results

For our experiments we use two datasets, COMPAS Recidivism Racial Bias [1] comprising after cleaning 60843 observations and 15 columns, and a Candidate Selection dataset [9] comprising 31349 observations and 10 columns. We consider as target labels y either *gender* (both datasets), or *ethnic code* (Caucasian or not, in COMPAS) and *selected* (hired or not - Candidate).

Table 1 reports the accuracies of these four classifiers $\overline{C}$, that we consider as baselines for our experiments. For the reprogramming tasks we consider four scenarios: i) We don't change neither dataset nor task (Same Dataset Same Task, SDST); ii) We change the task but not the dataset (Same Dataset Different Task, SDDT); iii)

We change dataset while maintaining the same task (Different Dataset Same Task, DDST); iv) We change both dataset and task (Different Dataset Different Task, DDDT). We remark that passing from COMPAS to Candidate requires a dimensionality reduction, while the vice versa requries a dimensionality expansion.

In all experiments, we use the architecture of Section 2.2. The latent dimension is set to 10, which is the smallest value that does not affect the classification accuracy in the results of Section 3.1.

	COMPAS-Gender	COMPAS-Ethnic code	Candidate-Gender	Candidate-Selected
Accuracy	82.8	67.2	78.8	71.7

Table 1: Accuracy of the classifiers trained on different dataset and target labels.

3.1 Tabular Reprogramming

We first test simply tabular reprogramming, i.e., without fairness constraint. In other terms, the only objective we are trying to achieve is to efficiently fool the classifier in order to maintain high accuracy, regardless of how we generate the data. We consider the classifier trained on the Candidate dataset to predict the label *gender*, and report the results of the four transfer learning scenarios SDST, SDDT, DDST, DDDT in the left part of Table 2. The model works very well in three out of four cases, even outperforming the baseline. Observe that this is possible since the architecture includes now also the optimizable encoder, and thus the overall model has more degrees of freedom. Only in the DDDT setting, which is ideed the more challenging, we observe a limited reduction of 4% in the accuracy. Thus, we can affirm that we have successfully reprogrammed across tabular datasets.

	SDST	SDDT	DDST	DDDT	γ	SDST	SDDT	DDST	DDDT
Reprogramming	78.9	78.7	79.1	74.5	0.5	74.2 ✓	57.6 ✓	61.1 ✓	52.7 ✓
					100	76.3 ×	64.8 ×	69.1 ✓	64.8 ✓
Baseline	78.8	78.8	78.8	78.8		82.8	67.2	78.8	71.7

Table 2: Accuracy results of tabular reprogramming (left, see Section 3.1) and GAN reprogramming (right, see Section 3.2), compared to the corresponding baseline models obtained by direct training.

3.2 GAN and FairGAN Reprogramming

We now add the data realism constraint, so that we both reprogram the classifier and require the generated data to be similar to the input one. As described in Section 2.2, a parameter γ balances the importance of classification and of data realism, where larger values of γ increase the relative importance of classification. The setting of γ is itself a challenging task. Cross validation over the values of γ in combination

with the learning rate η have identified a values $\gamma = 0.5$, $\eta = 10^{-3}$. However, preliminary investigations have shown that reasonable results may be achieved with $\gamma \in [10^{-1}, 10^{2}]$. We report the results in Table 2, where we also report the case of $\gamma = 0.5$ for comparison. Each experiment reports also a green check or a red cross to indicate if the data realism constraint is met. In these preliminary experiments, this is checked by comparing the histograms of the distributions of the single true and generated columns. Unsurprisingly, moving across datasets seems to be more challenging for our model, but we manage to keep a relatively small decay in the accuracy, especially considering the semantic distance between the two datasets and the respective tasks.

Adding the fairness constraint we can finally test the entire FairGAN model, where we tested the model on several randomly selected columns used as the protected attribute. In this case the loss comprises the three terms of classification accuracy, realism, and fairness, and their relative importance is controlled now by the two hyperparameters δ and γ. To measure the success of the fairness constraint, we check if the validation accuracy of the discriminator is close to 50% on a validation set, meaning that the protected attribute is not predictable from the cleaned data. In this case, no value of the two parameter give a sufficiently accurate result in SDST and SDDT, while for DDST and DDDT we managed to obtain a validation accuracy close to 50%. This apparently counter-intuitive result may be due to preliminary nature of our experiments, and will be addressed in future research.

4 Conclusions

In this work we introduced for the first time a framework for the reprogramming FairGANs on tabular data, i.e., the possibility of using a pre-trained FairGAN and apply it to other datasets and/or tasks, maintaining acceptable levels of *data utility*, *classification utility* and *data fairness*. Our novel architecture leverage VAEs as a basic building block, and combines it with two dicriminators which are trained with a GAN loss to forse the generation of data that meets the desired constraints. Preliminary experiments on two benchmark datasets have shown that the model can be effectively trained to reprogram FairGANs on tabular dataset. Nevertheless, the incremental addition of multiple constraints makes the training increasingly challenging. Even if the experiments lean towards positive results, some issues remain unanswered, especially in the design of an effective balancing mechanism between the various components of the model.

Robust statistics

Combinatorial Analysis of Factorial Designs with Ordered Factors

Analisi Combinatoria di Piani Fattoriali con Fattori Ordinali

Roberto Fontana and Fabio Rapallo

Abstract In recent literature a new combinatorial algorithm for the selection of robust fractional factorial designs has been introduced. In this work we analyze the application of this algorithm in the case of ordered factors.
Abstract *È stato sviluppato recentemente un nuovo algoritmo combinatorio per la selezione di piani fattoriali frazionari robusti. In questo lavoro analizziamo la sua applicazione nel caso di fattori ordinali.*

1 D-optimality, robustness, and combinatorial objects

The choice of a design from a set of candidate runs is one of the most relevant problems in Design of Experiments. When working in the framework of factorial designs, the candidate set is usally the full-factorial design containing all the possible level combinations of the factors. There are several criteria for choosing a design. Here we restrict our attention to model based techniques. Thus the linear model on the candidate set $\mathscr{D}$ is written in the form

$$\mathbf{y} = X_{\mathscr{D}}\beta + \varepsilon\,, \tag{1}$$

Roberto Fontana
Dipartimento di Scienze Matematiche, Politecnico di Torino, Corso Duca degli Abruzzi 24, 10129 Torino, e-mail: roberto.fontana@polito.it

Fabio Rapallo
Dipartimento di Economia, Università di Genova, via Vivaldi 5, 16126 Genova, e-mail: fabio.rapallo@unige.it

where $X_{\mathscr{D}}$ is the full-design model matrix with dimensions $K \times p$, β is the p-dimensional vector of the parameters, ε is the error, and $\mathbb{E}(\mathbf{y}) = X_{\mathscr{D}}\beta$.

The classical theory leading to the class of alphabetical optimality criteria (D-optimality, A-optimality, etc.) is based on the maximization of some quantities computed using the model matrix $X_{\mathscr{F}}$ of the selected fraction $\mathscr{F} \subset \mathscr{D}$. In their basic form, the selection algorithms work with a pre-defined and fixed dimension $n = \#\mathscr{F}$ of the fraction. As general reference for optimal designs, refer to [6].

When the design may be incomplete, e.g. for time limitations, there are methods to choose the order of the runs in order to achieve first the most informative runs, so that a possibly incomplete design is as much effective as possible for parameter estimation. Fractional Factorial Designs with removed runs are studied in, e.g., [1], [7]. In such a case the set $\mathscr{D}$ is usually a candidate set different from the full-factorial design.

Both optimality with a fixed run size and with possibly incomplete designs has been recently analyzed under a geometric and combinatorial point of view using a special representation of the basis of the kernel $\ker(X_{\mathscr{D}}^t)$ of the model matrix for the candidate set, namely the circuit basis. In particular, the property that naturally reflects the geometry of the design points is the robustness, first introduced in [4].

Definition 1. The robustness of a fraction $\mathscr{F}$ with design matrix $X_{\mathscr{F}}$ is defined as

$$r(X_{\mathscr{F}}) = \frac{\#\left\{ \text{ saturated } \mathscr{F}_p \right\}}{\#\left\{\mathscr{F}_p\right\}} = \frac{\#\left\{ \text{ saturated } \mathscr{F}_p \right\}}{\binom{n}{p}}$$

where $\mathscr{F}_p$ denotes a fraction with p runs and $\#\{\cdot\}$ denotes the cardinality of the set $\{\cdot\}$. $\mathscr{F}$ is a saturated fraction if $\#\mathscr{F} = p$ and the parameters β are estimable.

On the other hand, the circuit basis of the matrix $A_{\mathscr{D}} = X_{\mathscr{D}}^t$ is defined as follows.

Definition 2. 1. A vector $\mathbf{u} = (u(1), \ldots, u(K))$ in $\ker(A_{\mathscr{D}})$ is a circuit if it has relatively prime entries and minimal support. The support of a vector is the set of indices for which the entries are non-zero.
2. The (finite) set of all the circuits is the circuit basis of $\ker(A_{\mathscr{D}})$, and it is denoted by $\mathscr{C}(A_{\mathscr{D}})$.

For a concise reference on the circuits, their combinatorial properties, and their applications to optimization problems, the reader can refer to [8]. The circuit basis of an integer matrix $A_{\mathscr{D}}$ can be computed through several packages for symbolic computation. The computations presented in the present paper are carried out with `4ti2`, see [9].

In [2] and [3] it is shown that robust fractions correspond to the fractions which minimize the intersections between the fraction and the support of the circuits. For space limits, we do not introduce here the full details of the theory, but we summarize the algorithm for finding nested robust fractions using the circuit basis.

1. Start with an arbitrary fraction $\mathscr{F}$ of a specified size n;
2. Repeat:

a. Consider the circuits of $\mathscr{C}(X_{\mathscr{D}})$ which are contained in $\mathscr{F}$;
b. For each run R in $\mathscr{F}$, compute the number of circuits in which R is contained. This is the loss function associated to R;
c. Remove from the fraction the run with the highest loss function. In case of ties, randomize.

2 Circuits in case of ordered factors

In the previous section we have not mentioned the problem of the choice of the coding of the factor levels. Indeed, the combinatorial analysis introduced above is usually applied in the framework of qualitative nominal factors. In such a case, the linear model in Eq. (1) can be written in the standard ANOVA form. For instance:

$$\mathbb{E}(Y_{ij}) = \mu + \alpha_i + \beta_j + (\alpha\beta)_{ij} \tag{2}$$

with the constraints $\sum_i \alpha_i = 0$, $\sum_i \beta_i = 0$, $\sum_i (\alpha\beta)_{ij} = 0$,$\sum_j (\alpha\beta)_{ij} = 0$.

Using the model written in the form of Eq. (2) with qualitative factors, there is a large class of codings which are equivalent in terms of the kernel of the matrix $A_{\mathscr{D}} = X_{\mathscr{D}}^t$. Among these parametrizations, one can use a polynomial model in the form $\mathbb{E}(Y) = \sum_{\alpha \in L} c_\alpha X^\alpha$, where c_α are real coefficients, X^α are monomials, and L is a suitable list of exponents. The proof of the equivalence is based on the Identity Theorem for Polynomials, see [5] for a detailed analysis and examples.

To encode ordered factors we use here two codings:

1. For a linear ordered factor (e.g., the discretization of a quantitative factor) with s levels, we use the set $\{0,\dots,s-1\}$ for a linear effect, and its powers for higher-order effects;
2. For a cyclic factor with s levels, we use the coding based on the roots of the unity:

$$\left\{ \omega_k = \frac{2\pi i k}{s} \ : \ k = 0,\dots,s-1 \right\} \tag{3}$$

With this choice, the monomials $X, X^2, X^3, \dots$ encode the cyclical nature of the factor. For computational reasons, the roots of the unity in Eq. (3) can be replaced with suitable Fourier-type functions, such as linear combinations of sin and cos functions.

Notice that there is a major difference between nominal and ordered factors. While for nominal factors all parametrizations are equivalent, when ordered factors are considered one can add to the model only a linear effect, or the linear effect plus some powers. This implies that when using the algorithm described in the previous section with ordered factors, special attention must be given on the circuit basis, taking the correct effects in the model matrix. In the next section we illustrate two examples involving ordered factors.

3 Examples

The first example considers two 2-level factors (X_1, X_2) and one 5-level factor (X_3) with two different models. The first model is linear in X_1, X_2, and X_3 and contains a constant term: $\mathbb{E}(Y_{(x_1,x_2,x_3)}) = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \beta_3 x_3$. The number of degrees of freedom of this model is $p = 1+3 = 4$. For this model, the circuit basis is formed by 44 circuits with cardinality of the supports ranging from 2 to 5. The robustness of a D-optimal design with $n = 10$ runs is analyzed. The 10-run D-optimal design has been obtained using the full factorial design $\mathscr{D} = \{0,1\}^2 \times \{0,\ldots,4\}$ as candidate set. The exact distributions of the values of the robustness of the fractions which are obtained removing $k = 1,\ldots,n-p = 6$ points are computed and compared with the values of the robustness corresponding to the fractions found by the algorithm. Table 1 compares the values of the robustness of the fractions found by the algorithm (r_*) with the 75th, 90th and 95th percentile of the distributions of the robustness (p_{75}, p_{90}, p_{95} respectively) for different number of points (k) removed by the initial design. The value corresponding to the robustness of the initial design (r_0) is given at $k = 0$. It is worth noting that for each number k of points removed the algorithm provides values of robustness equal to the 95th percentile.

k	p_{75}	p_{90}	p_{95}	r_*
0		r_0=0.457		
1	0.476	0.476	0.476	0.476
2	0.529	0.529	0.529	0.529
3	0.629	0.629	0.629	0.629
4	0.6	0.6	0.867	0.867
5	0.8	1	1	1
6	1	1	1	1

Table 1: Example 1, $\mathbb{E}(Y_{(x_1,x_2,x_3)}) = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \beta_3 x_3$

Unlike the first model, the second one contains also the powers of X_3 of order 2,3,4: $\mathbb{E}(Y_{(x_1,x_2,x_3)}) = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \sum_{k=1}^{4} \beta_{3k} x_3^k$. The number of degrees of freedom of this model is $p = 1+2+4 = 7$. From the combinatorial point of view this model is simpler than the linear one: there are only 4 circuits in the circuit basis. Also in this case the robustness of a D-optimal design with $n = 10$ runs and obtained using the full factorial $\mathscr{D}$ as candidate set is analyzed. The exact distributions of the values of the robustness of the fractions which are obtained removing $k = 1,\ldots,n-p = 3$ points are computed and compared with the values of the robustness corresponding to the fractions found by the algorithm. In this case we do not display all the results, but the performance of the algorithm is similar to the previous example.

The second example is taken from [11] and is based on [10]. An animal scientist wants to compare wildlife densities in four different habitats over a year. However, due to the cost of experimentation, only $n = 16$ observations can be made (in the original example the requested size was $n = 12$, but $n = 16$ allows us to describe the

method better than $n = 12$). The following model is postulated for the density $Y_j(t)$ in habitat j during the month m:

$$\mathbb{E}(Y_j(t)) = \mu_j + \gamma m + \sum_{k=1}^{4} \alpha_k \cos\left(k\frac{\pi m}{4}\right) + \sum_{k=1}^{3} \beta_k \sin\left(k\frac{\pi m}{4}\right) \tag{4}$$

The model includes the habitat as a classification variable ($\mu_j, j = 1,\ldots,4$), the effect of time with an overall linear drift term γm, $m = 1,\ldots,12$ ($m = 1$ corresponds to January, $\ldots$, $m = 12$ corresponds to December), and cyclic behavior in the form of a Fourier series. There is no intercept term in the model and the number of parameters is $p = 4+1+4+3 = 12$.

The Optex procedure [11] is used to generate a D-optimal design $\mathscr{F}$ with $n = 16$ runs using the full factorial arrangement of four habitats by 12 months (48 runs) as candidate set. The model matrix $X_{\mathscr{F}}$ corresponding to the 16-run D-optimal design that has been generated by the Optex procedure is reported in Table 2. The month $m \in \{1,\ldots,12\}$ is expressed as a number $t \in [-1,+1]$ using the linear transformation $t = -1 + (2/11)(m-1)$.

Table 2: Model matrix $X_{\mathscr{F}}$ corresponding to the 16-run D-Optimal design

The circuits of a matrix A can be computed for an integer matrix A. Then we have to build an approximate version $\tilde{X}_{\mathscr{F}}$ of $X_{\mathscr{F}}$. Let us denote with x_{ij} and $\tilde{x}_{ij}$ the elements of the matrices $X_{\mathscr{F}}$ and $\tilde{X}_{\mathscr{F}}$ respectively, $i = 1,\ldots,16$, $j = 1,\ldots,12$. We do not modify the coding of the habitats, $\tilde{x}_{ij} = x_{ij}, j = 1,\ldots,4$, we code the month using again the integer m as above ($\tilde{x}_{ij} = m$) and we round the remaining values defining $\tilde{x}_{ij} = 10r(x_{ij})$ where $r(x)$ returns the rounding of x to one decimal place. For example for the first row of $\tilde{X}_{\mathscr{F}}$ we have $\tilde{x}_{14} = 1$, $\tilde{x}_{15} = 3$ and $\tilde{x}_{16} = -7$ which correspond to the parameters μ_4, γ, and α_1 respectively. However the circuits

encodes the complexity of the model: there are 26 circuits in the circuit basis but the supports now range from 8 to 10 points.

From Table 3 it is worth noting that for each number k of points removed the algorithm provides values of robustness equal to the 95th percentile.

k	p_{75}	p_{90}	p_{95}	r_*
0		r_0=0.527		
1	0.527	0.527	0.527	0.527
2	0.571	0.571	0.571	0.571
3	0.615	0.769	0.769	0.769
4	1	1	1	1

Table 3: Example 2, $\mathbb{E}(Y_j(t)) = \mu_j + \gamma m + \sum_{k=1}^{4} \alpha_k \cos(k\frac{\pi m}{4}) + \sum_{k=1}^{3} \beta_k \sin(k\frac{\pi m}{4})$

Robustifying the Rasch model with the Forward Search

Modello di Rasch robusto, mediante la Forward Search

Anna Comotti and Francesca Greselin

Abstract We introduces a forward search method for identifying atypical observations in Item Response Theory models for binary data (Rasch models). Our proposal introduces diagnostic tools, based on robust high-breakdown methodologies, to avoid distortion in the estimation of the model, and to single out outlying response patterns. Atypical response patterns usually deserve further investigation. Methods to initialize, progress, and monitor the Forward Search are explored. The simulated dataset showcases the effectiveness of the method in the presence of outliers.
Abstract *Introduciamo un metodo di Forward Search per identificare osservazioni atipiche nei modelli di Item Response Theory per dati binari (modelli di Rasch). Presentiamo strumenti diagnostici, basati su metodologie robuste, per evitare distorsione nella stima del modello e per individuare risposte anomale. Risposte atipiche solitamente necessitano ulteriori indagini. Vengono introdotti metodi per inizializzare, far progredire e monitorare la Forward Search. Risultati ottenuti mediante simulazioni mostrano l'efficacia del metodo in presenza di valori anomali.*

ployed models for assessing unobserved constructs, such as abilities, attitudes, exposure to an illness, and socioeconomic status.

Data are usually collected through surveys and measured over a scale. Atypical response patterns could arise due to cheating or guessing - when measuring abilities - and careless or systematic responding, exaggerated answers and also erroneous interpretation of an item, in all cases. Such cases should be identified and dealt with specific care. Moreover, aberrant response patterns could severely bias parameter estimation, and robust methodologies are needed to overcome this issue.

One of the first studies on the binary IRT model to remove the effects on random guessing in latent ability estimates is due to Waller Waller (1974). Based on the consideration that an item which is very difficult for a particular individual is an item which invites guessing, a conditional ML Estimation method is proposed, omitting from estimation any interaction for which this estimated probability is lower than some cutoff point, P_c.

A few years later, Wainer & Wright (1980) shows that gains in recovering abilities in the presence of guessing and untoward responses of other kinds can be obtained through the use of a robust jackknife. The jackknife procedures were supported only on empirical bases, therefore results cannot be generalized to two- or three-parameter logistic model.

A robust estimator of location is introduced in Mislevy & Bock (1982) based on the principle of Tukey's biweight. The larger the weighted differences between difficulty and ability, the heavier the down-weighting of the observation. The latter method is prone to produce infinite ability estimates for unexpected response patterns, whenever correct answers are sparse, so that Schuster & Yuan (2011) propose to adopt the Huber-type estimator.

A more recent paper Patton et al. (2019) proposes an iterated approach. First, the careless respondents are detected using the person-fit statistics in its standardized log-likelihood version l_z^* (Drasgow et al. 1985), then the corresponding responses are removed from the dataset, and this process continue by iteratively updating the item parameter estimates. An analogous method was used by Hong & Cheng (2019) and applied to the graded response models (polytomous scored items). First, the item parameters are estimated from the full data. Next, normalized l_z^*'s p-values are used as the weights to re-estimate the model.

Among some very recent contributions, Hong et al. (2020) investigated the efficacy of Insufficient Effort Responding (IER) detection methods as a data cleansing method. They evaluated six different detection methods and demonstrated which were best for flagging different types of IER.

A further iterative method was introduced by Liu & Liu (2021). The authors proposed to apply an iterative purification process based on a response time residual method with fixed item parameter estimates to detect non-effortful responses.

An IRT approach for detecting person-level outliers which rely on likelihood-based statistics has been proposed in Felt et al. (2017) to determine the most typical response patterns. The model is firstly estimated over the whole data and then new weights (derived from the limited information test statistic M_2, defined in Section 2), are employed to correct it.

Most methods cited till now start upon a first inference performed on the entire dataset. Therefore, they will not be preserved from the issue of *masking* and *swamping*. The masking effect occurs when an outlier is undetected because of the presence of a cluster of outliers and the swamping effect occurs when a *good* observation is incorrectly identified as an outlier.

The remaining part of the paper is organized as follows: Section 2 outlines the methodological extension of the Forward Search (FS) algorithm to the IRT model; Section 3 presents an application of the proposed methodology in published IRTs and simulated datasets; Section 4 discusses the main findings and provides directions for using the proposed diagnostic methodology for IRT.

2 The Forward Search for Rasch models

We propose a procedure for the detection of multiple outliers in IRT data based on the Forward Search (FS). The FS algorithm was initially introduced as an outlier detection tool for the estimation of covariance matrices Hadi (1992), and regression models Atkinson et al. (2000). It was subsequently extended to standard multivariate methods Atkinson et al. (2004), and factor analysis Mavridis & Moustaki (2009), and was recently applied in meta-regression Petropoulou et al. (2021).
We will use graphs to understand the relationship between a model and the data to which the model is fitted. Along model estimation, in a classical setting, we can lose information about the effect of individual observations on inferences about the form and parameters of the model. FS methods, instead, reveals how the fitted model depends on individual observations and on groups of observations. Robust procedures can sometimes reveal this structure, by down-weighting or discarding some observations. The novelty in FS is to combine robustness and a *forward search* through the data with model diagnostics and computer graphics. We introduce here easily understood plots for IRT models that use information from the whole sample to display the effect of each observation on a wide variety of aspects of the fitted model. The examples on simulated data show the amount of information the plots generate and the insights they provide.

Let Y be an $n \times k$ data matrix representing n observations on k items. We first introduces a plausible method to select a *basic* subset which contains p *good* observations and a *non-basic* subset which contains the remaining $n-p$ observations. Starting from the n initial observations, we extract a sub-sample of size p. The best basic set is chosen according to a test statistic which indicates how well the data are fitted by the estimated model. We have chosen to adopt the *limited information test statistic* M_2^* to evaluate such fit, due to its well known asymptotic properties

$$M_2^* = n(\pi - \hat{\pi})' C (\pi - \hat{\pi}). \tag{1}$$

It is called *limited information test statistic* because it is calculated for bivariate margins with positive responses to pair of items and it is widely used to assess

goodness-of-fit in the IRT field. C is a weight matrix of response patterns, π and $\hat{\pi}$ are the vectors of observed and expected (under the model) proportions for all the possible distinct 2^k response patterns. The M_2^* statistic is asymptotically χ^2 distributed and indicates an adequately fitting model when $p > 0.05$.

Second, for progressing in the forward search we increase the *basic* set adding the response pattern with the highest likelihood contribution. The likelihood contribution of the response pattern i, denoted by $\mathbf{Y_i} = (Y_{i1}, ..., Y_{ik})$, is given by

$$l_i = \prod_{j=1}^{k} p_{ij}^{Y_{ik}} (1 - p_{ij})^{1-Y_{ik}} \tag{2}$$

where, according to 1-PL model with $\lambda_j = 1 \; \forall j$, $p_{ik} = \dfrac{e^{\theta_i - \beta_k}}{1 + e^{\theta_i - \beta_k}}$. Likelihood contribution l_i is then weighted by the frequency of the $i-th$ response pattern already present in the basic set, to avoid that those patterns observed only once are most likely to enter in the last steps of the search.

Third, we rearrange such $n-p$ observations in the *non-basic* subset in ascending order accordingly, then increase the *basic* subset by adding to it the most plausible observation and decrease the *non-basic* subset to $n-p-1$ observations. This process is repeated until an appropriately chosen stopping criterion is met (usually derived from the FS plot itself).

3 Applications to simulated data

We generate 500 responses pattern from the 1-PL model with $k = 4$ items, with difficulty parameter estimation equal to $\beta_1 = -1, \beta_2 = -0.5, \beta_3 = 0.5, \beta_4 = 1$. In 1-PL model, the discrimination parameter is constrained to be the same for all items and we set it equal to 1. To test the proper functioning of the algorithm, we changed the last 25 response patterns of the initial dataset, forcing them to be equal to the most atypical response pattern (i.e., *0-0-1-1*). Such a response pattern is the least plausible one (having a score of 0 on the easiest items and a score of 1 on the most difficult ones); it appears only twice in the initial synthetic dataset.

We determine the *basic* set choosing the *best* among $H = 10$ sub-samples of size $p = 100$, randomly extracted from the initial sample. We choose this subset according to best fit given by (1). At each step of FS, we select the best candidate among response patterns in the non-basic set (which progressively decreases) to enter in the basic. Plots in Figure 1 shows the limited information goodness-of-fit statistic and the corresponding asymptotic p-values at each of the $n-p = 400$ steps of the forward search. It is clear that even when the search is initialized from a subset that yields large values for the M_2^* fit statistic, the *basic* set is incremented so that the fit is improved and stabilized for the larger part of the search; it substantially deteriorates in the last steps. The same, of course, holds for p-value: it reached very

high values after 100 steps of the FS and started to rapidly decrease in the last steps. The 25 atypical responses *0-0-1-1* enter in the last 30 steps of the search.

Figure 2 represents the forward plot for the adjusted residuals $r_{adj}(i)$ for each response pattern $i = 1, \ldots, 2^k$, given by $r_{adj}(i) = (\pi_i - \hat{\pi}_i)/\sigma_i$ where σ_i is the estimated standard deviation for $\pi_i - \hat{\pi}_i$. Pattern *0-0-1-1* reports a very high residual even in the last FS steps. Moreover, also the response pattern *0-0-0-1* (it appears only seven times in the initial synthetic dataset) has residuals far from 0 for all the FS steps.

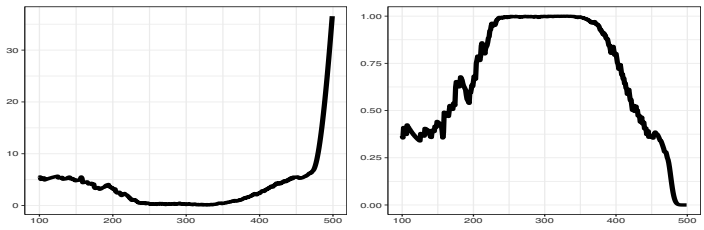

Fig. 1 Limited information statistics (left) and corresponding p-values (right). In the X axis the size of the basic set is indicated.

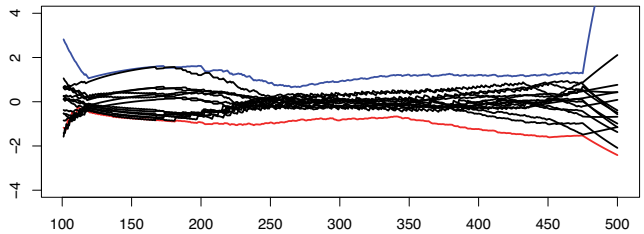

Fig. 2 Adjusted residuals for each response pattern, along the FS. The more extreme residuals are found for *0-0-1-1* (blue) and *0-0-0-1* (red). In the X axis the size of the basic set is indicated.

4 Conclusion and future directions

We explored the topic of atypical response pattern detection using the Forward Search in the IRT modelling approach. Such method was applied to the simplest IRT model, the Rasch model where the discrimination parameter is constrained across items to be equal to 1. Even if this work is still in progress, the good results obtained on simulated data generated from a 4-items Rasch model encourage further developments, which will be performed on 2-PL model and polytomous models. They also established the first promising application of FS algorithm to IRT models.

A novel estimation procedure for robust CP model fitting

Perfezionamento della procedura per la stima robusta del modello CP

Valentin Todorov and Violetta Simonacci and Michele Gallo and Nikolay Trendafilov

Sommario The usual way of parameter estimation in CANDECOM/PARAFAC (CP) is an alternating least squares (ALS) procedure that yields least-squares solutions and provides consistent outcomes but at the same time has several deficiencies, like sensitivity to the presence of outliers in the data, slow convergence, and susceptibility to degeneracy conditions. A number of works have addressed these weaknesses, but to our knowledge, there is no outlier-robust procedure that is highly computationally efficient at the same time, especially for large data sets. We propose a robust procedure based on an integrated estimation algorithm, alternative to ALS, which guards against outliers and is computationally efficient at the same time.

Sommario *Il metodo comunemente usato per la stima dei parametri nel modello CP è una procedura dei minimi quadrati alternati (ALS). Questo algoritmo fornisce soluzioni ai minimi quadrati e produce risultati stabili ma, allo stesso tempo, registra diverse carenze come la sensibilità alla presenza di valori anomali nei dati, convergenza lenta, e suscettibilità a condizioni di degenerazione. Numerosi lavori hanno affrontato queste debolezze ma, per quanto ne sappiamo, non esiste una procedura robusta che sia allo stesso tempo altamente efficiente dal punto di vista computazionale, specialmente per grandi insiemi di dati. Proponiamo una procedura robusta basata su un algoritmo di stima integrato, alternativo all'ALS, che protegge dai valori anomali ed è computazionalmente efficiente allo stesso tempo.*

Key words: ALS, ATLD-ALS, robustness, outliers, computational efficiency

1 Introduction

The standard multivariate analysis addresses data sets represented as two-dimensional matrices. In recent years, an increasing number of application areas like chemometrics, computer vision, econometrics and social network analysis involve analysis of data sets that are represented as multidimensional arrays and multiway data analysis becomes popular as an exploratory analysis tool. Different techniques exist to analyze such multi-way data but CANDECOMP/PARAFAC (CP) is one of the most popular. The usual way of parameter estimation in CP is an alternating least squares (ALS) procedure which yields least-squares solutions and provides consistent outcomes. Together with these desirable features, the ALS procedure suffers several major flaws which might be particularly problematic for large-scale problems: slow convergence and sensitiveness to degeneracy conditions such as over-factoring, collinearity, bad initialization and local minima. Furthermore, it is well-known that algorithms which rely on least squares easily break down in the presence of outliers. The issue of non-robustness of the ALS procedure was addressed by [2] and software is available in the R package **rrcov3way**. The other issues were addressed in a number of works proposing algorithms more efficient than ALS. However, often these do not provide stable results because the increased speed might come at the expense of accuracy. An integrated algorithm was proposed in [4] which seems to combine improved speed and stability. The purpose of this work is to develop further this algorithm by adding capabilities for dealing with outliers present in the data.

2 The CP model, the ALS algorithm and its robust version

The CP model [1, 3] decomposes the 3-way data array $\underline{\mathbf{X}}(I \times J \times K)$ with a generic element x_{ijk} into three loading matrices $\mathbf{A}$ $(I \times R)$, $\mathbf{B}$ $(J \times R)$, $\mathbf{C}$ $(K \times R)$ with R components (using the same number for each mode). The CP model can be written formally as

$$\mathbf{X}_A = \mathbf{A}(\mathbf{C} \otimes \mathbf{B})^\top + \mathbf{E}_A, \tag{1}$$

where $\mathbf{X}_A$ and $\mathbf{E}_A$ are are the original array and the error array unfolded with respect to mode A and the symbol $\otimes$ represents the *Kronecker product* between two matrices. To estimate the optimal component matrices the residual sum of squares

$$||\mathbf{E}_A||^2 = \sum_{i=1}^{I}\sum_{j=1}^{J}\sum_{k=1}^{K}(x_{ijk} - \hat{x}_{ijk})^2 = \sum_{i=1}^{I}||\mathbf{x}_i - \hat{\mathbf{x}}_i||^2 = \sum_{i=1}^{I} RD_i^2 \tag{2}$$

is minimized. The residual distance (RD) for observation i is thus given by

$$RD_i = ||\mathbf{x}_i - \hat{\mathbf{x}}_i|| = \sqrt{\sum_{j=1}^{J}\sum_{k=1}^{K}(x_{ijk} - \hat{x}_{ijk})^2} \tag{3}$$

and the estimation is equivalent to the minimization of the sum of the squared distances. With ALS the component matrices are estimated one at a time, keeping the estimates of the other component matrices fixed, i.e. we start with initial estimates of **B** and **C** and find an estimate for **A** conditional on **B** and **C** by minimizing the objective function. Estimates for **B** and **C** are found analogously. The iteration continues until the relative change in the model fit is smaller than a predefined constant.

The idea of a robust version of CP is to identify enough ”good“ observations and to perform the classical ALS on these observations. This is repeated until no significant change is observed. Finally, a reweighting step is carried out to improve the efficiency of the estimators. In order to identify the "good" observations a robust version of principal component analysis on the unfolded array is used. We will call this procedure R-ALS in the rest of the paper. It is obvious that the robust procedure will be much more time consuming than the classical one, repeating many times the ALS optimization. Therefore, any improvement of the performance of the parameter estimation procedure will contribute to the improvement of the performance of the complete robust procedure.

3 The ATLD and INT2 algorithms

The alternating trilinear decomposition (ATLD) proposed by [6] seems to be the most efficient method among the proposed alternatives to ALS. It is based on the use of three loss functions with different response surfaces. However, these advantages are obtained at the cost of unstable results and non-least-squares solutions. To cope with these issues [4] proposed a multi-optimization procedure in which ATLD is followed by ALS estimation steps which is demonstrated to be quite effective. The robust procedure R-ALS described in Section 2 is entirely based on ALS and thus suffers the slow convergence and other disadvantages of this algorithm. We propose to replace ALS by INT2 thus obtaining a new robust estimation procedure which we will call R-INT2. As before it starts by robust principal components to identify any outlying points and then iterates using the INT2 algorithm until no significant change is observed. After convergence a reweighting step with INT2 is conducted which produces the final solution.

4 Simulation study

The performance of the newly proposed algorithm R-INT2 for robust estimation of trilinear CP models will be demonstrated in a brief simulation study comparing

classical CP, R-ASL and R-INT2. First of, all we want to verify that R-INT2 works well on data sets with and without contamination by identifying the outliers at least as good as R-ALS retrieving solutions with good statistical quality. At the same time we want to verify that the convergence is improved significantly and thus the computational time is reduced.

These two aspects will be illustrated on three-way data generated as in [4], [5] and [2]. The three-way arrays have $I = 50$ observations, $J = 100$ variables and $K = 10$ occasions and the number of factors is $R = 2$. The loadings matrices $\mathbf{A}$, $\mathbf{B}$ and $\mathbf{C}$ are generated as randomly multivariate normal distributed $N_R(\mathbf{0}, \boldsymbol{\Sigma}_R)$ where $\boldsymbol{\Sigma}_R$ is a diagonal matrix with (10, 2) on the diagonal.

Such data does not contain any contamination to start. Different configurations of outliers can then be considered. In this work, because of the space constraints, only the so-called bad leverage points will be generated. An example of such outliers is shown in the outlier map illustrated in the left panel of Fig. 1 - these are the observations lying in the upper right quadrant. Regular observations lie in the lower left quadrant. Other types of outliers, not exemplified here, include good leverage points (lower right quadrant) and residual outliers (upper left quadrant). For more details about the generation of the different types of outliers see [2, page 158]. In the simulation study, apart from the case with no contamination, two other cases will be studied - with 10% and 20% of bad leverage points. For each setup, in order to account for minor statistical fluctuations 20 replicates were computed yielding the following three quantities which will represent how close the obtained estimates are to the original data: the mean square error (MSE), the angle between the estimated subspace and the true subspace spanned by the B-loadings and analogously, for the C-loadings. Also, the computation time and the number of iterations were recorded. The mean squared error (MSE) is given by

$$MSE = \frac{1}{w} \sum_{i=1}^{I} \sum_{j=1}^{J} \sum_{k=1}^{K} w_i (x_{ijk} - \hat{x}_{ijk})^2 \tag{4}$$

with $w = \sum_{i=1}^{I} w_i$ and $w_i = 0$ if the i-th observation is outlier or $w_i = 1$ otherwise. Thus the MSE will be computed only for the regular observations. The angle between the estimated subspace and the original one is given by

$$maxsub = \max_{\mathbf{b}_1} \min_{\mathbf{b}_2} \arccos(\mathbf{b}_1^\top \mathbf{b}_2) \tag{5}$$

This subspace angle has to be as small as possible and is reported in radians. We use the function `subspace()` from the **R** package **pracma** to compute *maxsub*.

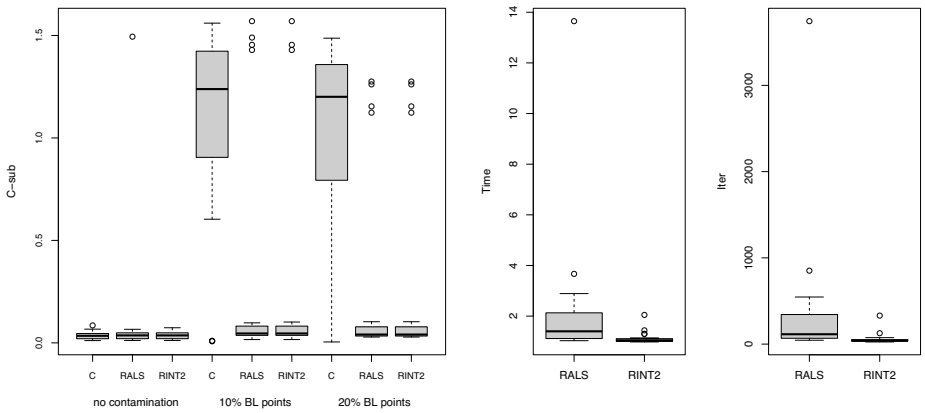

Figura 2 Angle of C-loadings (left) of classical CP (C), robust CP with ALS (R-ALS) and robust CP with INT2 (R-INT2) for simulation settings with no outliers, 10% and 20% bad leverage points and computational time and number of iterations (right) for 20% bad leverage points.

All three estimators perform equally well on clean data both in terms of MSE and maxsub (see Fig. 1, right panel and Fig. 2, left panel). However, when outliers are added to the data (10% and 20%) the classical CP is influenced - the MSE increases and the quality of the fit of the loadings decreases. These effects are even more pronounced when the outlier fraction is increased to 20%. There is no much difference in the performance of the two robust methods in terms of MSE and maxsub, howe-

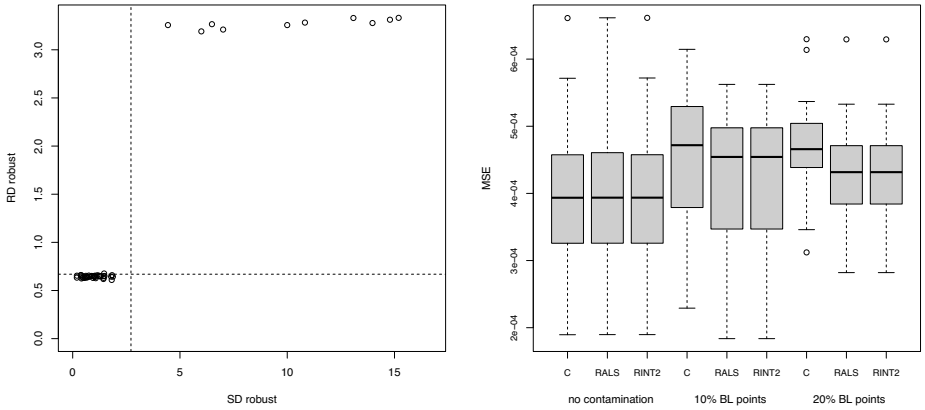

Figura 1 Example of an outlier map for simulated data with 20 percent bad leverage points (left) and MSE values of classical CP (C), robust CP with ALS (R-ALS) and robust CP with INT2 (R-INT2) for simulation settings without contamination and with bad leverage points (right).

ver, if we look at the right panel of Fig. 2 which presents their performance in terms of computational time and number of iterations the gain in performance is obvious. The median time of R-INT2 is more than 30% lower than that of R-ALS which also has much higher variance. This is due to the reduced number of iterations, as it is seen in the right part of the same Figure.

5 Summary and conclusions

We combine the robust procedure for CP proposed by [2] with the highly efficient estimation algorithm INT2 proposed by [4] in order to obtain a fast estimation and robust to outliers CP modeling technique. The conducted simulation study demonstrates the advantages of the new procedure in terms of computational time and at the same time shows that the robustness properties and the statistical efficiency have not been affected. Future work should bring a thorough investigation of the properties of the algorithm, comparison to the many existing fast alternatives and studying the possibilities for combination with other computational algorithms.

A robust approach for functional ANOVA with application to additive manufacturing

Un approccio robusto per l'ANOVA funzionale con un'applicazione all'additive manufacturing

Fabio Centofanti, Bianca Maria Colosimo, Marco Luigi Grasso, Alessandra Menafoglio, Biagio Palumbo, Simone Vantini

Abstract A new robust nonparametric functional analysis of variance method is presented, which reduces the weights of outlying functional data on the results of the analysis. It is implemented through a permutation test based on a statistic obtained via a functional extension of the classical robust M-estimator. Its favourable properties are shown in an additive manufacturing application based the laser powder bed fusion process.

Abstract *In questo lavoro, viene presentato un nuovo metodo robusto nonparametrico per l'analisi della varianza funzionale, in grado di mitigare l'eventuale distorsione dovuta alla presenza di dati anomali. Il metodo si basa su un test di permutazione con una statistica test ottenuta tramite un'estensione funzionale del classico stimatore M robusto. Le ottime proprietà statistiche del metodo proposto vengono illustrate mediante un'applicazione nell'ambito della produzione additiva basata sul processo di fusione laser a letto di polvere.*

1 Introduction and methods

The development of data acquisition methods allow the analysis of complex systems in several operating conditions. To address this increasing complexity new statistical tools are needed. To this end, functional data analysis (FDA) [15, 9, 10], has been introduced and model observation units as functions defined on a compact domain. Several industrial applications, which apply FDA methods, have appeared in the literature so far [14, 18, 13, 19, 1, 4, 2, 5].

In this setting, the functional analysis of variance (FANOVA), which is extension of the classical (non-functional) analysis of variance problem, consists in the identification of significant differences in group functional means belonging to a sample with varying experimental conditions. As in the classical setting, FANOVA methods tend to be highly sensitive to the presence of data points that differ significantly from other observations, i.e., *outliers*. FANOVA methods rely in fact on statistics that combine in a quadratic fashion the functional mean, which are known to be highly sensitive to the presence of outliers.

In this work, we consider the robust FANOVA method (RoFANOVA), proposed by Centofanti et al. [3], that is able to test, in a nonparametric fashion, the differences among group functional means. The RoFANOVA approach is based on the scale equivariant functional M-estimator, which extends the M-estimator [17]. It is estimated through the FuNMAD estimator of dispersion, which is the functional extension of the normalized median absolute deviation [12], and it is obtained numerically through the standard iteratively re-weighted least-squares algorithm [17]. Several versions of the scale equivariant functional M-estimator are available by using the Huber, Tukey, Hampel, and optimal families of loss functions [3].

The significance of the coefficients in the two-way FANOVA model is tested through a nonparametric permutational approach based on the functional extension of the robust F-statistic proposed by Schrader et al. [16], which is a robust version of the classical F-test statistic. This test statistic is obtained as the difference between the standardized residual sum of dispersions under the reduced and the full model and measures the discrepancy between residuals of the model under the null and the alternative hypotheses. The distribution of the considered statistic under the null hypothesis is estimated through a permutational approach that consists in permuting the data without constraints [11].

2 An additive manufacturing application

In this section, the RoFANOVA approach is applied to a metal additive manufacturing process known as laser powder bed fusion (L-PBF) [7, 6, 8]. The video image frames, acquired during the process, are transformed into a functional format to obtain the *spatter intensity*, defined as the amount of spatters observed in any given region of the bi-dimensional video-frame space. Six specimens are produced by varying the energy density provided by the laser to the material, for six production layers. For

each layer, the laser moves along a predefined path that consists of parallel scan lines and whose orientation changes layer by layer. The aim of the analysis is to assess whether the energy density level, layer, and interaction significantly influences the spatter intensity. The cross-sections of the spatter intensity function are represented in Figure 1 at different energy density levels and in different layers.

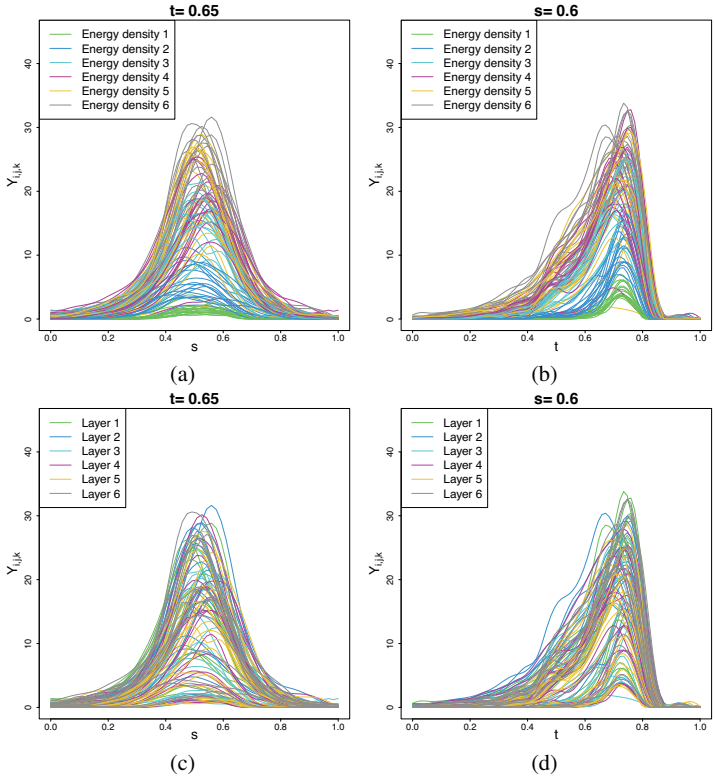

Fig. 1 Cross-sections of the spatter intensity function ($Y_{i,j,k}$), for different energy density levels ((a) and (b)) and different layers ((c) and (d)).

In these setting, the RoFANOVA test can be suitably applied. Several loss functions are considered and tuned to achieve the 95% asymptotic efficiency at the normal model. All tests agree that the energy density and the layer as well as their interaction effects are significant. Moreover, the energy density is increasing with the intensity of the spatter, and different layers show different increasing patterns which may be related with different scan directions. Thus, the influence on the spatter intensity of the energy density, the production layer and their interaction is found significant, differently from competing FANOVA methods that do not consider significant the interaction between energy density and layer [3].

Modeling unconditional M-quantiles in a regression framework

Modelli di regressione quantile per la stima di M-quantili marginali

Luca Merlo, Lea Petrella and Nicola Salvati

Abstract In this paper we develop a quantile regression model for estimating unconditional M-quantiles in the presence of covariates. Extending the paper by Firpo et al (2009), we assess the impact of small changes in the explanatory variables across the entire unconditional distribution of the dependent variable by running a mean regression of the recentered influence function on the covariates. The proposed method is applied on data originating from the May 1985 Current Population Survey conducted by the US Census Bureau.

Abstract *In questo articolo sviluppiamo un modello di regressione quantile per la stima di M-quantili marginali della variabile dipendente in presenza di covariate. Estendendo il lavoro di Firpo et al (2009), stimiamo l'effetto marginale delle variabili esplicative sull'intera distribuzione marginale della variabile dipendente tramite un'analisi di regressione della funzione d'influenza sulle covariate. La metodologia proposta viene applicata sui dati raccolti dal Current Population Survey del 1985 condotto dall'US Census Bureau.*

1 Introduction

Quantile Regression (QR), as proposed by Koenker and Bassett Jr (1978), has proven to be a powerful tool to explore conditional distributions in many empirical applications. However, if one is interested in how the whole unconditional distribution of the dependent variable responds to changes in the covariates, using the well-known QR would yield misleading inferences (see Firpo et al 2009 and Borah and Basu 2013). Motivated by this interest, Firpo et al (2009) proposed the Unconditional Quantile Regression (UQR) approach for modeling unconditional quantiles of a dependent variable as a function of the explanatory variables. This method builds upon the concept of Recentered Influence Function (RIF) which originates from a widely used tool in robust statistics, namely the Influence Function (IF) discussed in Hampel et al (2011). The RIF of a distributional statistic ν is obtained by adding back the statistic to the IF and it can be thought of as the contribution of an individual observation on ν. In the regression framework where covariates are available, Firpo et al (2009) proposed to replace the dependent variable with the RIF to model the unconditional quantiles of the response and evaluate the effect of changes in the law of the covariates on unconditional quantiles. When the interest of the research is concentrated on the entire distribution of a response variable, in addition to the classical QR, a possible alternative is represented by the M-quantile regression (MQR) approach proposed by Breckling and Chambers (1988). This method provides a "quantile-like" generalization of the mean regression based on influence functions, combining in a common framework the robustness and efficiency properties of quantiles and expectiles (Newey and Powell 1987), respectively.

In this article, we extend the UQR of Firpo et al (2009) to the M-quantile regression framework by using the well-known Huber loss (Huber 1964). Specifically, we develop the Unconditional M-quantile Regression (UMQR) to model the M-quantiles and expectiles of the unconditional distribution of the response variable. In order to analyze the impact of changes in the distribution of explanatory variables on the entire unconditional distribution of the response, we regress the RIF of the proposed model on the covariates.

2 Methodology

Let Y denote a scalar random variable with absolutely continuous distribution function F_Y. The M-quantile of order $\tau \in (0,1)$ of Y is defined as the solution, $\theta_\tau \in \mathbb{R}$, of the following estimating equation:

$$\int \psi_\tau(y-\theta_\tau) dF_Y(y) = 0, \tag{1}$$

where $\psi_\tau(u) = \mid \tau - \mathbf{1}_{(u<0)} \mid \psi(u/\sigma_\tau)$, with ψ being the first derivative of a convex loss function ρ and σ_τ is a suitable scale parameter. In this work, we consider the

popular Huber influence function (Huber (1964)):

$$\psi(u) = u\mathbf{1}_{(|u|\leq c)} + c\,\text{sign}(u)\mathbf{1}_{(|u|>c)}, \tag{2}$$

where c denotes a tuning constant bounded away from zero that can be used to trade robustness for efficiency in the model fit, with increasing robustness when c is chosen to be positive and close to 0 and increasing efficiency when c is chosen to be large and positive. In particular, M-quantiles nicely include quantiles when $c \to 0$, $\psi(u) = \text{sign}(u)$, and expectiles when $c \to \infty$, $\psi(u) = u$.

To build the UMQR model, it follows from Firpo et al (2009) and Hampel et al (2011) that the RIF of the M-quantile θ_τ is defined as:

$$RIF(y;\theta_\tau) = \theta_\tau + IF(y;\theta_\tau) = \theta_\tau + \frac{\psi_\tau(y-\theta_\tau)}{\int \psi'_\tau(y-\theta_\tau)dF_Y(y)}, \tag{3}$$

where $IF(y;\theta_\tau)$ is the IF of θ_τ and $\psi'(u) = \mathbf{1}_{(|u|<c)}$ is the derivative of ψ in (2). In a regression framework when covariates $\mathbf{X} \subset \mathbb{R}^k$ are available, from (3) we define the UMQR model as follows:

$$\mathbb{E}[RIF(Y;\theta_\tau) \mid \mathbf{X} = \mathbf{x}] = \theta_\tau + \mathbb{E}\Big[\frac{\psi_\tau(y-\theta_\tau)}{\int \psi'_\tau(y-\theta_\tau)dF_Y(y)}\Big|\mathbf{X} = \mathbf{x}\Big]. \tag{4}$$

Our objective is to identify how small changes in the distribution of $\mathbf{X}$ affect the M-quantile of the unconditional distribution of Y. From (4) and Firpo et al (2009), the unconditional effect of the τ-th M-quantile, that we denote Unconditional M-quantile Partial Effect, α_τ, is formally defined as:

$$\alpha_\tau = \int \frac{d\mathbb{E}[RIF(Y;\theta_\tau) \mid \mathbf{X} = \mathbf{x}]}{d\mathbf{x}} dF_{\mathbf{X}}(\mathbf{x}) = \frac{1}{s_\tau}\int \frac{d\mathbb{E}[\psi_\tau(Y-\theta_\tau) \mid \mathbf{X} = \mathbf{x}]}{d\mathbf{x}} dF_{\mathbf{X}}(\mathbf{x}), \tag{5}$$

where $F_{\mathbf{X}}$ is the distribution function of $\mathbf{X}$ and $s_\tau = \int \psi'_\tau(y-\theta_\tau)dF_Y(y)$. As suggested by Firpo et al (2009), we can estimate α_τ in (5) via a mean regression of the $RIF(Y;\theta_\tau)$ as dependent variable onto $\mathbf{X}$ by using a two-step procedure. Specifically, an estimate $\widehat{\theta}_\tau$ of θ_τ is obtained by solving (1) via Iterative Reweighted Least Squares, substitute $\widehat{\theta}_\tau$ in (3) and then regress the $RIF(Y;\widehat{\theta}_\tau)$ on $\mathbf{X}$.

3 Application

We investigate the impact of unions on the distribution of hourly wages using a sample of 534 observations originating from the 1985 Current Population Survey conducted by the US Census Bureau. We fit the proposed model at different M-quantile levels, $\tau = (0.1, 0.5, 0.9)$, and compare the results with standard conditional M-quantile regressions. The tuning constant c in (2) has been set to 1.345 and 100 which, in the second case, allows us to obtain the Unconditional Expectile Regres-

sion (UER). The results in Table 1 highlight that the estimated effect of union status is very different on the conditional and unconditional distributions of log wages, especially in the upper tails. Specifically, by looking at the conditional M-quantile and expectile regressions (MQR and ER), the effect of unions is positive and monotonically declines as the M-quantile level increases. On the contrary, unions have a positive but increasing effect on the unconditional distribution of wages and their impact is not statistically significant at $\tau = 0.9$. This demonstrates that if one is interested in the overall effect of unions on wage inequality, the proposed unconditional regression should be used to obtain such unconditional effect.

Model-based clustering

Bayesian mixtures of semi-Markov models

Misture Bayesiane di modelli semi-Markov

Rosario Barone and Andrea Tancredi

Abstract In this paper we propose a clustering technique for continuous-time semi-Markov models in order to take account of groups of individuals having similar process realizations. In fact fitting standard parametric models in presence of heterogeneity between population groups may produce biased inferences for relevant process feautres. To model individual heterogeneity we consider a Dirichlet process mixture (DPM) of semi-Markov continuous-time models. We also consider the case of discretely observed trajectories of continuous time processes, providing an algorithm which clusterize the observations after having reconstructed the continuous-time paths between the observed points. Full MCMC inference is performed with an application to a real dataset.

Abstract *In questo articolo proponiamo un metodo di clustering per modelli semi-Markov a tempo continuo al fine di tenere conto di gruppi di individui con realizzazioni del processo simili. Infatti, l'utilizzo di modelli parametrici standard in presenza di eterogeneità può produrre inferenze distorte. Per modellare l'eterogeneità individuale consideriamo una mistura di processi di Dirichlet (DPM) di modelli semi-Markov a tempo continuo. Consideriamo anche il caso di processi a tempo continuo osservati in punti discreti, presentando un algoritmo che consente di raggruppare le osservazioni dopo aver simulato le traiettorie tra i punti discreti. nel lavoro verrà presentato un algoritmo MCMC e un'applicazione con dati reali.*

1 Introduction

In a panel data set with individuals observed in time, clustering techniques may be useful for finding groups of similar individuals. With exception for the Markov case [1], all the mixtures approaches for multi-state models are related to finite mixtures and consider completely observed processes [2]. In this paper we tackle the clustering problem for the class of semi-Markov processes. In general, note that inference for semi-Markov models may present computational difficulties when observations are at discrete time points, so that the process is not completely observed. In fact, the likelihood function is not available and approximation methods are required. [3] reconstruct the likelihood function by simulating the trajectories between the observed points with a Metropolis-Hastings step based on Markovian proposals drawn from the uniformization algorithm [4]. Here, we extend their approach by considering a Bayesian nonparametric mixture model for both completely and discretely observed continuous time semi-Markov models. More specifically, by defining infinite mixtures of semi-Markov, with a Dirichlet process (DP) prior [5] on the mixing measure, we get a Dirichlet Process Mixture (DPM) [6] of semi-Markov models.

2 Semi-Markov multi-state models

Let us consider a continuous time process $Y(\cdot) = \{Y(t), t \geq 0\}$ with discrete state space $\mathscr{S} = \{1, \dots S\}$. We assume that the process $Y(\cdot)$ is semi-Markov. This is equivalent to say that the instantaneous transition rates $q_{rs}(t, \mathscr{F}_t)$, conditionally on the past history of the process, depend only on the time spent in the current state, i.e.

$$q_{rs}(t, \mathscr{F}_t) = \lim_{\delta t \to 0} \frac{P\{Y(t+\delta t) = s | X(t) = r, T^* = t-u\}}{\delta t}$$

where T^* denotes the entry time in the last state assumed before time t. Hence, semi-Markov models can be obtained by defining the transition functions $q_{rs}(u)$ and setting

$$P\{Y(t+\delta t) = s | Y(t) = r, T^* = t-u\} = \begin{cases} q_{rs}(u)\delta t + o(\delta t) & s \neq r \\ 1 - \sum_{l \neq r} q_{rl}(u)\delta t + o(\delta t) & s = r \end{cases}$$

Notice that a semi-Markov process $Y(t)$ can be also defined as the result of a state sequence generated by a Markov chain with transition probabilities p_{rs} and sojourn times having distribution functions F_{rs}, that is depending only on the departure and arrival states. To specify the functions $q_{rs}(u)$ we can also proceed directly by fixing the transition probabilities p_{rs} and the conditional sojourn distributions F_{rs}. By doing so, the resulting hazard functions turn out to be $q_{rs}(u) = p_{rs}F'_{rs}(u)/(1 - F_r(u))$ where $F_r(u) = \sum_{l \neq r} p_{rl}F_{rl}(u)$. Several parametric distributions can be proposed for $q_{rs}(u)$ or $F_{rs}(u)$. Assuming for example cause-specific hazards proportional to those of a distribution on positive values with parameters depending only on the initial

state, i.e. $q_{rs}(u) = p_{rs}q(u;\phi_r)$, the transition probabilities are p_{rs}, and the density of trajectory y on the interval $[0,T]$ can be generally written as

$$p_\theta(y) = p_\theta(s,z) = \left(\prod_{i=1}^{n} p_{s_{i-1}s_i} q(z_i - z_{i-1};\phi_{s_{i-1}}) e^{-\int_0^{z_i - z_{i-1}} q(u;\phi_{s_{i-1}},)du}\right) \times e^{-\int_0^{T-z_n} q(u;\phi_{s_n})du},$$

where $z = (z_1,\ldots,z_n)$ is the sequence of jump times, $s = (s_1,\ldots,s_n)$ is the sequence of visited states and $\theta \in \Theta$ is the vector with all the process parameters.

3 Dirichlet Process Mixture of semi-Markov models

In this section we introduce the notation of the DPM model. Let $p_\theta(y)$ be the probability density function of a semi-Markov trajectory $y(t) = (s,z)$. Let G be a probability distribution defined on the parameter space Θ. We define the density function of an infinite mixture of semi-Markov models p_G with respect to the mixing measure G as

$$p_G(s,z) = \int p_\theta(s,z)dG(\theta).$$

By assuming a $DP(M,G_0)$ on the mixing measure G, we get a DPM of semi-Markov models. Let $y_i(t) = (s,z)_i$, for $i = 1,\ldots,N$, be N fully observed paths on $[0,T_i]$. Note that N represents the number of sample individuals. We may rewrite the model in a hierarchical form:

$$\begin{aligned} y_i(t)|\theta_i &\overset{ind}{\sim} p_{\theta_i} \\ \theta_i|G &\overset{iid}{\sim} G \\ G &\sim \mathrm{DP}(MG_0). \end{aligned}$$

4 MCMC sampling

We now outline the MCMC algorithm. Let $\mathbf{y} = (\mathbf{s},\mathbf{z})$ be the set of N observed trajectories of a continuous time multi-state model defined on the state space $\mathscr{S}$. Let θ_h^*, $h = 1,\ldots,k$ denote the $k \leq N$ unique values among the N individual parameters and let $\Psi_h = (i : \theta_i = \theta_h^*)$. An important property of the Dirichlet process is in fact to produce discrete distributions for G so that the trajectories y_i are clustered on the base of the unique values generated by G. We represent the clustering by an equivalent set of cluster membership indicators, $\psi_i = h$ if $i \in \Psi_h$, i.e. the i-th observation belongs to the h-th cluster. Let $\mathbf{y}_h^*$ indicate the trajectories arranged by clusters, i.e. the set of trajectories belonging to the h-th cluster. Let the multiset $\rho_n = \{\Psi_1,\ldots,\Psi_k\}$ be a random partition of the trajectories $\{1,\ldots,N\}$. The DPM implies a model on

a random partition ρ_n of the experimental units. Let $\pi(\rho_n)$ be the Pólya urn prior on the random partition ρ_n. The posterior conditional densities $\pi(\psi_i = h|\psi_{-i}, \mathbf{y})$ are derived as follows:

$$\pi(\psi_i = h|\psi_{-i}, \mathbf{y}) \propto \begin{cases} N_h^- \, p((s,z)_i|\mathbf{y}_h^{*-}) & \text{for } h = 1,\dots,k^- \\ M p((s,z)_i) & \text{for } h = k^- + 1 \end{cases},$$

where N_h^- is the number of paths in the h-th cluster with exclusion of the i-th observation, M represents the precision parameter of the DP, k^- indicates the unique values of θ with exclusion of the i-th observation, $p((s,z)_i) \equiv \int p_{\theta_h^*}((s,z)_i) G_0(d\theta_h^*)$ and $p((s,z)_i|\mathbf{y}_h^{*-}) = \int p_{\theta_h^*}((s,z)_i) d\pi(\theta_h^*|\mathbf{y}_h^{*-})$. However, with the semi-Markov kernel density there is not conjugate centring measure G_0. Therefore, approximation methods are required in order to evaluate the integrals.
Since there is no conjugacy between the base measure G_0 and the semi-Markov kernel density, we adopt the approach of [7], by defining a valid Markov chain algorithm by drawing $(N-k)$ auxiliary values for θ from the centring measure G_0. More in detail, if $N_h > 1$, the posterior model on the random partition ρ_n is defined as:

$$\pi(\psi_i = h|\psi_{-i}, \mathbf{y}) \propto \begin{cases} N_h^- \, p_{\theta_h^*}((s,z)_i) & \text{for } h = 1,\dots,k^- \\ \frac{M}{k^-+1} p_{\theta_{k^-+1}^*}((s,z)_i) & \text{for } h = k^- + 1 \end{cases}, \tag{1}$$

while if $N_h = 1$, $\psi_i = h$ is imputed to form a singleton cluster. Therefore, with probability $(k-1)/k$ leave ψ_i unchanged, otherwise remove ψ_i from the h-th cluster, relabel the θ_h^* to comply with the no-gaps rule, and then update ψ_i. By considering $y_i = (s,z)_i$, $i = 1,\dots,N_h$, the density of the data lying inside the h-th mixture component conditional on the partition and on the kernel parameters is

$$\pi(\mathbf{y}|\theta_h, \psi) = \prod_{i=1}^{N_h} p_{\theta_h}((s,z)_i|\psi_i = h),$$

by Bayes theorem we get the posterior density of the h-th mixture component parameters:

$$\pi(\theta_h|\psi, \mathbf{y}) \propto \pi(\mathbf{y}|\theta_h, \psi) \cdot G_0(\theta_h). \tag{2}$$

4.1 Discretely observed semi-Markov processes

We now extend the DPM of semi-Markov models to the the case of discretely observed trajectories, that is when the exact jump times are unknown and the density function $p_\theta(y)$ is not available. In particular we use the algorithm proposed by [3], which allows to reconstruct the trajectories between the discretely observed points for each observed individual via a Metropolis-Hastings step based on a Markovian approximation of the semi-Markov process. By indicating with $Q(s,z|\theta,x)$ the conditional distribution of a whole sample path conditionally on an observed set of

points summarized by the vector x, the MCMC algorithm for the discretely observed case may be summarized as follows:

- *Trajectory reconstruction*: for $i = 1\ldots,N$ draw $(s,z)_i \sim Q(s,z|\theta_i,x_i)$;
- *Clustering*: for $i = 1\ldots,N$ draw ψ_i from (1);
- *Updating cluster parameters*: for $h = 1,\ldots,k$ draw θ_h from (2).

5 Application

As a real data application, we analyze the progression of coronary allograft vasculopathy (CAV) [8] with a data set available with the R package `msm`, see [9]. The data provides the disease status (CAV-free (1), mild CAV (2) and moderate or severe CAV (3)) observed approximately each year after transplant for a set of 622 subjects followed up until their most recent visit if alive at the end of the observation period or until death (state (4)). Death times are exactly observed. Moreover, since data comprises apparent transitions from higher to lower states, which are in fact the results of a misclassification since the deterioration of the arterial walls is an irreversible process, we recode all the reverse transitions as remaining in the higher of the two states and permit transitions only to the adjacent states or to the death state. To specify the semi-Markov model we assume Weibull sojourn times. The parameter set is $\theta = (p,\gamma,\alpha)$ where γ and α are the vector with the rate and shape parameters of the Weibull sojourn times and p is the matrix with the transition probabilities. For the Dirichlet process we chose a precision parameter $M = 1$ and defined the centering measure to be the product between Dirichlet distributions for the rows of p, Gamma distributions for the rate parameters and log Normal distributions for the sahpe parameters, that is $G_0 \equiv \mathrm{Dir}_{\mathscr{S}-1} \times \mathrm{Gamma}_{\mathscr{S}-1} \times \log\mathrm{N}_{\mathscr{S}-1}$. We run the MCMC sampler for 10000 iterations with a burnin of 2000. The model gives evidence of the existence of two groups of observations with different features inside the sample. In Table 1 and Figure 1 we show the results by reporting some posterior summaries for the proposed model.

Specification of informative priors for capture-recapture finite mixture models

Specificazione di a-priori informative per modelli cattura-ricattura a misture finite

Pierfrancesco Alaimo Di Loro[1], Gianmarco Caruso[2], Marco Mingione[2], Giovanna Jona Lasinio[2], Luca Tardella[2]

Abstract Many models involve binomial terms depending on parameters $p \in [0,1]$ representing probabilities. That is the case of capture-recapture experiments, where capture and survival of each individual at different occasions are modelled as Bernoulli trials with unknown probabilities. In most actual data applications, the population of interest typically exhibits unaccounted heterogeneity, presumably depending on its partitioning into a finite set of sub-populations, each one having its parameter value. If the sub-population labels are unknown, Finite Mixture Models (FMM) can be exploited to recover the unknown labels and all other model components jointly. Nevertheless, the naive application of finite mixture models within the Bayesian machinery is affected by the so-called *label-switching* problem. The group-specific parameters are assigned ordering constraints to identify their relative roles to overcome this issue. That is usually achieved by specifying conditionally uniform densities that respect such constraints, preventing the possibility to shape the prior according to available prior knowledge. In this work, we propose two flexible classes of joint priors based on manipulating Beta distributions. The idea is to specify a joint prior that retains the flexibility to induce the desired marginal behaviour while still guaranteeing the desired ordering.

Abstract *Diversi modelli includono componenti Binomiali dipendenti da parametri $p \in [0,1]$, che rappresentano probabilità. Questo è il caso di modelli cattura-ricattura, dove la cattura e la sopravvivenza di ciascun individuo in ciascuna occasione sono visti come esperimenti Bernoulliani con probabilità incognite. Nella maggior parte delle applicazioni reali, la popolazione di interesse presenta ulteriore eterogeneità, presumibilmente dovuta al partizionamento della popolazione in sottopopolazioni, ciascuna avente il proprio valore del parametro. Se le etichette della sottopopolazione sono incognite, i modelli a mistura finita possono essere usati per stimare congiuntamente le etichette e le altre componenti del modello. Tuttavia, la semplice applicazione di questi modelli in un contesto Bayesiano soffre del cosiddetto problema di label-switching. Per risolvere questo problema, i parametri gruppo-specifici vengono sottoposti a vincoli di ordinamento. Questo si ottiene tipicamente attraverso la specificazione di distribuzioni Uniformi condizionate che rispettano l'ordinamento, ma che non permettono l'elicitazione di distribuzioni a priori basate su un'eventuale conoscenza pregressa del fenomeno. In questo lavoro, si propongono due classi flessibili di distribuzioni a priori congiunte, basate sulla distribuzione Beta. L'idea è quella di specificare una a priori congiunta che mantenga una flessibilità tale da indurre marginalmente il comportamento desiderato, garantendo allo stesso tempo l'ordinamento.*

Key words: Finite mixture, Bayesian Statistics, Prior elicitation, Capture-recapture, Binomial model

1 Introduction

The implementation of capture-recapture methods in a Bayesian context often involves the specification of Beta distributions to model the prior beliefs on the capture and survival probabilities of the individuals.

[1]LUMSA, Via Pompeo Magno 28, Rome, Italy, e-mail: p.alaimodiloro@lumsa.it
[2]University of Rome "La Sapienza", P.le Aldo Moro 5, Rome, Italy.

The Beta distribution is a very common candidate as a prior for such parameters p: it is compactly supported on $[0,1]$. It can be shaped to represent non-informative or informative settings by manipulating its two shape parameters. However, real data often exhibit additional heterogeneity concerning standard modelling assumptions, as not all the individuals in the population behave in the same way. For instance, the population may be partitioned into a finite set of G sub-populations, or groups, (e.g. by gender, residency pattern, size, etc.), each one having its own parameter value, say p_g, $g = 1,\dots,G$ [McLachlan et al., 2019]. When the group labels are unknown, the partition must be estimated to get reliable inferences. In many applied sciences, the partition is often recovered in advance and subsequently passed to the model as an input [Pace et al., 2021]. Nevertheless, it is usually preferable to perform the classification and the estimation simultaneously to quantify the uncertainty of both better. In this respect, capture-recapture models can be embedded in a Finite Mixture (FMM) setting [Pledger, 2000, 2005; Böhning et al., 2005]. Each unit is uniquely assigned a latent label representing its membership to one of the G possible groups. The posterior distribution of the unknown labels is recovered jointly with all other model components, properly propagating the uncertainty of all the unknowns.

The naive application of finite mixture models within the Bayesian machinery is affected by the so-called *label-switching* problem. That is, at each Markov Chain Monte Carlo (MCMC) step, the groups may interchange their relative role [Jasra et al., 2005]. Under genuine multimodality, an effective and trivial solution is to uniquely identify the components by including prior information about their marginal and relative behaviour, as by imposing ordering constraints that define the group-specific parameters' positions in a hierarchy [Diebolt and Robert, 1994; Stephens, 2000]. When the parameters are constrained in the $[0,1]$ set, the corresponding joint prior could be derived as the product of conditionally specified uniform densities that respect such constraints. It inevitably jeopardizes the possibility of eliciting informative priors whenever the information is available. In this work, we propose two flexible classes of joint priors for this scenario, based on the manipulations of the Beta distribution. The idea is to specify a joint prior that guarantees the desired ordering constraints and retains the flexibility to include prior information in each component's marginal.

2 The modeling framework

For the sake of brevity, we here report the modelling framework, in which we included our proposals when the number of sub-populations is $G = 2$. Remark that this can be easily generalized to $G > 2$ cases simply by re-iterating the conditioning process.

Let $\boldsymbol{y}_1,\dots,\boldsymbol{y}_n$ be n realizations of an l-dimensional random vector with distribution $\boldsymbol{Y} \sim f(\cdot\,|\,\boldsymbol{p})$, where $\boldsymbol{p} = (p_1, p_2)$ and

$$f(\boldsymbol{y}\,|\,\boldsymbol{p}) = \sum_{k=1}^{2} w_k \cdot f(\boldsymbol{y}\,|\,p_k).$$

This is a finite mixture distribution with 2 components and prior weights w_k, $k = 1,2$. This setting can be more efficiently represented by augmenting the space with a latent indicator variable $\zeta \in \{1,2\}$ that denotes from which of the two densities each observation come from. The component weights w_k are the prior probabilities that each unit belongs to one group or the other $P(\zeta_i = k) = w_k$, $i = 1,\dots,n$, $k = 1,2,$. It represents the relative proportion of observations coming from the two groups. Bayesian inference is usually pursued through the following hierarchical specification:

$$\begin{aligned}
&\boldsymbol{Y}\,|\,\boldsymbol{p},\zeta,\boldsymbol{w} \sim f(\cdot\,|\,p_\zeta)\\
&\zeta\,|\,\boldsymbol{w} \sim MN_2(\boldsymbol{w}), \quad \boldsymbol{p} \sim \pi_{\boldsymbol{p}}(\cdot)\\
&\boldsymbol{w} \sim Dir(\boldsymbol{\alpha}),
\end{aligned}$$

where $MN_2(\cdot)$ is the two-components multinomial distribution, $Dir(\cdot)$ the Dirichlet distribution and $\pi_{\boldsymbol{p}}(\cdot)$ is the joint prior on the group specific probabilities p_1, p_2. In order to avoid the label-switching problem, the prior on $\boldsymbol{p}$ shall envision an ordering constraint to solve the symmetry in the posterior distribution and make the two components identifiable. For

instance, we could enforce $p_1 < p_2$ by specifying the joint prior in a conditional fashion:

$$\pi_{\boldsymbol{p}}(p_1, p_2) = \pi_{p_1}(p_1) \cdot \pi_{p_2|p_1}(p_2), \tag{1}$$

where $\pi_{p_2|p_1}(\cdot)$ guarantees $p_2 > p_1$, e.g. has a support depending on p_1. When p_1 and p_2 are probabilities (i.e. $\in (0,1)$), the most striaghtforward solution is to have a Beta prior on p_1 and then specify $\pi_{p_2|p_1}(\cdot) = Unif(\cdot \,|\, p_1, 1)$. In practice, any other specification of $\pi_{p_2|p_1}(\cdot)$ complying with the ordering constraint could be valid. Nevertheless, there is very few literature that explores the marginal distribution induced on $p_2 \sim \pi_{p_2}(\cdot)$ obtained by integrating p_1 out from Eq. 1.

In Sec. 3 and Sec. 4, we investigate some alternative specifications that allow for controlling the marginal expected value and variance, and possibly also the form of the two marginals. These tools can be exploited to embed prior information in the estimation process, which can, in turn, favour the proper identification of the two components.

3 The Beta and truncated Beta

It is possible to derive the marginal prior distribution of p_2, when $p_1 \sim Beta(\alpha_1, \beta_1)$ and $p_2|p_1 \sim tBeta(\alpha_2, \beta_2, p_1, 1)$, where $tBeta(\cdot,\cdot,l,u)$ denotes the *truncated Beta* in (l,u). However, the expression of the marginal $\pi_{p_2}(\cdot)$ is not trivial unless we set $\alpha_2 = 1$, for which we obtain:

$$\pi_{p_2}(p_2) = \frac{B(\alpha_1, \beta_1 - \beta_2)}{B(\alpha_1, \beta_1)} \beta_2 (1-p_2)^{\beta_2 - 1} F_{Beta(\alpha_1, \beta_1 - \beta_2)}(y), \quad \text{with } \beta_1 > \beta_2.$$

In particular, when $\alpha_1 = \beta_2 = k$ and $\beta_1 = k+1$, i.e. $p_1 \sim Beta(k, k+1)$ and $p_2|p_1 \sim tBeta(1, k, p_1, 1)$, then we obtain the following convenient result for the marginal:

$$p_2 \sim Beta(k+1, k), \quad k > 0. \tag{2}$$

Notice that, in this particular case, the marginal distribution induced on p_2 is symmetrical with respect to the distribution of p_1 around the vertical line $p^* = 0.5$.

4 The Beta and restricted Beta

The *restricted Beta* (also called *4-parameters Beta*) is a Beta random variable which has been shifted and scaled to lie on a different domain (l,u).

In other words, if $X \sim Beta(\alpha, \beta)$ and $Z = l + X \cdot (u-l)$, then $Z \sim rBeta(\alpha, \beta, l, u)$. The expected value and variance of Z are:

$$\mathbb{E}[Z] = \frac{\alpha}{\alpha+\beta} \cdot (u-l) + l = \frac{u\alpha + l\beta}{\alpha+\beta}, \qquad \mathbb{V}[Z] = \frac{\alpha\beta}{(\alpha+\beta)^2(\alpha+\beta+1)} \cdot (u-l)^2$$

The restricted Beta can be exploited to specify a compelling joint prior for p_1 and p_2. If $p_1 \sim Beta(\alpha_1, \beta_1)$ and $p_2 \,|\, p_1 \sim rBeta(\alpha_2, \beta_2, p_1, 1)$ then the corresponding marginal expected value and variance of p_2 can be derived as a function of mean and variance of p_1 using the *Tower Law*:

$$\begin{aligned} \mathbb{E}[p_2] &= \frac{\alpha_2}{\alpha_2+\beta_2} + \mu_1 \frac{\beta_2}{\alpha_2+\beta_2} \\ \mathbb{V}[p_2] &= \sigma_1^2 \cdot \frac{\beta_2^2}{(\alpha_2+\beta_2)^2} \left(1 + \frac{\alpha_2}{\beta_2(\alpha_2+\beta_2+1)}\right) + (1-\mu_1)^2 \cdot \frac{\alpha_2\beta_2}{(\alpha_2+\beta_2)^2(\alpha_2+\beta_2+1)} \end{aligned} \tag{3}$$

where $\mu_1 = \mathbb{E}[p_1]$ and $\sigma_1^2 = \mathbb{V}[p_1]$. Thus, once chosen α_1 and β_1 to comply with some prior information on μ_1 and σ_1^2, we can elicit the values of α_2 and β_2 to respect prior knowledge on μ_2 and σ_2^2 simply by solving a linear system based on Eq. (3).

5 Application in Capture-Recapture analysis

Here, we illustrate the component-specific parameters' prior specification in the context of Capture-Recapture methods.

Capture-Recapture methods are widely employed in estimating the size of elusive populations whose units are subject to multiple captures across several occasions. Here, we assume that the population of interest is *closed* and individuals belonging to the population are *captured independently* one another [Otis et al., 1978]. When this is the case, even when the sampling occurred at J on different occasions, the overall capture frequencies of each individual are sufficient to make inference on the unknown population size N.

Let y_i be the capture frequency of the i-th unit across the J occasions, for $i = 1,\dots,N$, and let D be the total number of distinct *observed* individuals (i.e. captured at least once). The unknown populations size N can range from D to infinity. Following Royle and Dorazio [2012], we can bound the parameter space of N with a large (at will) upper bound M and augment the data sample with null capture frequencies $(y_{D+1},\dots,y_M) = (0,\dots,0)$ (representing fake individuals) in order to exploit classical MCMC sampling in a Bayesian framework. This is achieved by introducing a collection of i.i.d. latent variables $z_1,\dots,z_M$ that indicate whether the individual i belongs ($z_i = 1$) or not ($z_i = 0$) to the true population of N individuals. It is straightforward to see that $N = \sum_{i=1}^{M} z_i$. The advantage of this kind of modelling lies in the possibility to perform Bayesian inference without the need to jump between parameter spaces of varying dimensions, and this avoids the implementation of application-specific *Reversible Jump MCMC* [King and Brooks, 2002].

In particular, a uniform prior distribution in the discrete set $\{0,\dots,M\}$ is induced on N if we consider the hierarchical specification $z_i \,|\, \psi \sim Bern(\psi)$, $i = 1,\dots,M$ and $\psi \sim Unif[0,1]$, where ψ is the probability that an individual of the augmented dataset of size M is a member of the true population.

With the purpose of modelling the capture heterogeneity between individuals, this framework can be embedded in a FMM setting by considering finite mixture of two binomial distributions [Pledger, 2000] for the counts y_i

$$y_i|z_i \sim w \cdot Bin(J, p_1 \cdot z_i) + (1-w) \cdot Bin(J, p_2 \cdot z_i),$$

where w is the probability that individual i belongs to the first mixture component and p_g ($g = 1,2$) is the capture probability of the g-th component. Notice that $y_i = 0$ almost surely when $z_i = 0$ so that the previous model corresponds to a finite mixture of zero-inflated binomial distributions.

5.1 Simulation experiment

This section shows comparative merits of alternative prior specifications in dealing with label switching and exploiting prior information on group-specific parameters. We simulated $k = 1,\dots,50$ alternative capture-recapture datasets from closed populations with 2 groups. The simulation scheme mimics the model described in Sec. 5. Captures have been organized in $J = 10$ different occasions on a *super-population* of size $M = 500$, with a probability to be included in the actual population of $\psi = 0.3$, for all datasets. This yields an expected value of $\mathbb{E}[N_k] = 150$ across all datasets. Individuals have been allocated to the two groups evenly, setting $w = 0.5$. The group-specific capture probabilities have been set to $p_1 = 0.2$ and $p_2 = 0.4$. Under the closure hypothesis, the capture histories of each dataset have been collapsed into the vector of individual overall capture frequencies $\boldsymbol{y}_k = \left[y_1,\dots,y_{D_k}\right]$, where D_k is the number of distinct observed individuals of the simulated set k. The following five priors on the group-specific capture probabilities are considered, which correspond to those represented in the upper panels of Fig. 1:

A) $p_1 \sim Unif[0,1]$ and $p_2 \sim Unif[0,1]$;
B) $p_1 \sim Beta(1.08, 4.32)$ and $p_2 \sim Beta(3.44, 5.16)$, with hyperparameters centered on the true values $\mathbb{E}[p_1] = 0.2$ and $\mathbb{E}[p_2] = 0.4$ with $\mathbb{V}[p_1] = 0.2/10$ and $\mathbb{V}[p_2] = 0.4/10$;
C) $p_1 \sim Unif[0,1]$ and $p_2|p_1 \sim Unif[p_1,1]$, naive constrained prior inducing an improper marginal prior on p_2;

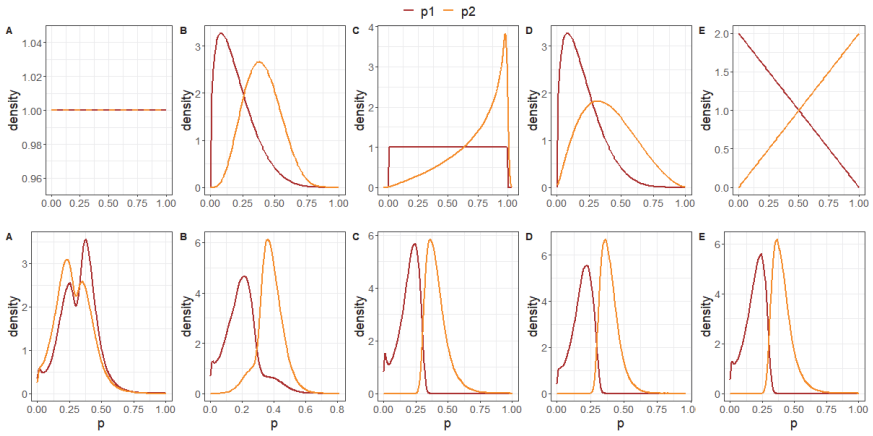

Fig. 1: Comparison between the marginal prior (*upper panels*) and posterior (*lower panels*) distributions for the parameters p_1 and p_2 for the five considered settings (A-E).

D) $p_1 \sim Beta(1.4, 5.6)$ and $p_2|p_1 \sim rBeta(0.826, 2.478, p_1, 1)$, inducing a marginal prior distributions on p_2 with the same means and variances of those considered in setting B;
E) $p_1 \sim Beta(1,2)$ and $p_2|p_1 \sim tBeta(1,1,p_1,1)$ which induces a marginal prior $p_2 \sim Beta(2,1)$ favoring repulsion between the two components.

The model in Sec. 5 is then coded and estimated in JAGS [Plummer et al., 2003] separately on each dataset and for each prior specification. Posterior samples of the capture probabilities p_1 and p_2 corresponding to different datasets have been merged (by prior setting) to analyze their overall behavior. The lower panels in Fig. 1 show their distribution, highlighting how they seem to be correctly identified whenever an ordering constraint between p_1 and p_2 is present (cfr. C-E). On the other hand, when independent priors (cfr. A-B) are considered, the posterior samples are affected by the label switching issue. Notably, regardless of the prior specifications, posterior distributions on p_1 and p_2 tend to be similar in settings C to E. Finally, the differences between the estimated posterior mean $\hat{N}_k$ and its true value N_k have been evaluated for each dataset $k = 1, \ldots, 50$. The overall performances of the different prior setting have been compared in terms of *average Predictive Interval Width* (PIW), *Root Mean Squared Error* (RMSE) and *Deviance Information Criterion* (DIC). Results are reported in Table 1, which highlights how the *constrained informative* prior (i.e. setting D) provides the best performances in all indicators, shortly followed by Setting E and A. Notably, including prior information without introducing constraints to avoid the label switching issue does not yield any improvement (on the contrary it worsens the results).

	A	B	C	D	E
PIW	46	49	51	41	43
RMSE	6.7	7.1	7.5	5.9	6.3
DIC	785.6	787.8	787.7	776.9	787.8

Table 1: 95% Prediction interval width (PIW), Root Mean Squared Error (RMSE) for N, and DIC for the five considered settings (A-E).

6 Final discussion

In light of the above, we can state that constrained priors on capture probability parameters are effective in avoiding the label switching issue, as shown in Sec. 5.1. In particular, if prior information is elicited correctly, it can improve the estimation and predictive performances of the model under the condition that constraints to avoid label switching are present (setting D).

Such a proposal's effectiveness must be tested on a real data example for which the finite mixture assumption is suitable. The simulation study could then be extended to a number of groups $G > 2$ in order verify the robustness of the procedure. Eventually, the whole prior setting could be extended to the more general case where the population is open, including also entrance and survival probabilities that my be assumed to be group-specific or not.

Clustering multivariate categorical data: a graphical model-based approach

Clustering di dati categoriali multivariati: un approccio basato su modelli grafici

Francesco Rettore, Michele Russo, Luca Zerman, Federico Castelletti

Abstract Clustering multivariate data using mixture models is a well-studied topic in statistics. In this contribution we propose a Bayesian framework for clustering categorical data which makes use of graphical models to account for possible group-specific dependence relations between variables. Our mixture model formulation allows to simultaneously infer a clustering structure of the units and the network of dependencies between variables.

Abstract *Il clustering di dati multivariati attraverso modelli mistura è un problema ampiamente studiato nella letteratura statistica. In questo contributo proponiamo un modello bayesiano per il clustering di dati categoriali che attraverso l'impiego di modelli grafici consente di considerare relazioni di dipendenza tra variabili che siano specifiche di ciascun gruppo. Il modello mistura proposto permette quindi di individuare gruppi latenti di osservazioni e al tempo stesso di stimare la struttura di dipendenza tra variabili del sistema.*

1 Introduction

Clustering individuals is a pervasive issue in statistics, with applications in several domains, and primarily social sciences. Traditionally, the two main clustering frameworks are represented by *distance-based* techniques that are opposed to *model-based* methods. The former implement a suitable measure of distance between observations and assign units to the same cluster whenever these are "close" in terms of the adopted metric; in this setting the most popular heuristic method is represented by the original k-means algorithm of [2] together with several of its extensions. Differently, model-based clustering techniques are probabilistic models based on *mixtures*, where each mixture component corresponds to a given cluster; see for instance [3].

In this work we assume that *multivariate categorical* observations are available. Categorical data are widely diffuse in many fields, and in particular social studies, where the information on individuals' preferences is collected through surveys; these consist of a battery of items, most of which are typically qualitative. In addition, the so-obtained data can be widely heterogeneous, as subjects differ by individual characteristics such as age and gender, among others. Most importantly, these features are expected to reflect the very way each given subject responds to the survey's items. When groups are known beforehand, one can perform independent analyses on each sub-dataset. However, this choice may produce *unreliable* inferential results due to the small group-sample sizes. On the other hand, modelling the whole dataset as a unique single group can produce *biased* results since it does not account for possible heterogeneity in the sample. In addition, finding clusters of individuals sharing similar features in terms of preferences w.r.t. the items can be of interest in itself, for instance to develop personalized marketing strategies.

In this contribution we propose a model-based framework for clustering categorical observations. Our method fully accounts for dependence relations between variables/items that are encoded in the available data. Specifically, we represent conditional independence relations by using a graphical model-based approach [1]. Graphical models are probabilistic models for a collection of random variables which provide a powerful tool to impose dependence relations between variables in the joint density through a graph structure $\mathscr{G}$. The latter is made up of a set of *nodes* V, each corresponding to a variable in the system, and a set of *edges* E, representing dependence relations between nodes. We consider a Bayesian *non-parametric mixture model* based on a Dirichlet Process prior [7], where each component of the mixture corresponds to a suitable categorical graphical model. Our model formulation allows to simultaneously learn dependence relations between variables and infer a clustering structure among individuals represented by latent groups of units sharing the same set of dependence statements.

The rest of this contribution is organized as follows. In Section 2 we introduce graphical models for categorical data under a Bayesian framework. In Section 3 we describe our mixture of categorical graphical models, while in Section 4 we provide computational details relative to a Markov chain Monte Carlo (MCMC) scheme for posterior inference on clustering and graphs.

2 Categorical graphical models

Let $(X_1,\ldots,X_q)$ be a categorical random vector such that for each $j=1\ldots,q$, $X_j \in \mathscr{X}_j$, the set of levels of the categorical variable X_j. Let also $\mathbb{X}$ be an (n,q) dataset whose rows are i.i.d. realizations of the random vector $(X_1,\ldots,X_q)$, namely $\mathbf{x}^{(i)} = \left(x_1^{(i)},\ldots,x_q^{(i)}\right)^\top$, for $i=1,\ldots n$. It follows that each $\mathbf{x}^{(i)} \in \mathscr{X} := \bigotimes_{j=1}^q \mathscr{X}_j$, the product space generated by the levels of the q categorical variables. We then let $\pi(\mathbf{x}) \in (0,1)$ be the probability to observe a given configuration $\mathbf{x} \in \mathscr{X}$. Starting from the data matrix $\mathbb{X}$, we can compute for each $\mathbf{x} \in \mathscr{X}$ the corresponding *configuration count* $n(\mathbf{x})$ defined as

$$n(\mathbf{x}) = \sum_{i=1}^{n} \mathbf{1}\{\mathbf{x}^{(i)} = \mathbf{x}\}. \tag{1}$$

In addition, for a given subset $S \subseteq \{1,\ldots,q\}$ and each $\mathbf{x}_S \in \mathscr{X}_S$, the corresponding *marginal configuration count* can be computed as

$$n(\mathbf{x}_S) = \sum_{i=1}^{n} \mathbf{1}\big\{\mathbf{x}^{(i)}(S) = \mathbf{x}_S\big\} = \sum_{\mathbf{x}\in\mathscr{X}} n(\mathbf{x})\mathbf{1}\big\{\mathbf{x}(S) = \mathbf{x}_S\big\}, \tag{2}$$

where $\mathbf{x}(S)$ is the sub-vector of $\mathbf{x}$ with components indexed by S. Similarly, we can define the *marginal probability*

$$\pi(\mathbf{x}_S) = \sum_{\mathbf{x}\in\mathscr{X}} \pi(\mathbf{x})\mathbf{1}\big\{\mathbf{x}(S) = \mathbf{x}_S\big\}. \tag{3}$$

By assuming independence among the n observations, we can write the likelihood function as

$$\begin{aligned} p(\mathbf{N} \mid \theta) = \prod_{i=1}^{n}\prod_{\mathbf{x}\in\mathscr{X}} \pi(\mathbf{x})^{\mathbf{1}\{\mathbf{x}^{(i)}=\mathbf{x}\}} &= \prod_{\mathbf{x}\in\mathscr{X}} \pi(\mathbf{x})^{\sum_{i=1}^n \mathbf{1}\{\mathbf{x}^{(i)}=\mathbf{x}\}} \\ &= \prod_{\mathbf{x}\in\mathscr{X}} \pi(\mathbf{x})^{n(\mathbf{x})}, \end{aligned} \tag{4}$$

where θ is the model parameter collecting the probabilities $\{\pi(\mathbf{x}), \mathbf{x}\in\mathscr{X}\}$, and $\mathbf{N}$ denotes the collection of counts (data) $\{n(\mathbf{x}), \mathbf{x}\in\mathscr{X}\}$.

Let now $\mathscr{G} = (V,E)$ be a decomposable undirected graph (UG) on the set of nodes $V = \{1,\ldots,q\}$. A decomposable UG is uniquely characterized by its set of *cliques* and *separators*; see for instance [1]. More importantly, as we associate each categorical variable X_j to a node in $\mathscr{G}$, the conditional independencies encoded in $\mathscr{G}$ are imposed to the joint density of $(X_1,\ldots,X_q)$ and the likelihood function factorizes as

$$p(\mathbf{N} \mid \theta, \mathscr{G}) = \frac{\prod_{C\in\mathscr{C}} p(\mathbf{N}_C \mid \theta_C)}{\prod_{S\in\mathscr{S}} p(\mathbf{N}_S \mid \theta_S)}, \tag{5}$$

where $\mathscr{C}$ and $\mathscr{S}$ denote, respectively, the sets of cliques and separators of $\mathscr{G}$. Also, $\mathbf{N}_C$ and θ_C represent the contingency tables of marginal configuration counts and probabilities, $\{n(\mathbf{x}_C), \mathbf{x}_C \in \mathscr{X}_C\}$ and $\{\pi(\mathbf{x}_C), \mathbf{x}_C \in \mathscr{X}_C\}$ respectively; see also [4].

We complete the model specification by assigning a prior to θ. Specifically, we assume that conditionally on $\mathscr{G}$, θ follows a *Hyper Dirichlet* (HD) distribution with hyperparameter $\mathbf{A} = \{a(\mathbf{x}), \mathbf{x} \in \mathscr{X}\}$, namely

$$p(\theta \mid \mathscr{G}) = \frac{\prod_{C \in \mathscr{C}} p(\theta_C \mid \mathscr{G})}{\prod_{S \in \mathscr{S}} p(\theta_S \mid \mathscr{G})}, \tag{6}$$

where for each $S \in \mathscr{S}$, $\theta_S \mid \mathbf{A}_S \sim \mathrm{Dir}(\mathbf{A}_S)$, with $\mathbf{A}_S = \{a(\mathbf{x}_S), \mathbf{x}_S \in \mathscr{X}_S\}$ and

$$a(\mathbf{x}_S) = \sum_{\mathbf{x} \in \mathscr{X}} a(\mathbf{x}) \mathbf{1}\{\mathbf{x}(S) = \mathbf{x}_S\}; \tag{7}$$

similarly for each $C \in \mathscr{C}$; see [4] for full details. Finally, a prior $p(\mathscr{G})$, for any $\mathscr{G} \in \mathbb{S}_q$, the set of all decomposable UGs on q nodes, can be assigned through a Beta-Binomial distribution on the number of edges in the graph; see for instance [6].

The HD distribution provides a conjugate prior for the model parameter θ; accordingly, the posterior distribution of θ is still HD and the *marginal likelihood* of $\mathscr{G}$, $m(\mathbf{N} \mid \mathscr{G}) = \int p(\mathbf{N} \mid \theta, \mathscr{G}) p(\theta \mid \mathscr{G}) \, d\theta$, is available in closed form. The latter feature is essential for the implementation of the MCMC scheme for posterior inference on graph structures and clustering introduced in Section 4.

3 Mixture model formulation

We extend the previous framework to a *mixture* of categorical graphical models, thus allowing for possible heterogeneous dependence relations among subjects that are linked to a latent clustering structure of the data. We base our model formulation on a *Dirichlet Process* (DP) prior [7], by assuming

$$\begin{aligned} \mathbf{x}^{(i)} \mid (\theta_i, \mathscr{G}_i) &\sim p\big(\mathbf{x}^{(i)} \mid \theta_i, \mathscr{G}_i\big), \\ (\theta_i, \mathscr{G}_i) \mid M &\sim M, \\ M &\sim DP(M_0, \alpha), \end{aligned} \tag{8}$$

where in particular $DP(M_0, \alpha)$ represents the Dirichlet Process with base distribution M_0 and concentration parameter α. We then take $p(\theta, \mathscr{G}) = p(\theta \mid \mathscr{G}) p(\mathscr{G})$ as the baseline measure M_0, with $p(\theta \mid \mathscr{G})$, $p(\mathscr{G})$ defined as in Section 2.

A well known equivalent representation of the previous model can be obtained by taking the limit as K goes to infinity of a finite mixture model with K components (clusters) of the form

$$\begin{aligned} \mathbf{x}^{(i)} \mid c_i, \{\theta_i, \mathscr{G}_i\}_{k=1}^K &\sim p\big(\mathbf{x}^{(i)} \mid \theta_{c_i}, \mathscr{G}_{c_i}\big), \\ (\theta_k, \mathscr{G}_k) &\sim M_0, \\ c_i \mid \mathbf{p} &\sim \text{Discrete}(p_1, \ldots, p_K), \\ \mathbf{p} &\sim \text{Dir}(\alpha/K, \ldots, \alpha/K). \end{aligned} \tag{9}$$

In particular, each $c_i \in \{1, ..., K\}$ is a random variable indexing the cluster associated with the i-th observation; for each $k = 1, \ldots, K$, $(\theta_k, \mathscr{G}_k)$ are instead cluster-specific parameters.

The latter representation allows for the implementation of a *collapsed* MCMC scheme where parameters θ_k's are integrated out and the algorithm approximates a marginal posterior distribution over the space of graphs and cluster indicators $c_1, \ldots, c_n$.

4 Computational details

Our sampling scheme for posterior inference relies on Algorithm 2 of [5], which applies to conjugate models whereas model-dependent parameters can be integrated out. Accordingly, the target is represented by the joint posterior

$$p\left(K, \{c_i\}_{i=1}^n, \{\mathscr{G}_k\}_{k=1}^K, \mid \mathbb{X}\right), \tag{10}$$

where K is the (random) number of clusters.

Given an initial state where the data $\mathbf{x}^{(1)}, \ldots, \mathbf{x}^{(n)}$ are divided into K clusters (equivalently, the indicator variables $c_1, \ldots, c_n$ have been fixed) and graphs $\mathscr{G}_1, \ldots, \mathscr{G}_K$ are associated with each of the K components, an MCMC algorithm can be implemented by reiterating the following two steps.

As a first step we update the indicator variables $c_1, \ldots, c_n$ and, implicitly, the number of clusters K through a Gibbs sampling scheme which sequentially samples each c_i $(i = 1, \ldots, n)$ from its full conditional distribution. Specifically,

if $c_i = c_j$ for some $j \neq i$,

$$P(c_i = k \mid \mathbf{c}_{-i}, \mathbb{X}, \mathscr{G}_1, \ldots, \mathscr{G}_K) \propto \frac{n_{-i,k}}{n - 1 + \alpha} \int p(\mathbf{x}^{(i)} \mid \theta_k, \mathscr{G}_k)\, dH_{-i,k}(\theta_k \mid \mathscr{G}_k);$$

if $c_i \neq c_j \; \forall j \neq i$,

$$P(c_i \neq c_j \forall j \neq i \mid \mathbf{c}_{-i}, \mathbb{X}, \mathscr{G}_1, \ldots, \mathscr{G}_K) \propto \frac{\alpha}{n - 1 + \alpha} \int p(\mathbf{x}^{(i)} \mid \theta^*, \mathscr{G}^*)\, dM_0(\theta^* \mid \mathscr{G}^*),$$

where in particular:

- $n_{-i,k} = \sum_{j \neq i} \mathbf{1}\{c_j = k\}$, i.e. the number of indicator variables (excluding c_i) that are equal to k;

- $H_{-i,k}$ denotes the posterior distribution of θ_k based on the prior M_0 and given the data $\{\mathbf{x}^{(j)}, j \neq i, c_j = k\}$ and graph $\mathscr{G}_k$;
- $\mathscr{G}^*$ corresponds to an empty cluster (graph) which is randomly sampled from the baseline measure on $\mathbb{S}_q$.

Since the two integrals correspond, respectively, to posterior and prior predictive distributions and the categorical HD model is conjugate, we can provide closed-form expressions for both the two terms (we omit details).

Finally, conditionally on the cluster-indicator variables $c_1, \ldots, c_n$, each graph $\mathscr{G}_k$, $k = 1, ..., K$, can be updated as follows. Consider first a partition of the n observations into K clusters, $\{C_1, \ldots, C_K\}$, where

$$C_k = \{\mathbf{x}^{(i)} : c_i = k\}, \quad k = 1, \ldots, K.$$

We then update $\mathscr{G}_k$ through a Metropolis-Hastings step where a new graph $\mathscr{G}'_k$ is proposed from a suitable proposal distribution $q(\mathscr{G}'_k \mid \mathscr{G}_k)$ and then accepted with probability

$$\alpha_k = \min\left\{1, \frac{m(C_k \mid \mathscr{G}'_k)}{m(C_k \mid \mathscr{G}_k)} \cdot \frac{p(\mathscr{G}'_k)}{p(\mathscr{G}_k)} \cdot \frac{q(\mathscr{G}_k \mid \mathscr{G}'_k)}{q(\mathscr{G}'_k \mid \mathscr{G}_k)}\right\},$$

where $m(C_k \mid \mathscr{G}_k)$ denotes the marginal likelihood of graph $\mathscr{G}_k$ given the data C_k.

The Gaussian mixture model-based clustering for the comparative analysis of the Healthcare Digitalization Index in the Italian local health authorities

La cluster analysis basata sul modello di mistura di Gaussiane per l'analisi comparativa dell'Indice di digitalizzazione sanitaria nelle ASL italiane

Margaret Antonicelli[1], Michele Rubino[2], Filomena Maggino[1]

Abstract In recent years, the COVID 19 pandemic has highlighted the limitations of the health system which, with the digital transformation, can ensure benefits for patients and physicians. Digitization is a complex process that depends on numerous variables that can have a strong territorial connotation considering the organizational aspects of the Italian health system. This study aims to build a digitization index of Italian local health authorities, based on 6 parameters, with which we will carry out a comparative analysis between the regions through a Gaussian mixture model-based cluster analysis.

Abstract *In questi ultimi anni, la pandemia da COVID 19 ha evidenziato i limiti del sistema sanitario che con la trasformazione digitale può assicurare benefici per medici e pazienti. La digitalizzazione è un processo complesso che dipende da*

1 Introduction

The COVID 19 pandemic highlighted the limits of the Italian health system and the need to accelerate its digital transformation processes. Healthcare represents a fundamental strategic area on which to build the development and restart of the country to respond quickly and effectively to events that impact the health of citizens (Nunez et al., 2021). At the same time, digital transformation is an important element in driving change in the national health system to improve relationships between patients and physicians. In fact, digitization is an enabling element for new healthcare based on data and information, the interoperability of systems, and services that are usable and accessible to citizens (Tortorella et al, 2020).
Some recent studies have shown that Italian healthcare is lagging in the digital transformation process and that services are inadequate (Patrone et al., 2018). The Italian Ministry of Health highlighted that the digitalization process of the health system is fragmented and inhomogeneous and that a central role in the management of relations between citizens and territories is played by local health authorities. On the above premises, this study aims to answer the following research questions:

RQ1: What is the digitization level of the Italian local health authorities? Are there differences between the different areas of the country or aspects worthy of attention?

To address these questions, this study aims to build a digitization index of Italian local health centers, based on 6 parameters, with which we will carry out a comparative analysis between the regions through a Gaussian mixture model-based cluster analysis.
The remainder of the paper is organized as follows. Section illustrates the methodology. Section 3 presents and discusses the research findings. Finally, implications and concluding remarks are given in Section 4.

2 Methodology

2.1 Research method

This study is based on two distinct and integrated methodologies: the construction of the health digitalization index (HDI) through the recovery of 6 parameters through web scraping analysis; the use of the clustering approach based on Gaussian mixture models to conduct the comparative analysis. The research was conducted by analysing the 101 Italian local health authorities active in December 2019 based on the public registers released by the Ministry of Health.

Referring to the HDI, 4 fundamental parameters are identified in the literature: presence of an electronic record; booking of online services; collection of online reports; online payment of health services. Each of these four parameters was measured through a fictitious variable, which was assigned the value 1 if these services were provided by the hospital, therefore present and active on the site, 0 if it was not provided. Given the complexity of the phenomenon, the organizational aspects are fundamental for its explanation; therefore, in addition to what has already been outlined, two other parameters were selected in order to construct the indicator: specialized IT personnel [5, 6] expressed as a percentage of qualified personnel out of total employees; chatbot for patient assistance, where the value 1 was assigned if this service was provided by the hospital, therefore present and active on the site, 0 if it was not provided [7, 8, 9]. We collected all data extracted from various sources using the vivid functionality of the scrapy web crawler using scripts written in Python 3.6 and further analysed according to customer needs where the data is stored in the company's database [10].

The data extraction process consists of 3 phases: 1) coding: the basic web crawling script used shows the scanned and stored data in the product database from a hospital site, in this case Reddit with the XPath method involved to find the details of each element of the Frequent Research; 2) testing: the project was tested using the various components as defined above and executed on the browser. The extraction carried out is completely relevant and the analysis carried out is estimated; 3) results: the overall results of the project are useful for understanding. Once all the parameters have been detected through web scraping, a further fundamental process is the construction of an index that evaluates and, above all, summarizes the complexity of the phenomenon of "digitization" in the healthcare sector. To this end, the most suitable methodology was considered for the benefit of the doubt, an application of the Date Envelopment Analysis (DEA). This method sees the composite indicator as the ratio between the performance of the single unit with that of the benchmark, ensuring that the optimal set of weights guarantees each associated unit the best possible position compared to all the others. The optimal weights are obtained as follows:

$$CI_c^* e^x = max_{w\,cq} \frac{\sum_{q=1}^{Q} I_{cq} w_{cq}}{max_{kc\,(1\ldots c)} \sum_{q=1}^{Q} I_{cq} w_{cq}}, \qquad \forall c = 1$$

where the weights are placed non-negative and I_{cq} represents the normalized score of the q-th simple indicator (q = 1, ..., Q) for the unit c (c = 1, ... C) and w_{cq} the

corresponding weight. The resulting composite indicator will therefore vary between 0 (the lowest performance) and 1 (the benchmark).

2.2 The Gaussian mixture model-based clustering

The Gaussian Mixture Model (GMM) assumes that the data comes from a finite mixture of G p-multivariate normal distributions, that is, that the population density can be expressed as:

$$f\ (y, \theta, \tau) = \sum_{k=1}^{G} \tau_k f_k\ (y, \theta_k)$$

where f_k and θ_k are the density and the parameters of the k-th component of mixture, and τ_k is the probability that the observation $\underline{y}$ belongs to the k-th component

$$(\ \tau_k \geq 0; \sum_{k=1}^{G} \tau_k = 1)$$

and f_k is a multivariate Normal density function, where θ_k is the parameter given by $\underline{\mu_k}$, Σ_k

$$l\ (\theta, \tau, z_i\ |x) = \sum_{1=1}^{n} \log \left[\sum_{k=1}^{G} z_{ik} \tau_k f_k\ (y_i | \theta_k) \right]$$

where z_i means that we have an unobservable vector z for each observation. These values must be estimated together with $\underline{\theta}$ (where θ_k represents in this case the "joint parameter" ($\underline{\mu_k}$, Σ_k) and $\underline{\tau_k}$ (k=1, … G).
An EM algorithm is used to estimate unknown parameters and unobservable variables. The criterion used to select the number of components (clusters) of the Gaussian mixture is the Bayesian Information Criterion (BIC):

$$BIC = 2l\ (\hat{\theta}, \hat{\tau}, \hat{z}_i\ |x) - (\#parameters) * \log(n)$$

in which

$$l\ (\hat{\theta}, \hat{\tau}, \hat{z}_i\ |x)$$

is the maximized value of the log-likelihood, (#parameters) is the number of parameters estimated, and *n* is the sample size. The BIC index is generally defined with the opposite sign compared to the definition used in this package (and therefore, smaller index => better).

3 Result and discussion

To proceed with the analysis, the 6 parameters that make up the HDI are grouped. It is useful, in this phase, to carry out evaluations of a descriptive nature; to this end, we proceed with the calculation of Pearson's linear correlation coefficients (the correlation character is scaled based on the size of the absolute correlation) and their level of significance with confidence level $\alpha = 0.05$ are reported (Table 1).

Table 1 - Pearson's linear correlation coefficients

	1	2	3	4	5	6
1 - Presence of electronic folder	1					
2 - Online service reservations	0,65*	1				
3 - Online report collection	0,59**	0,64	1			
4 - Online payment of healthcare service	0,48	0,77***	0,28	1		
5 - Specialized IT employees	0,51	0,38*	0,56**	0,35	1	
6 - Chatbot for assistance to patients	0,69**	0,72**	0,27*	0,39*	0,81***	1

The next step is the grouping of the 101 Italian local health authorities analysed using a model-based approach using Gaussian mixture models. The choice to use this approach depended on the fact that a unsupervised approach, where the number, shape and size of clusters are achieved through inferential statistics methods (BIC coefficient). Among the possible distributive hypotheses on the data, we focus on the multivariate Gaussian density mixture for its ability to approximate the density function of any unknown distribution.
The cluster analysis was conducted using the R Mclust software package, in which it was decided to use the variable volume model, equal shape and equal orientation and 3 components (clusters). In the Table 2 reports the indicators' means of each component and the number of units.

Table 2 - Means of components and number of units.

Parameters	Cluster 1	Cluster 2	Cluster 3
Presence of electronic folder	0,69	0,78	0,51
Online service reservations	0,84	0,87	0,63
Online report collection	0,52	0,81	0,39
Online payment of healthcare service	0,49	0,66	0,35
Specialized IT employees	0,41	0,84	0,28
Chatbot for assistance to patients	0,35	0,47	0,19
Number of Unit	47	25	29

The analyses carried out show a very strong territoriality of the phenomenon analysed. In particular, the territorial health units with average levels of digitalisation have returned to the first cluster; these are essentially located in central Italy, in Liguria, Sardinia and in part of Puglia. As regards the second cluster, which includes healthcare companies with high levels of digitization, these are concentrated exclusively in the north, with the sole exception of Rome. Finally, the third cluster groups the health units with medium-low levels of digitization, essentially located in southern Italy and Sicily.

4 Conclusion

The HDI is a suitable indicator for comparing the levels of digitalization between the various Italian ASLs. The classification of the various health bodies through clustering based on Gaussian mixture models, given the complexity of the phenomenon analysed, made it possible to make a reading and the results obtained much easier and more understandable and, consequently, allowed to make the comparison between the various territorial entities highlighting the substantial territoriality of the phenomenon that sees the entities of Northern Italy in a much better situation than those of the Southern regions.

Student performance evaluation

Rasch model *versus* Rasch Mixture model: strengthens and limits in identifying factors affecting students' performance in mathematics

Il modello di Rasch a confronto con il modello di mistura di Rasch: punti di forza e limiti nell'individuare i fattori che influenzano la performance degli studenti in matematica

Clelia Cascella

Abstract The Rasch model has been widely used in educational research to measure students' performance and to identify factors affecting it. Despite its multiple strengths, the Rasch model shows some limitations in exploring the relationship between students' performance and their (e.g., socio-demographic) characteristics, thus calling for the employment of alternative analytical solutions. In the current paper, I employed the Rasch Mixture Model to analyse data collected by INVALSI (at grade 5, in 2017), to (i) identify students' answers profiles, and (ii) understand if/how answers profiles are associated with students' characteristics. Similarities and differences between the Rasch model and the Rasch Mixture Model have been presented and discussed.

Abstract *Il modello di Rasch è stato diffusamente utilizzato nella ricerca educativa per misurare la performance scolastica degli studenti e identificare i fattori che la influenzano. Nonostante i suoi molteplici punti di forza, il modello di Rasch mostra alcuni limiti nell'esplorare la relazione tra la performance degli studenti e le loro caratteristiche (ad esempio, sociodemografiche), dunque suggerendo la necessità di implementare soluzioni analitiche alternative. In questo articolo, ho utilizzatoil modello di mistura di Rasch per analizzare i dati raccolti da INVALSI (al grado 5, nel 2017), per individuare i profili di risposta degli studenti e osservare se/come tali profili siano associati alle caratteristiche degli studenti. Somiglianze e differenze tra il modello di Rasch ed il modello di mistura sono state presentate e discusse.*

Key words: Rasch model, Mixture Rasch model, Mathematics, students' profiling

1 Introduction

Mathematics has been listed by the European Commission as one of the key competences needed by all for personal fulfilment and development, employability, and active citizenship. Understanding what factors can affect students' performance in mathematics is thus considered as a priority for both the national and the international agenda.

So far, most educational research has employed the Rasch model (RM) (Rasch, 1960), the first Item Response Theory (IRT) model, to estimate students' *ability*, a technical term used to refer to the latent trait measured via an achievement test (Andrich & Marais, 2019), consisting of a set items (i.e. questions). The Rasch model assumes that: (i) the latent trait is (at least, predominantly) unidimensional, (ii) the latent trait is measured via a set of items whose probability of being successfully encountered is assumed to be locally independent (i.e., the observed responses to each item are independent of responses to all other items, conditional upon the underlying trait); and, that (iii) the conditional probability of giving a correct answer follows a monotone non decreasing function of students ability (Hambleton & Swaminathan, 1985).

Within such an analytical framework, the Differential Item Functioning (DIF) analysis (Osterlind & Everson, 2009) has been extensively used to test for *measurement invariance* (Engelhard, 2009, 2013) of students' ability, measured across sub-groups of students, *matched on ability* and grouped by sex, ethnicity, socioeconomic status, or any other characteristic of interest. DIF analysis is used to test for measurement invariance because the RM assumes that the probability of giving a correct answer to an item is given by student's *relative ability*, that is his/her intrinsic ability (e.g., in mathematics) compared with item difficulty. DIF occurs when item's difficulty changes across sub-groups of students: if the same item is perceived as more or less difficult by students matched on ability ability, then the grouping variable is somehow associated with student's probability of encountering that item successfully. Such a relationship between the grouping variable and the probability of encountering an item successfully violates Rasch model assumptions as the RM assumes that the probability of encountering an item successfully is a function of students' relative ability, and that no other factor (sex, ethnicity, or any other variable) can affect it: any association between variable other than student's relative ability and the probability of encountering an item successfully is not modelled within the framework of the RM and can threat measurement invariance (Wright & Stone, 1979).

DIF analysis is thus a powerful tool to test for data-model fit, but it shows some serious drawbacks, especially in large-scale assessment, as it assumes homogeneity within sub-groups of students. For example, in a DIF analysis carried out by students' sex, results may "lead to a stereotypical view of an item as being more advantageous to all members of the group (males or females) favoured by DIF item, while ignoring the true heterogeneity within each group" (Cohen & Bolt, 2005): so, the same item could differently work in (and thus results as easier or as more difficult for) sub-groups of students within the male or the female group. Moreover,

DIF analysis can account for just one variable at time, without considering the possible intersectionality between variables. Results based on DIF analysis that ignores such an intra-group variability may thus mislead data interpretation.

In the current paper, I dealt with such a problem by employing the Rasch Mixture Model (RMM) (Rost, 1990), "a generic approach for modelling data that is assumed to stem from different groups (or clusters [or components]) but group membership is unknown" (Frick, Strobl, Leisch, & Zeileis, 2012a).

The analysis of large-scale assessment data collected in Italy has been used to present and discuss the differences between RM and RMM, and present one of the possible uses of RMM in educational research.

2 Methodology

Students' ability in mathematics is the latent trait investigated in present study. I measured it by analysing data collected by the Italian national institute for the evaluation of educational system (*Tr. Istituto Nazionale per la Valutazione del Sistema di Istruzione e formazione* - INVALSI). Data were collected by administering a mathematics achievement test[1] consisting of 13 multiple-choice items, 9 True/False items and 24 open-ended items, covering the subareas of (i) "space and shape" (roughly geometry), (ii) "change and relationship" (algebra), (iii) "quantity" (arithmetic), and (iv) "uncertainty" (probability), in a range of difficulty from those that require simple mathematical operations to those that require complex thinking. This achievement test was administered, in 2017, at both census (491,658 students) and sample level (35,000 students), in primary school (grade 5), (on average 10-years old students)[2].

Since the RMM is very sensitive to sample size and the model can over-extracts latent classes (when it is employed to analyse very large data sets), I tentatively extracted (from the INVALSI sample) five, smaller samples (of 25,000, 20,000, 15,000, 10,000 and 5,000 students each). Then, I comparatively analysed them by employing the RMM. The iterative procedure based on different sample sizes has been briefly described in the results section.

INVALSI data have been preliminary analysed via the Rasch (i.e. 1- parameter logistic) model, and via either 2- or 3- parameter logistic IRT models[3] to explore data-model fit as, if data fit the 2- or 3-PL IRT model better than 1-PL model, then applying a RMM may result in an overextraction of latent classes (Alexeev,

[1] The administered mathematics achievement test is available on-line at https://invalsi-areaprove.cineca.it/docs/file/05_Matematica_Fasc_1_2017.pdf

[2] A description of the sample is available on-line at https://www.dropbox.com/scl/fi/oj9xvzwxbj4utu7h7rssi/Sample-description.xlsx?dl=0&rlkey=0n97gnsghphyt5os99o9fq50b

[3] The 2- and the 3-PL models allow for the estimation of item discrimination and guessing, respectively: in the former item discrimination is allowed to vary item by item (as apposed to the Rasch model where item discrimination is supposed to be the same for each item); whereas the latter also estimates guessing, i.e. the probability of correctly answering an item by accident (Andrich & Marais, 2019).

Templin, & Cohen, 2011). Therefore, first, I checked for data model fit by performing a fit analysis within the framework of the 1-, 2- and 3-PL model, and then I analysed INVALSI data by using the RMM.

RMM modelling challenges Rasch estimates' invariance by allowing parameter to vary among latent classes (Rost, 1990), rather than assuming trait unidimensionality (Rasch, 1960). Mixture Rasch thus allows the exploration of a "mixture of latent sub-populations that are qualitatively different but within which a measurement model based on a continuous latent variable holds. In this modelling framework, one can characterize students by both their location on a continuous latent variable as well as by their latent class membership" (De Ayala & Santiago, 2017). Exploring the possible existence of latent classes can be precious because using a single or the same parameter estimation for all groups may result in a loss of information as it does not account for the heterogeneity in the population analysed (von Davier & Carstensen, 2007).

In the present study, the model with the lowest BIC has been presented in the results section. All the analyses have been carried out in R, by using both eRM (Mair & Hatzinger, 2007) and psychomix (Frick, Strobl, Leisch, & Zeileis, 2012b).

3 Results

The preliminary fit analysis (not reported here) showed that data fit both the 2- and the 3-PL IRT model slightly better than 1-PL model. Since that data fit both the 2- and the 3-PL model a bit better than the 1-PL model, then the Rasch Mixture Model may extract a number of latent classes greater than the actual number of clusters in the data. Nonetheless, the difference in BIC between the 1-, 2- and 3-PL model is small. An empirical analysis of INVALSI data via the MRM has thus been performed.

Results based on different sample sizes (25,000, 20,000, 15,000, 10,000 and 5,000) confirmed that the larger the sample size, the large the noise in the data: results based on 25,000, 20,000 and 15,000 students showed between 7 and 11 latent classes with just 1 latent class whose posterior probabilities were either high or low. In the ideal case, posterior probabilities of the observations for *each* latent class are either high or low, yielding a U-shape in all panels (Frick et al., 2012a).

In contrast results based on smaller sample sizes (both 10,000 and 5,000 cases) showed that the optimal model (i.e., that showing the lowest AIC and BIC) was that with 5 latent classes (Figure 1). In this case, the rootogram of posterior probabilities shows that in 3 out of 5 latent classes posterior probabilities were either high or low, yielding in a U-shape in 2 out of 5 classes (class 3 and 4). The remaining three classes (i.e., 1, 2, and 5) showed a decreasing shape, thus raising concerns about their interpretability. These three classes may be "not real", but over-extracted (Alexeev e 2011). Nonetheless, it is worth noting that this just an interpretative hypothesis: determining the best fitting model is still a challenging, open problem in the existing literature that calls for further research.

Item difficulty changes by class. Figure 3 shows a selection of items whose estimated difficulty largely changes by class. By comparing item distribution by class, on average, estimated item difficulty is relatively lower in class 3 than in the other classes, with some exceptions (such as item the D12 and the item D20, whose estimated difficulty is sharply higher than that in most of the other latent classes). In line with both the national and the international literature, students' probability of belonging to class 3 is higher for Italian males, whose age is that expected for grade 5 (i.e., neither retained nor in advance student), and from high-SES families.

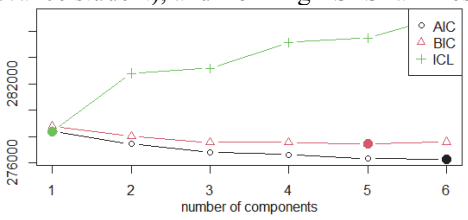

Figure 1. *Number of components extracted*

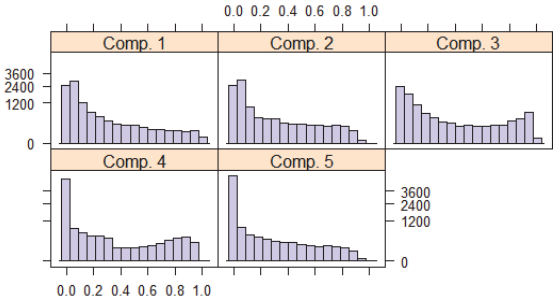

Figure 2. *Rootogram of posterior probabilities*

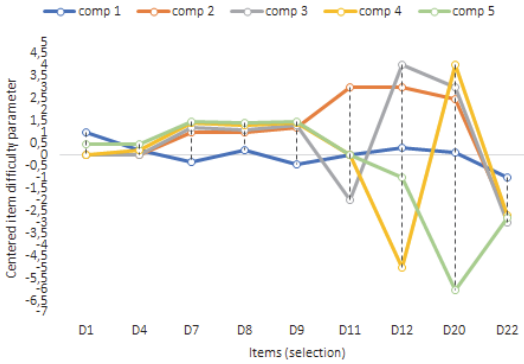

Figure 3. *Item profiles for the 5-component (selection of items showing the highest difference in terms of estimated difficulty between latent classes)*

4 Discussion and conclusions

Identifying factors affecting students' performance in mathematics is a priority for both the national and the international agenda. Existing methods to address such an

aim (such as DIF analysis within the framework of the Rasch analysis) show some technical criticalities.

The present paper aimed to show the functionality of an alternative analytical approach based on the RMM. As opposed to the RM (Rasch, 1960/1980), the RMM (Rost, 1990) does not assume data unidimensionality, but it accounts for data heterogeneity by allowing parameter to vary among latent classes (Rost, 1990).

In the present study, I anaysed INVALSI data by employing the Rasch Mixture Model to (i) detect latent classes that differ in patterns of item difficulty; and, (ii) associate students' characteristics to the probability of belonging to each of the latent classes extracted and, thus, to items' difficulty.

Studying such an association can solicit new research questions. For example, why items D12 was perceived as more difficult by students whose probability of belonging to the latent class 3 is higher (even though, on average, students' ability in mathematics is higher than in the other latent classes)? Why such a gap (in items difficulty) is larger between class 3 and class 4 even though all the other items difficulty were similar (and thus students seem to be matched on mathematics ability)? Do students' characteristics play a role in explaining such a gap?

Does taking additional Maths classes improve university performance?

A clustered case-control study based on Italian high-school and university data

Martina Vittorietti, Andrea Priulla, Massimo Attanasio

Abstract Several recent studies in educational literature showed how students' skills in maths affect their success at higher levels of education. The aim of this paper is to evaluate the effect of taking additional maths class at high school on first-year performance of Italian university students. However, university performance and the choice of the high-school depend on several factors that make this evaluation challenging. Using information coming from three different sources, we carry out a multilevel propensity score procedure to estimate the average treatment effect between the applied sciences track and the traditional scientific one. After balancing for school- and student-level covariates, the results of a logistic regression model suggest no difference between the two school tracks.

Abstract Studi recenti nell'ambito dell'istruzione secondaria hanno mostrato come le abilità matematiche degli studenti abbiano un effetto sul loro futuro successo scolastico e universitario. L'obiettivo di questo lavoro è valutare se studiare più matematica a scuola è associato ad una migliore performance al primo anno di università. La performance universitaria e la scelta della scuola dipendono tuttavia da molteplici fattori che rendono complessa questa analisi. Utilizzando dati provenienti da tre diverse fonti, applichiamo un multilevel propensity score matching per stimare l'effetto medio di due trattamenti: "il liceo scientifico delle scienze applicate" e il "liceo scientifico tradizionale". Dopo aver bilanciato le caratteristiche della scuola e degli studenti, i risultati di un modello logistico mostrano che non emergono differenze tra i due percorsi scolastici.

Key words: propensity score, fine balance, educational data, multilevel propensity score, optimal network flow

1 Introduction

Mathematics is perceived as the foundation for scientific and technological knowledge that is cherished by societies worldwide. Due to its relevance and application, mathematics is widely regarded as one of the most important school subjects and a central major of the school curriculum [8]. mathematics underpins the study of many disciplines at university, not only in science, technology, engineering and mathematics (STEM) but also in agriculture, pharmacy and economics [10]. In Italy, there is at least one mathematics or mathematics related course in most of the degree courses, and it is often regarded as one of the toughest exams. Several surveys at both international level, such as the PISA tests promoted by OECD, and at national level, such as INVALSI tests, are conducted for investigating mathematical skills in high school. Italy is characterized by a high school system organized in separate tracks, which sorts students according to their academic or vocational orientation. Despite the existence of different tracks, the high school could be described as tripartite, with a 5-year academic oriented generalist education provided by lyceums, with further distinctions in humanities, science activities, languages, pedagogical sciences, 5-year technical schools, and 5-year vocational schools. In 2010, Italy underwent a reform of the secondary school education. One of the main innovations was the introduction of a new school curriculum: the applied sciences curriculum. The main difference with respect to the traditional scientific track was the substitution of the Latin language class with classes in scientific subjects such as mathematics, physics, natural sciences, and the addition of computer science as a new subject. In [12] the author compares the in-going and out-going mathematical skills of the students of the two different curricula, underlying the strengths and the weaknesses of both tracks, but as far as the authors' knowledge there are no results about the academic performances related to this new high school track. Therefore, the main objective of this paper is to compare the academic performances of the students coming from traditional scientific or applied sciences tracks, in order to answer the following question: "Does taking additional maths classes improve the university performance?" Before answering this question, it should be noted that university performance lies above an incredibly intricate net of multi-dimensional factors. Therefore, the question in the present form is ill-posed because of social and cultural factors that affect the choice of studying more mathematics or more correctly the choice of the applied sciences track, that eventually will affect university choice and the university performance too [1]. Among the social and cultural factors, the most relevant are: gender [3, 6], social level, location of the high school [2, 11], socio-economic status of the family [4, 16]. For investigating the difference between the two tracks, a balancing for all the possible factors related to both the school track and the academic performance is needed. Analogously to clinical studies, we investigate the effect of the *treatment* "Studying more maths". It is possible to see this study as a clustered case-control study, in which the cases are the students who attended the applied sciences track, and the control are the students who attended the traditional Scientific track. We propose a multi-level balancing approach of the the socio-demographic characteristics using a multi-level propen-

sity score model. This procedure aims to eliminating the selection bias due to the fact that, in observational studies, the choice of the high school track, is not random, because it is related to socio-economic and cultural factors[4]. The number of ECTS achieved by the two group of students, treated and controls, in their first academic year is then compared and the average treatment effect (ATE) is estimated.

2 Data

The dataset used in this paper is built by linking three distinct administrative sources: aggregate data coming from the National Archive of Schools (ANS-S); micro-data on high school career from the National Evaluation Institute for the School System (INV);

As most of the educational data, the data at hand presents a hierarchical structure. In fact, it is possible to distinguish variables based on two levels:

1. *school-level*: macro-region, university enrollment rate and the Economic, Social, Cultural Status index (ESCS) used by INVALSI [14];
2. *student-level*: gender, ESCS, high school career's regularity.

3 Methods

Educational data often presents a multilevel structure, so, it is common to speak of clustered treatments. In clustered-treatment observational studies, treatments are applied to entire cluster (schools) or to individuals (students or teachers), or to multiple levels simultaneously (schools and students) [13]. Let S be the number of matched pairs of schools $s = 1,\dots,S$. Each school presents both classes belonging to the applied sciences and the traditional scientific track, $j = 1,2$, the treatment and the control respectively, for a total of $2S$ units. Each school track of each school s_j contains $n_{s_j} > 1$ students, $i = 1,\dots,n_{s_j}$. Each pair is matched on a vector of observed pre-treatment covariates $x_{s_{j_i}}$. Let X_{s_j} be the matrix whose rows consists of the $x_{s_{j_i}}$ vectors for each student i in the j-th track of the s-th school with support $\mathbf{X} \subset \mathbf{R}$. A student i in school track j of school s is described by both observed covariates and possibly unobserved covariates $u_{s_{j_i}}$. In our study, treatment assignment occurs at class level as whole classes are assigned to treatment or to control. If the j-th class in pair s receives the treatment $Z_{s_j} = 1$, whereas if it receives the control $Z_{s_j} = 0$, thus $Z_{s_1} + Z_{s_2} = 1$, for each s as each pair contains the treatment classes and the control classes. Following the designed structure, the statistical analysis strategy uses a propensity score model as a matching strategy [9, 15]. In particular, we follow the optimal multilevel matching using network flows proposed in [13], in which first we match the schools on school-related covariates and then we match students using individual socio-demographic characteristics. After the matching procedure, we fit a logit regression model with random effects on the matched data, to evaluate the

effect of the treatment on the probability of achieving at least 37 ECTS. We chose the cut-point of 37 ECTS because empirical evidences suggest that 37 is the best cut-point predictor of university success

4 Results

In Table 1 we assess the balance among the students covariates before and after the matching procedure.

	Unmatched				Matched			
	Treated	**Control**	**SMD**	**P-value**	**Treated**	**Control**	**SMD**	**P-value**

Table 1 Student covariates comparison in the treatment and control groups before and after the matching.

According to the standardized mean difference (SMD) [5] before the matching procedure, the major imbalance is in terms of gender, while no imbalance is recorded for the INVALSI math results. After the matching procedure all the student covariates are balanced, in fact no SMD is statistically significant.

In Table 2, the results of two logistic models with random effects on the university field of study fitted on unmatched and matched data are reported. The main differences are: before matching, the treatment effect was negative and significant, suggesting that the applied sciences students have worse performance with respect to their peers of the traditional scientific; after matching, the treatment is not anymore effective. Moreover, in Figure 1, it is possible to see how the treatment varies after the matching procedure with respect to the field of study: if on unmatched data the treatment had a positive effect for the STEM courses and negative on no STEM courses, after the matching the effect is reversed.

5 Conclusions

In this paper we compare the university performance of students that attended two different school tracks, to assess the effect of different skills. The main results show that the two groups significantly differ by gender, socio-economic level, final high school grade and scores in English and Italian INVALSI tests, while no difference are observed in maths test scores. After having balanced both school and students

covariates, the results of a logit regression model with random effects with respect to the university field of study suggest that there is no difference between the two tracks. However, some considerations are needed. We evaluate the difference among the two different school tracks just with respect to their academic performance. In reality, it already exists a difference in the enrollment rates of the students belonging to the two groups, strongly in favor of the traditional scientific school track. This tunes the matching approach towards a specific direction: it selects the best students of the applied sciences school track. The Italian high school system is still hierarchical and the traditional scientific track is then considered as characterized by a better "social context" compared to the applied science track. Our procedure can not balance for this social context, which is an unobservable variable.

University dropout and churn in Italy: an analysis over time

Abbandono degli studi universitari e churn in Italia: un'analisi nel tempo

Barbieri Barbara, Porcu Mariano, Salaris Luisa, Sulis Isabella, Tedesco Nicola and Usala Cristian

Abstract This paper analyses dropout and churn in the 1st year at the university by using micro data related to the cohorts of freshman students enrolled in Italian universities between 2010 and 2018 based on ANS data. The analysis focuses on the role that students' education background and the choices related to the field of study have on influencing the outcomes of the university system. Moreover, the paper pays attention on the role that the quality of university facilities and communication have in preventing possible system inefficiencies.

Abstract *Questo lavoro analizza il fenomeno dell'abbandono degli studi universitari e del "churn"(cambio di istituzione universitaria) per gli studenti immatricolati nelle università italiane tra il 2010 e il 2018 utilizzando i microdati dell'ANS forniti dal MUR. L'analisi si concentra sul ruolo che il background scolastico degli studenti e la scelta del gruppo disciplinare hanno sull'influenza dei risultati osservati. Il contributo, inoltre, presta attenzione al ruolo che la qualità delle strutture e della comunicazione universitaria hanno nella prevenzione delle inefficienze del sistema.*

1 Introduction and aim

The inefficacy of the Italian university system has been largely discussed in Italy, with main interest after the 3+2 reform toward the monitoring the regularity of students' careers and the identification of good policies and practices to prevent academic dropout [1-4]. On the national scene, in fact, the events of irregularity of university careers and the dropout - the two itineraries with which the university dispersion takes shape - are revealed with a consistency that is much higher than that recorded in the main nations of the continent.

The analysis focuses on the role that the students' educational path and their university choices (in terms of local and non-local universities, and of course of study) have in influencing the indicators of the inefficiency of a university system in terms of dropout and churn. Moreover, the paper pays attention on the role that the quality of university facilities and communication have in preventing both phenomena thanks to the use of CENSIS indicators on contributions, communication, service, facilities available for 2011-2018.

We move from the hypotheses that the inefficiency of tertiary education institutions is determined by factors external and internal to the university system. The former factors are strictly linked to students' previous educational backgrounds [5-7]. The positive or negative impact that the educational background has in determining students' success at the university is a topic of great relevance to make guidance and tutoring services able to provide the best support to students in the transition from secondary school to university. Nonetheless, the internal factors can be related to the peculiarities of the field of study chosen but also to several policies that universities can implement to prevent adverse events.

This contribution also hypothesizes that university policies aimed at improving the functionality of communication and digital services (university websites, official social profiles) and their effectiveness in providing effective support to students, can prevent churn. For this aim, the microdata provided by the MUR relating to cohorts of students enrolled in the period 2010-2018 were analysed and students were classified according to their career after one year as regular, drop out (student who has not renewed enrolment to any Italian university), churn (student who changed university between the first and second year). The three CENSIS indicators related to the quality of university facilities, communication and digital services and grants for 2011-2018 have been used to assess the role that universities policies addressed to enhance these dimensions have in order to prevent inefficiencies of the university system over and above the differences in students' profiles related to demographic characteristics, previous education experiences, the choice of attending a local or non-local universities, and the heterogeneity in the field of studies. Multilevel multinomial logit models have been used to this aim as they allowed us to disentangle the effect that factors which act and individual level and field of study level can play in preventing crunch and dropout.

2 Data

The data here considered are from the ANS – Anagrafe Nazionale Studenti (Italian National Student Archive) for the academic year 2010-2018 (Database MOBYSU.IT) which includes the cohorts of students who enrolled during the same years in a Bachelor degree program of an Italian University. The following covariates have been considered: age, gender, foreigner status, high school grade, high school, macro area of residence, year of enrollment and ISCED field, mobility status (free movers and forced movers) [1]. CENSIS indicators on grants, communication, service, structures available for 2011-2018 where used to integrate information on university contributions, communication, service, facilities.

The analysis covers a period of 9 years (from 2010 to 2018) looking at the careers of an average of 200 thousand enrolled per year for a total of 1.8 million students (Figure 1). Figure 2 reports their distribution according to ISCED field.

Figure 1 – Students by year (2010-2018) (absolute number)

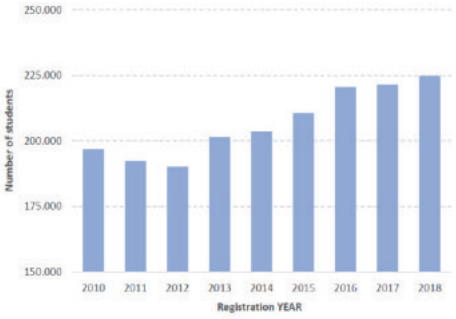

Figure 2 – Students by ISCED field (percentage)

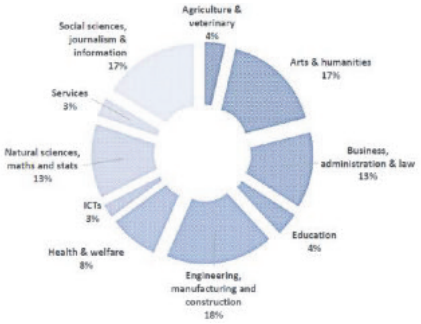

As concerns the careers (Figure 3), it is noted that on average 80.9% of students after the first year continue their studies in the same course and University in which they have enrolled, 14.9% dropout and 4.2% churn. The percentage of student that churn does not show significant variations in time, while dropout has instead decreased, passing from 17.6% in 2010 to 14.2% in 2018 (-3.4%).

Males and females do not behave in the same way with respect to the propensity to dropout, with males dropping out more frequently (17.5%) than females (12.7%). There are also some differences with respect to the diploma, students from the classical and the scientific institute in fact record lower percentages of drop out

[1] Free movers: students who select a non-local university that is located more than 15 minutes of travel time from the closest university to their city (local university) and the closest university offers courses in the field of study where they enrolled.
Forced movers: students who select a non-local university that is located more than 15 minutes of travel time from the closest university to their city (local university) and the closest university does not offer courses in the field of study where they enrolled.

(respectively 7.9% and 8.6%) and higher of churn, and by contrast the students arriving from technical institutes (23.7%) and vocational institutes (29.6%) register higher proportion of drop out.

Finally, as regards ISCED field (Figure 4), the areas of Information Communication & Technologies (ICTs) and of Agriculture & Veterinary that record the highest percentages of drop out. It is interesting to note that for Natural Sciences, Mathematics and Statistics there is a significant weight of churn.

Figure 3 – Carrier outcome by year (percentage)

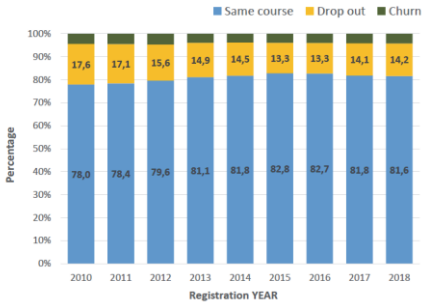

Figure 4 – Drop out and Churn by ISCED field (percentage)

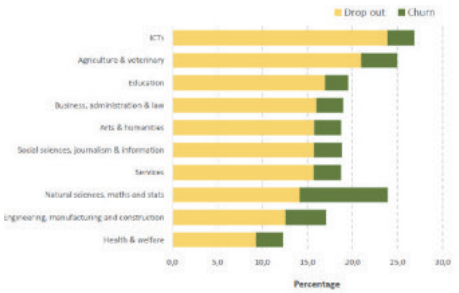

3 Modelling approach and results

A multinomial multilevel logit model has been adopted to study factors mainly associated with the probability of dropout or churn during the first year at the university. The baseline event, model the probability to enrol in the second year at the same university. We considered several factors, which are associated with students' success during the study to shape some lights on internal and external factors, which can influence both outcome and their trend over time. We include three set of predictors which allow us to account for divergences in socio-demographic factors (gender, age, area of residence; foreigner status), educational background (high school, and high school grade), university choices (in terms of local and non-local university and field of study) and university policies in supporting students (CENSIS indicators on grants, communication, services, and structures).

The results of the multinomial logit model reported in Table 1 show that in terms of socio-demographic characteristics female students from the North who select non-local universities have a lower probability of dropout. Moreover, the probability of dropping out is highly associated with previous educational experiences. Namely students from vocational and technical schools are those with the highest risk to dropout during the first year and this event is negatively affected by the high school grade. The sign and the size of the coefficients of the dummy indicators for monitoring divergences across cohorts show a progressive reduction of the dropout

rate between 2011 and 2017 and a turnaround from 2017. The churn rate shows a different behaviour with respect to high school provenience with the highest churn rates associated with students from Scientific High School and who selected non-local universities. The negative sign of the coefficients of the CENSIS indicators shows that the quality of communication, and structures has an average a positive, even if weak, effect in preventing churn and dropout events.

4 Discussion

In line with the scientific literature, the data from this study show that dropout probability is strongly associated with previous educational experiences, particularly for students with vocational and technical backgrounds. Furthermore, the choice of attending a non-local university appears as a factor which prevent dropout especially for females studying in Northern Italy universities.

This study also sought to assess student dropout and churn based on the presence and quality of certain services offered aimed at increasing the efficiency and effectiveness of engagement programs. Our study shows that CENSIS indicators have an average positive, albeit weak, effect in the prevention of dropout and churn events. If the issue of strengthening entry-level training orientation initiatives and the development of orientation services *in itinere*, recovery and didactic tutoring, especially during the first year of studies, certainly remain key issues for limiting dropouts.

The ANOGI for detecting the impact of education and employment on income inequality

L'ANOGI per studiare l'impatto del titolo di studio e dell'occupazione sulla disuguaglianza dei redditi

Elena Fabrizi and Alessio Guandalini and Alessandra Spagnoli

Abstract The ANOGI proposed by Frick et al. (2006) decomposes the overall inequality measured by Gini index by three components: within, between and overlapping. Based on ADSILC data we analyze the inequality of income, by separating two aspects: inequality due to education and to the career. The overlapping component shows how intertwined the subgroups are, whereas increases in stratification can cause a negative effect on inequality. In this context, its definition has been extended to compare pairs of workers according to their career and education. We demonstrated that workers with higher education are associated to the highest level of stratification.

Abstract L'analisi ANOGI proposta da Frick et al. (2006) permette di scomporre la disuguaglianza misurata dall'indice di Gini in tre componenti: within, between and overlapping. Basandoci sulla banca dati ADSILC abbiamo analizzato le disuguaglianze delle retribuzioni, separando l'effetto della disuguaglianza riconducibile all'istruzione da quella dovuta ad una carriera lavorativa. La componente overlapping definisce l'interconnessione tra i sottogruppi, mentre un aumento della stratificazione può causare un effetto negativo in termini di disuguaglianze. In questo contesto, tale definizione è stata estesa in modo da comparare gruppi di lavoratori con carriere e livelli di istruzione differenti. I nostri risultati indicano che i lavoratori con istruzione elevata sono associati ad elevati livelli di stratificazione.

1 The Gini index decomposition by subgroups

The Gini index (Gini, 1914) constitute a common measure to investigate the inequality in the income distribution. Several expressions of the Gini index have been proposed in the literature (for a deep investigation see, e.g., Giorgi, 1992, 2019).

An interesting expression for the Gini index in the overall population, G, has been proposed by Lerman and Yitzhaki (1984)

$$G = \frac{2\,\mathrm{cov}\,(y, F(y))}{\mu}, \tag{1}$$

that is, G is equal to twice the covariance between the income y and the rank $F(y)$ divided by the mean income, μ.

When a population can be divided in k $(i = 1, \ldots, k)$ partitions, according to one or more characteristics of the individuals in the population, G can be given by (Yitzhaki, 1994)

$$G = \underbrace{\sum_{i=1}^{k} s_i\, G_i\, O_i}_{\text{inequality within}} + \underbrace{G_b}_{\text{inequality between}}. \tag{2}$$

$s_i = (p_i\, \mu_i)/\mu$, is the ratio between the mean of the income y in the subgroup i, μ_i, multiplied by its share, $p_i = N_i/N$, and the mean of y computed on the whole population, μ, G_i is the Gini index within the subgroup i, O_i is the overlapping index of group i with the entire population and G_b is the between subgroup inequality.

1.1 Overlapping versus stratification

The within inequality is directly influenced by the overlapping term:

$$O_i = \frac{\mathrm{cov}_i\,(y, F(y))}{\mathrm{cov}_i\,(y, F_i(y))}. \tag{3}$$

O_i is defined as the ratio between the covariance of the income y of the units belonging to the subgroup i and its rank in the overall income distribution and the covariance of y and the rank within subgroup i.

Overlapping is a measure of the inverse of stratification (Yitzhaki and Lerman, 1991), that represent the extent one subgroup is overlapped by the other. In fact, stratified society can bear less the inequality because, looking at (2), increases in stratification can cause a negative effect on inequality.

The term O_i moves between $1/p_i$ and $(2 - p_i)/p_i$, where:

- $O_i = 1/p_i$ when subgroup i does not form a strata at all.
- $O_i = 1$ when subgroup i is perfectly stratified.

- $O_i = (2 - p_i)/p_i$ when subgroup i in turn is composed of two subgroups. This is a very extreme case, where group i is not a subgroup at all, but rather is composed of two perfect strata.

The value of O_i is larger as the share of the subgroup is small.

However, the overlapping index O_i related to a given subgroup i in (3) can be written in terms of the overlapping index between two groups, i and j,

$$O_i = \sum_j p_j O_{ij} = p_i O_{ij} + \sum_{j \neq i} p_j O_{ji} = p_i + \sum_{j \neq i} p_i O_{ij}$$

where (Yitzhaki, 1994)

$$O_{ji} = \frac{\operatorname{cov}_j (y, F_j(y))}{\operatorname{cov}_i (y, F_i(y))}.$$

represents the overlapping index of subgroup j by group i and provides a measure of the presence of group j units within the group i. In particular, following (Frick et al., 2006, p. 437),

- $O_{ji} = 0$ no member of subgroup j lies in the range of subgroup i. Subgroup i is a "perfect stratum" because its range is not "contaminated" by members of the j group.
- $O_{ji} = 1$, the distributions of subgroup i and j are identical. In fact, $O_{ii} = 1$.
- $O_{ji} = 2$ if all observations of distribution j are in the range of i and are concentrated at the mean of distribution i.

It is important to point out that O_{ji} is not symmetrical, that is the higher O_{ji} the lower O_{ij}.

1.2 Between subgroups inequality

Another essential element is the measurement of the between-group inequality (G_b). The between-group inequality can be determined as

$$G_b = \frac{2 \operatorname{cov} (\mu_i, \bar{F}_{ui}(y))}{\mu},$$

that is twice the covariance between the mean of variable y of each subgroup and the subgroups' mean rank in the whole population divided by μ. However, G_b is not really a concentration index because it can be negative.

When the population is perfectly stratified the between subgroup inequality is called between subgroup Pyatt inequality, G_b^p (Pyatt, 1976, p. 247). In this case, it can be obtained as the covariance between the mean of each subgroup and the subgroups' mean rank,

$$G_b^p = \frac{2\,\mathrm{cov}\left(\mu_i, \bar{F}_i(y)\right)}{\mu},$$

Yitzhaki and Lerman (1991, p. 322) demonstrated that $G_b^p \geq G_b$.

1.3 The analysis of the Gini index (ANOGI)

From expression (2), with simple algebra, Frick et al. (2006) made explicit four components,

$$\begin{aligned} G &= \sum_{i=1}^{k} s_i G_i + \sum_{i=1}^{k} s_i G_i \left(O_i - 1\right) + G_b^p + \left(G_b - G_b^p\right) \\ &= IG + IGO + BG + BGO, \end{aligned}$$

where IG ($0 \leq IG \leq G$) is the within inequality, BG ($0 \leq BG \leq G$) is the between inequality, IGO the overlapping within and BGO ($-BG - IGO - IG \leq BGO \leq 0$) is the overlapping between, BGO is always negative because the overlapping reduce the ability to distinguish between subgroups.

2 Application

2.1 Data description

The ADSILC dataset is provided by two different sources: information from administrative archives, held by the National Institute of Social Security (Inps), and the Italian database of the European Union Survey on Income and Living Conditions (Eu-Silc), collected by the National Institute of Statistics (Istat). Each individual interviewed in It-SILC cross-sectional waves for the 2004-2017 period has been merged with data driven from Inps archives updated to 2019, using the tax code as key. As a result, the longitudinal information provided by the two different sources include information regarding the socio-demographic and economic status of interviewed (collected in It-SILC survey), enriched with working history of individuals (driven by Inps archives).

2.2 Results

In this section we present an overview of the results of the Gini decomposition (ANOGI) for detecting the impact of education and employment on income inequality (see Table1). The total inequality is principally due to the within component.

When *IGO* and *BGO* are included, the inequality due to between differences account, respectively, 6% and 11% for the education and the employment taken separately. The introduction of the interaction term intensify the spread: the between component represent 3% of total inequality.

Table 2 shows that the average income among the subgroups decline driven by contractual stability. The Gini index (last coloumn) shows, as expected, that among civil servant inequality are very limitated. In the rest of the labour market we observe a spread of income, expecially among unstable and workers with high education. The overlapping index is also used to compare pairs of workers according to their career and level of education (Fig. 2.3). Workers with high educational attainment hired with fixed term contract seems to be category the less stratified with respect to the self-employer and atypical workers.

2.3 Conclusions

Based on ADSILC data we analyze the inequality of income, by separating two aspects: inequality due to education and to the career. Following the ANOGI, the Gini index is decomposed by three components: within, between and overlapping. The latter term shows how intertwined the subgroups are, whereas stratified society can bear the less inequality. Different careers, especially in the private sector, for workers with higher education are associated to the highest level of stratification, according to the overlapping index.

Fig. 1 Overlapping matrix subgroups according to the employment and the educational level.

What Causes Juvenile Crime? A Case-Control Study

Cosa Causa la Criminalità Giovanile? Uno Studio Caso-Controllo

Elena Dalla Chiara and Federico Perali[1]

Abstract This work analyses the causes of juvenile crime within a case-control study undertaken in the Italian regions of Veneto and Sicily. We show that family background matters. Parents' education and family income have no effect on crime rates in the Veneto region but are significant risk factors in Sicily. Dropping out of school substantially increases the probability that an adolescent is involved in crime activities. Poor parental relations with children or living in a broken family significantly raises the odds to be in conflict with the law.

Abstract *Questo lavoro analizza le cause della criminalità minorile con uno studio caso-controllo condotto nelle regioni italiane del Veneto e della Sicilia. Lo studio dimostra che il background familiare è importante. L'istruzione dei genitori e il reddito familiare non hanno effetto sui tassi di criminalità nella regione Veneto, ma sono fattori di rischio significativi in Sicilia. L'abbandono scolastico aumenta di molto la probabilità che un adolescente sia coinvolto in attività criminali. Relazioni dei genitori con i figli non buone o il vivere in una famiglia disgregata aumenta significativamente la probabilità che un minore sia in conflitto con la legge.*

Key words: case-control study, juvenile crime, multi-dimensional poverty, single parent

1 Introduction

This research studies the causes of juvenile crime in Italy. We are interested in learning how the income dimension of poverty and other non-material dimensions of

[1] Elena Dalla Chiara, Interdepartmental Center of Economic Documentation (CIDE), University of Verona, email: elena.dallachiara@univr.it
Federico Perali, University of Verona (Italy), Department of Economics and CHILD, email: federico.perali@univr.it

poverty (Dalla Chiara and Perali, 2021) can have a causal role in explaining youth offending. We also inquire whether the identified risk and protective factors may contribute to aggravating or alleviating the incidence of juvenile crime after the occurrence of critical events such as a perduring economic crise or a pandemic emergency (Brandford Wilcox *et al*., 2021; McCarthy *et al*., 2021).

Our young people are leaving the health emergency behind with educational deficits and heavy relational problems within the family. Loneliness, often due to an improper use of social networks, and fear of the other may have affected the personality traits of minors in a delicate developmental phase (Nobili, 2020) thus exposing our young people to the risk of engaging in criminal activities. In general, the crisis has been accompanied by greater poverty and serious gaps in parental control, especially in single parent households, that may transform juvenile crime in a serious public health problem. It is then urgent to design evidence-based policies that may prove effective in preventing and curing juvenile crime in Italy.

To this end, we collected individual and household level data in 2010 about young people who committed an offence before the age of 18 and were still serving their sentences under the supervision of the Juvenile Social Service Offices (USSM), that helped identifying a priori the subjects who had problems with the law, in Veneto and Sicily as representative regions of the social and economic situations in the North and South of Italy. These cases have been compared with a control sample with similar design to better understand what causes juvenile crime in Italy.

2 Methodology

One of the main epidemiological questions that we investigate, controlling for potential confounders, is whether "poverty" causes the risk that young people become offenders, where income or other non-monetary forms of poverty is the exposure and offending is the outcome.

We undertake a case-control study because, differently from, for example, the United States where panel data such as the National Longitudinal Survey of Youth (NLSY) have been collected since 1979 (Levitt and Lochner, 2001), no cohort studies sufficiently large to record the occurrence of a public health problem, such as juvenile crime, is available. Further, the case-control approach allows us to investigate a wide range of exposures. In case-control studies of juvenile crime a group of young offenders ('cases') and a suitable group of subjects without the condition of having experienced problems with the law ('controls') are selected and their exposure to risk factors is ascertained. If the level of exposure among cases and controls is different, it is possible to infer that the exposure may be associated with an increased or decreased occurrence of the outcome of interest.

We administered a questionnaire to young offenders and one to their families to form a sample of 138 cases in Veneto and 178 cases in Sicily to implement a north-south comparison of general policy interest. Though official statistics about population features related to the prevalence of juvenile crime by type of offence are not available, on the basis of sampling statistics typical of rare target populations, as

is the case for the population of young offenders, we maintain that the subsample of young subjects in custody at the Juvenile Social Service Offices (USSM) is representative. The questionnaires have a socio-ecological design collecting information about socio-economic and psychological characteristics, relational aspects and social capital, consumption, income and wealth, intra-household distribution of resources, and time use. We record a wide range of questions relevant to criminal activity, including theft, drug sales, use of force, causing injury to someone or causing property damage. We aggregated these activities in property crimes and crimes of violence that are likely to be determined by social and economic factors accounting also for the fact that youth engaged in one criminal activity are also likely to be involved in other illegal activities.

The integrated design of the sample of cases requires an integrated control sample constructed matching three ISTAT surveys (living standard, consumption and time use surveys) and the Survey on Family Conditions and Social Capital conducted by CISF for the same year of collection of the cases (Dalla Chiara, Menon and Perali, 2019). As control sample we selected families with at least a family member aged 0-19 years with a representative sample of 888 and 313 controls in Veneto and Sicily respectively. The variables in both questionnaires have a common definition.

The socio-ecological design has the objective to identify the causal importance of social factors such as individual characteristics, traits and responsibilities, family background, quality of parenting and their relations with the children, female-headed households, education, youth, and community circumstances along with the degree of "social control" exerted by a community, and economic factors such as income, unemployment, and poverty (Becker, 1968). It was not possible to evaluate some putative factors recorded for the cases such as the cognitive and noncognitive abilities of the young offenders because it was not available in the controls.

The analysis places special emphasis on potential sources of selection bias, confounding and reverse causality. We first analyze odds ratios and then we pose our attention to the estimation of conditional causal odds ratios using logistic regression after adjusting for potential confounding variables (Borgan *et al*., 2018).

The odds ratio is an index defining the cause-effect ratio between two factors. It is defined as the odds of the social problem (disease) between exposed subjects divided by the odds of the problem among non-exposed subjects. If OR=1, the odds of the exposed cases is equal to the odds of the exposed in the control, that is the risk factor does not affect the occurrence of the problem, if OR>1 the risk factor can be a cause of the problem, while if OR<1 the risk factor is a protective factor against the problem. Under the assumption that all members of each group have a comparable risk of becoming an offender, the estimated odds ratio is an average causal effect (Holland and Rubin, 1987) because of the assumed within groups homogeneity. All potential risk factors are analyzed as dummies where 1 is the exposure.

3 Results

Table 1 shows that the estimated odds ratios for the association between crime and potential risk factors vary substantially in the Veneto and Sicily groups. The employment condition of the parents whether they are jointly employed, or only the father or the mother works are significant protection factors, especially in Sicily. The working status is highly associated with the level of education and family income. A low level of parents' education is a risk factor, especially high in Sicily, affecting also children's school attendance and performance as signalled by the OR levels of the variables "dropout" and "low parents' education and dropout" in both regions. Being a single parent (90% in the case sample are mothers as compared to 85% of single parent in the control sample) is also a critical risk factor.

Income poverty is a significant risk factor for all types of crime (violent, property, drug) in both regions. Social capital in the form of trust relations with family members (bonding) is significantly more important than the bridging type of social capital based on the quality of relationships outside the family in both regions. The poor quality of parental relations with children and the scarcity of time spent together is a strong risk factor only for the Veneto region.

Logistic regression provides the modelling framework to adjust for confounding factors. We select the variables with the most relevant influence in explaining the odds to be in conflict with the law. Table 2 presents the marginal effects computed as discrete changes from the base level for all crime types and property crimes only

for both Veneto and Sicily. We place a special emphasis on property crime because it has the highest prevalence in both regions. Controlling for potential confounding reveals that living in a broken home significantly raises the probability of involvement for all crime types and property crimes. The marginal effect is relatively higher in Sicily. Parents' education and family income have no effect on either general or property crime rates in the Veneto region. This result is consistent with the findings of Levitt and Lochner (2001) for the United States. On the other hand, these factors significantly raise participation rates for both general and property crimes in Sicily. Dropping out of school substantially increases the probability that an adolescent, mainly male, participates both in all crime types and property crime in both regions, as evinced by the coefficients on dropout. Interestingly, poor relations with children significantly raises the probability to be involved in both general and property crime only in the Veneto region. The quality of time spent together does not play a significant role neither in Veneto nor in Sicily.

A few important considerations can be drawn from this logit regression. First, family background matters. Adolescents raised in families where both parents are present are much less likely to engage in crime. This conclusion agrees with the evidence from the US NLSY (Brandford Wilcox *et al*., 2021; Levitt and Lochner 2001), though we can further qualify that the low quality of relations may cause greater criminal involvement as is the case of the Veneto region where families seem to be relatively more fragile. Parents' education has a significant effect on criminal involvement only in Sicily. Adolescents who drop out of school, a factor that increased dramatically during the pandemic, are significantly more exposed to the risk of getting involved with crime.

4 Conclusions

The successful development of young people requires that we protect and nurture a set of interrelated physiological, cognitive, and socio-emotional systems especially during enduring critical events such as the pandemic. What happens to children in early life and adolescents can have long-term consequences and may carry over to the next generation. Depending on the timing, transmission mechanisms, and context, the consequences for children's physical, cognitive, and socio-emotional development may be costly and irreversible. The health crisis, accompanied by a reduction in public expenditures for social services, can affect an adolescent through a variety of settings, including the individual, the family, the school, and the community.

In the recovery from the pandemic will then be crucial for communities to invest on household support programs encouraging positive developments of adolescents and healthier parent-child relationships, especially in the North of Italy. Also, target investments in schools or community programs, where many adolescents at risk of dropping out of school can be reached to mitigate some of the negative effects experienced within the family, are strongly recommended. These programs should offer services of multi-systemic therapy involving family, school, and peers, and functional family therapy aiming at reducing risk factors and recidivism. Diversion policies with the objective of rebuilding family and community ties would have a very positive impact on the child, the victim, and the community. Because diversion is cost-effective, it is non-stigmatising and reduces the likelihood of children reoffending, it should have a high priority in the social agenda of the recovery plan.

Methods and Applications in Survival analysis

Recursive Partitioning for Survival Data

Partizionamento Ricorsivo per Dati di Sopravvivenza

Ambra Macis

Abstract During the years many machine learning methods have been introduced for analyzing survival data. Among these, survival trees are a useful method for defining homogeneous groups according to their survival probability. In this context there are still some unclear points, both related to theoretical and practical issues in model fitting and performance evaluation. The aim of this contribution is to shed light on some of these points.

Abstract *Negli anni diversi metodi di machine learning sono stati introdotti per l'analisi di sopravvivenza. Tra questi, gli alberi di sopravvivenza sono un metodo utile per definire gruppi omogenei sulla base della loro probabilità di sopravvivenza. In questo contesto ci sono ancora alcuni punti poco chiari legati sia a questioni teoriche che pratiche nell'adattamento del modello e nella valutazione della performance. Lo scopo di questo contributo è di fare luce su alcuni di questi punti.*

Key words: Survival data, Machine learning, Recursive partitioning, Survival Trees

1 Introduction

Survival analysis aims to study the occurrence of a specific event (endpoint) during an observed period of time (follow-up) with particular interest on estimation of the survival probability and of the risk of a group of subjects, usually characterized by a set of covariates.

The main feature of survival data is *censoring*. Censoring occurs when the endpoint of interest has not been observed for a certain subject under study during the

Ambra Macis
University of Brescia - Department of Economics and Management, C.da Santa Chiara 50, 25122 Brescia, Italy e-mail: a.macis@unibs.it

observation time; so, the only known thing about a censored subject is the last time he did not experience the event.

During the years statistical models firstly, and machine learning methods later, have been proposed for analyzing survival data. Among the last ones, survival trees, i.e. tree-based algorithms for censored data, are an interesting tool for defining homogeneous groups according to their survival probability.

Through the years many proposals have been advanced, mainly extending Classification and Regression trees (CART) to survival data (see [1]). Most of these works are based on modifications of the splitting criterion and the pruning algorithm using specific tools for right-censored data. Among the most interesting algorithms there are relative risk trees [4] and conditional inference trees [2, 3]. Other extensions have also been proposed over the years (see Table 1 and [5]). Despite up to now many proposals have been presented, there are still some unclear points about the best models to use and about how to use these tools practically. A guide for simulating right-censored data, fitting survival trees and evaluating their performance with the statistical software *R* can be found in [5].

The main aim of this work is to shed light about some of the available packages for fitting and evaluating survival trees for right-censored data, showing the main issues encountered. Particular attention has been given to relative risk trees (RRTs), conditional inference trees based on the *ctree* algorithm (CITs) and conditional inference trees based on the *SurvCART* algorithm (SCTs).

The article is organized as follows. In the next section a brief presentation of the methodological framework is reported. Then, section 3 shows the available *R* packages and the related issues. The paper ends with an application on real data.

2 Survival Trees and Performance Evaluation

Relative Risk Trees. RRTs [4] are an extension of CART based on the Cox proportional hazard model. They are equivalent to Poisson trees, due to the connection between the proportional hazards full likelihood and Poisson model likelihood.
In details, the algorithm splits the covariate space into regions that maximize the reduction in one-step deviance realized by the split. Once a large binary tree is grown, it is then pruned through the classical cost-complexity pruning algorithm of CART [4]. The node summary is the quantity in (1), that can be interpreted as the ratio between observed and expected number of events in each node under the assumption of no structure in survival times:

$$\theta_k = \frac{\sum_{i \in S_k} \delta_i}{\sum_{i \in S_k} \hat{H_0}^1(t_i)}\,, \tag{1}$$

where S_K is the index set of k^{th} node, δ_i is the event indicator (equal to 1 for events and 0 for censoring) and $\hat{H_0}^1$ is an estimate of the cumulative baseline hazard (see [4]).

Conditional Inference Trees. CITs [2] stand on the conditional inference framework. The splitting procedure is divided in variable and split point selection. Firstly, the global null hypothesis of independence between any of the covariates and the outcome variable is tested through a non-parametric permutation test, and the covariate with the strongest association is chosen as splitting variable. Then, the best cut-off is selected through any splitting criterion, e.g. the log-rank test.

Very recently, an alternative way for growing conditional inference survival trees has been proposed [3]. The *SurvCART* algorithm differs from that of CITs for two main aspects: (i) it incorporates a particular distribution for survival times in the parameter instability tests, and (ii) it allows to also consider censoring heterogeneity. So, SCTs are a powerful tool in presence of *conditionally independent censoring*, i.e. when censoring is independent of the time-to-event distribution only conditional on the set of covariates. To this extent, heterogeneity on both the time-to-event and censoring distributions is tested and the most significant variable is chosen. Then, the best cut-off value is selected, usually through the maximization of log-rank statistic, considering the most heterogeneous distribution. The procedure is then repeated until the null hypothesis of homogeneity cannot be rejected.

For both CITs and SCTs the estimated median survival time and the Kaplan-Meier (K-M) survival curve at each terminal node can be easily obtainable.

Performance Evaluation. The most used measures for evaluating performance of survival methods are the concordance index (C-index), the Area Under the Curve (AUC), the Brier score (BS) and the Integrated BS (IBS). The first two are discrimination measures, while the last two measure at the same time discrimination and calibration.

Both C-index, AUC and BS can be evaluated at a single time point. C-index is a ranking measure based on the comparison of each possible pair of subjects with respect to observed times and predicted survival/hazard and it ranges between 0 and 1. An overall C-index can be obtained through a weighted average; the most used weights are those of Harrel and Uno. AUC also measures the discriminating ability of the model. The main differences with classical ROC analysis are censoring and the fact that the outcome of an observation can change over time.

Finally, BS and IBS quantify through a quadratic loss function the distance between observed and predicted outcome. The lower the value the better the performance. IBS is obtained integrating over the time-period the BS at each time point.

For more details and literature review see [5].

3 Growing Survival Trees and Assessing Their Performance in *R*

Many *R* packages allow to fit survival trees. Among these there are *rpart* (with the homonymous function), *partykit* (with the *ctree* function) and *LongCART* (*SurvCART* function) for fitting RRTs, CITs and SCTs respectively. Many other packages exist (see Table 1); however, these are not shown here for the following reasons:

1. *LTRCtrees*, that allows to extend RRTs and CITs to left-truncated and right-censored data, is exactly based on the *rpart* and *ctree* functions. So, in the examined setting (i.e. right-censored data), it provides identical results to the abovementioned *R* functions;
2. *rocTree* can be used for fitting ROC-guided survival trees. It has been seen that it provides a lot of splits and its computation time is slow. The algorithm can be of interest but it seems that it still needs some improvements (e.g. computation speed, clarity of the documentation).
3. *partDSA* implements the PDS algorithm; unfortunately there is little documentation for survival trees implementation.

For what concerns RRTs, CITs and SCTs the respective functions are easy to implement. However, some doubts emerge concerning the interpretation of the node outcome for *rpart*. Indeed, in the available *R* documentation there are not clear examples about survival trees; it is straightforward to deduce that RRTs are grown as Poisson trees, but it is not exactly clear what the "estimated response rate" means in survival analysis. However, it should represent a measure of risk of the node [4]. The other two algorithms, instead, provide very intuitive results. The only drawback for *ctree* is that it is quite complicate to manage the related object. Indeed, there is little documentation about its structure, making it difficult to extrapolate much information about trees structure (useful, for example when performing simulation studies). On the contrary, *SurvCART* is easily manageable and interpretable.

Once a survival tree is grown, its performance can be evaluated. Some of the most used *R* packages are *pec*, *SurvMetrics*, *Hmisc*, *survAUC* and *riskRegression* (see Table 1). The *pec* package differs from all the others because it requires to transform the fitted tree in a compatible *pec* object through some specific functions; while the others only require a vector of predicted values.

The first issue is that both *pec* and *predict* are not compatible with *SurvCART*. Future research will involve the construction of a new function that allows to evaluate its performance. However, it is still possible to obtain a measure of overall concordance for SCTs extracting, for each observation, the estimated median survival time from the *subj.class* matrix of the *SurvCART* object. Moreover, with *predict* it is not possible to estimate survival probabilities at given time points for all tree algorithms; this issue can be overcome through the use of *pec::predictSurvProb*. However, in some specific cases this function returns NA, making it impossible to evaluate many metrics; future research work will involve this aspect.

Furthermore, also in this step, the main issue concerns little documentation about almost all these functions. Indeed, for many of these, for example, it is not specified if risk or survival predicted values are required. This could imply possible wrong evaluation assessments, since, for example, C-index is based on ranking and survival and risk have an inverse trend. It has been empirically verified, using simulated data, that *Hmisc::rcorr.cens* and *SurvMetrics::Cindex* require survival probabilities, while *survAUC::UnoC* requires a measure of risk. If it is not possible to obtain this measure from trees, a tricky solution is to provide as argument the opposite of survival probabilities, maintaining therefore the right ranking (of course also the viceversa holds). Moreover, in many cases, it is not declared which weights are used

Table 1 Packages and functions for fitting survival trees for right-censored data (extensions of CART) and evaluating their performance

R function (package)	Algorithm
rpart (rpart)	Relative risk trees
ctree (partykit)	Conditional inference trees
partDSA (partDSA)	Partition substitution addition algorithm
LTRCART (LTRCtrees)	RRTs[a] for left-truncated and right-censored data
LTRCIT (LTRCtrees)	CITs[b] for left-truncated and right-censored data
rocTree (rocTree)	ROC-guided survival trees
SurvCART (LongCART)	Conditional inference trees for accounting censoring heterogeneity
R function (package)	**Performance measure**
cindex (pec)	Uno's Concordance index
UnoC (survAUC)	Uno's Concordance index
Cindex (SurvMetrics)	Harrel's Concordance index
rcorr.cens (Hmisc)	Harrel's Concordance index
Score (riskRegression)	Time-dependent AUC[c] with IPCW[d]
AUC.hc (survAUC)	Time-dependent AUC[c]
Brier (SurvMetrics)	Brier Score at a single time-point with Kaplan-Meier IPCW[d]
pec (pec)	Brier Score
IBS (SurvMetrics)	Integrated Brier Score with Kaplan-Meier IPCW[d]
pec (pec)	Integrated Brier Score

[a] Relative risk trees; [b] Conditional inference trees with *ctree* algorithm; [c] Area Under the Curve; [d] Inverse probability censoring weights

for evaluating C-index. After an in-depth analysis it has been verified that *SurvMetrics::Cindex* and *Hmisc::rcorr.cens* evaluate Harrel's C-index; while *pec::cindex* and *survAUC::UnoC* provide Uno's version.

Time-dependent AUC can be evaluated by using *riskRegression::Score* and *survAUC::AUC.hc*; the two functions usually provide similar results.

Finally, BS can be evaluated with *SurvMetrics::Brier* and *pec::pec*; while IBS can be evaluated by using *SurvMetrics::IBS* and pec::pec functions. After the analysis of the *SurvMetrics* functions code (no information was provided in the documentation) it has been verified that it evaluates the index by only using K-M estimator for obtaining the inverse probability censoring weights (IPCWs). Differently, *pec* allows the use of different censoring models.

For both functions an issue related to estimated survival probability was encountered. Indeed, as already hinted, *predictSurvProb* returns NA when only events occurred in a node, implying the impossibility of estimating BS and IBS after that time point. The solution to this problem is deferred to future research work.

A case study. A comparison of the overall performance of RRTs, CITs and SCTs has been carried out on the dataset collected by the German Breast Cancer Study Group [6]. All the three methods identify *pnodes* as the most important variable, followed by *progrec*. Only CIT also identifies *horTH* as a splitting variable. A higher number of positive nodes, lower levels of the progesterone receptor and not receiving an hormonal therapy lead to a higher risk of recurrence. As already hinted, for

SCTs only overall concordance measures could be obtained. In particular, for evaluating C-index for both CIT and SCT, estimated median survival times greater than the length of follow-up were artificially fixed to a maximum value (see [5]). The three methods lead to similar results both in terms of interpretation and goodness-of-fit (Figure 1).

	RRT	CIT	SCT
Harrel's C	0.686	0.672	0.688
Uno's C	0.614	0.553	0.608
IBS	0.165	0.165

Detecting survival patterns in a digital learning platform

Rilevare i modelli di sopravvivenza in una piattaforma di apprendimento digitale

Marta Cannistrà, Mara Soncin and Federico Frattini

Abstract In an ever-changing world, having the right competences for the job market represents the key challenge. Hence, the number of digital platform for learning is increasing. Anyway, less is known about the learners' profiles or the time spent on it. The present work aims at filling this gap, by proposing a deep analysis to identify latent subgroups of learners with similar behaviour within an online learning platform. Then, the identified subgroups are described in terms of personal features and survival profiles. From findings, it is observed the emerging of three distinctive latent classes, with very different survival profiles. The analysis allows to better personalize contents according to the type of learner in order to support him/her to conclude the assessment and "survive" the platform, acquiring the right skills for the job market.

Abstract *In un mondo in continua evoluzione, avere le giuste competenze per il mercato del lavoro rappresenta la sfida chiave. Di conseguenza, il numero di piattaforme digitali per l'apprendimento è in aumento. Ad ogni modo, si sa meno sui profili degli studenti o sul tempo impiegato su di esso. Il presente lavoro mira a colmare questa lacuna, proponendo un'analisi approfondita per identificare sottogruppi latenti di studenti con comportamenti simili all'interno di una piattaforma di apprendimento online. Quindi, i sottogruppi identificati sono descritti in termini di caratteristiche personali e profili di sopravvivenza. Dai risultati, si osserva l'emergere di tre classi latenti distintive, con profili di sopravvivenza molto diversi. L'analisi permette di personalizzare al meglio i contenuti in base alla tipologia di discente in modo da supportarlo nel concludere la valutazione e "sopravvivere" alla piattaforma, acquisendo le competenze giuste per il mercato del lavoro.*

Introduction

The necessity of better aligning job requirements and education is increasingly topical, mainly due to the wide spread of digitalisation, which is transforming all sectors. Hence, job market requires a continuous competences adaptation to stay on track and be competitive. To strengthen this perspective, the Digital Agenda for Europe 2020 described the principles for ensuring the acquisition of digital skills and literacy for all citizens (Levano-Francia et al., 2019). The Future Jobs Report, prepared by the World Economic Forum (2018) predicts that the large number of professions that exist today and in the coming years will require digital skills to be able to perform their work. In this view, educational institutions are called to align their academic offer with labor market needs to increase employability, stay competitive and strengthen the cooperation between university and industry as one of the main drivers of innovation.

Technological advancements enabled the delivery of educational digital platforms that can keep the pace of such a fast and evolving need of knowledge. However, it is documented that dropout rates of e-Learners are substantially higher than in-presence counterparts (Levy, 2007). In some case, the main predictor of learners' retention in online platforms is the general level of satisfaction, which represents a proxy of their engagement. Hence, the actual challenge is to understand learning paths and learners' behaviours in digital platforms, aiming at reaching higher retention and pursuing professional and academic goals of the learners.

The present work aims at contributing to the existing academic literature about learners' dropout in online educational platforms. The research objectives concern (i) the identification of subgroups of learners with similar digital behaviours, and (ii) test whether subgroups differ in their survival curves in the platform. Identifying early signals of disengagement before dropout would be relevant to foster the educational potential of personalised digital platforms.

The personalized digital platform

The digital platform analysed has been developed in 2019 by the Business School of a leading Italian technical university. The "digital mentor" allows learners to get closer to settled professional goals along a continuous, personalised learning pathway. Before starting, every learner is asked to fill a short questionnaire about their actual job, role and competences and set the aspirations for future professional career. According to settled goals, aspirations and market job requirements, the digital mentor, based on AI algorithms, provides tailored suggestions and contents to explore. The typical learning pathway lasts for six months, after which the learner can set new learning goals. The features of the platform include periodical skills assessment, qualified training, challenges, networking with the whole digital community, and job postings from selected companies. The platform proposes three kinds of activities: daily workout, structured as "knowledge "nuggets", learning

pathway, with a long-run perspective, and search bar, where learner may find contents by themselves. The digital mentor allows every learner to reach the settled goals within six months from the registration. This period will be then used as reference to evaluate learner's success (or not).

Data and Methods

Data are extracted from the platform and, after the cleaning processing, the number of observations (learners) is 2403. Variables can be categorised into three groups: (i) platform-learner interaction, (ii) learners' characteristics and (iii) learner survival time within the platform. The latter describes the learning path in the platform: the status defines whether the learner completed the learning pathway after six months from the registration and, if he/she dropped out before, when the event occurs. This information is essential to study the survival function of latent classes, in line with the second research objective.

Two different methodologies are adopted along the study. First, a Latent Class Analysis is used with the aim of detecting hidden patterns in learners' interaction with the platform and classify them into latent subgroups (Muthén & Muthén, 2000). By latent subgroups, we mean clusters of learners, who share underlying common features in terms of important dimensions (in our case, the level of interaction and the type of activity in the platform). Firstly, the latent classes are defined based on indicators about learner-platform engagement. As a result of step 1, each observation is assigned to the group for which the probability of class membership is the highest. The number of classes is selected assessing the goodness of fit of the model through the Bayesian Information Criterion (BIC) and the Lo-Mendell-Rubin (LMR) test (Lo et al., 2001). In step 2, multinomial regression is run to characterise the latent classes by means of personal information of learners.

The second methodology is the survival analysis (Ameri et al. 2016), employed with the aim of studying the survival curves of the identified latent subgroups. The Kaplan-Meyer functions, $S(t_i)$, are estimated to visualise the probability of "surviving" on the platform with time-dynamics. This is a step-function, a non-parametric estimation characterised by discontinuities at points given by time events: $S(t_i) = S(t_{i-1}) * (1 - \frac{d_i}{n_i})$. $S(t_{i-1})$ is the probability of being alive at t_{i-1}, n_i is the number of active learners just before t_i and di is the number of events at t_i. The event is defined when at least one learner drops-out (not survive). The underlying assumption is that the drop-out events are uncorrelated.

Results

The number of latent classes that proxy our data at best is equal to three, as indicated by the lowest value of the BIC, and the platform-learner interaction profile of each class is presented in Figure 1. The first class is composed by a low share of learners (6.0%) and characterised by a high profile of activity. Their activities mainly relate to daily workout sessions, thus they are often logged in as confirmed by the high number of sessions with a relatively short duration. Also, they open and like contents proposed by the digital mentor, and for this reason can be labelled as *Platform-engaged learners*. The second class, represented by the 20.5% of the learners, report a high number of sessions, but their activity is mainly characterised by searching contents by themselves. For this reason, they can be labelled *Self-engaged learners*. Lastly, 73.5% of learners interact very poorly with the platoform. They are the least active and log in few times for long time, thus they can be labelled *Disengaged learners*.

The multinomial regression in Table 2 provides a picture about some of classes' characteristics. The probability of being a *Self-engaged learner* is higher for young learners, compared to the other groups of learners. For all the other characteristics, *Self-engaged* and *Platform-engaged* learners are rather similar, while *Self-engaged* and *Disengaged learners* differ in terms of citizenship (Italians are less likely to be part of the latter) and assessment status – *Disangaged learners* are more likely to have not even started or completed the initial skill assessment. In this respect, *Disengaged learners* tend to be so since their enrolment in the platform. Finally, having followed one or more courses at the Business School does not affect the probability of belonging to a specific class of learners.

In order to address the second research objective, the Kaplan Mayer (KM) curves, depicted in Figure 2, give a visual estimate of how fast the survival probability of each latent class decreases over time. Results suggest that *Disengaged learners* have a completely different survival function compared to the other two classes. The curve registers an initial drop at time = 0, meaning that many learners log in the platform one time to never come back. The other two KM curves are very similar each other, even though *Platform-engaged learners* show an initial drop, too. Interestingly, the survival probability of *Self-engaged learners* is higher than that of *Platform-engaged* learners until the 140th day after registration, when the curves overlap and then switch. It is worth to note that the probability of "surviving" until the end of the learning path (after six months) is quite low (<25%) for all the three classes.

Conclusions

The paper explores data derived from a digital learning platform based on AI algorithms to explore patterns of platform-learner interaction and observe the probability to persist on the platform until the end of the learning pathway. The high drop-out rate and risk of disengagement is a critical issue in online education (Levy, 2007; Bañeres Besora & Conesa Caralt, 2017) that may undermine the effectiveness even of highly personalised learning experiences (Moreno-Marcos et al. 2020).
Findings suggest that most learners (73.6%) do not even take a step further after registering, a behaviour observed also among MOOC learners (Agasisti et al., 2021). The paper contributes to the academic debate on the identification of online learners' profiles (Binali et al. 2021), showing that despite the high personalisation of contents, learners show high levels of disengagement, as observed in other online formats (Korableva et al., 2019). In terms of practitioners' implications, findings suggest possible early warning signals that may help to prevent learners' drop-out, as disengaged students tend to show their attitude since the very beginning – and, for instance, are more likely to skip the initial steps of skills assessment.

An extension of proper Bayesian bootstrap ensemble tree models to survival analysis

Un'estesione degli alberi ensemble con bootstrap Bayesiano proprio all'analisi di sopravvivenza

Elena Ballante

Abstract In this work, a new bagging survival tree model is proposed. An exension of Efron's bootstrap procedure, that is usually implemented in bagging methods, is integrated in the classical bagging survival tree model. The proper Bayesian bootstrap allows to enrich the original feature space with new observations sampled from a prior distribution, that are not already present in the original data.
Empirical results are shown in a simulated study. The proposed model reaches competitive performances with respect to classical survival models (Cox model and survival random forest) in terms of integrated Brier score with higher stability, especially when small sample size are involved.
Abstract *In questo lavoro viene proposto un nuovo modello ensemble basato su alberi decisionali. Un'estensione del bootstrap di Efron è stata integrata all'interno del modello di bagging di alberi di sopravvivenza. L'utilizzo dell'algoritmo di bootstrap Bayesiano proprio permette di arricchire lo spazio delle variabili con nuove osservazioni che vengono campionate da una prior e che non sono già presenti all'interno del dataset originale.*
I risultati empirici sono mostrati grazie all'analisi di dati simulati. Il modello proposto mostra performance competitive rispetto a modelli di sopravvivenza classici (modello di Cox e survival random forest) in termini di Brier score integrato e una maggiore stabilità, soprattutto quando si analizzano dati con una bassa numerosità.

1 Introduction

In this paper we extend the Bayesian non-parametric learning applied to ensemble tree modeling defined in [1] to the analysis of right-censored survival data.
As shown in [1], that the application of different resempling techniques, as the Proper Bayesian Bootstrap [2], in ensemble tree modeling can improve the stability of the model with competitive prediction performance. On the basis of the promising results in classification and regression frameworks, time-to-event data analysis can benefit from the introduction of this new model.
Bootstrap resempling techniques are applied to approximate the posterior distribution of a statistic of interest, that for ensemble tree models is the statistical functional $\Phi(F)$, where F is a random distribution function as defined in Proper Bayesian Bootstrap [2] and $\Phi(F)$ is a decision tree.
This methodological proposal inherits the main advantages of Bayesian nonparametric learning such as the flexibility and the computational strength, considering also prior opinions and thus overcoming the main drawbacks of Efron's and Rubin's bootstrap procedures ([3], [4]) used in classical ensemble decision tree models.
Coupled with these considerations, we want to underline that survival data are commonly analyzed using methods that rely on restrictive assumptions, e.g. proportional hazards. Most of the models considered are parametric (or semi-parametric as Cox model), with all the implied assumptions and limitations.
Some nonparametric models are defined for survival data: survival tree models are defined in [5] and survival random Forest is proposed in [6], deploying Efron's bootstrap technique in the algorithm.
Based on these considerations, we underline the importance of developing and applying non parametric innovative models that can lead to higher performances in survival analysis.

The rest of the paper is organized as follow: Section 2 describes the methodological proposal, Section 3 describes the computational setting and the preliminary results of the study and Section 4 contains the conclusions.

2 Proposed model

The purpose of this paper is to give a first definition of Proper Bayesian bootstrap ensemble tree model for survival data analysis. The Proper Bayesian bootstrap defined in [2] is considered and adapted to survival data analysis.
The statistic of interest of ensemble tree models is $\phi(F,\mathbf{X})$, which is a decision tree model based on a distribution F and on observed data $\mathbf{X}$. As well explained in [1], an estimation of the posterior distribution of ϕ can be obtained through bootstrap procedures. Each tree is obtained fitting the model on the drawn weighted dataset and the obtained predictions are an approximation of posterior mean.
To apply the Proper Bayesian bootstrap we define a prior distribution $D(kF_0)$ for F,

which is a Dirichlet process. In order to explain a response variable y given a list of P covariates $x_1,...,x_P$, the parameter F_0 of the Dirichlet process is a joint distribution depending both on $(\mathbf{x},y)$.
The algorithm that describes the sampling method from the posterior of $\phi(F,\mathbf{X})$ is defined in [1] and reported in this work as Algorithm 1.

Input: Training set T
for *b in 1:B* **do**
  Sample $(\mathbf{x}_1^*,y_1^*),...,(\mathbf{x}_m^*,y_m^*)$ from $(k+n)^{-1}(kF_0+nF_n)$;
  Draw $\mathbf{w}^b$ from $D(\frac{n+k}{m},...,\frac{n+k}{m})$;
  Get $\phi^b=\phi(\mathbf{w}^b)$ running weighted tree on the new sample $\mathbf{x}_1^*,...,\mathbf{x}_m^*$
end

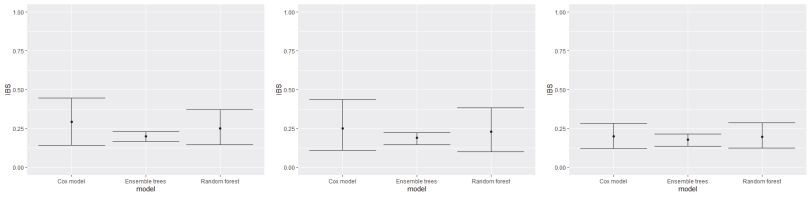
Algorithm 1: Proper Bayesian Bootstrap in ensemble tree models

The bootstrap resample $(\mathbf{x}_1^*,y_1^*)...,(\mathbf{x}_m^*,y_m^*)$ is generated by a mixture of distributions of the prior guess F_0 and the empirical distribution F_n. Since the covariates are assumed to be independent, when a new observation of bootstrap resample is generated from F_0, a new vector of covariates $\mathbf{x}$ is generated from the original prior distributions $F_0(x_k)$, then the new value of the response variable is associated on the basis of the chosen prior distribution.
The main differences introduced for the application to the survival analysis are the two: the response variable associated to the vector of covariates generated from the prior is obtained with a suitable survival model and the aggregation method of the predictions should be performed taking into account the nature of the time-to-event data.
More specifically for this second point, the output of the model is a bootstrap aggregated version of the estimted conditional survival function S for a new observation $\mathbf{x}_{new}$ computed by $\hat{S}_A^B(\cdot|\mathbf{x}_{new})=\hat{S}_{L_A^B(\mathbf{x}_{new})}(\cdot)$, as suggested in [7].
The main element of novelty with respect to classical ensemble procedure, is that the prior F_0 allows to generate new observations, not contained in the training set, which can enrich our prediction model. The obtained bootstrap samples are less dependent one to each other, reducing overfitting and leading to a more stable method, as shown in Section 3. For these reasons we think that the proposed model can guarantee more stable results and, in some settings, better performances than the classical models.

3 Experimental setting and preliminary results

A simulation study is performed in order to show the potential of the method proposed with different sample size and different weights assigned to the prior distribution F_0. The simulated datasets are composed of 5 numerical covariates and a time-to-event target variable where a 20% of censored observations are considered. The simulation of the data is performed by the flexible-hazard method as described

in [8]. The sample size is set as $N = 30$, $N = 50$ and $N = 100$.
The prior for each covariate is set as a uniform distribution on the range of that covariate in the original dataset and the parameter k is set such that the weight $w = \frac{k}{k+n}$ assigned to the prior F_0 is equal to 0.25.
The prior relation between y and $\mathbf{x}$ is evaluated with an exponential regression model.
The proposed model is compared with the most common models in the survival analysis: the Survival Random Forest [6] and the Cox model [9].
Prediction performance was evaluated in terms of Integrated Brier Score (IBS) in a 5-fold cross validation exercise. For each setting, 100 datasets are generated. Mean values and nonparametric confidence intervals of the resulting IBSs are presented.



(a) N=30 (b) N=50 (c) N=100

Fig. 1: Comparison of mean and nonparametric confidence intervals for IBS obtained in cross validation for the 100 simulated datasets in three different setting of sample size.

From the results presented in Figure 1, we can see that IBS average is lower for the proposed method, but not significantly lower considering the width of the confidence interval for classical methods.
The difference between Proper Bayesian Bootstrap ensemble trees and the other two methods becomes less evident increasing the sample size. The higher quantity of information already present in a bigger dataset make the impact of the prior sampled observation less evident.
The most evident result is that the confidence intervals of the proposed model is much smaller than the classical methods, underlying that our proposal is more stable in terms of prediction performance.

4 Conclusion

In this paper we present a new ensemble tree model based on Proper Bayesian Bootstrap and we show its potential with respect to classical survival models. The model proposed shows in a simulated framework higher stability coupled with competitive performances.

The introduction of synthetic data generated from a prior distribution, that were not already present in the original dataset, makes the final ensemble model more stable, especially with small sample size datasets. Further investigation are planned, as a sensitivity analysis on different percentage of censored data, different values of k (the confidence assigned to the prior F_0) and a comparative analysis for the different priors chosen for covariates.
The analysis of performance on real datasets is another fundamental point that will be investigated in a future work.

Modelling time to university dropout by means of time-dependent frailty COX PH models

Modelli di COX tempo-dipendenti con frailty per la modellizzazione del tempo all'abbandono universitario

Mirko Giovio, Paola Mussida, Chiara Masci

Abstract University dropout is studied worldwide, with the aim of identifying its determinants and of preventing it. In this study, we model and predict the time to dropout of university students, following a survival analysis approach. We analyse data about 50,000 students, enrolled in 18 different bachelor of science in Engineering at Politencico di Milano. Given the potential heterogeneity in the dropout determinants over time and the two-levels structure of the data (students nested within degree programmes), we applying a Cox PH model that includes time-varying covariates, to track students careers over time, and a frailty, to take into account the heterogeneity across degree programmes. The strength of the method is twofold: to describe the dropout over time and to identify a good trade-off between a high prediction accuracy and the development of an early warning system.

Abstract *Il dropout universitario è un fenomeno studiato in tutto il mondo, con l'obiettivo di caratterizzarlo e prevenirlo. In questo studio, analizziamo il tempo all'abbandono univeristario, seguendo un approccio di analisi di sopravvivenza. Analizziamo le carriere di 50,000 studenti immatricolati in 18 corsi di studio di Ingegneria del Politencico di Milano. Viste le potenziali differenze nelle determinanti del dropout nel tempo e la struttura annidata dei dati, applichiamo un modello di COX che include covariate tempo-dipendenti, per tracciare la carriera degli studenti nel tempo, e una frailty, per modellizzare la variabilità tra corsi di studio. La forza del metodo proposto è duplice: descrivere le dinamiche del dropout nel tempo e identificare un giusto trade-off tra una previsione accurata e una previsione precoce.*

1 Introduction

The Italian Higher Education (HE) system measures a high level of dropout, with many students abandoning their studies during the Bachelor. According to ANVUR, the dropout rate is around 28.2%, with almost 2/3 of them dropping out in the first two years [3]. Many studies aim at individuating personal features of students who are more likely to drop in order to act as soon as possible and partially prevent the phenomenon, and most of them use a classification approach [1, 4]. Recent evidences show that university dropout might be very heterogeneous in time, in its determinants over time and across universities and degree programmes [5]. For these reasons, we propose a survival analysis approach [6] to university dropout in which the target variable is the *time to dropout*. We analyse data about 50,000 careers of students enrolled in 18 different bachelors of science in Engineering at Politecnico di Milano (PoliMI). PoliMI dropout rate in engineering is around 30%, with the majority of students dropping out during the first year [5]. PoliMI collects student-level data that regard (i) personal information at the enrolment, (ii) the career status and career track over time of the student, continuously updated, (iii) and the degree programme in which the student is enrolled. To model the time to dropout, we adopt a Cox Proportional Hazard (PH) model [7] in which the response variable is the time to dropout of each student within three years after the enrolment, if any. Given the hierarchical structure of the observations and in order to model the heterogeneity given to it, we include a random frailty in the Cox PH model. Moreover, we consider the extension of the frailty Cox PH model to handle time-varying covariates, in order to take into account the credits and the grade point average (gpa) of studens, updated each semester, in the prediction of the time to dropout.

Survival analysis has already been applied in the framework of student dropout [2, 8], but, to the best of our knowledge, this is the first study that a frailty Cox PH model with time-varying covariates is adopted is this context. The advantage of this modelling regards the possibility to explore the latent heterogeneity across degree programmes and to evaluate the improvement in the model predictive power due to the update of information semester by semester.

The aim of this study is twofold: to accurately describe the dropout phenomenon and its heterogeneity and to develop an early warning system to predict the time to dropout of the enrolled students. In this perspective, we put a special focus on the effect of the inclusion of student career information over time on the model predictive power in order to identify the best trade-off between a very accurate prediction and the development of an early warning system.

2 Dataset

The dataset of interest is collected by PoliMI and contains information about 56,970 students (careers) enrolled in a bachelor of science in Engineering at PoliMi, between a.y. 2010/2011 and 2020/2021. 32% of the careers are active, 19% are con-

cluded with a dropout and 49% are concluded with a graduation. Our target variable is the time to dropout, expressed in semester, measured from the enrolment. In this analysis, we exclude from the sample those students who dropped out during the first semester[1]. Student-level variables are collected at the enrolment and during the career. As time-invariant variables collected at the enrolment, we consider the gender, the age, the type of previous studies, the high school grade, the family income, the origins and the PoliMi admission score. As time-varying variables, updated each semester, we consider the gpa and the cumulative number of credits obtained. The observed time to dropout is distributed between 1 and 6 semesters, with a median dropout time of 2.2 semesters and a mean dropout time of 3.1 semesters.

3 Methodology

Survival Analysis is the process that studies the time that passes from a particular moment until a certain event occurs [6]. If for an individual the event never occurs (during the follow-up period), the observation is considered as censored. For each individual $i = 1,\dots,N$, we call T_i^* the event time (observed if the event occurs) and C_i the censoring time (observed if the event does not occur).

The target variable is therefore identified by $D = \{(T_i, \delta_i), i = 1,\dots,N\}$ where $T_i = min(T_i^*, C_i)$ and $\delta_i = I(T_i^* \leq C_i)$ is the indicator variable that indicates whether the $i-$th observation is censored or not.

Letting T denote the non-negative random variable of survival time with probability density function $f(t)$ and distribution function $F(t) = P(T \leq t)$, we define the *Survival function* $S(t)$ as the probability to survive until time t and the *Hazard function* $h(t)$ as the instantaneous risk of event at time t. In particular,

$$S(t) = P(T > t) = 1 - F(t)$$

and

$$h(t) = \lim_{\Delta t \to 0} \frac{P(t \leq T < t + \Delta t | T \geq t)}{\Delta t}.$$

Given these quantities, the frailty Cox PH model with time-invariant and time-varying covariates assumes the Hazard function $h_{ij}(t)$ of the $i-$th individual within the $j-$th group to be expressed as follows:

$$h_{ij}(t|X(t)) = h_0(t) \times w_j \times \exp\left(\sum_{p=1}^{P_f} x_{ijp}\beta_p + \sum_{v=1}^{P_v} z_{ijv}(t)\alpha_v\right)$$

[1] In the perspective of modelling and predicting the time to dropout of students observing at least first semester information, we need to exclude first semester dropout. A separate and specific analysis can be conducted on this sample of students, for which the dropout determinants are potentially various and unpredictable.

where

- $h_0(t)$ is the baseline hazard function
- $\mathbf{x}_{ij} \in \mathscr{R}^{P_f}$ is the vector of P_f time-invariant covariates relative to the $i-$th observation within $j-$th group and $\beta \in \mathscr{R}^{P_f}$ is the vector of coefficients
- $\mathbf{z}_{ij}(t) \in \mathscr{R}^{P_v}$ is the vector of P_v time-varying covariates relative to the i-th observation within $j-$th group and $\alpha \in \mathscr{R}^{P_v}$ is the vector of coefficients
- $w_j \sim Gamma(1,\theta)$ is the shared frailty of $j-$th group.

4 Results

In the application of the frailty Cox PH model to the PoliMi dataset, the student dropout represents the event of interest and the Survival probability function $S(t)$ indicates the probability of not dropout until time t. We divide the sample into a training (70%) and a test set (30%) and we run four frailty Cox PH models: *Model 1* considering only covariates measured at the enrolment, *Model 2* considering covariates measured at the enrolment and at the end of first semester, *Model 3* considering covariates measured until the end of second semester (i.e., including time-varying covariates measured at the end of first and second semesters) and *Model 4* considering covariates measured until the end of the career (i.e., including time-varying covariates measured at the end of each semester). Figures 1 and 2 report the results for *Model 4* in terms of estimated fixed-effects coefficients and frailty distribution, respectively.

In terms of students characteristics (Figure 1), results show that students with low income level or with scholarship (LS) have on average a lower risk of dropout with respect to students with a medium income level; commuters have on average a higher risk of dropout with respect to students living in Milan, while offsite students have on average a lower risk of dropout; students coming from technical highschools have on average a lower risk of dropout with respect to students coming from a scientific school; students who enroll at university at an older age have on average a lower risk of dropout with respect to other students; the higher the number of credits and the gpa, the lower the risk of dropout. The C-index results to be 0.9146 for the training set and 0.9133 for the test set.

By looking at Figure 2, we observe that the baseline hazard functions differ across degree programmes with four degree programmes having a statistically significant higher risk of dropout (net to the effect of student-level covariates) with respect to the average and four of them having a statistically significant lower risk of dropout. The estimated variance of the frailty w_j is $\hat{\theta} = 0.02027$ (p-value = 0.014), confirming a significant difference between the baseline hazard functions of different degree courses.

The analysis of the model predictive power reveals that, with respect to the baseline model, as expected, including the career information over time (by including time-varying covariates in the Cox model) increases the predictive accuracy.

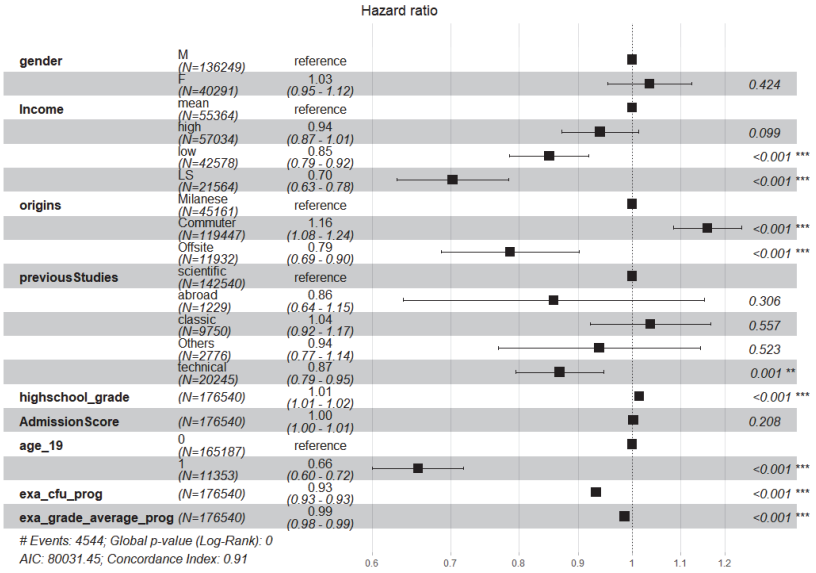

Fig. 1 Frailty cox PH model with time-varying covariates updated each semester until the end of the career (*Model 4*).

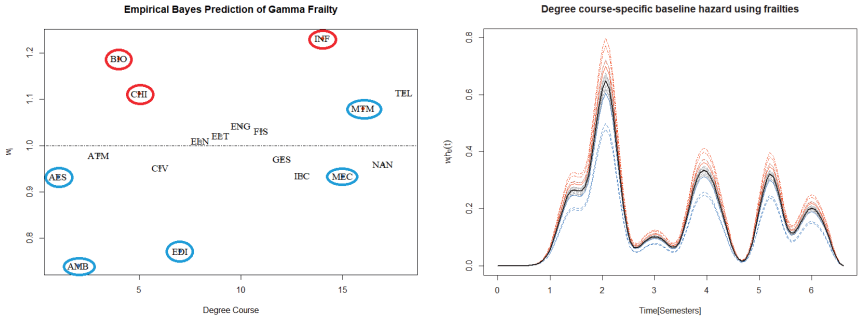

Fig. 2 Estimated frailty distribution in *Model 4*. Left side figure reports the 18 estimated frailties, one for each degree programme. Red dots represent degree programmes with a frailty significantly higher than 1, while blue dots represent degree programmes with a frailty significantly lower than 1. Right side figure reports the baseline hazard for each degree programme.

Nonetheless, while we observe a big gap in the predictive accuracy between *Model 1*, *Model 2* and *Model 3*, the inclusion of the career information regarding later semesters only slightly increases the predictive accuracy, suggesting that first year information is already very powerful in predicting time to dropout.

5 Conclusions

In this work, we apply Frailty Cox PH models with time-varying covariates to model and predict time to dropout of Politecnico di Milano engineering students, within three years after the enrolment. The Frailty Cox PH model with time-varying covariates allows to estimate the association between student characteristics and their risk of dropout over time, to estimate the effect of different degree programmes on the dropout risk of their students and to quantify the advantage, measured in terms of predictive power, of the inclusion of the student career information over time as time-varying covariates of the model.

The survival analysis approach results to be very informative when applied to university dropout data. Future work directions regard the enlargement of the follow-up window and the development of a time-varying frailty COX model that allows the baseline hazard to have different functional forms across degree programmes.

Family history in survival and disease development

Familiarità nella sopravvivenza e nello sviluppo di malattie

Maria Veronica Vinattieri and Marco Bonetti

Abstract We are interested in a specific aspect related to modeling survival, i.e. the study of family-specific risk. We focus on the genetic "from birth" risk component as opposed to the environmental component. Indeed, the true genetic family risk may be assumed to be latent from birth, and it can be either discrete (with two or more ordered risk levels) or continuous. We explore some latent multiplicative frailty multivariate time-to-event models, clustered at the family level. In particular, we focus on: (i) a binary mixture model with two family frailty levels (high vs. other); (ii) a continuous frailty model. Our contribution is about the prediction of the estimated family-specific risk of a subject from the observed family history (birth and time of event or censoring).

Abstract *Siamo interessati ad un aspetto specifico riguardo ai modelli di sopravvivenza, cioè lo studio del rischio familiare. Ci concentriamo sulla componente genetica "dalla nascita" del rischio, opposta alla componenete ambientale. Infatti, il vero rischio familiare genetico si può assumere come latente dalla nascita, e può essere discreto (con due o più livelli di rischio ordinati) o continuo. Studiamo dei modelli latenti moltiplicativi frailty multivariati per la sopravvivenza, raggruppati per famiglia. In particolare, ci focalizziamo su: (i) un modello mistura binario con due livelli di frailty familiare (alto o altro); (ii) un modello di frailty continuo. Il nostro contributo riguarda la previsione del rischio specifico familiare stimato per un soggetto dalla storia familiare osservata (nascite e tempi all'evento o di censura).*

1 Introduction

We are interested in studying the effect of family-specific risk on survival. The definition of family history refers to the collection of the survival experience of other family members. We assume that families can be defined as clusters, within which individuals share the same risk. The interest is in classifying a subject's family to one of a set of risk groups or, more generally, to estimate the family-specific risk from the available data.

First consider the effect of family risk on longevity, that is defined as the difference between the age at death and the expected age of death as based on temporal and environmental factors. For the jth individual, we let t_j be the longevity, and $s_j \in \{\text{male, female}\}$ the sex. Below we use the subscripts m (mother), f (father) and p (generic parent) to identify the family members. Two models explain the heritability of longevity [5]:

$$t_j = \alpha_0 \frac{(t_{m_j} + t_{f_j})}{2} + \beta$$
$$t_j = \beta_0 + \alpha_0 t_{p_j} + \alpha_1 \mathbb{I}(s_j, s_{p_j}) + \alpha_2 (t_{p_j} \times \mathbb{I}(s_j, s_{p_j}))$$

where $\mathbb{I}(s_j, s_{p_j}) = 1 \iff s_j = s_{p_j}$. Estimation of such models can be performed by least square method [5] from data consisting of individual's medical and biological information in population-scale family trees.

We investigate an alternative model that can be used to study the family risk from a fully multivariate perspective. Differently from above, the quantity of interest t_j is the time-to-event from birth to death. We assume that families are split into groups with different hazard and survival functions. We define a mixture of survival models, where the latent family risk is the mixing variable. For simplicity, we let all family members share the same hazard function.

Mixtures of survival functions are indeed studied through frailty models, where the frailty is a random effect that captures the unobserved heterogeneity among groups (families), so that the distribution of the frailty random variable is the mixing distribution. With a multiplicative frailty variable R, we have that the R-specific hazard functions satisfy the proportional hazard (PH) assumption.

As a special case, if families are split into two groups, say a low and a high risk group, the latent family risk takes values R=low/high, then the hazard function in the two groups can be defined as $\lambda_0(t)$ and $\lambda_1(\text{t}) = \beta\lambda_0(\text{t})$ for R=0 and 1, respectively. Under such PH structure, the survival functions in the two groups are thus:

$$S_0(t) = e^{-\int_0^t \lambda_0(u)\mathrm{d}u};\ S_1(t) = e^{-\int_0^t \lambda_1(u)\mathrm{d}u} = e^{-\int_0^t \beta\lambda_0(u)\mathrm{d}u} = [S_0(t)]^\beta .$$

Moving beyond the two-group case (or the similar k-group case), one can define the multiplicative frailty model with hazard function $\lambda(t|R) = R \cdot \lambda_0(t)$, where $\lambda_0(t)$ is the reference hazard function corresponding to $R = 1$, and $f_R(r)$ is the corresponding frailty density function. If all family members have the same frailty, this describes a clustered shared frailty multivariate time-to-event model with families

representing the clusters (see e.g., [8]). Parameter estimation and family-specific prediction for R can then be based on the available (typically, right-censored) survival data of all relatives in all families.

We now describe estimation in such models and classification into a high risk group.

2 Classification from a clustered multiplicative frailty multivariate time-to-event model

As in Section 1, we call R the continuous frailty variable that follows a parametric distribution characterized by θ. Within such framework, we use i to identify the family (out of G) and j to identify its n_i members. Following [4] we develop the complete likelihood $L(\underline{R};\underline{\mathbf{Z}})$ for the problem, where $\underline{\mathbf{Z}} = \{\underline{\mathbf{z}}_i, i = 1,\ldots,n\}$, and $\underline{\mathbf{z}}_i = (z_{ij}, \delta_{ij})^T$, $z_{ij} = \min(t_{ij}, c_{ij})$, $\delta_{ij} = \mathbb{I}(t_{ij} \leq c_{ij})$ following the usual notation, that has t indicate the survival time and c indicate the (independent) censoring time. X_{ij} indicates the baseline covariate vector for subject j in family i. The complete likelihood $L(\underline{R};\underline{\mathbf{Z}})$ can be written in terms of the frailty parameter θ and the survival parameters, i.e. the vector coefficient β for the covariate effects and the baseline hazard function λ_0. So, following the shared frailty hazards structure, we have $\lambda_{ij}(t|x_{ij}, R_i) = R_i \cdot \lambda_{0ij}(t|x_{ij})$, and $\lambda_{0ij}(t|x_{ij}) = \lambda_0(t)\exp(x'_{ij}\beta)$ for family i. The full likelihood is composed by two quantities: $\mathscr{L}(\beta, \lambda_0, \theta) = \mathscr{L}_1(\theta)\mathscr{L}_2(\beta, \lambda_0)$. The estimation procedure follows the approach from [4] with the notation from [9]. The frailty R can be taken to be distributed as a Gamma with shape θ and rate $1/\theta$:

$$\mathscr{L}_1(\theta) = \prod_i \frac{1}{\Gamma(1/\theta)\theta^\theta} R_i^{\theta-1} e^{-R_i/\theta},$$

$$L_1 = \log\mathscr{L}_1(\theta) = \sum_i \left[-\log(\Gamma(\theta)) - \theta\log(\theta) + (\theta-1)\log(R_i) - \frac{R_i}{\theta}\right].$$

We compute also the survival component of the likelihood:

$$\mathscr{L}_2(\beta, \lambda_0) = \prod_{i=1}^{G}\prod_{j=1}^{n_i} \lambda_{ij}(z_{ij})^{\delta_{ij}} S_{ij}(z_{ij}) = \prod_{i=1}^{G}\prod_{j=1}^{n_i} \left(R_i \cdot \lambda_{0ij}(z_{ij}|x_{ij})\right)^{\delta_{ij}} \exp(-R_i \cdot \Lambda_{0ij}(z_{ij}|x_{ij})),$$

$$L_2 = \log\mathscr{L}_2(\beta, \lambda_0) = \sum_{i=1}^{G}\sum_{j=1}^{n_i} \delta_{ij}\log(R_i \cdot \lambda_{0ij}(z_{ij}|x_{ij})) - R_i \cdot \Lambda_{0ij}(z_{ij}|x_{ij}),$$

where $\Lambda(t)$ indicates the cumulative hazard function. The full log-likelihood is then $L(\theta, \beta, \lambda_0) = L_1(\theta) + L_2(\beta, \lambda_0)$.

In order to estimate the model parameters, we may specify the form of the baseline hazard function. Indeed, the baseline hazard can assume a parametric form or it can be left unspecified (this corresponds to the semi-parametric case) [3].

For example, for the parametric specification a common model for the time-to-event variable is the Weibull distribution $T \sim \text{Weibull}(\text{shape}=\gamma, \text{scale}=\mu)$ with the corresponding hazard functions. Given the multiplicative frailty structure, one can re-parametrize the conditional (on R) survival distribution as $T \sim \text{Weibull}(\text{shape} = \delta, \text{scale} = \mu/R^{1/\delta})$. Parameter estimation is then achieved by maximizing the log-likelihood function [7] through the Expectation Maximization (EM) algorithm [3], [2]. In both parametric and semi-parametric cases, all parameters can be estimated and used to perform classification.

We move now to the classification procedure. In the parametric approach, the prediction follows a method based on the expectation step of the EM algorithm [7]. Our contribution refers to the semi-parametric approach instead. We suggest to perform risk prediction by fixing a grid of values $\{u_1, \ldots, u_K\}$ for the frailty quantity and implementing the following steps:

(i) obtain $\widehat{S}_0(z_{ij})$ and $\widehat{\lambda}_0(z_{ij})$ from the Breslow estimator;
(ii) compute $\widehat{f}(\underline{\mathbf{z}}_i|u_k) = \prod_{j=1}^{n_i} \left[(\widehat{\lambda}_0(z_{ij})u_k)^{\delta_{ij}} [\widehat{S}_0(z_{ij})]^{u_k} \right]$;
(iii) compute $\widehat{f}(\underline{\mathbf{z}}_i, u_k; \widehat{\theta}) = \prod_{j=1}^{n_i} \left[(\widehat{\lambda}_0(z_{ij})u_k)^{\delta_{ij}} [\widehat{S}_0(z_{ij})]^{u_k} \right] f(u_k|\widehat{\theta})$, $\forall u_k$ in the grid;
(iv) compute the integral $\widehat{f}(\underline{\mathbf{z}}_i; \widehat{\theta}) = \int_{\mathbb{R}^+} f(\underline{\mathbf{z}}_i|u_i) f(u_i; \widehat{\theta}) \mathrm{d}u_i = \sum_k \Delta(u_k) \widehat{f}(\underline{\mathbf{z}}_i, u_k; \widehat{\theta})$, where $\Delta(u_k) = u_{k+1} - u_k$;
(v) compute $\widehat{f}(u_k|\underline{\mathbf{z}}_i; \widehat{\theta}) = \widehat{f}(\underline{\mathbf{z}}_i, u_k; \widehat{\theta}) / \sum_k \Delta(u_k) \widehat{f}(\underline{\mathbf{z}}_i, u_k; \widehat{\theta})$.

The predicted continuous shared frailty value $\widehat{R}_i$ for each family i is computed with the rule below, i.e. it takes the value corresponding to summing up the estimated (as above) density function on the grid values until a desired threshold quantile $q \in [0,1]$:

$$\widehat{R}_i = u_k : \sum_{j:u_j \le u_k} \widehat{f}(u_j|\underline{\mathbf{z}}_i; \widehat{\theta}) \Delta(u_j) \le q. \tag{1}$$

Indeed we choose the posterior percentile so that it minimizes the misclassification rate.

In order to explore the discrete splitting of families into, say, two risk groups, we may transform the continuous frailty into a binary 2-group variable. We can then carry out the (actionable) classification according to the rule:

$$\widehat{RB}_i = \begin{cases} \text{low} & P(u_i < \widehat{\eta}_u|\underline{\mathbf{z}}_i; \widehat{\theta}) \ge q \\ \text{high} & P(u_i < \widehat{\eta}_u|\underline{\mathbf{z}}_i; \widehat{\theta}) < q \end{cases} \Leftrightarrow \begin{cases} \text{low} & \text{Quant}(u_i|\underline{\mathbf{z}}_i; \widehat{\theta}) \le \widehat{\eta}_u \\ \text{high} & \text{Quant}(u_i|\underline{\mathbf{z}}_i; \widehat{\theta}) > \widehat{\eta}_u \end{cases} \tag{2}$$

where $\widehat{\eta}_u = \text{Quantile}\left(\text{Gamma}(\widehat{\theta}, 1/\widehat{\theta})\right) \in [0,1]$, $\text{Quant}(u_k|\underline{\mathbf{z}}_i; \widehat{\theta}) = u_k : P(u_k|\underline{\mathbf{z}}_i; \widehat{\theta}) \le q$ with $q \in [0,1]$ as above. And, $P(u_k|\underline{\mathbf{z}}_i; \widehat{\theta}) = \sum_{j:u_j \le u_k} \widehat{f}(u_j|\underline{\mathbf{z}}_i; \widehat{\theta}) \Delta(u_j)$.

We now describe a simulation scenario that can be used to implement the classification procedure introduced above.

3 A simulation scenario

One can generate some family structures and survival times, and implement the 2-group classification above. We firstly fix the number of families in our dataset. We count for each woman a mother and a grandmother. Plus, we assume a varying number of sisters and aunts that can be distributed as a Poisson(λ_s) and a Poisson(λ_a) respectively. We fix $\lambda_s = 1,\ \lambda_a = 0.5$, so that the varying family size is

$$\text{family size} = 3 + \text{Poisson}(1) + \text{Poisson}(0.5).$$

The expected value of the sample size is therefore $\mathbb{E}(N) = 3+1+0.5 = 4.5$. We generate the time-to-event T from the frailty Weibull distribution $T \sim \text{Weibull}(\text{shape} = \gamma, \text{scale} = \mu/R^{1/\gamma})$, with $R \sim \text{Gamma}(1,1)$, $\mu = 1,\ \gamma = 5$. The censoring times are generated from a Uniform distribution $C \sim \text{U}(0,12)$, and for each subject we generate $Z = \min(T,C)$ and $\delta = \mathbb{I}(Z = T)$.

One can then implement the parametric and semi-parametric estimation with setting described in Section 2, and apply some diagnostic tools in order to analyse the goodness of the classification, such as the scatter-plot of R versus $\widehat{R}$ (see 1) to obtain a visual analysis of the classification accuracy, and the confusion matrix between the median-based risk group $RB = \mathbb{I}(R \leq \text{Median}(R))$ and the estimated risk group $\widehat{RB}$ obtained as in 2 for $q = 0.5$. We also extend to $q = 0.25$ so that we keep low (and realistic) the posterior high risk families proportion. We can use the agreement index Cohen's kappa [6], in order to have a summary of the binary classification results.

$$\text{Cohen's kappa } k = \frac{2(TP \cdot TN - FN \cdot FP)}{(TP+FP)\cdot(TN+FP) + (TP+FN)\cdot(TN+FN)},$$

with TP, TN, FP, FN indicate the true positive, true negative, false positive and false negative proportions, where positive (negative) stands for $\widehat{RB}$=high risk (low risk). The classical accuracy[1] can be also computed:

$$\text{accuracy} = \frac{TP+TN}{TP+TN+FP+FN} \geq 0.$$

Both indices vary in the range $[0,1]$, where zero means no agreement and one means perfect agreement. Sensitivity and specificity can also be used as classification accuracy measures.

Thus, we sample 3000 families and we explore the classification accuracy in three different scenarios: (i) parametric hazard and binary classification with median as threshold; (ii) semi-parametric case with $q = 0.5$; (iii) semi-parametric case with $q = 0.25$. We carry out this analysis for family size and overall. The results for family size are not reported because irrelevant, while the summary of the overall results is in table [1]. The posterior high risk families proportion in the semi-parametric case, varying q, is: 0.21 ($q = 0.25$); 0.27 ($q = 0.5$).

	Cohen's k	Accuracy	Sensitivity	Specificity
(i)	0.73	0.91	89.89	87.34
(ii)	0.89	0.95	97.97	93.51
(iii)	0.92	0.96	94.65	96.92

Table 1: classification accuracy indices for the three scenarios (see text).

4 Discussion

Preliminary results suggest the absence of important differences in classification accuracy across different family sizes (results not shown). We notice a substantial difference in classification accuracy between the parametric and the semi-parametric setting, up to the use of the median as classification threshold. Moreover, the use of the first quantile seems to be preferable in terms of classification accuracy and posterior proportion of high risk families. This was confirmed also through further checks (results not shown), as the scatter-plots (see text). We plan to extend this study to the case of development of a disease (e.g. breast cancer), where risk classification can help implement tailored, more intensive screening schedules for subjects with higher risk of developing the disease, as estimated from frailty member's history of breast cancer.

Topics & Metaverse: an explorative analysis

Tematiche e Metaverso: un'analisi esplorativa

Emma Zavarrone, Alessia Forciniti, Emanuele Parisi and Maria Gabriella Grassia[2]

Abstract In October 2021 Zuckerberg drew the attention of media, businesses and common people to a virtual reality platform called Metaverse, so that its search has become a trend. In this paper, we explored the people's opinion in Italy on Twitter by analysing the hashtags. Through the *Latent Dirichlet Allocation*, we detected latent topics of hashtags and projected them in an inter-topic distances map which clustered similar topics in two-dimensional space. To study the inter-topic distances, we used the measures of saliency and distinctiveness. Despites the saliency presents similarities between the groups, the distinctiveness denotes that one topic is generalist, based on platforms interconnection, and the other one is specialistic and focused on virtual technologies and virtual economies.

Abstract *Nell'ottobre 2021 Zuckerberg ha attirato l'attenzione di media, imprese e persone su una piattaforma di realtà virtuale chiamata Metaverso, così che la sua ricerca è diventata un trend. In questo paper, abbiamo esplorato quello che dicono le persone in Italia su Twitter analizzando gli hashtag. Con la Latent Dirichlet Allocation, abbiamo rilevato gruppi latenti di hashtag e li abbiamo proiettati in una mappa di distanze inter-topic che raggruppa i topic simili in uno spazio bidimensionale. Per studiare le distanze inter-topic, abbiamo usato misure di salienza e distintività. Nonostante la salienza presenti similarità tra i gruppi, la distintività denota un topic più generalista, basato sull'interconnessione tra le piattaforme, l'altro più specialistico focalizzato sulle tecnologie e economie virtuali.*

Key words: metaverse, virtual world, LDAvis, intertopic-distance, hashtag

1 Introduction

In October 2021 Mark Zuckerberg announced Facebook's name changed to Meta shifting everyone's attention towards a new virtual reality called *Metaverse*. It is a new platform of encountering between the physical and digital world (Nesbo, 2021) which through a deep user-experience has the potential to contribute to the access of new creative, social and economic opportunities for consumers and enterprises. The platform represents a 3D virtual world where the activities are carried out by means of augmented and virtual reality equipment, allowing to collaborate, meet, buy, sell, play games, and socialize in 3D spaces. The economic aspect is based on cryptocurrencies as medium exchange and on Non-Fungible Tokens (NFTs), digital items bought and sold using the blockchain technology. These systems - focused on virtual social connection and virtual economy - became popular during the pandemic of Covid-19 for remote working and online activities of leisure or shopping.

The metaverse is not a new concept since the term appeared for the first time during 1992 in a science fiction novel by Neal Stephenson called Snow Crash. In the novel, the metaverse was presented as the integration between the virtual and physical spaces. In fact, the concept has never been more popular as today to indicate the combination between virtual reality, augmented reality, and virtual economies (Newton, 2021). The concept has turned into a trend topic for journalists, researchers, investors and common people. For some, the aim is to emphasize development progress of technologies (Neiger, 2021), for others, to discuss criticism and concerns connected to feasibility, information privacy (Lee *et al*., 2021), user safety (Chalmers, 2022), social issues (Huddleston, 2022).

Since Zuckerberg presented this platform and revealed to the media that he had made significant investments in it, the frequency of the query 'metaverse' on the search engines around the world was 1,339 from 10th October 2021 to 25th February 2022, and in Italy equal to 1,147. At the same time, many companies such as Microsoft, Samsung, Nike and others are engaging to take their place in this market.

The need to search what metaverse is and to take part in it has become a popular trend, but few or none know exactly what metaverse is.

In this paper, we explored what people say in Italy about the metaverse on social media and on Twitter recognized as 'collective brain' (Ceron *et al*., 2014) of the society. The focus of analysis was on hashtags as distinctive elements to refer to themes, contents, and events. By means of techniques of textual analytics and more properly through the topic modelling of Latent Dirichlet Allocation, we detected the main topics as distribution of hashtags to find meaningful latent topics and the relationships between topics and hashtags. In this way, we can better understand the people's opinion on metaverse. We used a web-based interactive visualization which allowed to estimate the hashtag relevance as topic-specific frequency of each hashtag and to project an inter-topic distances map which via multidimensional scaling has faithfully clustered similar topics in two-dimensional space.

To follow, section 2 presents data; section 3 describes the methodology; section 4 shows the results and discussion.

2 Data

To investigate topics of hashtags, we extracted the tweets posted by users from 2nd to 13rd February 2022. Data extraction was performed by means of the *application programming interface* (API) of Twitter and the library *rtweet* (Kearney, 2019) by using the keywords such as 'metaverso, nft, blockchain'. With respect to monitoring period, we extracted 36,449 tweets of which 7,731 in Italian language. Before proceeding to the pre-processing and analysis of the corpus steps, we improved extraction by filtering the tweets according to user's account. Precisely, we used machine learning methods proposed by Kearney in 2018 to classify Twitter accounts as bots or non-bots. The model based on a gradient boosted system uses both users-level (as bio, location, number of followers and friends, *etc*) and tweets-level (as number of hashtags, mentions, etc, in a user's most recent 100 tweets) data to estimate the probability of users being bots. However, Twitter's REST API rate limits the filtering to only 180 estimates per every 15 minutes, even if by default the model shows accuracy equal to 93.53% to classify bots and of 95.32% to classify non-bots. The model allowed to estimate 179 bot accounts, whose tweets have been selected and deleted from the dataset. By cleaning the corpus from bots, we obtained 2,359 non-bot tweets of which only 1,396 included the word 'metaverse'.

3 Methodology

The methodological approach was based on *Natural language Processing* (*NLP*) and specifically textual analysis techniques. At first, data pre-processing was performed on 1,396 texts parsed and tokenized by means of the canonical steps of normalization, lemmatization, removal of punctuation, numbers, stop words, usernames, retweets and elements of noise like URLs, link, emoji, special characters. We obtained a vocabulary composed of 740 types by filtering nouns, adjectives and verbs and 186 hashtags. We focused our attention on topic extraction of the hashtags to obtain a thematic knowledge of the phenomenon. In this case, our aim was not based on bag-of-word coding but it was oriented to study the context in which the hashtags were inserted in the discourse. To reach this goal, we adopted the unsupervised topic modelling method known as *Latent Dirichlet Allocation* (*LDA*) (Blei *et al.,* 2003). This approach represents a fully generative model for identifying sets of latent arguments (Ostrowski, 2015) for each of which it associates a sequence of words in terms of multinomial distribution. We used this approach to work on

short text (e.g.; Chen *et al*., 2016) and detect topics of hashtags. To detect the meaning of each topic, the prevalence of topics and their relationships, we based our work on a web-based interactive visualization called *LDAvis* (Sievert & Shirley, 2014) useful to make the results easily interpretable. It allows to examine the topic-hashtag relationships, the corpus-wide frequency of a given hashtag as well as the topic-specific frequency of the hashtag as proposed by Chuang *et al*., 2012 (in Sievert & Shirley, 2014). The texts visualization shows the inter-topic differences by means of the topic representation in a two-dimensional space given by multidimensional scaling. The inter-topic distances are computed using Jensen-Shannon divergence also known as information radius or total divergence to the average, which represents a method to measure the similarity between two probability distributions.

In addition, to better understand the topic model, the authors have reproduced the Chuang *et al.*'s tool (2012) based on two main measures: distinctiveness and saliency. By computing the Kullback-Liebler divergence, we can obtain the distinctiveness between the distribution of topics given the hashtag and the marginal distribution of topics, and the saliency as hashtag's overall frequency. A tuning parameter λ in the computation of relevance was instead developed by Sievert & Shirley (2014) where $0 \leq \lambda \leq 1$: $\lambda=1$, the parameter ranks hashtags in decreasing order of their topic-specific probability and $\lambda=0$ the parameter ranks hashtags based on the ratio between the probability of generic hashtag, belonged to the topic k and marginal probability distribution of the same hashtag in the corpus.

4 Results and discussion

LDAvis allows a global view of the topics, both their prevalence and similarity to each other in a compact space split in two pieces.
The left panel shows the identified hashtag groups in a two-dimensional space, using an inter-topic distance map via multidimensional scaling. The topics are visualized by the principal components (PC) axis distribution. Each topic is represented by a circle and its overall prevalence is encoded using the areas of the circles, which are proportional to the relative prevalence of the topics in the corpus. As shown in the *Figure 1* the first three topics have a greater marginal topic distribution than others. The areas of first and second circle describe a marginal topic distribution of 10% of the corpus; while the third one describes it at 5%. In fact, in the 15-topic model presented, the first three topics comprise respectively 23%, 19.3% and 7.2% of the corpus. The circle's centers are defined by the computed distance between topics.
The inter-topic distance on the map of the PC shows groups of hashtags. Some of these groups are overlapped, denoting a strong positive correlation. We can observe how the map splits in the positive correlated thematic areas. Specifically, there is a positive correlation between the groups 1 and 6; the groups 8, 15, 12, 13; the groups

2, 9,14,10,11; the groups 3, 4 and 5. Between the first two groups which present the greater relative prevalence of the topics in the corpus, we note that the thematic group 2 is more away from the origin and then better represented on the factorial map. The right panel consists of a horizontal bar chart whose bars represent the individual hashtag. This section is effective to interpret the topic groups, depending on the selected topic. The hashtags are ranked according to the relevance in decreasing order. The relevance is important to understand how much the hashtags are discriminant for each specific topic and is measured by the parameter of topic-specific probability (λ), whose "optimal" value is 0.6 (Sievert & Shirley, 2014). In the *Figure 1* on the right, we see the most useful hashtags for interpreting the topic 1.

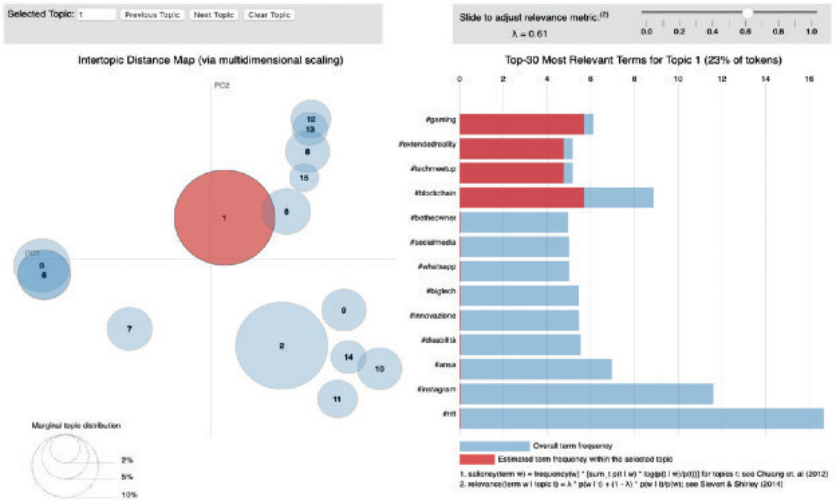

Figure 1*: Inter-topic distance map for all topics and relevance of hashtags for the Topic 1*

According to the abovementioned literature in the methodological paragraph, we can describe the results of the bar chart according to two measures: saliency and distinctiveness at relevance parameter λ = 0.6. The saliency - as hashtag's overall frequency - indicates most frequent #nft, #instagram, #blockchain, #ansa, but the distinctiveness - as estimated hashtag frequency within the topic 1 - brings out the importance of the emphasizing of the user-experience. The characteristic element is the extended reality as umbrella term that covers technologies which allow the human-to-PC screen interface in an immersing virtual environment, including the playful aspect of the virtual through gaming or communities, and that of buying and selling through blockchain technology. The *Figure 2* presents instead the most important hashtags to interpret the topic 2. The bar charts of the *Figure 1* and *2* allow to observe that they contain common hashtags. The right panel in Figure 2 indicates such as very salient #nft, #blockchain, #instagram and so on; but, the metric of distinctiveness suggests as discriminants #instagram, #socialmedia, #whatsapp. Thus, despite the saliency between the topic 1 and 2 presents similarities, the distinctiveness denotes that the topic 2 is generalist and based on

platforms interconnection, while the topic 1 is focused on the specificity of technology, virtual reality, virtual interactions, and virtual economies. This explains the reason why on the inter-topic distances map the two topics are not close. *LDAvis* showed a deep inspection of topic-hashtag relationships and of topic-topic similarity by LDA model. The graphic visualization and the metrics allowed to explore that, in some cases, people describe a phenomenon by the same word or same hashtag but it is the topic grouping to bring out a different semantic knowledge. Specifically, the weight of each hashtag in each topic makes two levels of knowledge on metaverse emerge: one approximative and the other aware of peculiarities, by leading to observe the distance between the topics despite using the same hashtag.

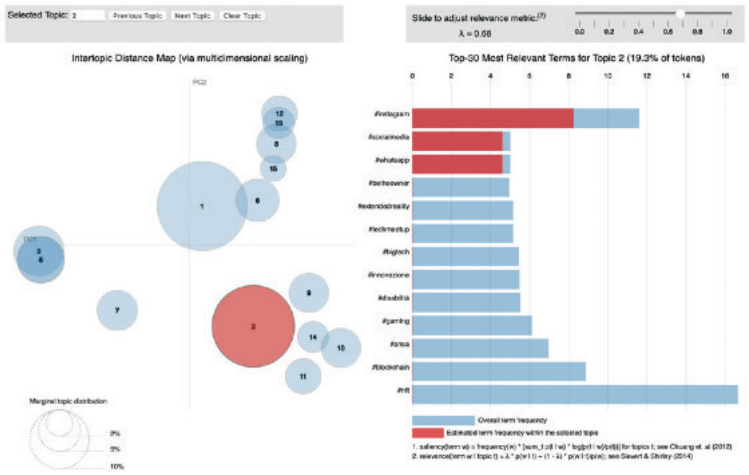

Figure 2*: Inter-topic distance map for all topics and relevance of hashtags for the Topic 2*

Applying Topic Models to bibliographic search: some results in basketball domain.

Applicazione dei Topic Models alla ricerca bibliografica: alcuni risultati nel dominio del basketball

Manlio Migliorati, Eugenio Brentari

Abstract Bibliographic search finalized to identify relevant material about the specific problem to be faced is normally the first phase to be accomplished when starting a new research activity. Such literature analysis can be heavily time consuming, and often only a little part of the analysed material is actually useful. In this short paper, results of using Topic Models approach as support tool for bibliographic search are reported and compared to results obtained analysing via the classic manual approach on a corpus of 495 papers about basketball domain.

Abstract *La ricerca bibliografica finalizzata a identificare il materiale relativo allo specifico problema oggetto di studio è, di norma, la prima attività da svolgersi quando si inizia un progetto di ricerca. Questa attività può risultare onerosa in termini di tempo, e spesso solo una piccola parte del materiale consultato si rivela effettivamente utile. In questo lavoro si riportano i risultati derivanti dall'utilizzo dei Topic Models come strumento di supporto per l'analisi bibliografica, e tali risultati sono confrontati con quelli ottenuti analizzando con la classica ricerca manuale un corpus di 495 documenti relativi al basketball*

Key words: Bibliographic search, topic models, text mining

1 Introduction

Bibliographic search is the first step to be accomplished in facing a new research activity, to identify the relevant material for the domain under analysis. To this purpose, in the last decades several web based services (for instance Web of Science (WoS) from Clarivate Analytics or Scopus from Elsevier) are born, grouping an impressive quantity of scientific material and offering several tools to select and investigate it. Nevertheless, the huge number of scientific sources to be considered,

University of Brescia, Department of Economics and Management, Contrada S. Chiara 50
e-mail: manlio.migliorati@unibs.it

constantly increasing, constitutes an actual challenge for researchers, particularly in approaching a new research field.
The typical approach to identify relevant material is based on querying the on-line repositories to make a preliminary selection, then filtering the results using the provided ad hoc tools and at last applying bibliometric tools as Bibliometrix [1] or manually analysing documents on the base of abstracts, keywords and other classification criteria. This process can actually be time consuming, and often only a little part of the analysed material is actually useful.
In this manuscript, results produced using the Topic Models approach as a support tool for bibliographic search are compared to the classical manual bibliographic analysis output, taking into account a dataset of 495 documents, related to data science applied to basketball domain, produced by on-line repositories querying tool. All implementations of this work have been done in R.
The short paper is structured as follows: section 2 describes the dataset of documents used in this work, section 3 contains a summary of the manual analysis results, section 4 informally summarizes the Topic Models approach, section 5 reports the output we obtained and section 6 presents some conclusions and directions for future steps.

2 The dataset

The specific bibliographic domain to be investigated for our research is related to the usage of data science in general, and machine learning techniques in particular, to the field of basketball, trying to address factors leading to team's victory. The dataset has been produced by a simple (trying to avoid to cut off elements) bibliographic search executed in WoS Core Collection using the query:
("data science" OR "machine learning" OR "business intelligence" OR "data mining" OR analytics OR statistics) AND basketball.
That query, designed to take into account publications years from 1999 to 2019 and to search in title, abstract, author keywords, and Keywords Plus (a set of keywords defined by WoS itself), has been executed on 10th of June 2019, producing a dataset containing 495 documents.

3 Manual analysis of the documents dataset

The original dataset has been manually filtered addressing our specific goal: in particular we are interested in application of statistics about factors addressing team victory. Application of tools made available by WoS, in terms of title analysis, categories and sources, reduced the dataset to 175 elements. Then, this intermediate dataset has been further filtered on the basis of the manual reading of abstracts (and,

in several cases, of the complete papers), to arrive to the final dataset composed by 117 elements, identified as relevant to our research purposes.

4 Using Topic Models

The first dataset produced by WoS query, counting 495 documents, has been classified via Topic Models [2] approach, a statistical modeling widely used in Natural Language Processing (NLP), to clusterize in an unsupervised way a corpus of documents on the basis of latent topics they refer to. In particular, in this work Latent Dirichlet Allocation (LDA) [3] has been used.
In this approach topics are seen as a mixture of words, and the β probability that a term being generated from a topic is calculated. Moreover, LDA models each document as a mixture of topics, and the γ probability that a document belongs to a topic is estimated. Two remarks about Topic Models approach:

1. documents are processed using NLP tools (see for instance [4]):
   - each document in the dataset is tokenized (i.e. words are identified)
   - the set of tokens is cleaned with respect to stop words (i.e. not relevant terms are erased: articles, prepositions, etc)
   - each remaining token must be rooted (i.e. normalized to a base form); in this work we describe the results of stemming, i. e. root form of a word obtained removing the last few characters, using the `SnowBallC` R package [5]).
   - finally, a terms-documents matrix is calculated, constituting the input of the LDA algorithm.

   In our analysis on the original dataset containing 495 documents, we found 55849 tokens, reduced to 4935 stems via the process described above.
2. the number of clusters to be used in classifying the documents of a corpus must be defined in advance. This is an important point, because a low number of clusters does not enable to identify the most interesting subsets, and viceversa a high number of clusters makes it hard to identify differences among them.

In this work we used the `topicmodels` R Package [6] for fitting Topic Models, and the `ldatuning` R Package [7] as a support tool to define the number of clusters. Application of `ldatuning` R Package to our data is represented in Figure 1, where a value (scaled between 0 and 1) is produced for different number of clusters; such a value must be minimed for metrics named *CaoJuan2009* [8] and *Arun2010* [10], and maximized for the metric named *Deveaud2014* [9].
We decided to consider 5 clusters, a number small enough to let us understand the differences among clusters, and corresponding to a local minimum for the metric *CaoJuan2009* and to a local maximum for the metric named *Deveaud2014* (in this case no useful information is provided by the metric *Arun2010*, where the value is monotonically decreasing with the increasing of the number of clusters).

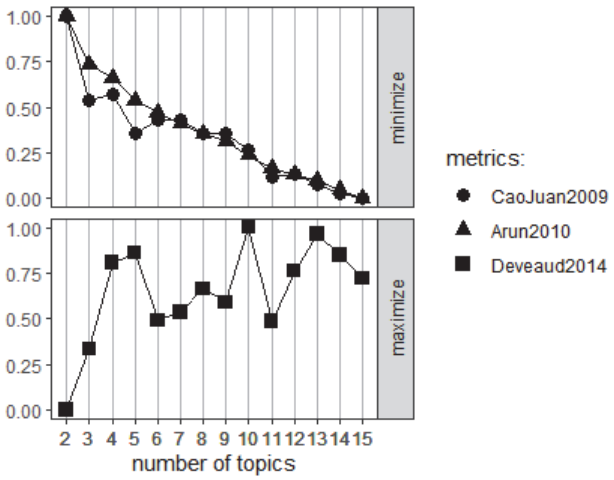

Fig. 1 Trends of some normalized metrics as function of the number of topics

5 First results of the analysis

Figure 2 shows the 10 most representative stems (highest β values) for each cluster:

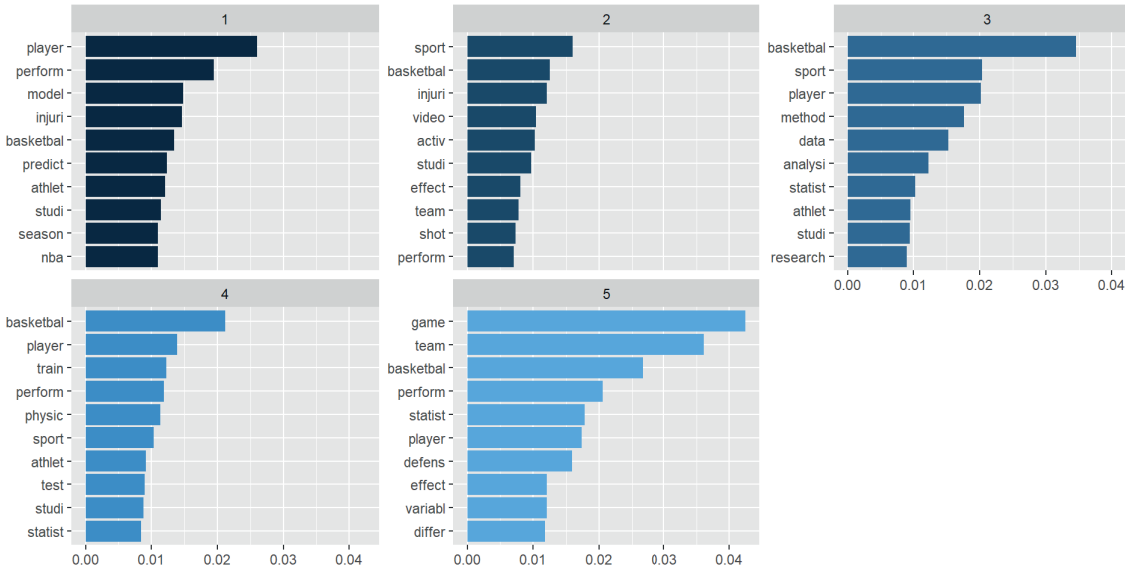

Fig. 2 Top β words for each of the 5 clusters.

Looking to the top beta words of Figure 2, we start to identify the most interesting clusters: cluster 1 seems more focused on single players (*player*, *injuri*, *athlet*); cluster 2 does not seem to address victory drivers, cluster 3 maybe could be interesting for our purposes (*data*, *analysi*, *statist*), cluster 4 seems focused on training and at last cluster 5 seems the most interesting one (*game*, *team*, *perform*, *statist*).
Moreover, for each document the γ probability of being classified in one of the 5 clusters is calculated, and a criterion can be defined to attribute a document to a cluster on the base of γ value. In this work a document is attributed to the cluster for which it has the highestγ, some examples are reported in Table 1.

Table 1 Examples of γ analysis: documents are attributed to a cluster considering the highest γ).

Doc ID	Cluster 1	Cluster 2	Cluster 3	Cluster 4	Cluster 5	Highest
1	0.00026	0.00026	0.91826	0.00026	0.08095	3
100	0.00061	0.00061	0.00061	0.70853	0.28963	4
216	0.00036	0.13561	0.34914	0.16657	0.34832	3

For each cluster, the 3 papers with the highest γ are then summarized (in terms of title, source, abstract, keywords), to help in confirming the actual interest for the cluster. For instance, Table 2 reports information[1] about the paper 459 (having the highest gamma among documents attributed to cluster 5), and on the basis of these information we can evaluate the relevance of the cluster.

Table 2 Summary of information about the top γ paper for cluster 5, used to evaluate if the relevance of the cluster.

paper	459
title	discriminant analysis of game-related statistics between basketball guards, forwards and centres in three professional leagues
source	European Journal of Sport Science
author keywords	basketball; discriminant analysis; player position;professional;league;game statistics

Quality of clustering has been evaluated on the basis of the distribution among the 5 clusters of the 117 manually adopting a specific criterion of attribution[2], in this work attributing the cluster with the highest γ, and results are reported in Table 3 (where the dataset is composed by 493 documents because of 2 documents with an empty abstract that have not been considered). From data in Table 3 it is possible to verify how about 48% of the 140 papers attribute to cluster 5, seeming to be the most interesting on the basis of β analysis, has been manually selected, and how it contains 58% of manually selected papers.
Considering together clusters 3 and 5, we have a set of 265 documents, containing more than 63% of manually selected papers, and including about 74% of all papers

[1] abstract is not reported to save space

[2] classification can be different adopting other criteria, e.g. attributing a document to a cluster only if γ probability is higher than a fixed threshold greater than 0.5

Table 3 Some Statistics about Topic Models application; 2 documents have not been considered, and all the 117 manually selected papers have been classified

Statistics	Cluster 1	Cluster 2	Cluster 3	Cluster 4	Cluster 5	Total
num docs per cluster	96	64	125	68	140	493
num manually selected docs per cluster	22	7	19	1	68	117
% manually selected docs VS docs in cluster	22.92	10.94	15.20	1.47	48.57	
% manually selected docs	18.80	5.98	16.24	0.85	58.12	

manually classified as relevant. This is an interesting result for an unsupervised classification mechanism as Topic Models is.

6 Conclusions and futures directions

In this paper we described the application of Topic Models approach to bibliographic search, and compared its results with the output of the classical manual selection process. First results seem to be interesting: in a 5 clusters model, the more promising cluster (number 5) includes 140 papers and about 48% of them is relevant, covering about the 58% of all manually selected papers. The union of clusters 3 and 5 includes 265 elements: more than 63% of them are manually selected papers, and that set includes about 74% of all paper manually classified as relevant. Future evolutions of this work will address the refinement of Topic Models application and the usage of different criteria in attributing documents to clusters.

Exploiting Text Mining and Network Analysis for future scenarios development: an application on remote working

Text Mining e Network Analysis per lo sviluppo di scenari futuri: una applicazione sul telelavoro

Yuri Calleo, Simone Di Zio, Vanessa Russo

Abstract In Future Studies, the scenario planning process represents a valuable approach to build images of plausible futures, to set better policy actions in the present. However, the whole process requires great efforts due to the time consuming in selecting the key drivers and issues on the selection of a panel of experts. With the proliferation of web-based quantitative and qualitative data, more information can be obtained, starting from bibliometric data. We propose a methodology to speed up the Scanning phase, by adopting a combination of text mining and network analysis in a chain of steps in which the two approaches integrate to each other. We applied the approach to create useful materials for building future scenarios for remote working.

Abstract *Nei Futures Studies, il processo di pianificazione di scenari rappresenta un approccio utile a costruire immagini di futuri plausibili, per definire migliori azioni politiche nel presente. Tuttavia, l'intero processo richiede sforzi specifici a causa del dispendio di tempo nell'identificazione dei fattori chiave e nella costruzione del panel di esperti. Con il proliferare di dati quantitativi e qualitativi su internet, si possono ottenere maggiori informazioni a partire dai dati bibliometrici. Proponiamo qui una metodologia per accelerare la fase di Scanning, combinando text mining e analisi delle reti in una catena di passaggi in cui i due approcci si integrano tra loro. Abbiamo applicato l'approccio per generare materiale utile alla costruzione di scenari futuri nel contesto del lavoro a distanza.*

Key words: future scenarios, topic analysis, network analysis, remote working

1 Introduction and theoretical framework

Remote working or distance working is a flexible work arrangement that allows an employee to work from a remote location outside the usual offices of the company. This mode of working has existed for many years but with the COVID-19 pandemic we have seen an explosion that has brought out and accentuated both its positive and negative aspects [1]. The future of remote working will be faced with many opportunities as well as challenges, and it is urgent to regulate the sector for the years to come, to safeguard both the well-being and rights of the worker and the needs of the employer. In a highly transitory time, it is practically impossible to predict what will happen, even in just 5 years, therefore we propose a foresight approach. In this paper we try to lay the foundations for the construction of future plausible scenarios on remote working by proposing a new methodological approach. In Futures Studies (FS) the idea of predicting the future has been abandoned decades ago and the research moved on to the issues of mapping alternative futures for better decision making [2]. Among the many methods of the Futures Research, the Delphi and the scenario method are the most widespread. The Delphi is a widely used method for gathering data from a panel of experts, [3] and future scenarios can be defined as descriptions of possible future situations together with the paths of development leading to those futures [4]. Within the FS the Delphi is often used inside the scenario development process and the most popular approach is known as Delphi-based scenarios (DBS) [5]. There are various approaches for the construction of a DBS and here we follow one of the more accredited, based on six steps: Framing, Scanning, Forecasting, Visioning, Planning, Acting [6]. Apart from the initial step of Framing, common in all approaches, Scanning is a crucial step. During this phase, all relevant information on the system under study (trends and key drivers) must be collected as comprehensively as possible. However, the Scanning phase remains a challenging task since the development of the Delphi's projections and the construction of the panel are complex and time-consuming. Commonly, a mix of desk research (review of the relevant literature and specialised reports) and experts' consultation (workshops, interviews, focus groups or Delphi) are performed, but the risk of ignoring important drivers remains. Humans are always subject to cognitive biases and personal views, which can limit and/or distort the search for relevant projections as well as the involvement of notable experts.

In this paper, we propose a new methodology for the Scanning phase through the automatic scanning of the relevant literature (by text mining) and the analysis of networks of experts (by network analysis) which has the following advantages: a) speed up and automatise the formulation of a draft list of Delphi's projections; b) extension of the spectrum of information taken into consideration; c) work around the cognitive biases; d) optimise and objectify the search and recruitment of the experts through the scanning of large networks of scholars and random sampling. Although the final list of projections must be drawn up manually, and the panel of experts must be refined by the research team, the outputs of the automatic analysis here proposed are valuable supporting materials for the Scanning phase of any DBS development.

2 Materials and methods

As known, in social sciences the mixed methods are important but in the Future Research the integration qualitative-quantitative is considered even indispensable [7]. In line with this, the approach proposed here takes advantage of an appropriate combination of qualitative and quantitative methods, which both speeds up the construction of the DBS and makes the development of the scenarios more objective and reproducible. The approach consists of the following tasks: 1) Text Mining for the extraction of the relevant topics on the matter of study. The topic modelling (unsupervised) is performed on bibliometric data (article's abstract) with semantic data from keyword's analysis. We propose a Latent Dirichlet Allocation [8] and a topic coherence metric (Normalised Pointwise Mutual Information) for setting the number of topics to extract. 2) Bibliometric Network analysis, exploiting the collaborations among authors, to create a network of potential experts on the research topic. This produces an undirected graph $G = (V, E)$ where V is the set of scholars (potential experts), E is the set of edges based on collaboration and $N = |V|$ is the number of scholars. Network analysis helps in identifying the most influential people as well as groups of scholars (subgraphs) sharing similar research lines. 3) The graph resulting from step 2) can be complete or disconnected. Let denote with c the number of cliques (i.e., induced subgraphs of G that are complete). Therefore, every clique $g_l = (v_l, e_l)$ - $v_l \subseteq V$; $e_l \subseteq E$; $l = 1, \dots, c$ - contains a group of scholars who collaborate with each other. The c subgraphs will be used both for sampling the expert and for the extraction of subgroups of articles on different research topics. If c were too large, a data driven choice will be made to select a congruous and manageable number of subgraphs (e.g., choosing the larger cliques) and, consequently, N will be restricted to the selected subgraphs. 4) Ranking of the papers within each of the c subgraphs according to the number of citations and subsequent extraction of an appropriate number (say k_l) from each subgraph (k_l can be constant or variable). Then, from each paper we extract authors, title, abstract and keywords, so to create K "cards" ($K = \sum_{l=1}^{c} k_l$). 5) Assigning to each of the N experts a measure of expertise. The problem of measuring the degree of expertise is huge and complex [9], however, here we propose an approach based on a weighted sum of three indicators: a) number of published papers on the topic (P_i); b) number of years referred to the first publication on the topic (Y_i); c) Scopus H-index (H_i). The measure assigned to each expert is $m_i = w_1 P_i + w_2 Y_i + w_3 H_i$ ($i = 1, \dots, N$; $\sum_{j=1}^{3} w_j = 1$) where w_j are weights to modulate the importance of the indicators. 6) Since N could be very large, to build a Delphi panel with an adequate number of experts (say n), it is important to select among the N potential experts according to an objective criterion. We propose a stratified random sampling exploiting the c subgraphs, based on variable probabilities π_i. According to a vertex sampling logic, from each stratum/subgraph we extract a subset of n_i vertices/scholars ($i = 1, \dots, c$; $\sum_{i=1}^{c} n_i = n$) where n_i can be constant or variable and $\pi_i \propto m_i$. This stratified sampling strategy is useful because it ensures the variability of the competences in the panel of experts and the variable probabilities allow scholars with greater expertise to be more likely to enter the panel. 7) Construction of a document-term matrix (dtm) consisting of titles and keywords to

subsequently create a co-occurrence matrix. A semantic co-occurrence network analysis will be developed to highlight specific semantic areas (in number S) using the Modularity algorithm [10]. This widens and strengthens the outputs of step 1).

The topics, the terms with their probabilities, the coherence of terms, the c subgraphs, the c lists of papers, the K cards and the S semantic areas are precious materials for the construction of the Delphi's projections. Even if the final list of projections cannot be automated, the previous results provide, in a very short time and objectively, valid and reliable qualitative/quantitative materials. Furthermore, sampling the scholars provides a fast and objective prototype panel for the Delphi.

3 Application on remote working: results and discussion

We extracted bibliometric data from Scopus with the R Bibliometrix package [11] by considering the following keywords: "smart working", "home working", "distance work", "remote working", "long-distance worker", "teleworking", "telework". Accordingly, we obtained 1031 contributions in a time span of 1 year (from 2020 to 2021). To determine the optimal number of topics we used Python applying coherence metrics; we referred to a coherence score with two validation sets, where $\alpha = 0.1$ and $\beta = 0.1$. We considered all the topics previous to a significant drop, choosing the topics from 6 to 10.

Table 1: *top ten terms of 5 topics sorted by the relevance scores*

Topic	***Keywords (score)***
Work	student (0.022), remote (0.020), work (0.016), employee (0.015), laboratory (0.015), teach (0.015), surgical (0.013), instructor (0.013), method (0.011), result (0.009)
Pandemic	nurse (0.038), bedside (0.019), review (0.015), retirement (0.015), covid (0.012), patient (0.012), clinical (0.012), telecommute (0.006), nursing (0.005), work (0.004)
Remote work and family	work (0.029), system (0.014), model (0.013), smart (0.013), home (0.012), family (0.010), learning (0.010), remote (0.008), individual (0.006), couple (0.005)
Environment	tax (0.030), city (0.025), air (0.015), climate (0.015), transport (0.013), spaces (0.010), energy (0.009), business (0.008), travel (0.007), emissions (0.006)
Anti-contagion measures	contact (0.038), public (0.029), virus (0.019), safe (0.010), masks (0.008), spread (0.006), guidance (0.006), mask (0.005), person (0.005)

We identified the topics semantically coherent with the purpose of our study, highlighting 5 topics with 10 relevant keywords (Tab. 1). Overall, the topics focused on three principal themes: a) the workplace environment and the possible complications due to the remote working (topic 1: "surgical", "teach", and

"instructor"), and the problems of remote working in the family (topic 3: "family", "learning", and "couple"); b) the environment and climate threats (topic 4: "climate", "emissions", "transport"; c) the health theme (topic 2: "nurse", "retirement", "patient") and the anti-contagion measures (topic 5: "contact", "masks", "measures" and "spread").

The academic collaboration matrix identifies an undirected graph of $|V| = 4008$ nodes (potential experts) and $|E| = 41226$ links. The graph is composed of $c = 899$ subgraphs, which is an unmanageable number for our purposes. Since the size of the cliques varies from $|v_l| = 2$ to $|v_l| = 104$, following a qualitative analysis of the structure of the graph and the distribution of $|v_l|$, the subgraphs with $|v_l| \geq 25$ were selected, leading to a reduced number of $c = 7$ larger connected components (Fig.1).

Clique	*# papers (sampled)*	*# Scholars (sampled)*
1	8 (5)	87 (10)
2	1 (1)	37 (10)
3	4 (4)	104 (10)
4	2 (2)	30 (10)
5	4 (4)	64 (10)
6	7 (5)	36 (10)
7	1 (1)	26 (10)
Totals	**27 (22)**	**384 (70)**

Figure 1 - Network of collaboration and data on the $c = 7$ cliques.

The number of papers in each of the 7 subgraphs varies from 1 to 8 (Fig. 1). Therefore, we decided to take all the papers in the subgraphs containing 5 or less papers and $k_l = 5$ papers in the subgraph with more than 5 articles (by taking the most cited). It resulted $K = 22$ selected papers. From each of them we extracted authors, title, abstract and keywords, to form 22 cards, representing a synthesis of the most quoted papers dealing with different aspects of the Remote Working, useful for the development of Delphi's projections. The 7 selected cliques contain $N = 384$ researchers (Fig. 1). Then we extracted a random sample of $n_i = 10$ potential experts from each subgraph. In this first practical trial, for each expert we extracted only the number of published papers (P_i), therefore $w_1 = 1$, $w_2 = w_3 = 0$, $m_i = P_i$ and $\pi_i = m_i / \sum m_i$. The group of $n = 70$ scholars is therefore a prototype panel of experts, representative of 7 areas of research around the theme of remote working. Considering the semantic content of Titles and Keywords, a Semantic Network analysis on co-occurrence links was developed. Through Network analysis, using the Modularity algorithm [12], it was possible to identify $S = 7$ specific clusters of words (i.e., semantic areas). The different themes emerging from the network analysis can be grouped into the following research areas: Social Inequality (Cluster 0; Cluster 4), Psychological Disease (Cluster 3, Cluster 4), Work (Cluster 5), Technological Progress (Cluster 6, Cluster 7; Cluster 1).

4 Concluding remarks

The approach proposed here provides new quantitative advancements for the development of DBS, speeding up the preliminary review of the literature and improving the experts' selection task, by adopting a combination of text-mining and network analysis. For future works, we recommend implementing this contribution adopting different strategies to expand the data scanning. In fact, it could be useful to analyse much larger datasets, referring to different keywords used for the extraction of bibliometric data. Different textual data (e.g., from newspaper articles, web pages of projects, blogs etc.) could be analysed in order to have a more general perspective. For the identification of the experts, we limited the analysis to the network of scholars but the networks from which to draw the experts of the Delphi panel must certainly be many more (e.g., organisations, web pages, journalists, professional associations, networks of enterprises, trade unions, etc.), to increase the variability of competences.

The indicators and the weights to measure the expertise can be of various types. We have proposed three indicators and a simple weighted arithmetic mean, but for future work it could be interesting to study other indicators as well as other aggregation formulas. Finally, it is worth noting that a measure of the expertise is useful not only to sample the experts, but also in the subsequent phase of analysing the results of the Delphi, to weigh the answers given by the participants.

Emotion recognition in Italian political language to predict positionings and crises government

Il riconoscimento delle emozioni nel linguaggio politico italiano per predire posizionamenti e crisi di governo

Alessia Forciniti and Emma Zavarrone

Abstract The paper aims to analyze the political language adopted on Twitter by the main Italian parties' leaders during the first two waves of Covid-19 pandemic.
A two-step model based on sentiment emotion recognition (ER) and Correspondence analysis detected which emotions characterized the political language and which changes happened between the two waves. The results showed the use of a language with a strong emotional weight for some political actors as opposed to others who used a neutral register of political language in both waves. The comparison between two waves denoted a shift from anger to sadness and fear for Meloni and a moving away Salvini by predicting through ER the rift of the right-wing.

Abstract *L'articolo mira ad analizzare il linguaggio politico adottato su Twitter dai principali leader di partito italiani durante le prime due ondate della pandemia di Covid-19. Un modello di analisi a 2-step basato su sentiment emotion recognition (ER) e Analisi delle Corrispondenze, ha rilevato quali emozioni hanno caratterizzato il linguaggio politico e quali cambiamenti sono avvenuti tra le due ondate. I risultati hanno mostrato l'uso di un linguaggio con un forte peso emozionale per alcuni attori politici in opposizione ad altri che hanno utilizzato un registro del linguaggio politico neutro. Il confronto tra le due ondate ha denotato il passaggio dalla rabbia alla tristezza e paura per la Meloni e un distacco da Salvini preannunciando con l'ER la spaccatura del centro-destra.*

Key words: emotion recognition, sentiment analysis, political leadership, correspondence Analysis

1 Introduction

The health emergency of Covid-19 represented a breaker point in terms of stability both in private life of individuals and in public domain, creating vulnerability in social, economic and political field. In this phase marked by a general perception of disorientation, the communication has assumed a decisive role in order to inform the citizens about the evolution of the pandemic and to explain the governments' containment measures aimed at addressing the behaviors of national communities. In Italy, communication has been broadcast both through traditional media and by means of social media, which have become the main channels for disseminating information and sharing opinions. In fact, during the lockdown period, in Italy the use of social media grown by 30% (Comscore, 2020). Institutional communication and specifically political parties' leaders have also followed this trend, concentrating their activities of communication on social media which, above all on Twitter, have found a large space of narration and representation (Paolillo & Forciniti, 2021). The language of politics represents the language of power (Lasswell, 1979) as exercise of persuasion and with the progressive affirmation of *media logic* has generated the definition of two registers of political language: one didactic - argumentative and the other polemical (Cepernich & Novelli, 2018) based on a very strong *affective* dimension. The register of political language used by institutional actors contributed to affect the so-called *connected public culture* (Boccia Artieri, 2012) through the fragmentation of the public sphere.

In this paper, we propose the study of the political language adopted on Twitter by the main Italian parties' leaders during the first two waves of the first phase of Covid-19 by means of a 2-step analysis model which combines methods for semantic orientation and emotion classification with the multivariate approach of Correspondence Analysis. Our contribution considers the difference existing between sentiment and emotion, the need to go beyond the classification of positive - negative polarity to better understand the semantic aspect enclosed in a text. More specifically, emotions have a central role in political discourse (Huguet Cabot *et al.*, 2020). Therefore, the research aims to classify the political language adopted by Italian leaders through the emotion recognition and the factorial projection to assess if the emotional approach is useful to predict changes in the political positioning and to anticipate crises of government.

The paper explores four main research questions:

RQ1) Which emotions characterized the Italian politicians' language during the first and second waves of pandemic on Twitter?

RQ2) The emotions detected are useful to characterize the use of register didactic - argumentative or polemical?

RQ3) Were there changes in the emotions adopted by the political leaders between the first and second wave?

RQ4) Can the recognition of emotions about political language predicts the political positioning and crises of government?

To follow, section 2 presents data; section 3 describes the methodology used to reach the research questions; section 4 shows results and discussion.

2 Data

We extracted the text content released by each political actor on own official Twitter account to investigate the four research questions. Data extraction was performed using the open-source programming interface Twitter *API* and the *library rtweet* (Kearney, 2019). The official accounts of seven political figures whose hierarchy and popularity dominated the national scene during the first two pandemic waves: Silvio Berlusconi, Giuseppe Conte, Luigi Di Maio, Giorgia Meloni, Matteo Renzi, Matteo Salvini and Nicola Zingaretti have been followed and downloaded. Two temporal slots have been considered: the first wave, from first February to 30 May 2020, and the second one, from first September to 30 November 2020. The monitoring period represents the main media hype about the pandemic, where both citizens and politicians are living uncertainty and bewilderment. Data extraction in two separate periods determined that two different corpora were obtained, thus, each corpus represents a different case of analysis. During the first wave 32,551 tweets have been obtained and the greater number, about it 69.16% (*Table 1*), comes from Matteo Salvini. With the second wave, we extracted 47,094 tweets, recording also in this case the Salvini's leadership in terms of posting on Twitter (74.10%).

Table 1: Percentage of tweets produced by leaders during the first and second wave

	Percentage of tweets	
Leader	*First wave*	*Second wave*
Silvio Berlusconi	7.47%	5.31%
Giuseppe Conte	3.39%	2.19%
Luigi Di Maio	5.64%	2.99%
Giorgia Meloni	9.02%	9.97%
Matteo Renzi	1.57%	2.28%
Matteo Salvini	69.16%	74.10%
Nicola Zingaretti	3.75%	3.16%

3 Methodology

To study the political language used by party leaders during the first and second pandemic wave and to determine if there were changes between the two waves, we adopted a 2-step analysis model.

At first step, we used emotion classification algorithms for Italian language. The literature on sentiment analysis is greater developed in English language than others which instead suffer the lack of resources, but Italian represents an interest evolving field (e.g.; Nozza *et al.,* 2020; Bianchi *et al*., 2021). In fact, after we cleaned the texts from link, URLs, emoji and other special characters, we used UmBERTo, a recent Italian Language Model trained with Whole Word Masking trained on

Commoncrawl ITA, a large number of Italian corpora implemented by means of Facebook Research Artificial Intelligence codes (Ott *et al*., 2019) and annotated with four basic emotions (Ekman, 1992): anger, fear, joy, sadness. The datasets consist in corpora of Italian tweets in a broad topic and domain coverage - from football matches to politics - for emotion and sentiment classification able to predict sentiments and emotions in text by training prediction models. UmBERTo uses two innovative approaches: the first, called Sentence Piece Model (SPM) is a language-independent sub-word tokenizer which creates sub-word units specifically to the size of the vocabulary through neural-based text processing; the second, denominated Whole Word Masking (WWM) applies a mask to an entire word, if at least one of all tokens was originally chosen as mask, so to maintain the sub-words. The task of emotion classification used is fine-tune called UmBERTo-FT, which obtains the best results in terms of the overall performance metrics (e.g.; accuracy, precision, recall) (Bianchi *et al.,* 2021).

At the second step, we coded information coming from the emotion recognition (ER) in a contingency table $\mathbf{T}_{lxe}$ where l indicates the leaders and e denotes the categories of emotions. The generic element t_{le} presents the total value of emotion detected into tweets of each leader for each emotion category.
Finally, the table $\mathbf{T}_{lxe}$ has been analyzed by the Correspondence Analysis (CA) (Benzécri, 1973; Greenacre, 1984). The performing of CA on $\mathbf{T}_{lxe}$ allowed to observe the association between leaders and categories of emotions in order to describe which emotions better characterized their political language at the time of Covid-19. At the same time, this allowed to detect similarities among leader according to emotions of political language adopted on Twitter.
This 2-step analysis has been performed separately both for the first wave corpus and for that the second wave in order to intercept changes in political language between the two periods examined.

4 Results and discussion

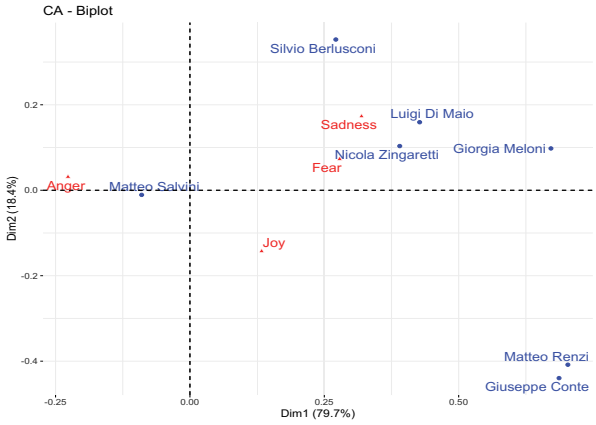
The CA map (*Figure 1*) shows the association between the leaders and the four categories of emotions (refers to Ekman, 1992) for the first pandemic wave. The factorial projection explains 77.3% of variance through the first dimension and 21.7% by means of the second dimension. We can observe the plane how split in four sections, each of which is characterized by a category of emotion ascribable to each leader. The emotional dimension can be interpreted by looking at the map from left to right. This interpretation makes it possible to determine a political language characterized by the shifting from anger to fear. More specifically, the exploratory analysis suggests that Silvio Berlusconi's political language was better represented by sadness; that adopted by Luigi di Maio and Nicola Zingaretti was instead imbued with fear; finally, Giorgia Meloni and Matteo Salvini's language were both associated to anger (RQ1).

These three association areas between political actors and emotions allowed to identify how the use of linguistic expressions with a strong emotional weight have a

central role in their political discourses, hence we can attribute to these leaders the use of register of political language very affective. However, we cannot ascribe any category of emotions to Matteo Renzi and Giuseppe Conte, thus we can find the use of a political language register that was not based on affective dimension during the first pandemic wave (RQ2).

Figure 1: Correspondence Analysis Map "leader by emotion" for the first wave

Figure 2: Correspondence Analysis Map "leader by emotion" for the second wave



The CA map referred to second pandemic wave (*Figure 2*) explains 79.7% of variance by means of the first dimension and 18.4% through the second dimension. On the horizontal axis, we affirm the transition from a political language based on anger to a language based on fear. In this case, we can intercept on the plane three sections which describe the emotions and political actors. More precisely, we observe the association between Luigi Di Maio, Nicola Zingaretti and Giorgia Meloni with emotions as fear and sadness; while Matteo Salvini's language remained characterized by anger (RQ1). No emotional category can be associated

with Matteo Renzi and Giuseppe Conte (RQ1), confirming a non-affective political language different from the other leaders mentioned above (RQ2).

Through the comparison between the CA maps of the first and second wave (*Figure 1* and *2*), it emerges a change in the political language, since in the *Figure 1* the language of Di Maio and Zingaretti was best characterized by fear, while in *Figure 2* we can see also sadness; as well as Meloni's language shifted from anger to sadness and fear. In fact, Meloni approached Di Maio and Zingaretti's language and moved away from Salvini. No change for Salvini, who remained characterized by anger, as well as Conte and Renzi that they are not associated with any category of emotions between the first and second wave (RQ3). ER in the political language adopted on Twitter between Meloni and Salvini in the second wave allowed to predict the rift and disaggregation of the right-wing coalition before the Draghi's government established in February 2021 (RQ4). An interesting aspect is the proximity between Conte and Renzi detected in the second wave, given that this last determined the Conte's government crisis. The first impression can indicate closeness in political strategic positioning as in the first wave. However, the map may show a different interpretation: the tactical outsider represented by Renzi, who based his language on emotionless register in the opposite to Meloni, Salvini, Zingaretti, to obtain consensus without polemics. Thus, in the second period, Renzi and Conte continued to use a similar neutral language but for different strategies.

What does your self-description reveal about you?

A pipeline to analyse StockTwits users

Cosa rivela di te la tua autodescrizione?

Una procedura per analizzare gli utenti di StockTwits

Riccardo Ricciardi

Abstract In this study, we propose a pipeline to analyse heterogeneity in self-descriptions for the users of StockTwits, a microblogging platform about the stock market. By combining word and document embeddings with clustering methods, we aim to study what textual self-descriptions can reveal about users' self-declared trading information. Preliminary results show that some patterns in texts reflect trading characteristics and encourage to explore the relation between textual and non textual self-description.

Abstract *In questo studio, si mostra una procedura per l'analisi dell'eterogeneità presente nelle autodescrizioni degli utenti di StockTwits, una piattaforma di microblogging sui mercati azionari. Combinando tecniche di word e document embedding con metodi di clustering, si propone di studiare il contenuto informativo delle descrizioni testuali riguardante le caratteristiche di trading autodichiarate dagli utenti. I risultati preliminari mostrano che talune informazioni sono estraibili dai documenti di testo, incoraggiando l'esplorazione della relazione tra autodescrizione testuale e non testuale.*

Key words: Natural Language Processing, Clustering, StockTwits, Self-Description

1 Introduction

Since the 2000s, the capacity of computer and information systems, and the proliferation of both social media and commercial applications have driven the development of *Natural Language Processing* (NLP). It is the field of study aiming at processing data created by *natural language*, that is language naturally developed by individuals belonging to the same social group [8].

Riccardo Ricciardi
Department of Economics and Management, University of Brescia, Via S. Faustino 74/b-25122 Brescia, Italy, e-mail: r.ricciardi@unibs.it

Since the coexistence of different groups of users on those platforms, recent studies have explored heterogeneity in language use and have showed how language understanding has to vary based on speaker's and writer's characteristics [1] [5].

Compared with the multitude of studies on other social media, such as Facebook, Twitter, and Reddit, few studies have applied NLP and statistical techniques to study the activity on the StockTwits (ST) social media platform.

ST was founded in 2009, to let investors, traders, and finance enthusiasts share their ideas about the stock market. ST is a microblogging platform: people's activity consists of posting messages, images, videos and similar content, also called *tweets*, and interacting with other users' content. Since the stock market is the central topic in ST, users usually tag their tweets with *bullish* or *bearish*, depending on their confidence in stock price rising. Thus, literature about ST have focused on exploiting the large volume of tweets on ST to predict the stock market behavior and for *sentiment analysis* [10] [14].

For the best of our knowledge, there is not any study leveraging self-descriptions and the other users' self-declared information to find patterns in groups of users.

In this respect, when people join ST, they are asked to complete their profile with personal information and information about their trading strategy. *Inter alia*, users may fill their profile with a *bio*, a short self-description with a maximum length of 250 characters, and the clarification of which kind of traders they are, according to their experience and their primary holding period.

This paper starts to explore users' bios and proposes a pipeline to capture what self-descriptions can reveal about users' trading characteristics.

For processing texts as data it is crucial the decision about the way of representing text documents. Before the spread of neural networks in NLP, the conventional approach was based on word frequencies: a document was represented as a vector composed of frequencies of words in that document [15]. Since these vectors are based on all the words in the available text corpus, this approach yields a high-dimensional and largely sparse document matrix, unable to capture the semantic relationships between words [12].

To solve these drawbacks, new methods were introduced. Based on the *distributional hypothesis* according to which "*a word is characterized by the company it keeps*" [4], researchers proposed to represent words with low-dimensional vectors, also known as *embeddings*, such that words appearing in similar contexts have similar vector representations [9] [11]. In particular, [9] proposed a method that leverages a simple and efficient neural network to obtain word vector representations as a by-product of a predictive task, and in a similar way, [7] introduced an approach to represent text documents in the same vector space. The latter technique is used in this study to train word and document embeddings.

Document embeddings can be used as input of clustering, and thus documents can be grouped through a similarity measure [6]. Several studies analysed clustering efficiency by mixing different document vectorization techniques and clustering algorithms [13] [3]. In particular, [13] highlighted that clustering algorithms benefit from low-dimensional representations of documents, whereas representations based on word frequencies suffer from the *curse of dimensionality*. In the pipeline

of the analysis proposed in this paper, we considered to compare the well-known *K-Means*, *K-Medoids* clustering and some their adaptations to find groups among documents [2] [6].

2 Data and methods

In this section, we describe the process of data extraction, filtering, and sampling, and moreover, the methodologies proposed to study the users' self-descriptions.

2.1 The data pipeline

Through the StockTwits's API[1], we accessed all the tweets from 2010 to 2021. In addition to the particular content and the interactions' records connected to it, each tweet keeps the information about the user; from it we extracted text documents and trading features for each user. First, we considered only users writing an English bio with a minimum length of 6 words. In this way, we obtained a filtered users database composed of about 25,000 people, i.e. 25,000 text documents.

Since we were interested in finding relationships between semantic groups and groups of users based on trading information, we considered users' information about trading to form groups of users. On the one hand, based on their experience, users define themselves as *novice*, *intermediate*, or *professional* traders. On the other hand, based on his/her primary holding period, i.e. the amount of time he/she usually holds stocks in portfolio, a user define themselves as *day trader*, *swing trader*, *position trader*, or *long term investor*. Finally, before fitting an NLP model on bios, we sampled 2,400 users from the database by balancing for trading experience and primary holding period.

2.2 Methods

After sampling, bios were preprocessed, by removing email addresses, URLs, symbols, and stopwords. The latter removal was obtained by using the well-know *Snowball* list of stopwords for English from the `stopwords` *R* package [2].

In this study we trained word and document vectors by using the *paragraph vector* model [7]. This model uses a feedforward neural network with one hidden layer to fully parameterise the word and document vectors. Thus, at the end of the learning process, each word w is described as a vector of the form:

[1] https://firestream-portal.stocktwits.com/

[2] https://cran.r-project.org/web/packages/stopwords/index.html

$$v(w) = (x_{w1}, x_{w2}, ..., x_{wp}) \tag{1}$$

and each document d as a vector of the form:

$$v(d) = (x_{d1}, x_{d2}, ..., x_{dp}) \tag{2}$$

where p is the dimension of the embedding.

To train these parameters, the network initialises them randomly, and then it adjusts them in the learning process whose objective is to maximise the conditional probability:

$$p(w_t | w_{t-\frac{s}{2}}, w_{t-\frac{s}{2}+1}, w_{t-\frac{s}{2}+2}, ..., w_{t+\frac{s}{2}-2}, w_{t+\frac{s}{2}-1}, w_{t+\frac{s}{2}}, d) \tag{3}$$

where w_t is the target word, $w_{t-\frac{s}{2}}, w_{t-\frac{s}{2}+1}, ..., w_{t+\frac{s}{2}-1}, w_{t+\frac{s}{2}}$ are the context words the occur around w_t with a window size of s, and d is the document in which all these words appear.

To find groups in document vectors we propose to compare the performance of *K-Means* and *K-Medoids* clustering, by using Euclidean distance and cosine dissimilarity, respectively, as measures of dissimilarity between documents; moreover, we propose *Spherical K-Means*, that lets us adapt *K-Means* to use the cosine dissimilarity, and *DBSCAN* clustering, in order to consider arbitrary shapes for clusters and the presence of outliers when partitioning objects.

Thus, in addition to internal validity measures for clustering, we propose to adopt an external validation on the entire pipeline, by using resampling methods to obtain new balanced samples.

3 Results and discussion

Here we describe the results of this exploratory analysis. In particular, we show here preliminary results about similarities among words and groups of documents, whereas in the near future we will show the results about document clustering, whose elaboration is in progress.

In Table 1 with respect to five different words, we illustrate the composition of the 10% most similar users by both trading experience and primary holding period, and, for the same terms, in Table 2, we illustrate the most similar words. Cosine similarity was used for this purpose.

First, for the terms *professional*, *intermediate*, and *novice*, among the 10% most similar bios, the majority is composed of users defining themselves as professional, intermediate, and novice traders, respectively. Moreover, we can see that moving from *professional* to *novice*, most similar words get far from the idea of ”success” and ”motivation”. In particular, *novice* is semantically close to contexts quite different from trading, like sports and hobbies.

It’s interesting to note that one of the most similar words for *professional* is *join*. Indeed, in many bios users invite people to join them either by following them on

ST or by clicking on their website and subscribing to their newsletter. It's quite expected that professionals spam their profile in their bios. Notice that users defining themselves as professionals can be either true professionals or not true professionals, but also bots.

In reference to the term *swing*, it is interesting to note how the most similar bios mostly come from day traders and swing traders, i.e. the kind of traders that usually holds stocks for short periods, from one day to one month. This kind of traders has to be always *active alert* on the *liquid* market, where there are large volume of operations, many agents, and low transaction costs.

Eventually, *planning* is mostly similar to bios written by long-term traders, and the most semantically similar word is *mortgage*, which is a long-term investment.

These preliminary results show that some patterns in bios can reflect group memberships, and so they encourage to explore the relation between language use in self-description and trading information. Future steps will cover both preprocessing steps and cluster analysis: on the one hand, words composed of more than one term, i.e. *bigram* and *trigram*, will be included; on the other hand, clustering results will be explored and resampling methods will be considered to validate the entire analysis pipeline.

Table 1 Trading groups' composition (%) of the 10% most similar bios with respect to five words in the vocabulary.

word	**10% most similar users**			
professional	**Intermediate**	**Novice**	**Professional**	
	12.9	24.6	62.5	
	Day Trader	**Long Term Trader**	**Position Trader**	**Swing Trader**
	23.3	22.1	12.5	42.1
intermediate	**Intermediate**	**Novice**	**Professional**	
	45.4	27.1	27.5	
	Day Trader	**Long Term Trader**	**Position Trader**	**Swing Trader**
	34.2	15.8	23.8	26.2
novice	**Intermediate**	**Novice**	**Professional**	
	32.1	54.6	13.3	
	Day Trader	**Long Term Trader**	**Position Trader**	**Swing Trader**
	24.2	25.8	28.3	21.7
swing	**Intermediate**	**Novice**	**Professional**	
	39.2	26.2	34.6	
	Day Trader	**Long Term Trader**	**Position Trader**	**Swing Trader**
	32.5	19.2	16.2	32.1
planning	**Intermediate**	**Novice**	**Professional**	
	37.9	36.7	25.4	
	Day Trader	**Long Term Trader**	**Position Trader**	**Swing Trader**
	20.8	36.7	27.1	15.4

Table 2 Most similar single terms and maximum similarity with respect to five different words in the vocabulary

word	Most similar words	Max similarity
professional	*join, succeed, recommended, advanced, executive, complex, improvement, seminars*	0.49
intermediate	*follower, constantly, basic, methodology, gap, mental, direction*	0.68
novice	*second, junkie, football, travel, hockey, reads, dogs, gamer, cooking*	0.52
swing	*wide, active, alert, day, liquid, profitable*	0.57
planning	*mortgage, concentration, junkie, enthusiast, pilot*	0.64

Variable selection and complete matrix approaches

A Statistical Approach for the Completion of Input-Output Tables

Un approccio statistico per il completamento delle matrici Input-Output

Rodolfo Metulini, Giorgio Gnecco, Francesco Biancalani and Massimo Riccaboni

Abstract The methodologies adopted by national statistical offices to collect data of within- and cross-country Input-Output (I/O) economic relations raises the issue of obtaining reliable data in a timely fashion, making the reconstruction of I/O tables of particular interest. In this work, we propose a method combining Hierarchical Clustering and Matrix Completion to impute missing entries of a partially unknown I/O matrix. Through a validation study based on World Input-Output Database as well as on synthetic matrices, we show the effectiveness of the proposed method to impute missing values from both previous years data and current data related to countries similar to the one for which current data are missing.

Abstract *Le metodologie adottate dagli uffici statistici nazionali per raccogliere i dati sulle relazioni economiche di Input-Output (I/O) pongono il problema di ottenere dati affidabili in modo tempestivo. La ricostruzione delle tabelle I/O risulta perciò di particolare interesse. Proponiamo un approccio statistico che combina clustering gerarchica e Matrix Completion allo scopo di imputare i dati mancanti di una matrice I/O. Attraverso uno studio di validazione basato su World Input-Output Database e matrici sintetiche, mostriamo l'efficacia del metodo proposto per imputare i valori mancanti utilizzando sia dati dello stesso paese negli anni precedenti sia dati dello stesso periodo relativi a paesi simili a quello che presenta dati mancanti.*

Key words: Matrix Completion, Hierarchical Clustering, missing data, LASSO-like Nuclear Norm Penalty.

1 Introduction

I/O tables portray flows of what is produced by some economic agents and consumed by other economic agents (either as intermediate or final consumption). Literature refers to the study of these flows with the term "Input-Output (I/O) analysis". Our work has to do with the completion of I/O matrices. The interest arises if one takes into account the aspects related to the methodology of data collection adopted by national statistical offices. Direct methods (e.g., surveys) lead to sampling errors. Moreover, to collect data in timely fashion, historical data are typically used to approximate the current ones [4]. Direct compilation of I/O tables also rely on administrative registers and sectorial reports. It follows that many different statistical sources are contrasted. This is a huge resources consuming operation, and the time gap between the publication of the data and its reference year is one of the reasons why also indirect methods exist [7]. In this work we propose to apply Matrix Completion (MC, [1]) to reconstruct part of an I/O table. Some studies highlighted the emergence of a clustering pattern among either countries or sectors [8]. Due to this reason, the I/O matrix might be well-approximated by a low-rank one. This low-rank property suggests, among other possible statistical techniques, the adoption of MC, which permits, through a choice of the regularization parameter, to select the number of non-zero singular values to be kept in the reconstructed matrix. Nevertheless, the application of MC to a full I/O table is not straightforward, as we found a complex structure characterized by sparsity and by a clear separation between i) large-to-large countries' values and small-to-small countries' ones, ii) within-country values and cross-country ones. This suggests performing a pre-processing step to restrict the application of MC to suitable groups of similar countries. We do so via a Hierarchical Clustering (HC, [5]) approach along with the use of Average Absolute Correlation Distance (AACD), highly related to the functioning of MC. The performance of our approach is validated in terms of the Root Mean Square Error (RMSE) - on a 5-year panel of I/O submatrices, where a known part of the matrix associated with a specific year has been artificially obscured. Results based on an application to real I/O tables, show the effectiveness of the proposed method to predict missing values in the current I/O matrix from both previous years data and current data related to similar countries. In contrast, the effectiveness reduces if similar countries are replaced by the ones belonging to quite different clusters.

2 Methods

MC is a statistical method used to predict unobserved entries of a matrix in terms of the set of the remaining observed entries. Given a matrix $\mathbf{M} \in \mathbb{R}^{m \times n}$, MC works by finding a suitable low-rank approximation of $\mathbf{M}$, by assuming the following model:

$$\mathbf{M} = \mathbf{C}\mathbf{G}^T + \mathbf{E}, \tag{1}$$

where $\mathbf{C} \in \mathbb{R}^{m\times r}$, $\mathbf{G} \in \mathbb{R}^{n\times r}$, whereas $\mathbf{E} \in \mathbb{R}^{m\times n}$ is a matrix of errors. We find the rank-r approximating matrix $\mathbf{C}\mathbf{G}^T$ by solving the following MC optimization problem based on a LASSO (Least Absolute Shrinkage and Selection Operator)-like nuclear norm penalty [2, 3]:

$$\underset{\hat{\mathbf{M}}\in\mathbb{R}^{m\times n}}{\text{minimize}} \left(\frac{1}{2} \sum_{(i,j)\in\Omega^{\text{tr}}} \left(M_{i,j} - \hat{M}_{i,j}\right)^2 + \lambda \|\hat{\mathbf{M}}\|_* \right), \tag{2}$$

where Ω^{tr} is a subset of pairs of indices (i, j) corresponding to positions of known entries of $\mathbf{M}$, $\hat{\mathbf{M}}$ is the matrix to be optimized, $\lambda \geq 0$ is a regularization constant, and $\|\hat{\mathbf{M}}\|_*$ is the nuclear norm of the matrix $\hat{\mathbf{M}}$. The regularization constant λ controls the trade-off between fitting the known entries of the matrix $\mathbf{M}$ and achieving a small nuclear norm. We solve equation (2) using the state-of-the-art "Soft Impute" algorithm [2]. We select λ by first randomly dividing the set of positions of unobserved entries of the matrix $\mathbf{M}$ into a validation set Ω^{val} (about 25% of the positions) and a test set Ω^{test} (the positions of the remaining entries)[1]. Then, the optimization problem is solved for several choices $\lambda_k \sim 2^{k/2-10}$, for $k = 1,\ldots,40$. Given

$$RMSE^{\text{s}}_{\lambda_k} := \sqrt{\frac{1}{|\Omega^{\text{s}}|} \sum_{(i,j)\in\Omega^{\text{s}}} \left(M_{i,j} - \hat{M}_{\lambda_k,i,j}\right)^2}, s = val, test, tr, \tag{3}$$

for each λ_k, RMSE of MC on the training set is computed, then the λ_k° that minimizes $RMSE^{\text{val}}_{\lambda_k}$ is found. The RMSE of MC on the test (and validation) set is then computed in correspondence of λ_k°. Clustering is used to find the groups of similar countries, for which the associated blocks of I/O tables are going to form matrix $\mathbf{M}$. We adopt a HC approach because alternative methods (e.g., k-means) require assumptions on the homoschedasticity, the spherical variance of the variables and clusters' dimension. HC performs well even when those assumptions are not satisfied. We use the Average Absolute Correlation Distance (AACD) because it is related to the formulation of the MC optimization problem, since it quantifies the average linear dependence of corresponding columns of blocks associated with different countries[2]. Given n and l to be the number of intermediate and final sectors,

$$AACD_{c_1,c_2} = 1 - \frac{\sum_{i=1}^{n+l} |corr(\mathbf{b}_i^{c_1}, \mathbf{b}_i^{c_2})|}{n+l} \tag{4}$$

is the complementary to 1 of the absolute correlation between the i-th columns $\mathbf{b}_i^{c_1}$ and $\mathbf{b}_i^{c_2}$ of $n \times (n+l)$ blocks associated with countries c_1 and c_2, averaged with respect to the columns. In our clustering step we compare any two countries c_1 and c_2 (except country c_h) in terms of what their $n+l$ sectors use from the n intermediate sectors of country c_h.

[1] The union of the validation and test sets corresponds to the positions of the artificially obscured entries (but available as a ground truth), the training set to the positions of the remaining entries.

[2] Moreover AACD, differently from the l_1 and l_2 norms, is not affected by country's dimension.

3 Application of clustering and matrix completion

We present an application of the proposed method based on World Input-Output Database (WIOD) release 2016 [6], considering 43 world countries and 61 sectors (56 intermediate, 5 finals) over the period 2000–2014. The main diagonal blocks (also called domestic blocks) are excluded, since they are characterized by much larger values than the other blocks and may cause troubles in the application of MC. To obtain groups of similar countries for the application of MC, simulations based on synthetic I/O tables have been performed to determine the proper number of clusters. Specifically, we present the case in which countries are grouped with respect to the similarity in terms of inputs from Italy. In doing so, we consider a 56×2562 matrix, where 56 is the number of italian industries and 2562 is the product of 61 industries and 42 countries (all except Italy), reporting all sectors' inputs from Italy to all other countries[3]. For the application of MC we consider groups of similar countries according to the dendrogram in Figure 1, in turn based on the HC performed on WIOD data and using the number of clusters as from the simulations. We start from WIOD tables relative to years 2010–2014 and we keep the information associated with a subset of countries (keeping only the off-main diagonal blocks). Then, for one of these pairs of countries, the information about the last year is obscured, and one tries to reconstruct it by MC. We consider a group of 4 similar countries (belonging to the same cluster, Austria, Belgium, Germany, and the Netherlands) and a group of 4 dissimilar ones (belonging to 4 different clusters, Australia, Belgium, Japan, and Malta). The MC algorithm is first applied

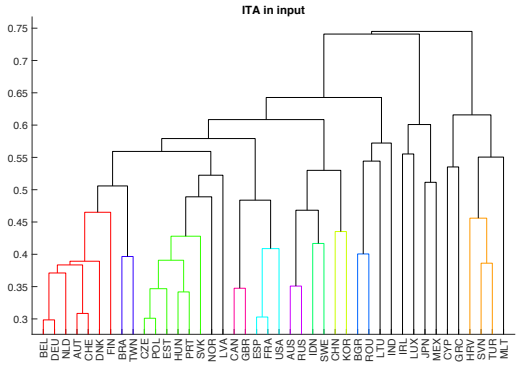

Fig. 1 Dendrogram of countries in terms of input from Italy, WIOD tables (years 2010–2013). HC with AACD (y-axis) and complete linkage. 21 desired groups. Countries in the same cluster are depicted with the same color. Countries in singleton clusters are highlighted in black.

[3] We perform HC with AACD and complete linkage on $N = 1000$ synthetic I/O matrices generated by adding normally distributed random terms ε to the WIOD submatrix above defined (where each element of the matrix $\varepsilon_{i,j} \sim \mathcal{N}(0, sd_\varepsilon), \forall i, \forall j$, sd_ε being a Gamma(1, 1) to obtain different levels of variability. We choose the optimal number of clusters to be the minimum number such that $\frac{WSS}{TSS} < 0.5$, WSS is the "Within-cluster sum of squares" and TSS is the "Total sum of squares".

to the submatrix of similar countries (top of Table 1), where the elements related to a specific output country in year 2014 (in bold) are obscured. To show a comparison of MC performance when dissimilar countries are considered, we also apply MC to the submatrix at the bottom of Table 1 (in bold the obscured part). As expected, the results show a better performance of the MC algorithm, measured in terms of the reduction of the RMSE on the validation set from the base case of $\lambda \simeq 0$ to the optimal choice of λ, in the case of similar countries.

4 Concluding remarks

This work represents the first attempt to adopt matrix completion combined with hierarchical clustering to forecast missing entries in I/O tables. The effectiveness

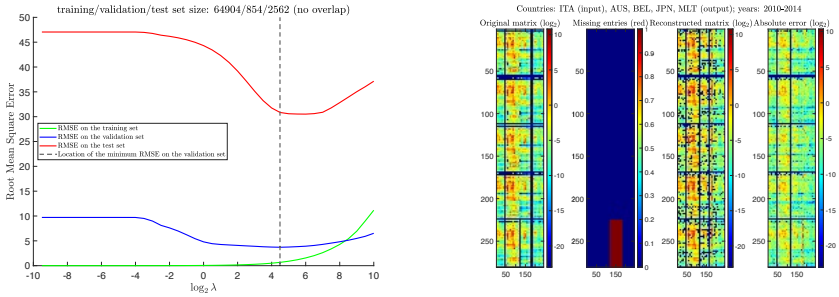

Fig. 3 RMSE results of MC for the WIOD submatrix in Table 1 (left); visualization of the original elements, positions of the missing entries, reconstruction obtained for the optimal regularization constant (RMSE criterion), and element-wise absolute value of the reconstruction error (right).

of the proposed method according to historical data available from previous years has been demonstrated for I/O subtables obtained by selecting similar countries. A first possible extension of the analysis concerns comparing matrix reconstruction of I/O tables based on the repeated application of matrix completion to several I/O subtables, instead of a single more computationally expensive and (presumably) less effective application to the whole table. Our approach could be compared with other imputation methods for missing entries in panel data models, which is left for future research.

On multivariate records over sequences of random vectors with Marshall-Olkin dependence of components

Record multivariati su successioni di vettori aleatori con dipendenza di tipo Marshall-Olkin

A. Khorrami Chokami and S. A. Padoan

Abstract Let us consider a sequence of independent and identically distributed random variables on the real line with a joint continuous distribution function F. The n-th random variable is called a record if it is greater than all the preceding ones. The stochastic behavior of the sequence of subsequent records is well known. Falk, Khorrami Chokami and Padoan (2018) considered multivariate records over sequences of random vectors with independent components, providing results on the arrival times process of the records. In this work, we study the case of records over sequences of random vectors where the dependence among their components is of the Marshall-Olkin type.

Abstract *Si consideri una successione di variabili aleatorie indipendenti e identicamente distribuite sulla retta reale, con distribuzione continua* F. *L'* n*-esima variabile aleatoria è detta record se è maggiore delle precedenti. La successione dei record nel caso univariato è stata ampiamente studiata in passato. Un'estensione al caso multivariato si ha in Falk, Khorrami Chokami e Padoan (2018), in cui vengono forniti risultati riguardanti il processo dei tempi d'arrivo di record multivariati su successioni di vettori aleatori indipendenti, con componenti indipendenti. In questo lavoro, invece, gli autori studiano i record multivariati su successioni di vettori aleatori indipendenti, ma con dipendenza fra le loro componenti di tipo Marshall-Olkin.*

Key words: Complete records, Marshall-Olkin dependence.

1 Introduction

Let us consider a sequence of independent and identically distributed (i.i.d.) random variables $X_1, X_2, \ldots$. The rv X_m is called a *record* if $X_m > \max(X_1, \ldots, X_{m-1})$, $m \geq 2$. Clearly, X_1 is a record. Records among a sequence of i.i.d. rv on the real line have been investigated extensively over the past decades, see [5, Sections 6.2 and 6.3] and [1]. It is, for example, well known that in the univariate case the indicator functions $I_m^{\mathrm{R}} = \mathbb{1}(X_m > \max(X_1, \ldots, X_{m-1}))$, $m \in \mathbb{N}$, are independent, see, e.g., [5, Lemma 6.3.3]. This implies in particular for integers $i \neq k$

$$\Pr(I_j^{\mathrm{R}} = 1, I_k^{\mathrm{R}} = 1) = \Pr(I_j^{\mathrm{R}} = 1) \Pr(I_k^{\mathrm{R}} = 1) = j^{-1}k^{-1}. \tag{1}$$

More recently, [2] found new results concerning records over sequences of random variables, in the novel framework of not knowing their position in the sequence of records. This new approach is adopted in [4] to address the problem of computing finite distributions of both single and joint records over stationary Gaussian processes.

Let $\boldsymbol{X}_1, \boldsymbol{X}_2, \ldots$ be i.i.d. random vectors (rv) in $\mathbb{R}^d$. Put for integers $j < k$

$$\boldsymbol{M}_j := \max_{1 \leq i \leq j} \boldsymbol{X}_i, \quad \boldsymbol{M}_j^k := \max_{j \leq i \leq k} \boldsymbol{X}_i,$$

where the maximum is taken componentwise. All our operations on vectors $\boldsymbol{x} = (x_1, \ldots, x_d)$, $\boldsymbol{y} = (y_1 \ldots, y_d)$, such as $\boldsymbol{x} < \boldsymbol{y}$, are meant componentwise.

Trying to generalize the concept of records to rv $\boldsymbol{X}_1, \boldsymbol{X}_2, \ldots$ in $\mathbb{R}^d$, the question which arises is how to define records in higher dimensions. Various definitions of records have been proposed in the past, see for example [6]. In this work, we consider the case of complete records: a rv $\boldsymbol{X}_m$ is a *complete* record if each component is a record itself, i.e., $\boldsymbol{X}_m > \boldsymbol{M}_{m-1}$.

Multivariate records have not been discussed that extensively, yet they have been approached by e. g. [7] or [1, Chapter 8]. For supplementary material on multivariate and functional records we refer to the thesis by [8].

We denote the event that $\boldsymbol{X}_m$ is a complete record by the indicator function $I_m^{\mathrm{CR}} := \mathbb{1}(\boldsymbol{X}_m > \boldsymbol{M}_{m-1})$. Results concerning complete records over sequences of random vectors with independent components can be found in [3].

This paper investigates, among others, the problem of which results for univariate records *do not* carry over to the multivariate case.

2 Marshall-Olkin

We have independence of record events in the univariate case and in the multivariate case with independent margins. One might conjecture that this is true, if we consider a convex combination of these two. The Marshall-Olkin standard max-stable distributions exactly provide this approach. When the elements of $\boldsymbol{X}$ are completely de-

pendent, then the probability that two joint records take place is equal to (1), while in the case the elements of $\boldsymbol{X}$ are independent we have

$$\Pr(I_j^{\mathrm{CR}} = 1, I_k^{\mathrm{CR}} = 1) = j^{-d}k^{-d}. \tag{2}$$

Therefore, one can conjecture that it also holds true when the elements of $\boldsymbol{X}$ are dependent. We show with a counter-example that this is not true. The relevant aspects of choosing the Marshall-Olkin copula lie in the fact that convex combinations of of complete dependence and independence structures represent a natural extension in exploring the properties of random vectors, and the parameter λ which rules the dependence is a flexible tool to have an idea on the role of the strength of the dependence. Moreover, as remarked in [1], the problem of studying records is the immediate difficulty of the necessary computations as soon as we move from the independence cases to better model the reality. The Marshall-Olkin distribution lets, not without complexities, to obtain exact formulas for complete records' occurrences, thus permitting comparisons with the known cases.

For simplicity assume $d = 2$. Suppose that $\boldsymbol{\eta}$ is a two-dimensional Marshall-Olkin distribution function:

$$\Pr(\boldsymbol{\eta} \leq \boldsymbol{x}) = \exp\left(-\{\lambda \left\|\boldsymbol{x}\right\|_\infty + (1-\lambda)\left\|\boldsymbol{x}\right\|_1\}\right), \qquad \boldsymbol{x} \leq \boldsymbol{0} \in \mathbb{R}^2, \tag{3}$$

where $\lambda \in [0,1]$ is a dependence parameter. The components of $\boldsymbol{\eta}$ are completely dependent when $\lambda = 1$, while they are independent when $\lambda = 0$.

Theorem 1. *Let $\boldsymbol{\eta}_1, \boldsymbol{\eta}_2, \ldots$ be i.i.d. rv with distribution function* (3)*. Then,*

$$\Pr(I_n^{CR} = 1) = \frac{1}{n(2-\lambda)}\left(\frac{2(1-\lambda)}{n} + \lambda\right) \tag{4}$$

and

$$\Pr(I_{j,k}^{CR} = 1) = \frac{1}{j^2k(2-\lambda)}\left(\frac{2(1-\lambda)}{k(2-\lambda)}\frac{(2-\lambda)k + (2-\lambda)(1-\lambda)j - \lambda(1-j)k}{k+(1-\lambda)j} + \lambda(2(1-\lambda)+j\lambda)\right). \tag{5}$$

Remark 1. When $\lambda = 0$ equation (5) becomes

$$\Pr(I_{j,k}^{\mathrm{CR}} = 1) = \frac{1}{j^2k^2},$$

while

$$\Pr(I_{j,k}^{\mathrm{CR}} = 1) = \frac{1}{jk},$$

when $\lambda = 1$, as expected.

Now, note that

$$\Pr(I_j^{\mathrm{CR}}=1)\Pr(I_k^{\mathrm{CR}}=1)=\frac{1}{jk(2-\lambda)^2}\left(\frac{2(1-\lambda)}{j}+\lambda\right)\left(\frac{2(1-\lambda)}{k}+\lambda\right)$$

and from this and (5) we have

$$\begin{aligned}&\Pr(I_{j,k}^{\mathrm{CR}}=1)-\Pr(I_j^{\mathrm{CR}}=1)\Pr(I_k^{\mathrm{CR}}=1)\\&=\frac{(\lambda-1)\lambda(k^2(\lambda(j-2)+2)-(\lambda-1)jk(\lambda(j-2)+2)+2(\lambda-1)(j-1)j)}{(\lambda-2)^2j^2k^2((\lambda-1)j-k)}\end{aligned}$$

and therefore the events $(I_j^{\mathrm{CR}}=1)$ and $(I_k^{\mathrm{CR}}=1)$ are not independent.

Proof (Theorem 1).

$$\begin{aligned}\Pr(I_n^{\mathrm{CR}}=1)&=\Pr(\boldsymbol{\eta}_n>\boldsymbol{M}_{n-1})=\int_{(-\infty,0]^2}\Pr(\boldsymbol{\eta}<(n-1)\boldsymbol{x})\mathrm{d}\Pr_{\boldsymbol{\eta}}(\boldsymbol{x})\\&=\int_{-\infty}^{0}\int_{-\infty}^{x_2}(1-\lambda)\,\mathrm{e}^{n(x_1+(1-\lambda)x_2)}\,\mathrm{d}x_1\mathrm{d}x_2\\&+\int_{-\infty}^{0}\int_{x_2}^{0}(1-\lambda)\,\mathrm{e}^{n(x_2+(1-\lambda)x_1)}\,\mathrm{d}x_1\mathrm{d}x_2\\&+\int_{-\infty}^{0}\lambda\,\mathrm{e}^{n(2-\lambda)x}\,\mathrm{d}x\\&=\frac{1-\lambda}{2-\lambda}\frac{1}{n^2}+\frac{1}{n^2}-\frac{1}{2-\lambda}\frac{1}{n^2}+\frac{\lambda}{2-\lambda}\frac{1}{n}.\end{aligned}$$

For what concerns the probability of the joint events we have

$$\begin{aligned}\Pr(I_j^{\mathrm{CR}}=1,I_k^{\mathrm{CR}}=1)&=\Pr(\boldsymbol{\eta}_j>\boldsymbol{M}_{j-1},\boldsymbol{\eta}_k>\boldsymbol{M}_{k-1})\\&=\Pr\left(\boldsymbol{\eta}_j>\frac{\boldsymbol{\eta}_1}{j-1},\boldsymbol{\eta}_k>\max\left(\boldsymbol{\eta}_j,\frac{\boldsymbol{\eta}_2}{k-j-1}\right)\right)\\&=\int_{(-\infty,0]^d}\int_{(-\infty,\boldsymbol{y}]}\Pr\left(\boldsymbol{\eta}_1<(j-1)\boldsymbol{x},\boldsymbol{\eta}_2<(k-j-1)\boldsymbol{y}\right)\mathrm{d}\Pr_{\boldsymbol{\eta}}(\boldsymbol{x})\mathrm{d}\Pr_{\boldsymbol{\eta}}(\boldsymbol{y})\\&=\int_{(-\infty,0]^2}\int_{(-\infty,\boldsymbol{y}]}\mathrm{e}^{(j-1)\|\boldsymbol{x}\|_\lambda+(k-j-1)\|\boldsymbol{y}\|_\lambda}\,\mathrm{d}\Pr_{\boldsymbol{\eta}}(\boldsymbol{x})\mathrm{d}\Pr_{\boldsymbol{\eta}}(\boldsymbol{y})\\&=\int_{-\infty}^{0}\int_{-\infty}^{y_1}\mathrm{e}^{(k-j-1)\|\boldsymbol{y}\|_\lambda}\,I(\boldsymbol{y})\mathrm{d}\Pr_{\boldsymbol{\eta}}(\boldsymbol{y})+\int_{-\infty}^{0}\int_{-\infty}^{y_2}\mathrm{e}^{(k-j-1)\|\boldsymbol{y}\|_\lambda}\,I(\boldsymbol{y})\mathrm{d}\Pr_{\boldsymbol{\eta}}(\boldsymbol{y})\\&+\int_{-\infty}^{0}\mathrm{e}^{(k-j-1)\|\boldsymbol{y}\|_\lambda}\,I(\boldsymbol{y})\mathrm{d}\Pr_{\boldsymbol{\eta}(\boldsymbol{y})}=I_1+I_2+I_3,\end{aligned}$$

where

$$I(\boldsymbol{y})=\int_{(-\infty,\boldsymbol{y}]}\mathrm{e}^{(j-1)\|\boldsymbol{x}\|_\lambda}\,\mathrm{d}\Pr_{\boldsymbol{\eta}}(\boldsymbol{x}).$$

Computation of I_1. In the case $y_1<y_2$, we have

$$I(\boldsymbol{y}) = \int_{-\infty}^{y_1}\int_{x_1}^{y_2}(1-\lambda)\,\mathrm{e}^{j(x_1+(1-\lambda)x_2)}\,\mathrm{d}x_2\mathrm{d}x_1 + \int_{-\infty}^{y_1}\int_{-\infty}^{x_1}(1-\lambda)\,\mathrm{e}^{j(x_2+(1-\lambda)x_1)}\,\mathrm{d}x_2\mathrm{d}x_1$$
$$+ \int_{-\infty}^{y_1}\lambda\,\mathrm{e}^{j(2-\lambda)}\,\mathrm{d}x = I_{1,1}+I_{1,2}+I_{1,3}.$$

Integrals $I_{1,1}$, $I_{1,2}$ and $I_{1,3}$ are equal to

$$I_{1,1} = (1-\lambda)\int_{-\infty}^{y_1}\mathrm{e}^{jx_1}\,\frac{e^{j(1-\lambda)y_2}-\mathrm{e}^{j(1-\lambda)x_1}}{j(1-\lambda)}\mathrm{d}x_1 = \frac{1}{j}\left(\mathrm{e}^{j(1-\lambda)y_2}\,\frac{\mathrm{e}^{jy_1}}{j} - \frac{\mathrm{e}^{j(2-\lambda)y_1}}{j(2-\lambda)}\right),$$
$$I_{1,2} = (1-\lambda)\int_{-\infty}^{y_1}\mathrm{e}^{j(1-\lambda)x_1}\,\frac{\mathrm{e}^{j\lambda x_1}}{j}\mathrm{d}x_1 = \frac{1-\lambda}{j^2}\,\frac{\mathrm{e}^{j(2-\lambda)y_1}}{j(2-\lambda)}$$
$$I_{1,3} = \lambda\,\frac{\mathrm{e}^{j(2-\lambda)y_1}}{j(2-\lambda)}.$$

Therefore,

$$I_1 = \int_{-\infty}^{0}\int_{-\infty}^{y_1}\frac{1}{j^2}\,\mathrm{e}^{j(y_1+(1-\lambda)y_2)} - \frac{1-j}{j^2(2-\lambda)}\lambda\,\mathrm{e}^{j(2-\lambda)y_1}\,\mathrm{e}^{(k-j)(y_1+(1-\lambda)y_2}\,\mathrm{d}y_1\mathrm{d}y_2$$
$$= \frac{1-\lambda}{j^2}\int_{-\infty}^{0}\mathrm{e}^{k(1-\lambda)y_2}\,\frac{\mathrm{e}^{ky_2}}{k} - \frac{\lambda}{2-\lambda}\,\frac{1-j}{k+(1-\lambda)j}\,\mathrm{e}^{(2-\lambda)k}\,\mathrm{d}y_2$$
$$= \frac{1-\lambda}{(2-\lambda)^2}\,\frac{1}{j^2k^2}\,\frac{(2-\lambda)k+(2-\lambda)(1-\lambda)j-\lambda(1-j)k}{k+(1-\lambda)j}.$$

The computation for I_2 is similar to that of I_1 and we obtain $I_2 = I_1$.

Computation of I_3. In the case $y_1 = y_2$, we have

$$I(\boldsymbol{y}) = 2\int_{-\infty}^{y}\int_{-\infty}^{x_2}(1-\lambda)\,\mathrm{e}^{j(x_1+(1-\lambda)x_2)}\,\mathrm{d}x_1\mathrm{d}x_2 + \int_{-\infty}^{y}\lambda\,\mathrm{e}^{j(2-\lambda)}\,\mathrm{d}x$$
$$= 2\frac{1-\lambda}{j^2(2-\lambda)}\,\mathrm{e}^{j(2-\lambda)y} + \lambda\,\frac{\mathrm{e}^{j(2-\lambda)y}}{j(2-\lambda)} = 2\frac{1-(1-j)\lambda}{j^2(2-\lambda)}\,\mathrm{e}^{j(2-\lambda)y}.$$

Therefore,

$$I_3 = \int_{-\infty}^{0}\lambda\left(2\frac{1-\lambda}{j^2(2-\lambda)} + \frac{\lambda}{j(2-\lambda)}\right)\mathrm{e}^{k(2-\lambda)}\,\mathrm{d}x = \lambda\,\frac{2(1-\lambda)+\lambda j}{(2-\lambda)}\,\frac{1}{j^2k}.$$

Finally

$$\Pr(I_j^{\mathrm{CR}} = 1, I_k^{\mathrm{CR}} = 1) = 2I_1 + I_3.$$

It is still an open question how to show this result for a sequence $\boldsymbol{\eta}_1,\ldots,\boldsymbol{\eta}_n$, without assuming a specific dependence form.

Note that from the previous formulas we can deduce $\Pr(I_n^{\mathrm{CR}} = 1\,i.o.)$:

- Case $\lambda = 1$. Since the I_n^{R}'s are independent and $\sum_{n=2}^{\infty}\frac{1}{n} = \infty$, then

$$\Pr(I_n^{\mathrm{CR}} = 1\,i.o.) = 1$$

by the second Borel-Cantelli Lemma;

- Case $\lambda = 0$. Since the I_n^{CR}'s are independent and $\sum_{n=2}^{\infty} \frac{1}{n^d} < \infty$ if $d > 1$, then

$$\Pr(I_n^{\mathrm{CR}} = 1\, i.o.) = 0$$

by the first Borel-Cantelli Lemma,

- Case $\lambda \in (0,1)$. Call $N = \sum_{n=2}^{\infty} I_n^{\mathrm{CR}}$, then

$$\mathrm{e}[N] = \sum_{n=2}^{\infty} \mathrm{e}[I_n^{\mathrm{CR}}] = \sum_{n=2}^{\infty} \Pr(I_n^{\mathrm{CR}} = 1) = \sum_{n=0}^{\infty} 2\frac{1-\lambda}{2-\lambda}\frac{1}{n^2} + \frac{\lambda}{2-\lambda}\frac{1}{n} = \infty.$$

These results are consistent with Theorem 5.3 in [6].

3 Conclusions

Despite the detailed study on records over independent sequences of random variables, the literature in the multivariate setting suffers of non extensive discussions. This is mainly due to two aspects: the first one concerns the various definitions of records which can be given over sequences of random vectors, the second one is the extreme complexity of the problem as soon as dependence between components of random vectors is taken into account. The Marshall-Olkin distribution is a handy tool to explore multivariate records where dependence is present, and represents the first step to consider to have an idea of which results are not true anymore in such cases. The main goal would be that of finding closed formulas for both the joint complete records occurrences and distribution without imposing defined dependence structures: this still represents an open question.

The Joint Censored Gaussian Graphical Lasso Model

Inferenza penalizzata del modello grafico Gaussiano congiunto

Gianluca Sottile, Luigi Augugliaro and Veronica Vinciotti

Abstract The Gaussian graphical model is one of the most used tools for inferring genetic networks. Nowadays, the data are often collected from different sources or under different biological conditions, resulting in heterogeneous datasets that exhibit a dependency structure that varies across groups. The complex structure of these data is typically recovered using regularized inferential procedures that use two penalties, one that encourages sparsity within each graph and the other that encourages common structures among the different groups. To this date, these approaches have not been developed for handling the case of censored data. However, these data are often generated by gene expression technologies such as RT-qPCR experiments. In this paper, we fill this gap and propose an extension of joint Gaussian graphical modelling to account for censored, or more generally missing, data.

Abstract *Il modello grafico Gaussiano è uno degli stimatori più utilizzati per fare inferenza sulle reti genetiche. Al giorno d'oggi, i dati raccolti sono spesso generati da diverse fonti o da diverse condizioni biologiche, risultando in dataset eterogenei, la cui struttura complessa viene analizzata utilizzando stimatori con due penalizzazioni per incoraggiare, da un lato, la sparsità all'interno di ciascun grafo e, dall'altro, le strutture comuni tra i grafi. Tuttavia, in diversi campi applicativi i limiti degli strumenti di rilevazione ne rendono teoricamente ingiustificato l'utilizzo, anche quando l'assunzione relativa alla distribuzione normale multivariata è soddisfatta. In questo articolo proponiamo un'estensione ai dati censurati.*

1 Introduction

Recently, sparse inference of Gaussian Graphical Models (GGMs) defined in a high-dimensional setting has received intense development. Given the assumption of independent and identically distributed data, a penalized estimator of a GGM is the maximizer of a specific objective function where the log-likelihood function is compensated by a sparsity inducing penalty function that controls the amount of shrinkage on the resulting estimators. The estimator proposed in Yuan and Lin (2007), called graphical lasso (glasso), uses a lasso-type penalty function and has been extensively used in applied research and well studied in the computational as well as theoretical literature (e.g. Friedman et al., 2008). The interested reader is referred to Augugliaro et al. (2016) for an extensive review.

Despite a widespread literature on the glasso estimator, the assumption of independent and identically distributed data has heavily reduced its application to modern datasets, which are often generated by more complex sampling schemes. A typical example of complex data structures is the case of data collected from different sources, such as gene expression data measured on multiple tissues. In this setting, sparse inference is typically carried out by using two specific penalty functions. These are chosen to encourage, on the one hand, sparsity within each graph and, on the other hand, the common structures across the graphs.

In this paper, we extend the estimator proposed in Danaher et al. (2014), called joint glasso (jglasso), to the setting studied in Augugliaro et al. (2020). That is, we consider the case where a part of the data is unobserved due to a known censoring mechanism. Gene expression measured by transcription quantitative polymerase chain reaction (RT-qPCR) is a well-known example of highly dimensional right-censored data.

The remaining part of this paper is structured as follows. Section 2 briefly reviews the inference of GGMs under censoring, while Section 3 proposes an extension of the jglasso estimator to the setting of multiple conditions. Computational aspects are addressed in Section 4 whereas in Section 5 we evaluate the performance of the proposed estimator by a simulation study. Finally, in Section 6 we draw some conclusions.

2 Background on censored Gaussian Graphical Models

Suppose that a p-dimensional random vector, say $\boldsymbol{Z} = (Z_1, \ldots, Z_p)^\top$, is distributed according to a multivariate Gaussian density function denoted by:

$$\phi(\boldsymbol{z}; \boldsymbol{\mu}, \Theta) = (2\pi)^{-\frac{p}{2}} |\Theta|^{\frac{1}{2}} \exp\left\{ -\frac{1}{2} (\boldsymbol{z} - \boldsymbol{\mu})^\top \Theta (\boldsymbol{z} - \boldsymbol{\mu}) \right\},$$

where $E(\boldsymbol{Z}) = \boldsymbol{\mu}$ and $\Theta = (\theta_{ij})$ is the precision matrix, that is, the inverse of the covariance matrix. Now, let $\boldsymbol{z} = (z_1, \ldots, z_p)^\top$ be a realization of $\boldsymbol{Z}$ and assume that a part of this vector is censored. Thus, $\boldsymbol{z}$ can be split into $\boldsymbol{z}^o$ and $\boldsymbol{z}^c$, i.e., the observed

and unobserved part of $\boldsymbol{z}$, respectively. Denoting by l_j and u_j the lower and upper censoring values of Z_j, respectively, it is easy to show that the probability density function can be written as follows (see Augugliaro et al. (2020) for more details):

$$\widetilde{\phi}(\boldsymbol{z}^o;\boldsymbol{\mu},\Theta) = \int_D^c \phi(\boldsymbol{z}^o,\boldsymbol{z}^c;\boldsymbol{\mu},\Theta)\mathrm{d}\boldsymbol{z}^c, \tag{1}$$

where the integral refers only to the variables whose index belongs to the set $c = \{j : z_j \text{ is censored}\}$, whereas the region of integration D is the Cartesian product of $|c|$ intervals, denoted by D_j, whose definition depends on whether z_j is left or right censored. Formally, $D_j = (-\infty, l_j)$ if $z_j \leq l_j$ otherwise we let $D_j = (u_j, +\infty)$.

Using (1), a censored GGM is the set $\{\widetilde{\phi}(\boldsymbol{z}^o;\boldsymbol{\mu},\Theta),\mathscr{G}\}$, where $\mathscr{G} = \{\mathscr{V},\mathscr{E}\}$ is the undirected graph encoding the conditional independences among the p random variables. More specifically, $\mathscr{V}$ is the set of nodes associated with the random variables, and $\mathscr{E}$ is the subset of the Cartesian product $\mathscr{V} \times \mathscr{V}$, such that $(i,j) \notin \mathscr{E}$ iff Z_i and Z_j are stochastically independent given all the remaining variables. As shown in Lauritzen (1996), the topological structure of the graph $\mathscr{G}$ is related to the entries of the precision matrix Θ, i.e., $(i,j) \in \mathscr{E}$ iff $\theta_{ij} \neq 0$, thus the problem of estimating $\mathscr{E}$ is equivalent to the problem of fitting a sparse precision matrix.

3 Sparse estimation of multiple GGMs with censored data

Suppose that n observations are collected from $K \geq 2$ different but related subpopulations, under a censoring mechanism and assuming a GGM for each subpopulation. To simplify our notation, all quantities related to the kth population are indexed by k. For instance, the kth censored GGM is denoted by $\{\widetilde{\phi}(\boldsymbol{z}_k^o;\boldsymbol{\mu}_k,\Theta_k),\mathscr{G}_k\}$. Under the assumption of independent sampling, the average observed log-likelihood function is

$$\bar{\ell}(\{\boldsymbol{\mu}\},\{\Theta\}) = \frac{1}{n}\sum_{k=1}^{K}\sum_{i=1}^{n_k}\log\int_{D_{i,k}}^{c_{i,k}} \phi(\boldsymbol{z}_{i,k}^o,\boldsymbol{z}_{i,k}^c;\boldsymbol{\mu}_k,\Theta_k)\mathrm{d}\boldsymbol{z}_{i,k}^c, \tag{2}$$

where $\{\boldsymbol{\mu}\} = \{\boldsymbol{\mu}_1,\ldots,\boldsymbol{\mu}_K\}$ and $\{\Theta\} = \{\Theta_1,\ldots,\Theta_K\}$. Maximum likelihood estimators are found by maximizing equation (2). However, these estimators have a very high variance when the sample sizes n_k are larger but close to p. Thus, to overcome the inferential problems related with the high-dimensional setting, we propose to extend the jglasso estimator of Danaher et al. (2014), by replacing the log-likelihood function with the function (2). The resulting estimator, that we call censored jglasso, is formally defined as follows:

$$(\{\widehat{\boldsymbol{\mu}}\},\{\widehat{\Theta}\}) = \arg\max \bar{\ell}(\{\boldsymbol{\mu}\},\{\Theta\}) - \rho\left(\alpha\sum_{k=1}^{K}\|\Theta_k\| + (1-\alpha)P(\{\Theta\})\right), \tag{3}$$

where $\alpha \in [0,1]$ is a tuning parameter that controls the trade-off between two convex penalty functions, where the first one is a lasso-type penalty function that encourages sparsity within each estimated precision matrix, while the second one $P(\{\Theta\})$ is chosen to encourage some form of similarity across the K graphs. Following Danaher et al. (2014), two possible choices are:

$$P_F(\{\Theta\}) = \sum_{k<k'} |\theta_{ij,k} - \theta_{ij,k'}| \quad \text{or} \quad P_G(\{\Theta\}) = \sum_{i \neq j} \left(\sum_{k=1}^{K} \theta_{ij,k} \right)^{1/2}.$$

The censored fused glasso (cfglasso) estimator is defined by solving problem (3) with $P_F(\{\Theta\})$ as the second penalty function whereas, using $P_G(\{\Theta\})$, we get the censored group glasso (cgglasso) estimator. Like the standard glasso, both estimators result in sparse precision matrices. However while cfglasso encourages a stronger form of similarity between the precision matrices, enforcing some entries of $\widehat{\Theta}_1, \ldots, \widehat{\Theta}_K$ to be identical, $P_G(\{\Theta\})$ encourages only a shared pattern of sparsity. Finally, the positive tuning parameter ρ controls the overall amount of shrinkage on the resulting estimators.

4 Computational Aspects

The estimator (3) can be efficiently solved by combining the penalized EM algorithm proposed in Augugliaro et al. (2020) with the alternating directions method of multipliers (ADMM) algorithm developed in Danaher et al. (2014).

The EM algorithm is based on the idea of repeating two steps until a convergence criterion is met. Since the multivariate Gaussian distribution belongs to the exponential family, the first step, called E-Step, simply requires the computation of the conditional expected values of the sufficient statistics. In our model, the E-Step requires the computation of the K imputed vectors of empirical means, denoted by $\bar{\boldsymbol{x}}_k$, along with the empirical covariance matrices $\boldsymbol{S}_k$ (see Augugliaro et al. (2020) for more details). In the second step of the EM algorithm, the M-Step, we first update the current estimates of the K expected values using $\bar{\boldsymbol{x}}_k$, and then the precision matrices are updated by solving the following maximization problem:

$$\max_{\{\Theta\}} \sum_{k=1}^{K} \frac{f_k}{2} \{\log|\Theta_k| - \operatorname{tr}(S_k\Theta_k)\} - \rho \left(\alpha \sum_{k=1}^{K} \|\Theta_k\| + (1-\alpha) P(\{\Theta\}) \right), \quad (4)$$

where $f_k = n_k/n$. The maximization problem (4) is equivalent to the problem studied in Danaher et al. (2014) and can be easily solved using the ADMM algorithm.

5 A Simulation Study

In this section, we compare our proposed estimator with jglasso (Danaher et al., 2014). For the latter, we use the R package `JGL` after imputing the censored data

with their limit of detection. The estimators are evaluated both in terms of recovery of the true graph (area under the precision-recall curve) and estimation of the true precision matrix (mean squared error). We set the right-censoring value to 40, the number of groups K to 3, and the sample size n_k to 100. Each right-censored response vector $\boldsymbol{z}_k$ is simulated according to sparse concentration matrices as reported in Fig. 1. The diagonal entries are fixed to 1 while the non-zero partial correlation coefficients $\theta_{h(h+j),k}$, with $h = 1, 6, 11, \ldots, p-4$ and $j = 1, \ldots, 4$, are sampled from a uniform distribution on the interval $[0.30, 0.50]$. In terms of graph theory what we have is a set of stars, i.e., complete bipartite graphs with only one internal vertex and four leaves. The values of the expected means are chosen in such a way that M

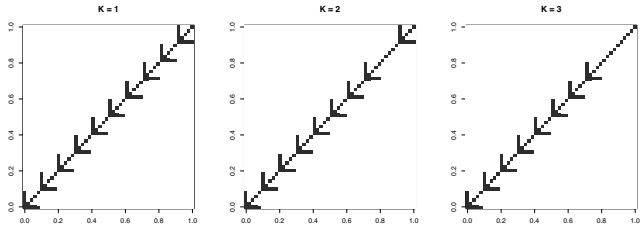

Fig. 1 True graph structure for the $K = 3$ concentration matrices

response variables are right-censored with probability equal to 0.40. The quantities p and M are used to specify the different scenarios used to analyze the behavior of the proposed estimators. In particular, we consider the following cases:

- **Scenario 1:** $p = 50$ and $M = 20$. This setting is used to evaluate the effects of the number of censored variables on the behavior of the estimators when $n > p$.
- **Scenario 2:** $p = 200$ and $M = 80$. This setting is used to evaluate the impact of the high dimensionality on the estimators ($p > n$).

For each scenario, we simulate 50 samples and in each simulation, we compute the coefficient path of cglasso and jglasso, respectively, using the group lasso penalty in both cases. The path is computed using an equally spaced sequence of ρ-values keeping the α parameter equal to 0.50. For each Scenario and along the path of ρ values, the precision-recall curves and the area under these curves (AUC) are computed and then averaged between the K groups. The curves report the relationship between precision and recall for any ρ-value, which are defined as:

$$\text{Precision} = \frac{1}{K}\sum_k \left\{ \frac{\text{TP}}{\text{TP} + \text{FP}} \right\}_k, \quad \text{Recall} = \frac{1}{K}\sum_k \left\{ \frac{\text{TP}}{\text{TP} + \text{FN}} \right\}_k,$$

where TP, FP, and FN are given by the number of correctly selected edges, the number of wrongly selected edges and the number of wrongly selected missing edges, respectively. Table 1 shows how cgglasso gives a better estimate of the concentra-

tion matrices in terms of AUC and a lower mean squared error, for any given value of ρ. We report only five evenly spaced values of ρ.

Table 1 The first 5 columns refer to the average mean squared error of the concentration matrices $\boldsymbol{\Theta}$ for five evenly spaced values of ρ under the specification of the two Scenarios. The last column refers to the mean area under the curves across the sequence of ρ-values. Standard errors are reported in brackets.

	$\rho/\rho_{\max}$					AUC
	0.10	0.25	0.50	0.75	1.00	
Scenario 1						
cgglasso	4.65 (0.54)	8.06 (1.37)	12.10 (3.18)	12.92 (3.82)	12.81 (3.83)	0.97 (0.01)
jglasso	10.19 (1.46)	13.67 (0.94)	16.56 (0.93)	16.84 (1.51)	16.76 (1.57)	0.83 (0.02)
Scenario 2						
cgglasso	17.65 (2.37)	34.85 (4.71)	52.84 (10.72)	55.18 (12.38)	54.65 (12.26)	0.96 (0.01)
jglasso	45.32 (10.09)	62.55 (9.16)	75.53 (4.94)	75.50 (2.65)	75.32 (2.56)	0.81 (0.01)

6 Conclusion

In this paper, we have proposed an extension of the joint glasso estimator to multivariate censored data generated under multiple conditions. A simulation study showed that the proposed estimator performs better than the existing estimators both in terms of parameter estimation and of network recovery.

Variable selection with unbiased estimation: the CDF penalty

Selezione delle variabili con stima non distorta: la penalizzazione CDF

Daniele Cuntrera, Vito M.R. Muggeo, Luigi Augugliaro

Abstract We propose a new SCAD-type penalty in general regression models. The new penalty can be considered a competitor of the LASSO, SCAD or MCP penalties, as it guarantees sparse variable selection, i.e., null regression coefficient estimates, while attenuating bias for the non-null estimates. In this work, the method is discussed, and some comparisons are presented.

Abstract *Proponiamo una nuova penalizzazione di tipo SCAD per modelli di regressione. La nuova penalizzazione può essere considerata un concorrente delle penalità LASSO, SCAD o MCP in quanto garantisce la selezione di variabili, cioè stime dei coefficienti di regressione esattamente nulle, mentre attenua la distorsione per le stime non nulle. In questo lavoro viene discussa la metodologia e vengono presentati alcuni confronti.*

1 Introduction

Variable selection is an essential issue in regression modelling. Nowadays, data collection can involve several hundred or even thousands of variables. Therefore, spotting noise and significant covariates is a major concern when studying the effect

on the response variable of interest. Out of the many existing variable selection techniques, including all-possible-regressions (Garside, 1965) or stepwise selection (Efroymson, 1996), L_1-penalized regression is one of the most widely used. In particular, the LASSO penalty (Tibshirani, 1996) is probably the most prominent and widespread approach in applications (Wu et al., 2009; Li et al., 2011; Lu et al., 2011). Unfortunately, in LASSO regression, the selected coefficients suffer from important bias. Therefore some alternatives have been proposed, notably: adaptive LASSO (Zou, 2006), the smoothly clipped absolute deviation (SCAD) (Fan and Li, 2001) and the minimax concave penalty (MCP) (Zhang, 2010), which enjoy the oracle property (unbiasedness, sparsity and continuity). There are also penalties such as bridge (Frank and Friedman, 1993) and elastic-net (Zou and Hastie, 2005) for purposes other than selecting variables, but we do not pursue them further in this paper.

The work is organised as follow: in section 2 we will talk about the method, then in section 3, we present our proposal. In section 4, a simulation study is presented. Then, the conclusions will follow.

2 Methods

In a classical linear regression context, the dependence of a response variable on one or more covariates is modeled as

$$y_i = x_i^T \beta + \varepsilon_i \qquad i = 1, ..., n,$$

where y_i is the response variable, x_i is the $1 \times p$ vector of explanatory variables, β are the coefficients of the model and ε_i are i.i.d. gaussian noise. The ordinary least squares (OLS) estimates are obtained by minimizing the sum of the model residuals, thus considering only the model's fidelity to the data. This way, we obtain a model that estimates a parameter for each covariate considered without considering that some parameters may be null. This ensures an unbiased estimate having however large variance.

The penalized regression models tend to mediate between the need to have a model as close as possible to the data and the need to select the variables useful in explaining the dependent variable, thus obtaining estimates with less variance. In the case of simple linear regression models, we can define the penalized objective loss function

$$-\mathscr{L}(\beta) + \sum_{j=1}^{p} p(\beta_j, \lambda) \tag{1}$$

$-\mathscr{L}(\beta)$ is the fidelity term, typically $\sum_i (y_i - x_i^T \beta)^2$, and $p(\beta, \lambda)$ is the penalty function that allows for selection of variables, and thus reducing the variance of the estimates. The tuning parameter λ determines the weight that the penalty has in the optimisation of the function: higher λ values result in the estimation of sparser but

potentially more biased models. Usually, the difference between various penalized regression models lies in the different specifications of the second term.

3 The proposal: the cumulative distribution function penalty

We propose to specify the penalty term in (1) via

$$p(\beta_j, \lambda) = \lambda\, p(|\beta_j|) = \lambda\ F(|\beta_j|; \theta) \qquad \beta_j \in \mathbb{R} \tag{2}$$

where $F(\cdot)$ is the cumulative distribution function of any specified random variable, such as Normal, Exponential or Chi-square. The penalty proposed in this work is derived from the best-known probability distribution, the Normal distribution. It is defined as

$$p(\beta_j, \lambda) = \lambda\, p(|\beta_j|) = \lambda\, \Phi_{0,s}(|\beta_j|).$$

It, therefore, consists of the cumulative distribution function (CDF) of β in absolute value. Note that it is considered a Normal distribution with mean 0 and standard deviation s: the central value equal to 0 ensures the singularity of the penalty at the origin (which makes the penalty capable of variable selection). In contrast, different values of s imply how "severe" the penalty is in bringing the parameters estimated by the model to a null value. The first significant difference that can be observed concerning SCAD and MCP penalties lies in the multiplication of the penalty for the tuning parameter λ: the definition of the penalty omits λ, and therefore it is not modified during the selection process of the tuning parameter.

As mentioned by Fan and Li (2001), a good penalty function must have three properties: unbiasedness (estimated non-zero parameters are near unbiased), sparsity (some estimates are equal to zero), and continuity (the estimator is continuous for the data, to avoid instability problems). Based on our evidence, the proposed penalty enjoys these three properties.

Suppose we have a data set (y_i, x_i), $i = 1, ..., n$, where $x_i = (x_{i1}, ..., x_{ip})^T$ are the covariates and y_i is the response. Operating in a simple linear regression framework, we assume independent observations, and that the set of covariates x_i is standardised. Denoted by $\hat{\beta} = (\hat{\beta}_1, ..., \hat{\beta}_p)^T$, the estimates of the model with CDF penalty are obtained as

$$\hat{\beta} = arg\,min\left\{ \sum_{i=1}^{n} (y_i - \sum_{j=1}^{p} \beta_j x_{ij})^2 + \lambda \sum_{j=1}^{p} \Phi_{0,s}(|\beta_j|) \right\}. \tag{3}$$

Problem (3) falls into a classic minimization problem of an objective function consisting of a fidelity component (the sum of the squared errors) plus a penalty component (precisely, the cumulative distribution function of the absolute values of the estimated parameters). A fundamental aspect concerns the choice of the s, which is used to weight the coefficients: there are more or less severe penalties for

different values of s. Based on our experience and simulations, a possible solution is to pre-estimate a model with s equal to 1; we take the higher value of λ that sets all the coefficients to 0 as the s used on the penalization. This ensures better stability on the path of the estimated coefficients.

4 Simulation study

A simulation study is conducted to compare the performance of the proposed penalty with alternatives already established in the literature (LASSO, SCAD and MCP). Models' performance is measured using mean square error (MSE) and false discovery rate (FDR). Both quantities are calculated using estimates corresponding to λ that minimize BIC. For SCAD and MCP, the constant is equal to 3.7.

To carry out the simulation, we generate the response variable as

$$y_i = x_i^T \beta_0 + \sigma_h \varepsilon_i \qquad h = 1,...,12, \qquad i = 1,...,n \tag{4}$$

where $n = 50$. Only the first 5 coefficients β_0 are non-null and equal to 1, then $\beta_0 = (1,1,1,1,1,0,...,0)^T$. The number of covariates is equal to 100. We generate regressor as $x_i \sim N(0,\Sigma)$, with the Toeplitz correlation matrix $\Sigma_{jk} = \frac{1}{2}^{|j-k|}$.

We also considered two different independent and identically distributed types of noise ε_i such that $E(\varepsilon_i) = 0$ and $E(\varepsilon_i^2) = 1$: the first one (a) $\varepsilon_i \sim N(0,1)$ and the second one (b) $\varepsilon_i \sim \frac{t_4}{2}^2$. The σ_h are twelve different equally-spaced values ranging in $[0.25, 3.0]$ of the random noise variance regulating the signal-to-noise ratio.

The results of the two experiments are shown in Figure 1.

In the first setting reported in Figure 1 we observe that, for all the values of σ tested, the value of MSE is always lower than SCAD and MCP, while better results than LASSO are observed only for high values of σ. Considering instead the fraction of coefficients erroneously different from 0, except for the smallest value of σ tested, our proposal is the one that has the lowest FDR compared to the other competitors.

Looking at the second simulation setting reported in Figure 1, the results do not change in a substance: our proposal has the lowest amount of MSE, just as it continues to be the method with the lowest FDR over the path of σ.

5 Conclusion

In this paper we have briefly introduced the problem of variable selection in regression models. We presented a novel proposal that we are working on, namely a penalty based on the cumulative distribution function of the Normal. The goal is to find a penalty that enjoys the stability of LASSO and some important propoprieties typical of SCAD and MCP (such as the oracle property). Results based on some

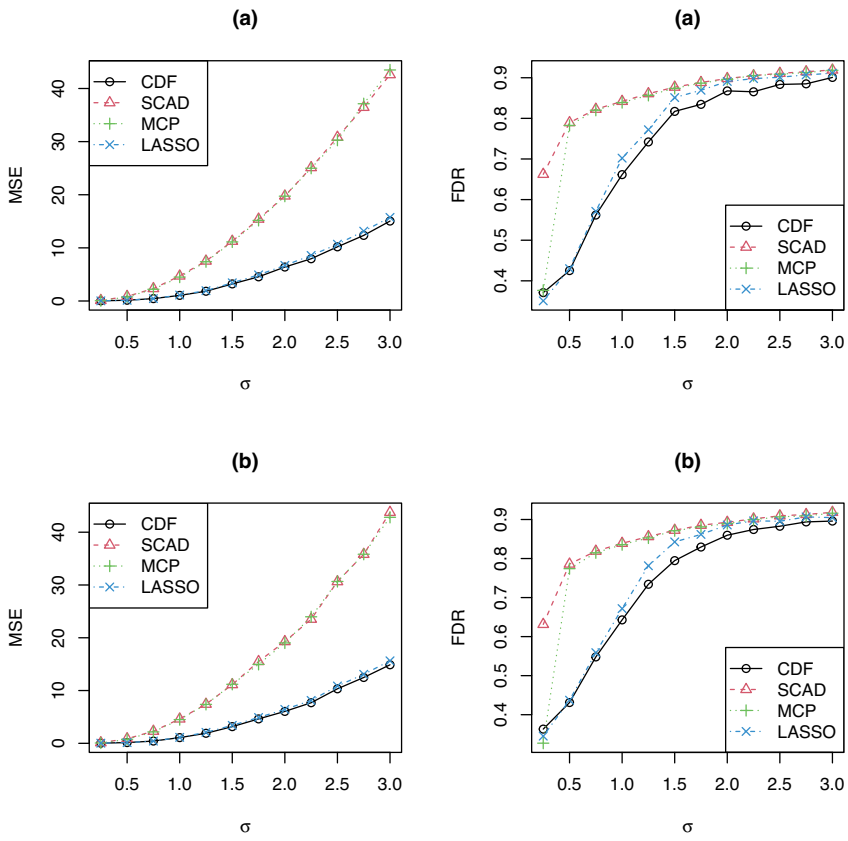

Fig. 1 MSE and average FDR for models estimated using CDF, SCAD, MCP and LASSO penalties, using settings (a) and (b) at different values of σ

simulation experiments showed that our proposal had good performance with respect to the traditional competitors: the CDF penalty attained the lowest value of MSE and FDR.

Automatic variable selection for MIDAS regressions: an application

Selezione automatica delle variabili per regressioni MIDAS: una applicazione

Consuelo Rubina Nava, Luigi Riso and Maria Grazia Zoia

Abstract Many micro and macroeconomic studies need to estimate and forecast time series using independent variables observed at higher frequencies than the dependent one. Mixed Data Sampling (MIDAS) regression models prove useful to model variables sampled at different frequencies. However, given that many time series are not very long, identification issues can emerge. To overcome this problem, we propose a two step procedure based on: i) the use of the so called "Best Path algorithm" for variable selection; ii) the identification and application of the best MIDAS regression specification. The test bed focuses on the half-yearly born of innovative start-ups in Italy, which are explained by using macroeconomic and financial indicators via a MIDAS regression. The results so obtained how advantages and powerfulness of the proposed approach.

Abstract *Molti studi micro e macroeconomici devono stimare e prevedere serie temporali utilizzando variabili indipendenti osservate a frequenze più elevate rispetto alla variabile dipendente. In questi casi è opportuno utilizzare i modelli di regressione Mixed Data Sampling (MIDAS) di recente sviluppo. Tuttavia, dato che molte serie temporali non sono molto lunghe, possono emergere problemi di identificazione. Al fine di superare questo problema, proponiamo una procedura in due fasi basata: i) sull'uso del cosiddetto "algoritmo Best Path" per la selezione delle variabili; ii) sull'identificazione e applicazione della migliore specifica di regressione MIDAS. Il banco di prova è basato su dati semstrali relativi alla nascita di start-up innovative in Italia, spiegati usando indicatori macroeconomici e finanziari*

in una regressione MIDAS. I risultati ottenuti mostrano i vantaggi e la potenza dell' approccio proposto.

Key words: MIDAS, U-MIDAS, automatic variable selection, Best Path algorithm, Start-ups

1 Introduction

The use of data sampled at different frequencies to explain and forecast variables that are emblematic in the many (micro and macro) economic sectors has increased in recent years. In fact, the need to estimate and forecast time series, taking advantage of independent variables observed (in may cases) at higher frequencies than the dependent one, emerges. This is one of the reason for which the recently developed Mixed Data Sampling (MIDAS) regression models has become extremely useful in such contexts [1, 2, 3].

However, given that in many empirical applications the available time series may be not very long and there may be a multitude of useful independent variables, identification issues can arise. To overcome this problem, together with the need to avoid weak multicollinearity problems, we propose a two step procedure. i) First an automatic variable selection algorithm, called the "Best Path algorithm" [6], is used to undertake a selection of the most relevant variables among the the ones suggested by the economic theory. Once a High-Dimensional Graph is built for the variables of the data set, the notion of mutual information between the latter is exploited to detect the path of the graph including the variables with the most explanatory power for the one of interest. ii) Then, the best MIDAS regression model, that considers different lags of the independent variables detected at the first step as well as different functional distributed lag polynomials, is built.

The powerfulness and the advantages of the proposed procedure is showed through an empirical application. The latter is based on the estimate of the born of innovative start-ups in Italy and considers a set of multiple macroeconomic and financial indicators as independent variables.

The paper is organized as follow. In Section 2 the methodology is proposed. Section 3 describes the dataset used for the empirical application and provides main results. Section 4 concludes the paper.

2 Methodology

In the following subsections, we describes in details the two steps characterizing the here proposed methodology.

2.1 Best Path Algorithm

We take advantage of a new algorithm [6] for an automatic variable selection procedure, based on high dimensional graphical models, which exploits mutual information. The algorithm first builds a high-dimensional graphical model by using the [5] algorithm and then detect the path of the graph that includes the variables with the most explanatory power for a node of interest by using the mutual information. As well known, mutual information is a measure of dependence or "closeness" between variables. The Best Path Algorithm proves useful in a many application as it allows to deal with mixed variables, either discrete or continuous. In case of linear models, the possibility of establishing a connection between the mutual information and the adjusted coefficients of determination ($\bar{R}^2$) makes the application of the algorithm very simple. Indeed, in this case, the last step of the algorithm turns out to be ultimately based on the analysis of the $\bar{R}^2$ of the models including the variables of the paths of graph. All the methodological details on the Best Path algorithm are reported in [6].

2.2 MIDAS regression

MIDAS regression models [1, 2, 3] can be usefully employed to avoid the ex-post aggregation of high-frequency data, that can discard potentially useful information in regression model devoted to the estimate and forecast of variables observed at lower frequency. MIDAS models allow either the prediction or the nowcast of the low-frequency variables as functions of higher-frequency ones. There are evidence that MIDAS regressions represent a more parsimonious alternative and are less sensitive to specification errors [2] with respect to other approaches such as State Space and mixed frequency VAR models.

In MIDAS regression, in fact, the frequency alignment is achieved by using a parametric functional constraint expressing the impact of the high-frequency variable on the lower-frequency one. More in details, let consider a dependent (low-frequency) variable y_t as function of r regressors, $x_\tau^{(i)}, i = 1,2,\ldots,r$, observed at higher-frequencies m_i, that is observed m_i times at time t, meaning $\tau = m_i t$ for all t, can be specified as follows

$$y_t = \alpha + \sum_{i=0}^{r} \sum_{k=0}^{K_i} \beta_k^{(i)} x_{tm_i-k}^{(i)} + \varepsilon_t, \;\; t = 1,2,\ldots,T \tag{1}$$

where $\sum_{k=0}^{K_i} \beta_k^{(i)} = 1$ for any i. To reduce the number $\sum_{i=0}^{r} K_i$ of the unknown parameters $\beta_0^0,\ldots,\beta_{K_0}^0,\ldots,\beta_0^r,\ldots,\beta_{K_r}^r$ a weighting scheme of the type

$$\beta_k^{(i)} = \frac{\psi(k,\boldsymbol{\theta}_i)}{\sum_{k=0}^{K_i} \psi(k,\boldsymbol{\theta}_i)} L^k \tag{2}$$

is assumed. In Eq. (2), the function $\psi(k, \boldsymbol{\theta}_i)$ depends on a low dimensional parameter vector $\boldsymbol{\theta}_i$, which allows a parsimonious parametrization. In general, the exponential Almon polynomial and the beta polynomial are used for this scope. When parameters in Eq. (1) are not constrained by a given function $\psi(k, \boldsymbol{\theta}_i)$, the resulting specification is called unrestricted MIDAS (U-MIDAS) [4]. The latter is particularly useful in macroeconomic applications when the sampling frequency gap between the variables included in the model is not so high, as in the empirical example undertaken in Section 3.

3 Data and Results

To show the powerfulness of the proposed approach, we have collected the half-yearly number of innovative start-ups from 2013 to 2021. Since 17 December 2012, the Law 221/2012 introduced in Italy this new class of firms defined as young companies, with a high technological contents and strong growth potentials. In particular, companies classified as innovative start-ups must match specific requirements to be inscribed into the special section of the the Italian companies register at the Chamber of Commerce. We have, thus, built a dataset combining the half-yearly number of innovative start-ups together with 28 macroeconomics and financial indicators/variables.

From this database we notice that, at the end of 2021, the number of innovative startups registered was equal to 14,083. They were principally firms providing services with a prevalence of software production and IT consulting and R&D. In fact, their Ateco 2007 classification principally refers to computer manufacturing, software production and R&D. This is confirmed also by Figure 1a which shows a text mining analysis, based on the description of the activity of each innovative start-up born from 2013 to 2021. From Section 2, both MIDAS and U-MIDAS regressions are suitable econometric models to estimate, nowcast and/or forecast the number of innovative start-ups. Following the MIDAS approach, the low-frequency variable consists of the number of innovative start-ups born every six months, while the macroeconomics and financial indicators are observed quarterly or monthly. Figure 1b shows the high dimensional model obtained from our dataset. The complete list of variables and the corresponding label node are summarized in Table 3. According to the results provided by the automatic variable selection algorithm, shown in Table 2, only two variables form the best path. We have, then, run all possible MIDAS (with the Almon specification) and U-MIDAS regressions that do not violate any identification issues. The resulting optimal model is a U-MIDAS regression specified as in Table 1. Finally, Figure 1c shows the forecasting performance of this optimal model given the two-steps procedure here developed.

4 Conclusions

The results obtained from the preliminary analysis, presented in Section 3, show that the proposed approach allows to: i) overcome potential identification issues; ii) identify the main relevant variables to be employed in MIDAS regression to estimate and forecast the variable of interest; iii) reduce the redundant information collected in the set of variables identified by the economics of innovation theory to explain the number of innovative start-ups registered, given the use of the "Best Path algorithm" which is grounded on mutual information.

Distribution Theory and Estimation

A general framework for unit distributions

Un framework generale per le distribuzioni a supporto unitario

Francesca Condino, Filippo Domma and Bozidar V. Popovic

Abstract In this paper, we present a general framework for probability distributions having bounded support which is based on techniques of random variables transformations. We show that different existing models can be viewed as particular cases of this general formulation, by choosing a proper transformation. Moreover, we propose two type of unit Dagum distribution, belonging to the general family, obtained by considering two different transformation of Dagum random variable.

Abstract *In questo articolo, presentiamo un contesto generale per distribuzioni di probabilità a supporto limitato che si basa su tecniche di trasformazione di variabili casuali. Mostriamo che diversi modelli esistenti in letteratura possono essere visti come casi particolari di questa formulazione generale, scegliendo una opportuna trasformazione. Inoltre, proponiamo due diverse distribuzioni definite sul supporto unitario, appartenenti alla famiglia generale, costruite considerando due diverse trasformazioni della variabile casuale Dagum.*

1 Introduction

In statistical literature, several proposal are done to develop new and more flexible distributions by using different techniques. Among them, various models are defined on bounded support, to address the need to interpret and model practical phenomena characterized by observations taking values in a limited range. In particular, the so-called unit distributions, having support in the unit interval, are suitable for the case of data derived as proportions, percentages or normalized values. Probably, the most used distribution for modelling continuous variables in the unit interval is the Beta distribution, but many other distributions are widely employed, such as Kumaraswamy distribution [7] and Topp-Leone distribution [11]. A substantial part of models with bounded support is obtained through the use of some transformation of random variables. Examples are the Unit-Burr III [10], Unit-Lindley [8], Unit-Gompertz [9], Unit-Burr XII [5], unit inverse Gaussian [3], Arcsecant-Hyperbolic Normal [6] and Logit-Slash [4], to name a few. In this work, we propose a general framework dealing with the approach based on transformations, that encloses most of the unit distributions already appeared in literature. Moreover, two new models will be proposed by transforming the well-known Dagum distribution.

2 General framework

The unit distributions recently proposed in literature can be described with a single probabilistic structure using simple techniques of transformations of random variables. To this end, suppose we have a random variable Y with probability density function (*pdf*) and distribution function (*df*), respectively, indicated by: $f_Y(y;\theta)$ and $F_Y(y;\theta)$, with $y \in I_Y \subset \Re$, $I_Y = [\underline{I}_Y, \bar{I}_Y]$. We also indicate with $y(p) = F_Y^{-1}(y;\theta)$, the *p-th* quantile, with $p \in (0,1)$, and with $h_Y(y;\theta)$ and $rh_Y(y;\theta)$ the hazard function and reversed hazard function, respectively. Let $k : I_Y \longmapsto J_W$, with $J_W = [\underline{J}_W, \bar{J}_W]$, be the application that defines the transformation of the random variable Y in the random variable W, which could also depends on a vector of parameters $\mathbf{a}$, i.e. $W := k(Y;\mathbf{a})$. To simplify the discussion, in this paper we assume that: (1) $\lim_{y\to\underline{I}_Y} k(y;\mathbf{a}) = \underline{J}_W > -\infty$ and $\lim_{y\to\bar{I}_Y} k(y;\mathbf{a}) = \bar{J}_W < \infty$, (2) $k(y;\mathbf{a}) \in C^1(J_W)$, where $C^1(.)$ is the class of differentiable functions whose first derivative is continuous. If $k'(y;\mathbf{a}) \neq 0$, $\forall y \in I_Y$ then $k'(.)$ is strictly positive (or negative) in I_Y and, therefore, $k(.)$ is a monotone function on I_Y. Consequently, $k(y;\mathbf{a})$ is invertible, its inverse $k^{-1}(.)$ is differentiable on J_W and

$$\left(k^{-1}(w;\mathbf{a})\right)' = \frac{1}{k'\left(k^{-1}(w;\mathbf{a})\right)}. \tag{1}$$

In this context, if $k(.)$ is an increasing monotone function, then the *df* of W is given by

$$F_W(w;\theta,\mathbf{a}) = P(W \leq w) = P\left(Y \leq k^{-1}(w;\mathbf{a})\right) = F_Y\left(k^{-1}(w;\mathbf{a});\theta\right) \tag{2}$$

Using (1), we can write the *pdf* of W as

$$f_W(w;\theta,\mathbf{a}) = \frac{\partial F_Y\left(k^{-1}(w;\mathbf{a});\theta\right)}{\partial k^{-1}(w;\mathbf{a})} \times \frac{\partial k^{-1}(w;\mathbf{a})}{\partial w} = \frac{f_Y\left(k^{-1}(w;\mathbf{a});\theta\right)}{k'\left(k^{-1}(w;\mathbf{a})\right)}. \quad (3)$$

It is immediate to verify that by (2) the *q-th* quantile, with $q \in (0,1)$ is $w(q;\theta,\mathbf{a}) = k\left(y(q;\theta);\mathbf{a}\right)$. and the hazard function (*hf*) and of the reversed hazard function (*rhf*) are given, respectively, by

$$h_W(w;\theta,\mathbf{a}) = \frac{f_W(w;\theta,\mathbf{a})}{1-F_W(w;\theta,\mathbf{a})} = \frac{h_Y(k^{-1}(w;\mathbf{a});\theta)}{k'\left(k^{-1}(w;\mathbf{a})\right)} \quad (4)$$

$$rh_W(w;\theta,\mathbf{a}) = \frac{f_W(w;\theta,\mathbf{a})}{F_W(w;\theta,\mathbf{a})} = \frac{rh_Y(k^{-1}(w;\mathbf{a});\theta)}{k'\left(k^{-1}(w;\mathbf{a})\right)}. \quad (5)$$

Evidently, if $k(.)$ is a decreasing monotone function, with small tricks, we can determine the quantities calculated above; in particular, the *df*, the *pdf*, the quantile of order q of W, respectively, are $F_W(w;\theta,\mathbf{a}) = 1 - F_Y\left(h^{-1}(w;\mathbf{a});\theta\right)$, $f_W(w;\theta,\mathbf{a}) = -\frac{f_Y\left(k^{-1}(w;\mathbf{a});\theta\right)}{k'\left(k^{-1}(w;\mathbf{a})\right)}$ and $w(q;\theta,\mathbf{a}) = k\left(y(1-q;\theta);\mathbf{a}\right)$. The *hf* and *rhf* are calculated accordingly. Most of the new proposal in literature can be thought as a particular case of the general framework above mentioned. For example, in the case of positive random variables, the most common transformations are $W = \frac{Y}{1+Y}$ and $W = e^{-Y}$. Through the first transformation, Unit-Burr III, Unit-Half-Normal, Unit-modified Burr III and Unit-Lindley distributions have been proposed, while with the second transformation Unit-Gompertz, Unit-Birnbaum-Saunders, Bounded Odd Inverse Pareto exponential, Unit-Burr XII, log-Bilal [1] and Unit Inverse Gaussian distributions have been obtained. In the case where Y takes values in the set of real numbers, the most used transformations is $W = \frac{1}{1+e^{-Y}}$, used to obtain Logit-Slash distribution. We point out that the non-monotone transformation $W = \frac{2}{e^{-Y}+e^{Y}}$, for $Y \in \Re$, was used to obtain the Arcsecant-Hyperbolic Normal distribution which, strictly speaking, does not belong to the general framework above described. In this paper, we restrict the use of arcsecant hyperbolic transformation to the case $Y > 0$, to have a monotone function. Finally, in general, to transform the variable Y, we can use any distribution function $G(\cdot)$ and obtain $W = G(Y)$.

3 Unit-Dagum distributions

The main objective of this section is to describe two transformations of the well-known Dagum model [2] that can potentially be more flexible unit-distributions than those present in literature. The Dagum random variable Y has, respectively, *df* and *pdf* $F_{Da}(y;\beta,\lambda,\delta) = \left(1+\lambda y^{-\delta}\right)^{-\beta}$, $f_{Da}(y;\beta,\lambda,\delta) = \beta\lambda\delta y^{-\delta-1}\left(1+\lambda y^{-\delta}\right)^{-\beta-1}$, with positive support $y > 0$, i.e. $I_Y = [0,\infty)$, and $\theta = (\beta,\lambda,\delta)$ with parameters $\beta > 0$,

$\lambda > 0$ and $\delta > 0$, (hereafter, in short $Da(\beta, \delta, \lambda)$). Parameter λ is a scale parameter while β and δ are shape parameters. The Dagum *pdf* has positive asymmetry and it is easy to verify that the mode is $y_m = \lambda^{\frac{1}{\delta}} \left(\frac{\beta\delta - 1}{\delta + 1}\right)^{\frac{1}{\delta}}$ for $\beta\delta > 1$. If $\beta\delta \leq 1$, the *pdf* is zero-modal. The *q-th* quantile of the Dagum distribution is $y(q) = F_{Da}^{-1}(q; \beta, \lambda, \delta) = \lambda^{\frac{1}{\delta}} (q^{-\frac{1}{\beta}} - 1)^{-\frac{1}{\delta}}$, thus, the median has an explicit expression. Moreover, the *r-th* moment is given by $\mu_{Da}^r = E(Y^r; \beta, \lambda, \delta) = \beta\lambda^{\frac{r}{\delta}} B\left(\beta + \frac{r}{\delta}, 1 - \frac{r}{\delta}\right)$ for $\delta > r$, where $B(.,.)$ is the complete Beta function.

3.1 Type I Unit-Dagum distribution

In the case of $Y > 0$, the hyperbolic secant transformation $W := k(Y) = \frac{2e^Y}{1+e^{2Y}}$ is a monotone function. Therefore, considering its inverse, it is simply to verify that the *df* of W is given by:

$$F_{I-UDa}(w; \beta, \lambda, \delta) = 1 - \left\{ 1 + \lambda \left[\log \frac{1 + \sqrt{1 - w^2}}{w} \right]^{-\delta} \right\}^{-\beta} \tag{6}$$

for $w \in (0, 1)$ and $\beta > 0$, $\lambda > 0$ and $\delta > 0$ (hereafter, in short $I - UDa(\beta, \delta, \lambda)$). Using (1), after simple algebra, we have $\left(k^{-1}(w; \mathbf{a})\right)' = \frac{-1}{w\sqrt{1-w^2}}$ and, therefore, the *pdf* of type I Unit-Dagum random variable is:

$$f_{I-UDa}(w; \beta, \lambda, \delta) = \frac{\beta\lambda\delta}{w\sqrt{1 - w^2}} \left[\log(w^*)\right]^{-\delta-1} \left\{ 1 + \lambda \left[\log(w^*)\right]^{-\delta} \right\}^{-\beta-1} \tag{7}$$

where $w^* = \frac{1+\sqrt{1-w^2}}{w}$. It is also possible to obtain the expression for *q-th* quantile, *r-th* moment, *hf* and *rhf* of the I-UDa (not shown, for space reasons). Figure 1 shows the *pdf* of I-UDa for two different set of parameters, while *hrf* of I-UDa for different values of β, λ and δ is shown in Figure 2.

3.2 Type II Unit-Dagum distribution

If we consider the transformation $W := k(Y) = e^{-Y}$ and its inverse, it is simply to verify that the *df* of W is given by

$$F_{II-UDa}(w; \beta, \lambda, \delta) = 1 - \left\{ 1 + \lambda \left[-\log(w)\right]^{-\delta} \right\}^{-\beta} \tag{8}$$

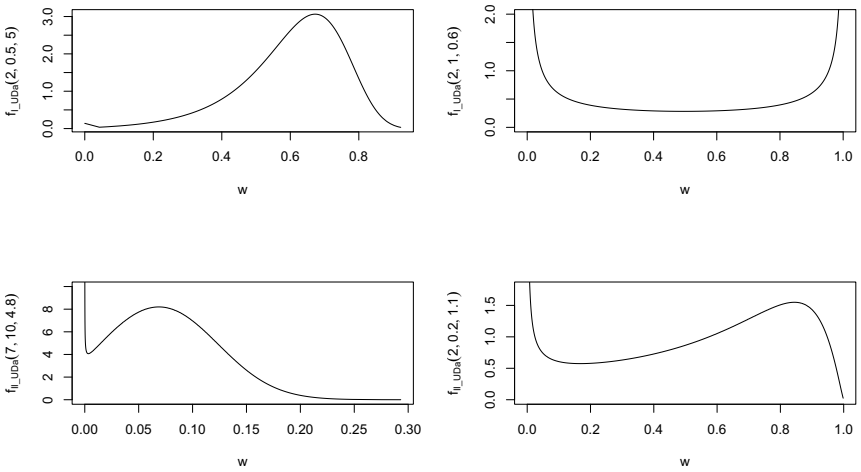

Fig. 1 Pdf of I-UDa (top panels) and II-UDa (bottom panels) for different values of parameters

for $w \in (0,1)$ and $\beta > 0$, $\lambda > 0$ and $\delta > 0$ (hereafter, in short II-UDa). Using (1), after simple algebra, we have $\left(k^{-1}(w;\mathbf{a})\right)' = -\frac{1}{w}$ and, therefore, the *pdf* of type II Unit-Dagum random variable is:

$$f_{II-UDa}(w;\beta,\lambda,\delta) = \frac{\beta\lambda\delta}{w}\left[-\log(w)\right]^{-\delta-1}\left\{1+\lambda\left[-\log(w)\right]^{-\delta}\right\}^{-\beta-1} \qquad (9)$$

Also in this case, the expression for *q-th* quantile, *r-th* moment, *hf* and *rhf* of the II-UDa can be obtained. Finally, Figure 1 shows two curves for the *pdf* of II-UDa for different values of β, λ and δ, while *hrf* is shown in Figure 2.

4 Conclusions and future work

This paper presents a general framework for distributions with bounded support and, consequently, general expressions for different aspects of models, such as quantiles, moments and hazard functions. A great number of distributions proposed in literature are enclosed in this framework. Moreover, it is shown how this approach can be considered to obtain new and very flexible distributions, through two different examples. For the future, others particular transformations could be considered in order to obtain more and more flexible models. Moreover, in the application contexts where specific indicators and/or characteristics of the distribution (such as location indicators, quantiles, variability measures, etc.) are of particular interest, we will try to construct regressive models on them in order to identify possible determinants of the phenomena under consideration.

Prediction intervals based on multiplicative model combinations

Intervalli di previsione basati su combinazioni moltiplicative di modelli

Valentina Mameli and Paolo Vidoni

Abstract The aim of this paper is to define prediction intervals based on multiplicative combination of elementary density functions as an useful surrogate of the true unknown predictive model for the interest random phenomenon. The specification of the weights associated to the individual density forecasts is performed by considering the continuous ranked probability score (CRPS) and its weighted extensions. A simple simulation study shows that, using a suitable weighted version of the CRPS, the estimated combined model provides prediction intervals having a coverage probability closed to the target nominal value.

Abstract *Lo scopo di questo lavoro è definire intervalli di previsione basati su combinazioni moltiplicative di modelli come un surrogato del vero modello predittivo per il fenomeno di interesse. La specificazione dei pesi associati ai singoli modelli della combinazione viene effettuata considerando lo score chiamato CRPS e le sue estensioni ponderate. Un semplice studio di simulazione evidenzia che, utilizzando un'opportuna versione ponderata del CRPS, il modello combinato stimato fornisce degli intervalli di previsione la cui probabilità di copertura è vicina a quella nominale.*

Key words: CRPS, coverage probability, estimative quantile, multiplicative model combination, prediction intervals, weigthed CRPS.

1 Introduction

Combining probability distributions is a relevant topic having potential implications for both inference and prediction. This issue, often called model or prediction pooling, is considered quite often in the econometric literature, with particular attention

Valentina Mameli · Paolo Vidoni
Department of Economics and Statistics, University of Udine, via Tomadini, 30/A I-33100 Udine Italy, e-mail: valentina.mameli@uniud.it, paolo.vidoni@uniud.it

to the specification of convenient predictive models (see, for example, [6]). The need of combined distributions may arise because it may not be possible to identify a reasonable model for the interest phenomenon or because the model could be so complex as not to allow the explicit calculation of the joint density function. Beyond that, several models (sometimes called expert opinions) may be available for a quantity of interest and, when these opinions are represented as probability distributions, a suitable (opinion) pooling operator is required.

Among the various pooling approaches proposed in the literature, we focus on multiplicative (logarithmic) model combinations and we face the crucial problem of assigning weights to the component distributions using the continuous ranked probability score (CRPS) as optimality criterion. In particular, we find that, using a suitable weighted version of the CRPS, the estimated combined model provides prediction intervals having a coverage probability closed to the target nominal value. In this respect, a simple simulation study, presented at the end of the paper, confirms this result even if a more in-depth theoretical analysis is required.

2 Multiplicative model combination for prediction

Let $(Y_1,\ldots,Y_n)$, $n \geq 1$, be a continuous random vector, following a suitable joint distribution, where $Y = (Y_1,\ldots,Y_{n-1})$ is observable, while $Z = Y_n$ denotes a future, or yet unobserved, random variable. This is a fairly general formulation but, for simplifying the exposition, we consider the simple case with independent, identically distributed random variables with marginal distribution and density functions given by $G(\cdot)$ and $g(\cdot)$, respectively. The aim here is to make effective prediction statements on the future random variable Z using the observed learning sample $y = (y_1,\ldots,y_{n-1})$ from Y and, in particular, to define prediction intervals or prediction limits having good coverage accuracy. More precisely, we look for α-prediction limits $c_\alpha(Y)$ such that

$$P_{Y,Z}\{Z \leq c_\alpha(Y)\} = E_Y[P_Z\{Z \leq c_\alpha(Y)\}] = E_Y[G\{c_\alpha(Y)\}] = \alpha, \tag{1}$$

for any fixed $\alpha \in (0,1)$. The above probability is called coverage probability and our objective is to define prediction limits, with nominal coverage α, which satisfies equation (1), exactly or approximately.

We consider the challenging situation where a parametric statistical model, including the true density function $g(\cdot)$, is not available and a set of $K \geq 2$ plausible parametric statistical models may be defined instead, giving alternative families of marginal density functions $f_k(\cdot;\theta_k)$ indexed by a d_k-dimensional unknown parameter $\theta_k \in \Theta_k \subseteq \mathbf{R}^{d_k}$, $k = 1,\ldots,K$. The aim is to use the information given by the observed data in order to define a combined model, having marginal density $f_c(\cdot)$, to be considered as a useful surrogate for the true density $g(\cdot)$. In particular, the combined model is expected to provide accurate prediction limits for Z, specified according to the coverage criterion defined above.

In this paper the focus is on multiplicative combinations of densities, called also logarithmic pools, so that

$$f_c(z;\theta,\omega) = \frac{\prod_{k=1}^{K} f_k(z;\theta_k)^{\omega_k}}{c(\omega)}, \quad z \in \mathbf{R}, \tag{2}$$

with $\theta = (\theta_1,\ldots,\theta_K)$, $c(\omega) = \int_{\mathbf{R}} \prod_{k=1}^{K} f_k(z;\theta_k)^{\omega_k} dz$ the normalizing factor and $\omega = (\omega_1,\ldots,\omega_K)$ a vector of non-negative weights, such that $\sum_{k=1}^{K} \omega_k = 1$. Compared to the linear pool, which defines linear mixture densities, the logarithmic one gives densities which are typically uni-modal and less dispersed. Moreover, this combination method is invariant under rescaling and it verifies the property of external Bayesianity [1, 3].

The combined density function (2) can be viewed as a surrogate for the true, unknown density function for Z, provided that a convenient choice for the weights $\widehat{\omega} = (\widehat{\omega}_1,\ldots,\widehat{\omega}_K)$ is made and suitable estimates $\widehat{\theta}$ for the model parameters θ, based on the available data y, are considered. In this case, the associated estimative prediction limit

$$\widehat{z}_\alpha^{\,c} = z_\alpha^c(\widehat{\theta},\widehat{\omega}) = F_c^{-1}(\alpha;\widehat{\theta},\widehat{\omega}) \tag{3}$$

can be used for prediction purposes, instead of the unknown true predictive quantile $z_\alpha = G^{-1}(\alpha)$; here, $F_c(\cdot)$ is the distribution function associated to the multiplicative density $f_c(\cdot)$.

Since the prediction limit (3) is based on a surrogate for the true model and, in addition, a plug-in procedure is considered to deal with the unknown parameters, the coverage probability is expected to differ from the target value α and, in many applications, the coverage error has been found to be substantial. This error can be viewed as the combination of the misspecification error, due to the use of $F_c(\cdot)$ instead of $G(\cdot)$, and an error term which depends on the plug-in approach, since an additional uncertainty is introduced when the unknown parameters ω and θ are substituted by the corresponding estimates $\widehat{\omega}$ and $\widehat{\theta}$.

3 Choosing the weights using a CRPS-based criterion

An effective approach for assessing the goodness of the combined models, and then useful for estimating the weights ω and the model parameters θ, is based on the CRPS. Following [4], the CRPS for the predictive distribution $F_c(\cdot)$, at a specific realization x, is defined as

$$\mathrm{CRPS}(F_c,x) = \int_{\mathbf{R}} \{F_c(u;\theta,\omega) - \mathbf{1}(x \le u)\}^2 du,$$

where $\mathbf{1}(\cdot)$ is the indicator function, which takes value 1 if the argument is true and 0 otherwise. If the quantile function $F_c^{-1}(\cdot;\theta,\omega)$ is uniquely defined, the CRPS can be expressed in the following equivalent form

$$\mathrm{CRPS}(F_c,x) = \int_0^1 2\left[\mathbf{1}\{x \le F_c^{-1}(\beta;\theta,\omega)\} - \beta\right]\{F_c^{-1}(\beta;\theta,\omega) - x\}d\beta.$$

The choice between the two specifications depends on the computational advantage obtained by specifying the predicted distribution as a distribution function or as a quantile function. In what follows, we consider the quantile version, generalized by considering the integrand multiplied by a suitable weight function $\pi(\cdot)$. As emphasized in [5], an appropriate choice for this function may emphasize the center or the tails of the interest variable's range, and this can be useful for specifying good predictions intervals. In particular, we consider

$$\mathrm{wCRPS}(F_c,x) = \int_0^1 2\left[\mathbf{1}\{x \le F_c^{-1}(\beta;\theta,\omega)\} - \beta\right]\{F_c^{-1}(\beta;\theta,\omega) - x\}\pi(\beta)d\beta$$

and, with $\pi(\beta) = \mathbf{1}(\beta \ge r)$ and $\pi(\beta) = \mathbf{1}(\beta \le l)$, where $l, r \in (0,1)$, we focus on the right or on the left tail of the distribution, respectively.

The (weighted) CRPS is a proper scoring rule and it can be used as a criterion for estimating both the model parameters and the system of weights required for defining the logarithmic pool (2). More precisely, we seek suitable values for θ and ω so that the expected score $E_X\{\mathrm{wCRPS}(F_c,X\}$ is minimized, where the random variable X is an independent copy of Y_i, $i = 1,\ldots,n$. Given the observed sample y, the estimates can be derived using, as objective function, the empirical counterpart of the expected wCRPS, that is

$$(\widehat{\theta},\widehat{\omega}) = \arg\min_{(\theta,\omega)} \frac{1}{n-1}\sum_{i=1}^{n-1} \mathrm{wCRPS}(F_c,y_i). \tag{4}$$

Since an explicit solution for this inferential problem is usually not available, the estimates can be obtained using iterative methods. One possibility is to set an initial value $\widehat{\omega}^{(0)}$ for the weights, e.g. $\widehat{\omega}^{(0)} = (1/K,\ldots,1/K)$, and to define $\widehat{\theta}^{(0)}$ as the solution of (4) with respect to θ, with $\omega = \widehat{\omega}^{(0)}$. Then the weights are updated by considering $\widehat{\omega}^{(1)}$, defined as the solution of (4) with respect to ω, with $\theta = \widehat{\theta}^{(0)}$, and the procedure continues sequentially until a suitable stopping criterion is satisfied. If the integral required for computing the wCRPS does not have an explicit solution, a suitable discrete approximation can be employed.

The estimative prediction limit $\widehat{z}_\alpha^c$ defined by (3), with $\widehat{\theta}$ and $\widehat{\omega}$ the wCRPS estimators given by (4), is supposed to have a coverage probability closed to the nominal value on the left or on the right tail of the distribution, according to the corresponding weight function considered in the wCRPS. We find out that, as emphasized in the simple application presented in the following section, choosing the weights and the model parameters using a criterion based on a suitable wCRPS may reduce the coverage error due to misspecification. In particular, when the uncertainty introduced by the plug-in procedure is not so pronounced, the coverage accuracy is closed to that one given by the improved prediction limit obtained using a suitable calibration procedure [2].

4 A simple simulation study

In this section, we perform a simulation study where the true data generating process is a Student t distribution with $\nu = 3$ degrees of freedom, in symbols $t(3)$. We consider the multiplicative combination of two normal distributions $N(\mu_1, \sigma_1^2)$ and $N(\mu_2, \sigma_2^2)$, where $\mu_1, \mu_2 \in \mathbf{R}$, $\sigma_1, \sigma_2 > 0$, are unknown parameters. Then the combined density given in (2) is again normal $N(\mu_c, \sigma_c)$, where $\mu_c = \sigma_c^2 \sum_{k=1}^2 \omega_k \mu_k / \sigma_k^2$ and $\sigma_c = \{\sum_{k=1}^2 \omega_k / \sigma_k^2\}^{-1/2}$. The estimative α-quantile is $\widehat{z}_\alpha^c = \Phi^{-1}(\alpha, \widehat{\mu}_c, \widehat{\sigma}_c)$, where $\Phi^{-1}(\cdot, \mu, \sigma)$ is the quantile function of a normal distribution and $\widehat{\mu}_c, \widehat{\sigma}_c$ are the plug-in estimates of the mean and of the standard deviation of the logarithmic pool, obtained using the estimates for $\omega = (\omega_1, \omega_2)$ and $\theta = (\mu_1, \sigma_1, \mu_2, \sigma_2)$ given by (4).

In the following, we consider the estimates based on the unweighted CRPS and on the weighted versions focusing on the left and on the right tails defined in the previous section, and indicated as wCRPS$_l$ and wCRPS$_r$, when $\pi(\beta) = \mathbf{1}(\beta \leq l)$ and $\pi(\beta) = \mathbf{1}(\beta \geq r)$, respectively. In the special case of the normal distribution, both the CRPS and the wCRPS can be easily derived in a closed form (see [7, 4]). Furthermore, the improved quantiles $\widetilde{z}_\alpha^c$ are obtained by adjusting, with the calibration procedure proposed in [2], the corresponding estimative quantiles $\widehat{z}_\alpha^c$ in order to achieve the nominal coverage level α, and for this reason they can be considered as benchmark values.

The simulation study compares the coverage probability of the estimative quantiles $\widehat{z}_\alpha^c$, based on the CRPS, wCRPS$_l$ and wCRPS$_r$, and of the associated improved quantiles $\widetilde{z}_\alpha^c$, for $\alpha = 0.05$ and $\alpha = 0.95$. Table 1 shows the results of a Monte Carlo simulation based on $N = 1{,}000$ replications. Estimated standard errors are smaller than 0.009. Coverage probabilities are obtained by using a bootstrap procedure based on $B = 500$ replications. The sample sizes are $n = 20, 50, 100$ and we set $l = r = 0.05$, for $\alpha = 0.05$, and $l = r = 0.95$, for $\alpha = 0.95$.

As it can be noted in Table 1, the estimative quantiles $\widehat{z}_\alpha^c$ have coverage probability equal or close to the target nominal value, depending on the sample size, whenever we focus on the right tail of the distribution with $r = 0.95$ for $\alpha = 0.95$ or on the left tail with $l = 0.05$ for $\alpha = 0.05$. As the sample size increases the gap between the estimated coverage probability and the target nominal level fades out, as expected. Moreover, the improved predictive quantiles $\widetilde{z}_\alpha^c$ show an accurate coverage probability, since it is almost equals to the nominal value α regardless of the sample size and of the CRPS criterion used. Finally, we can emphasize that estimative predictive intervals, obtained from the multiplicative model, exhibit a good predictive accuracy whenever a suitable choice of the weight function for the CRPS criterion is adopted, and then it is not necessary to improve the predictive performance using an additional, complex calibration procedure. Future work will consider the use of different model pools for prediction and also the possible extension to the time series framework.

Table 1 Coverage probabilities for estimative quantiles $\widehat{z}_\alpha^c$ and improved quantiles $\widetilde{z}_\alpha^c$ with level $\alpha = 0.05, 0.95$. Estimation is based on $1,000$ Monte Carlo replications and the estimated standard errors are smaller than 0.009. The bootstrap procedure is based on 500 samples. The true model is a $t(3)$ distribution, the sample sizes are $n = 20, 50, 100$ and $l = r = 0.05$, for $\alpha = 0.05$, and $l = r = 0.95$, for $\alpha = 0.95$.

		CRPS	wCRPS$_l$	wCRPS$_r$

Some advances on pairwise likelihood estimation in ordinal data latent variable models

Alcuni avanzamenti per la stima basata sulla verosimiglianza a coppie per modelli a variabili latenti per dati ordinali

Giuseppe Alfonzetti and Ruggero Bellio

Abstract This note compares three estimation methods suitable for GLLVMs with ordinal response data, given by maximum likelihood estimation, pairwise likelihood estimation and a variation of the latter, obtained by a suitable scaling of the estimating equations by means of optimal weighting. The three methods are compared in a simulation study with six items and two correlated latent factors, for different sample sizes. The results suggest that the pairwise likelihood approach entails a limited loss of efficiency with respect to maximum likelihood estimation, that is not significantly reduced by the application of optimal weights.

Abstract *Questa nota confronta tre diversi metodi di stima per un modello GLLVM con risposta ordinale, ovvero la stima di massima verosimiglianza, la stima ottenuta massimizzando la verosimiglianza a coppie, e infine una variazione di quest'ultima ottenuta mediante l'applicazione di opportuni pesi ottimali all'equazione di stima. I tre metodi sono confrontati in uno studio di simulazione per un modello con sei item, due fattori latenti correlati tra loro e varie dimensioni campionarie. I risultati suggeriscono una limitata perdita di efficienza della stima basata sulla verosimiglianza a coppie rispetto alla stima di massima verosimiglianza, con nessun apprezzabile miglioramento dato dall'applicazione dei pesi ottimali.*

Key words: Pairwise likelihood, Optimal weights, Latent variable models

1 Introduction

Whenever the interest of a researcher lies on analyzing some non-observable constructs given a set of observed variables, latent variable models may come to be of

Ruggero Bellio
University of Udine, e-mail: ruggero.bellio@uniud.it

help. It is not by chance their popularity in areas like psychometrics and social sciences, where latent traits are often the focus of research. A particular class of models has emerged to extend generalized linear models to incorporate latent variables, given by Generalized Linear Latent Variable Models (GLLVM); see [1] for an extended overview of the models and classical estimation methods for them. GLLVM can be seen as a generalization of normal factor analysis models where manifest data can be any member of the exponential family, allowing at the same time for a non-orthogonal latent space. Such flexibility allows to incorporate in GLLVM many classical models developed in psychometrics under the Item Response Theory (IRT) framework, where interest usually lies in discrete responses and parameters are estimated by the Maximum Likelihood (ML) method.

Here we focus on ordinal data, naturally suitable to model responses like ratings or preferences. An equivalent parameterization of GLLVM with ordinal data is given under the Underlying Response Variable approach (URV), where ordinal data are assumed to be a partial observation of a non-observed normal factor model. Under this framework, a pairwise likelihood (PL) approach has been proposed in [6]. This contribution aims at quantifying the efficiency loss of PL estimates with respect to ML ones by means of a simulation study, which also includes the refinement of PL estimation by means of optimal weighting system, as first proposed by [7]. Some brief remarks conclude the note.

2 Model and estimation methods

Let the observed dataset $y = (y_1^\top, \dots, y_n^\top)$ be the realization of a random matrix $Y \in R^n \times R^p$, with n the number of units and p the number of items. Likewise, the latent variables matrix $u = (u_1^\top, \dots, u_n^\top)$ is the realization of the random matrix $U \in R^n \times R^q$, where $q < p$ is the dimension of the latent space. At the i-th unit level, it follows that $y_i = (y_{i1}, \dots, y_{ip})^\top$ and $u_i = (u_{i1}, \dots, u_{iq})^\top$. Since we are dealing with ordinal data, for each item j, with $j = 1, \dots, p$, there are c_j possible increasing categories. It follows that $y_{ij} \in \{s_0, \dots, s_{c_j - 1}\}$. Furthermore we assume $u_i \overset{iid}{\sim} N_q(0, \Sigma_u)$ for $i = 1, \dots, n$, and Σ_u is constrained to be a correlation matrix. In the following, three different estimation methods are introduced.

2.1 Maximum likelihood estimation

ML estimation is traditionally performed under the IRT model parameterization. For the generic j-th item, $c_j - 1$ intercepts need to be estimated, such that the model intercept vector is defined with $\alpha = ({\alpha^{(1)}}^\top, \dots, {\alpha^{(p)}}^\top)^\top$ where the generic $\alpha^{(j)} = (\alpha_0^{(j)}, \dots, \alpha_{c_j - 2}^{(j)})^\top$ is the $(c_j - 1)$-dimensional intercept vector related to item j. The matrix of coefficients related to each item is defined with $B = (\beta_1^\top, \dots, \beta_p^\top)$, where

$\beta_j = (\beta_{j1}, \ldots, \beta_{jq})^\top$ for $j = 1, \ldots, p$. Let $\psi \in R^d$ be the vector collecting all the free parameters in B, α and Σ_u. The IRT parameterization assumes the items to be locally independent given the latent space, such that the likelihood contribution for the i-th unit is

$$L(B, \alpha; y_i|u_i) = \prod_{j=1}^{p} p(Y_{ij} = s_j|U_i = u_i; \beta_j, \alpha_j)\,. \tag{1}$$

Furthermore it is assumed that the conditional response probability is computed as

$$p(Y_{ij} = s_j|u_i; \beta_j, \alpha_j) = p(Y_{ij} \leq s_j|u_i; \beta_j, \alpha_j) - p(Y_{ij} \leq s_j - 1|u_i; \beta_j, \alpha_j)\,, \tag{2}$$

where the cumulative probability of a response is related to the linear predictor through the logit transformation, namely $\text{logit}\,(p(Y_{ij} \leq s_j|u_i; \beta_j, \alpha_j)) = \alpha_{s_j}^{(j)} - \beta_j^\top u_i$. For the computation of the marginal likelihood for the observed response, the latent variables have to be integrated out, so that the log-likelihood function is

$$\ell(\psi; y) = \sum_{i=1}^{n} \log \int_{R^q} p(u_i; \Sigma_u) \prod_{j=1}^{p} p(Y_{ij} = s_j|U_i = u_i; \alpha_j, \beta_j) du_i\,. \tag{3}$$

Since the q-dimensional integral has no closed-form solution, several estimation methods have been proposed in literature. The most popular approaches rely on the Expectation-Maximization algorithm, as reviewed in [1].

2.2 Pairwise likelihood estimation

Pairwise Likelihood estimation (PL) is a special case of composite likelihood [7], and it has been largely studied in literature to replace intractable likelihoods with the product of bivariate likelihood contributions. The method provides consistent estimates, with only a possible loss in efficiency; see [9] for an overview.

In the context of ordinal factor models, PL has been introduced under the Underlying Response Variable (URV) parameterization in [6]. In such setting, a different d-dimensional set of parameters is estimated, but it possible to re-express the estimates in the IRT parameterization. The URV parameters include the $c_j - 1$ thresholds for each item j, namely we define $\tau = ({\tau^{(1)}}^\top, \ldots, {\tau^{(p)}}^\top)^\top$ with $\tau^{(j)} = (\tau_0^{(j)}, \ldots, \tau_{c_j-2}^{(j)})^\top$, and a loading matrix $\Lambda = (\lambda_1^\top, \ldots, \lambda_p^\top)$ with $\lambda_j = (\lambda_{j1}, \ldots, \lambda_{jq})^\top$. Let $\theta \in \mathbb{R}^d$ be the vector collecting all the free parameters in Λ, τ and Σ_u. The data are assumed to be a partial observation of a normally distributed underlying continuous response y^*, such that $Y_j = s_j \iff \tau_{s_j-1}^{(j)} < y_j^* < \tau_{s_j}^{(j)}$, where $y^* = \Lambda u + \delta$ and $\delta \sim N_p(0, \Sigma_\delta)$ with $\Sigma_\delta = I_p - \text{diag}(\Lambda \Sigma_u \Lambda^T)$. In this case, the marginal likelihood is obtained by integration over the underlying response space, hence the integral is p-dimensional rather than q-dimensional, namely

$$\ell(\theta;y) = \sum_{i=1}^{n} \log \int_{\tau_{s_1-1}^{(1)}}^{\tau_{s_1}^{(1)}} \cdots \int_{\tau_{s_p-1}^{(p)}}^{\tau_{s_p}^{(p)}} \phi_p(y_i^*;\Sigma_{y^*}) dy_i^* \,. \tag{4}$$

The PL approach replaces $\ell(\theta;y)$ in (4) with a simpler function, given by the sum of the log-likelihood contributions coming from all the possible $P = p(p-1)/2$ pairs of items. In particular the pairwise log-likelihood computation requires the numerical evaluation of the bivariate normal cumulative density function. To this end, the probability of observing a specific bivariate pattern (s_k, s_l) on the pair of items k and l can be written as

$$\pi_{s_k s_l}^{kl} = p(Y_k = s_k, Y_l = s_l;\theta) = \int_{\tau_{s_k-1}}^{\tau_{s_k}} \int_{\tau_{s_l-1}}^{\tau_{s_l}} \phi_2(y_k^*, y_l^*; \rho_{kl}^{y^*}) dy_l^* dy_k^* \,,$$

where $\rho_{kl}^{y^*} = \lambda_k^T \Sigma_u \lambda_l$ and $\phi_2(x_1, x_2, \rho)$ is the density evaluated at (x_1, x_2) of a bivariate normal distribution with correlation ρ. It follows that the log-likelihood pair contribution can be computed as $\ell_{kl}(\theta;y) = \sum_{s_k=0}^{c_k-1} \sum_{s_l=0}^{c_l-1} n_{s_k s_l}^{kl} \log \pi_{s_k s_l}^{kl}$, where $n_{s_k s_l}^{kl} = \sum_{i=1}^{n} I_i^{s_k s_l}$ and $I_i^{s_k s_l}$ denotes the indicator function of $(Y_{ik}, Y_{il}) = (s_k, s_l)$. The marginal pairwise log-likelihood becomes then

$$\ell^{pl}(\theta) = \sum_{k=2}^{p} \sum_{l=1}^{k-1} \ell_{kl}(\theta) = \sum_{k=2}^{p} \sum_{l=1}^{k-1} \sum_{s_k=0}^{c_k-1} \sum_{s_l=0}^{c_l-1} n_{s_k s_l}^{kl} \log \pi_{s_k s_l}^{kl} \,. \tag{5}$$

2.3 Optimal weights for pairwise likelihood

The expression (5) implicitly assumes that the weight for each pair to be equal, there exists the possibility that a better weighting system for each term can be designed to achieve better statistical efficiency. This was already part of the original proposal of composite likelihood made by [7], who provided a theoretical method for obtaining weights which ensure some optimality properties for the resulting estimator. Such weights are rather complicated to obtain, so that the existing applications are limited to very simple statistical models; see [8] and the references therein. The latter article shows that in the scalar-parameter case one can retrieve a unique weight for each pair, whereas in the d-dimensional parameter case it is often not the case.

In d-dimensional case, the weights take the form of a $d \times dP$ matrix $W(\theta)$. In particular, let consider the dP-dimensional vector of stacked pair scores $\nabla \ell_{kl}(\theta)$ denoted by $g(\theta)$, the $dP \times dP$ covariance matrix of $g(\theta)$ denoted by $V(\theta)$, and finally the $dP \times d$ matrix obtained by stacking variances from $V(\theta)$, denoted by $D(\theta)$. Furthermore, consider a preliminary estimate $\tilde{\theta}$ of the parameter vector θ, which is needed in order to get a consistent estimate of the weights. Therefore, the weights are computed as $W(\tilde{\theta}) = D(\tilde{\theta})^T V(\tilde{\theta})^{-1}$, and the final estimate of θ requires the solution of the d-dimensional nonlinear system of equations

$$W(\tilde{\theta}) g(\theta) = 0 \,. \tag{6}$$

Solving (6) is a challenging task and may often lead to divergent estimates. Furthermore, it is worth stressing that computing the $dP \times dP$ covariance matrix $V(\theta)$ is often a computationally-intense operation.

3 Simulation Study

A comparison between the three methods has been performed on data simulated with the IRT parameterization and logit link. The setting consists of $p = 6$ items, each with 4 categories, $q = 2$ latent variables with correlation $\rho = .7$ and $n \in \{500, 1000, 5000\}$ units. The loading matrix has a simple structure, where each item depends only on one latent factor and each loading is uniformly distributed in $(-1, 1)$. The ML estimates were obtained by the EM method from the `mirt` R package [3], whereas the PL and the optimal weighted pairwise likelihood (OWPL) were obtained with custom `C++` code integrated in R via the `Rcpp` package [4]. In particular, the PL was maximized with the `nlminb` optimizer, whereas the OWPL used the PL estimates as preliminary point to compute the weights, and the package `nleqslv` [5] to solve (6). In order to be comparable to the ML estimates, PL and OWPL estimates have been converted to the IRT parameterization and then scaled by 1.7, as customary in IRT settings for moving between the probit and logit links; see [2] for further comments.

In Table 1 the various methods are compared according to the Mean Squared Error (MSE) and Mean Absolute Bias (MAB) of the estimates. In particular, results are summarized by the median error, classified by the type of parameter considered.

Table 1 Simulation results for ML, PL and OWPL over 100 repetitions for $n \in \{500, 1000, 5000\}$. Median MSE and MAB are reported for parameters in B, α, ρ and the complete vector parameter θ. Median computational time reported in seconds.

		ML		PL		OWPL

	B	0.0360	0.1623	0.1199	0.3145	0.1173	0.3119
	α	0.0019	0.0359	0.0019	0.0348	0.0019	0.0348
	θ	0.0098	0.0646	0.0285	0.0990	0.0283	0.0990
	time (s)	10.7		0.7		12.1	

All in all, the ML provides the best performance. This is most apparent in the results for the complete parameter vector θ, with PL leading to some efficiency loss. The loss may be enlarged by the use of the scaling constant 1.7, which leads to a further approximation of the IRT parameters for PL and OWPL.

The behaviour of OWPL with respect to PL is of some interest. Even though using optimal weights does not lead to a clear improvement for the individual parameters ρ, B and α, the estimates of the vector θ as a whole slightly moves towards the ML estimates, as expected in theory. At any rate, the overall improvement given by the weights is so small that it does not seem to be worth the remarkable computational effort required for computing the weights.

4 Conclusion and ongoing work

In the relatively simple setting considered, the ML estimates turned out to be the most reliable ones. Even though the efficiency loss of the PL is worsened by the approximation required to switch from probit to logit estimates, the loss cannot be neglected in principle. In different settings, with larger p and q, the ML computation may be instead rather challenging to obtain. Further research is needed in order to scale ML methods on higher latent spaces.

On the other hand, PL allows to scale the estimation on larger datasets at the cost of some efficiency loss, which does not seems possible to recover by suitable weighting, as suggested in the simulations proposed here. At any rate, the number of pairs to consider for PL grows with the square of p, which still remains the main challenge in order to scale PL estimation on datasets with a large number of items.

Functional Data Analysis

A new functional clustering method: the Functional Clustering and Dimension Reduction model

Un nuovo metodo di clustering funzionale: il modello CDR funzionale

Adelia Evangelista and Stefano Antonio Gattone

Abstract In this work a new general procedure to cluster functional observations in a subspace of reduced dimension is proposed. In particular the method simultaneously performs cluster analysis and dimension reduction of functional data. The Functional Clustering and Dimension Reduction (FCDR) is obtained as the combination of two objective functions: the Functional Principal Component Analysis (FPCA) and the Functional Factorial K-Means (FFKM). The advantage of this approach consists in the optimization of a single global objective function which, by means of the selection of a tuning parameter, incorporates several techniques varying from the FPCA to FFKM including intermediate cases of clustering and dimension reduction.

Abstract In questo lavoro viene proposta una nuova procedura generale per raggruppare dati funzionali in un sottospazio di dimensioni ridotte. In particolare, il metodo esegue simultaneamente la cluster analysis e la riduzione della dimensionalità dei dati funzionali. Il metodo Functional Clustering and Dimension Reduction (FCDR) è ottenuto come la combinazione di due funzioni obiettivo: la Functional Principal Component Analysis (FPCA) ed il Functional Factorial K-Means (FFKM). Il vantaggio di questo approccio consiste nell'ottimizzare una sola funzione obiettivo globale che, attraverso la selezione di un parametro di controllo, include diverse tecniche che vanno dalla FPCA al FFKM includendo casi intermedi di raggruppamento e riduzione dei dati.

1 Introduction

Cluster analysis has been well used in multiple areas [5] and it continues to play a significant role for analysts and researchers. Unsupervised classification (or clustering) methods aim to classify a sample of data into homogeneous groups, without having any previous information about the clustering structure. This work deals with the clustering of functional data which received specific consideration in the last decade, as a result of the relevance of the high frequency data collected with modern technologies ([7]). Several clustering techniques for multivariate data have been suitably modified in order to be applied to functional data ([6]). Jacques and Preda ([9]) made an interesting review of the most important works related to functional clustering. They identify three general approaches: dimension-reduction before clustering, model-based clustering and nonparametric distance-based methods. Several approaches have been introduced for clustering univariate and multivariate functional data. See for example ([2][3][10][17][12]).
This work is based on the Clustering and Dimension Reduction (CDR) technique proposed by Vichi *et al* [15] which simultaneously identifies the optimal subspaces and the optimal clustering for multivariate data. The idea is that dimension reduction can improve the clustering recovery when the data incorporate unimportant information and the clusters lie in a subspace of reduced dimension ([3]). To this end, the proposed general model called Functional Clustering and Dimension Reduction (FCDR) represents an extension to the functional case of the CDR technique. The work is organized as follows. Section 2 describes Functional Principal Component Analysis (FPCA), Functional Factorial K-Means (FFKM)([17]), and Functional Reduced K-Means ([8, 16]) . The objective function of the FCDR model is presented in Section 3. Some concluding remarks are given in Section 4.

2 Background knowledge: FPCA, FFKM and FRKM

2.1 FPCA

A functional random variable X takes values in a Hilbert space of functions defined on a continuous subset of $\mathscr{R}$, say T. Let $\{x_i(t)\}_{i=1}^n$ be the set of observed curves where $t \in$ T. Without loss of generality assume that data are centered, i.e. the mean function has been subtracted and $\sum_{i=1}^n x_i(t) = 0$, for all $t \in T$. Let $\Phi = \{\phi_1, \phi_2, \ldots, \phi_J\}$ be a set of basis functions. X can be expanded in terms of basis functions as

$$X(t) = \sum_{j=1}^{J} c_{ig}\phi_j(t) = c_i^T \Phi. \tag{1}$$

FPCA searches an optimal representation of the curves into a functional space of reduced dimension. In other words it tries to minimize the reconstruction error of the

Q-dimensional approximation of the data given by the following objective function:

$$\ell_{FPCA}(\Psi) = \sum_{i=1}^{n} \|x_i(t) - \sum_{q=1}^{Q} a_{iq}\psi_q(t)\|^2 \tag{2}$$

where $a_{iq} = \int_{\mathrm{T}} x_i(t)\psi_q(t)dt$ are the principal component scores, projections of $x_i(t)$ on the orthonormal eigenfunctions ψ_q with $\int_{\mathrm{T}} \psi_q(t)\psi_r(t)dt = 1$ if $q = r$ and 0 otherwise. The eigenfunctions ψ_q belong to the same linear space spanned by the basis Φ, *i.e.* $\psi_q = \sum_{j=1}^{J} b_{jq}\phi_j(t) = b_q^T\Psi$ with $\Psi = \{\psi_1, \psi_2, \ldots, \psi_Q\}$.
Let C be the $n \times J$ matrix of basis coefficients with generic component c_{ij}, W the $J \times J$ matrix with generic component given by $w_{js} = \int_{\mathrm{T}} \phi_j(t)\phi_s(t)dt$, and B the $J \times Q$ matrix with generic column given by b_q. The FPCA loss function can be expressed in matrix form as follows:

$$\ell_{FPCA}(B) = \| \left[C - CWBB^T\right] \Phi\|^2. \tag{3}$$

2.2 FFKM

Cluster analysis and dimension reduction are often performed in tandem ([1]). A standard approach is to first apply a dimension-reduction technique to obtain a fewer number of components than the number of variables, and subsequently using the extracted components for clustering objects (*tandem clustering*). For example, one may apply standard clustering algorithm on the functional principal component scores a_{iq} [11]. A more efficient way to proceed is to implement the clustering simultaneously with dimension reduction. The main subspace functional clustering are the Functional Reduced K-Means (FRKM) ([8, 16]) and the Functional Factorial K-Means (FFKM) ([17]). FFKM applies to functional data the Factorial K-Means technique ([14]) where a clustering and a continuous factorial model are fitted simultaneously to multivariate data.
Let $U = \{u_{ig}\}(i = 1, \ldots, n; g = 1, \ldots, G)$ be the binary matrix defining the cluster parameters, where $u_{ig} = 1$ if $x_i(t)$ belongs to the $g-th$ cluster and 0 otherwise. Let n_g be the size of cluster g, the cluster centroids functions $\bar{x}_g(t) = \frac{1}{n_g}\sum_{i=1}^{n} u_{ig}x_i(t)$ are assumed to lie in a lower dimensional space. FFKM aims at identifying the optimal projection expressing the cluster structure of the data by minimizing the within-cluster deviance of the clusters in the reduced space given by the following objective function:

$$\ell_{FFKM}(U, \Psi) = \sum_{i,g} u_{ig} \| \sum_{q=1}^{Q} \int_{\mathrm{T}} x_i(t)\psi_q(t)dt\,\psi_q(t) - \sum_{q=1}^{Q} \int_{\mathrm{T}} \bar{x}_g(t)\psi_q(t)dt\,\psi_q(t)\|^2 \tag{4}$$

subject to the weight functions $\{\psi_q\}_{q=1}^{Q}$ being orthonormal.

The FFKM loss function can be expressed in matrix form as follows:

$$\ell_{FFKM}(U,B) = \|CWB - H_U CWB\|^2 \tag{5}$$

where $H_U = U(U^TU)^{-1}U^T$ is the projection matrix onto the space spanned by the columns of U.

2.3 FRKM

Functional Reduced K-Means (FRKM) attempts to find an optimal subspace for clustering functional data by maximizing the between cluster deviance in the reduced space.The loss function of FRKM is given by:

$$\ell_{FRKM}(U,\Psi) = \sum_{i=1}^{n}\sum_{g=1}^{G} u_{ig}\|x_i(t) - \sum_{q=1}^{Q}\int_{\mathrm{T}} \bar{x}_g(t)\psi_q(t)dt\,\psi_q(t)\|^2 \tag{6}$$

subject to the weight functions $\{\psi_q\}_{q=1}^{Q}$ being orthonormal.

In matrix form the loss function becomes

$$\ell_{FRKM}(U,B) = \|[C - H_U CWBB^T]\Phi\|^2. \tag{7}$$

3 The Functional CDR

The two methodologies described in Section2 have been shown to perform better than the tandem analysis ([17]). However, one technique maximizes the between cluster deviance (FRKM) and the other minimizes the within cluster deviance (FFKM) in the reduced space. Following Vichi *et al* [15] a more general model can be considered which combines the two methodologies in order to optimize both the within and the between deviance: the clustering and dimension reduction model (CDR). The Functional CDR loss function is developed as the sum of the FPCA loss function given in (3) and the FFKM loss function given in (5):

$$\ell_{FCDR}(U,B) = \alpha\ell_{FPCA}(B) + (1-\alpha)\ell_{FFKM}(U,B). \tag{8}$$

Hence, the minimization of the loss function (8) is a trade-off amid FPCA and FFKM. Clearly, by setting the value of the constant $\alpha = 0$, (8) becomes the FFKM loss function, vice versa fixing $\alpha = 1$ it is equivalent to minimize the loss function of the FPCA. By varying α between 0 and 1 different weights are given to FPCA and FFKM. Interestingly, it can be shown that with $\alpha = 0.5$ the FCDR is equivalent to the FRKM loss function. Therefore, the clustering solution depends on the chosen value of the tuning parameter α, whose selection becomes crucial.

Vichi *et al* [15] proposed to use the pseudo F index in order to automatically select the value of α ([4]). In this work different criterion to select the value of α are

considered and their performance evaluated through a simulation study. A criterion could be clustering stability proposed by [18]. The idea is to evaluate the clustering algorithm on different samples taken from the same population. If the algorithm is good, it should assign the units to the same cluster from one sample to another. An alternative criterion might be the *gap statistic* suggested by [13] for estimating the number of groups in a data set.

4 Future works

A simulation study to evaluate the performance of the FCDR algorithm together with the criterion for the choice of the tuning parameter α is currently under development.
A possible application of the FCDR method could be the identification of homogeneous areas in an environmental setting. Indeed, the FCDR method seems to be an optimal solution when dealing with meteorological variables where correlation and redundant information are usually found in the data.

Nonparametric functional prediction bands: theory with an application to bike sharing mobility demand in the city of Milan

Bande di previsione non parametriche per dati funzionali: teoria con un'applicazione allo studio della domanda di mobilità bike sharing nella città di Milano

Jacopo Diquigiovanni, Matteo Fontana and Simone Vantini

Abstract The talk will focus on the prediction of a new unobserved functional datum given a set of observed functional data, possibly in presence of covariates, either scalar, categorical, or functional. In particular we will present an approach (i) able to provide prediction regions which could visualized in the form of bands, (ii) guaranteed with exact coverage probability for any sample size, (iii) not relying on parametric assumptions about the specific distribution of the functional data set, and finally (iv) being computational efficient. The method is built on a combination of ideas coming from the recent literature pertaining to functional data analysis (i.e., the statistical analysis of datasets made of functions) and conformal prediction (i.e., a nonparametric predictive approach from Machine Learning). During the talk we will present the general theoretical framework and some simulations enlightening the flexibility of the approach and the effect on the amplitude of prediction bands of different algorithmic choices. Finally, we will apply the method to the joint prediction of bike pick-ups, drop-offs, and unbalance daily curves in the docking station network of the largest bike-sharing provider in the city of Milan (Italy).

Abstract *L'intervento si concentrerà sulla previsione di un nuovo dato funzionale non osservato a partire da un insieme di dati funzionali osservati, eventualmente anche in presenza di covariate scalari, categoriche o funzionali. In particolare presenteremo un approccio (i) in grado di fornire regioni di previsione visualizzabili in forma di bande, (ii) in grado di garantire una copertura esatta per qualsiasi*

1 Introduction

Functional Data Analysis ([6] [14]) is a field of Statistics focusing on the statistical analysis of data sets made of functions. Starting from the forerunner work of Jim O. Ramsay [13], several authors have proposed many interesting findings in this field: Functional Boxplots [16], Functional Principal Component Analysis [14] and Functional Linear Regression [14] are only a few examples of works concerning this still very lively area of modern statistics characterized by many still open research problems. Among these, we deal with the issue of creating prediction sets for newly observed functional data. Specifically, given a nominal confidence level $1-\alpha$, the purpose is to develop a method able to output either exact - i.e. guaranteeing a coverage exactly equal to $1-\alpha$ - or valid - i.e. guaranteeing a coverage not smaller than $1-\alpha$ - prediction sets. This crucial and still open challenge in the functional data analysis framework has been faced in two ways. The former approach is based on parametric bootstrapping techniques [3, 2], while the latter one is based on dimensionality reduction techniques [9, 1]. Both approaches carry some drawbacks: first of all, both of them are either based on non-trivial distributional assumptions and/or asymptotic statements. In addition, the former class of techniques is computationally demanding, whereas the latter class is obviously affected by the approximation induced by the dimensionality reduction. In view of this, this contribution will focus on presenting a procedure able to overcome these shortcomings by means of a new approach in the field of Conformal Prediction [18].

2 Short Outline

Our contribution will start with a gentle introduction to Conformal Prediction in the univariate setting [18, 15]. This approach is an innovative nonparametric approach to create prediction sets firstly developed in the field of Machine Learning as a method to construct prediction intervals for Support Vector Machines [8] and already used also in the functional context via the use of a finite-dimension truncated basis expansion [11]. We will show that the core of the approach is the choice of a *nonconformity measure*, namely any measurable function which takes values in $\mathbb{R}^+$ and whose aim is to score the "extremity" of an observation with respect to the other ones. Specifically, we will restrict our focus to the so called Split Conformal approach which allows the computationally efficient construction of finite-sample valid prediction sets under the assumption of exchangeable data by using a "virtual resampling" kind of reasoning.

We will than move to the case of independent and identically distributed functional data, which is our novel original contribution to the existing literature. We will list the properties that a prediction set is expected to satisfy in the functional framework. We will deepen a very relevant aspect of practical interest which concerns the shape of the sets: in particular, we will show that a functional prediction set must be a band [12, 11]. This allows indeed an easy visualization of the prediction set in the natural graphical visualization of functional data [10].

After having introduced Split Conformal prediction for univariate data and the properties required to functional prediction set, we will introduce a new group of nonconformity measures for functional data based on the supremum metric allowing the construction of functional prediction bands. These distribution-free functional bands will be proven to be finite-sample either valid or exact and defined in closed form. Some emphasis will be also placed on the computational cost characterizing the method. The procedure is indeed highly scalable as the computational effort required by the procedure increases only linearly with the sample size n. We will also focus on the the size of the prediction sets returned by the procedure. Different nonconformity measures - belonging to the aforementioned group of nonconformity measures - will be compared in different scenarios through simulation studies.

We will finally extend our proposal to the more general scenario of multivariate functional data with possible scalar, categorical, or functional covariates. We will show that, this extension is theoretically easy and still computationally affordable. We will conclude our contribution presenting an application to the analysis of bike sharing data. The method will be applied to forecast the daily patterns of bike pick-ups, drop-offs, and unbalance in all the different docking stations of the network from the one-day ahead hourly weather forecast of temperature and rain precipitations. In detail, in Fig. 1, the daily drop-off and pick-up rate curves (top left, top right respectively) are reported together with corresponding fitted values (center left, center right) and corresponding residuals (bottom left, bottom right) which are obtained using a concurrent function-on-function regression model with daily temperature and precipitation curves as functional covariates and the day of the week as a categorical covariate, as proposed in [17]. In Fig. 2, an example of conformal

prediction bands for the drop-off rate curve (light blue band) and the pick-up rate curve (red band) of a specific day with joint coverage $1-\alpha = 0.75$ is reported.

A detailed description and a deep theoretical study of our proposal (together with further simulations and details about the application) can be found in [4] and [5]. An introduction to Conformal Prediction can be found instead in the review paper [7].

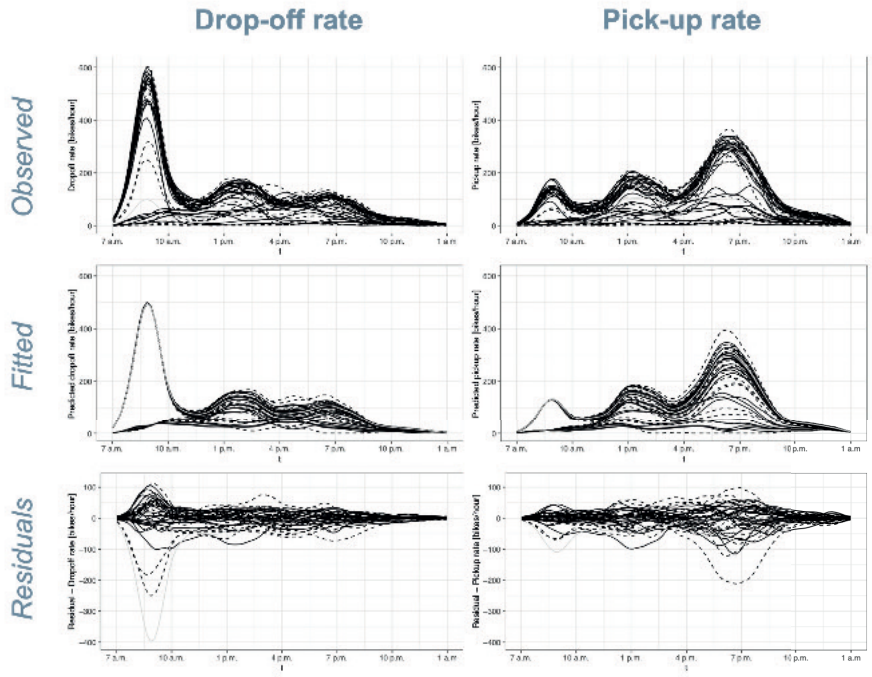

Fig. 1 Daily drop-off and pick-up rate curves (top left, top right respectively), corresponding fitted values (center left, center right), and corresponding residuals (bottom left, bottom right). Continuous curves refer to the observations in the training set, dashed curves to those in the calibration set.

An R package for the statistical process monitoring of functional data

Un pacchetto R per il monitoraggio statistico di processo di dati funzionali

Christian Capezza, Fabio Centofanti, Antonio Lepore, Alessandra Menafoglio, Biagio Palumbo, Simone Vantini

Abstract We present the R package `funcharts` for the statistical process monitoring (SPM) of multivariate functional data, which is useful for many industrial applications where data are available as multivariate profiles. Its objective is to build control charts to detect mean shifts in a process. The quality characteristic of interest is a scalar or functional variable and is assumed to be affected by multivariate functional covariates. Functional regression is used to model the relationship between the quality characteristic and the functional covariates in order to improve the ability to detect whether the process is out of control. Moreover, the package allows real-time monitoring of functional data with temporal domain. We show how to use `funcharts` via a real-case study in the shipping industry on the SPM of the CO_2 emissions from navigation of a roll-on/roll-off passenger cruise ship.

Abstract *Quest'articolo presenta il pacchetto R* `funcharts` *per il monitoraggio statistico di dati funzionali multivariati. Il pacchetto è utile per molte applicazioni industriali in cui i dati sono acquisiti come profili multivariati e il cui obiettivo è l'identificazione di derive di processo di una caratteristica di qualità, scalare o funzionale, influenzata da covariate funzionali multivariate. Per modellare la relazione tra la caratteristica di qualità e le covariate viene utlizzata l'analisi di regressione funzionale, in grado di migliorare il potere diagnostico delle classiche carte di controllo per dati funzionali. Viene infine mostrato come il pacchetto* `funcharts` *consente anche il monitoraggio in tempo reale di dati funzionali non completamente osservati. Il pratico utilizzo del pacchetto sviluppato viene mostrato attraverso un caso studio reale su dati raccolti a bordo di una nave da carico e passeggeri.*

Key words: Functional data analysis, statistical process monitoring, profile monitoring, R package

1 Introduction

A large amount of operational data about many process variables is nowadays available thanks to the installation of data acquisition technologies with multiple high-frequency sensors installed on board of devices. In this context, there are many applications where the quality characteristics is acquired in the form of multiple profiles, often referred to also as functional data [6, 10]. The increasing amount of available functional data is leading to a growing interest in the literature on profile monitoring [8, 9], whose objective is to check the stability over time of the process through a functional quality characteristic of interest, and to distinguish special causes of variation from normal ones acting on a process.

Most of the current approaches to profile monitoring build control charts to detect out-of-control (OC) conditions, without necessarily considering other variables that may intervene. A few exceptions are the recent works of [3] and [4], which extend the regression control chart [7] in the multivariate case to functional data. In these works, control charts are proposed to improve the effectiveness of the monitoring strategy by considering the influence on the quality characteristic of scalar or functional covariates, in a supervised fashion. In this background, we present the R package `funcharts`, available on CRAN [2], for the Phase II SPM of multivariate functional data.

2 Methodology

Centofanti et al. [4] proposed the functional regression control chart (FRCC) framework based on the function-on-function linear regression model

$$y_i(t) = \beta_0(t) + \sum_{p=1}^{P} \int_{\mathscr{S}} X_{ip}(s)\beta_p(s,t)ds + \varepsilon_i(t), \quad i = 1,\dots,n, \quad t \in \mathscr{T}, \qquad (1)$$

where $y_i \in L^2(\mathscr{T})$ is the functional response variable, $\boldsymbol{X}_i = (X_{i1},\dots,X_{iP})^\top \in \mathbb{H}(\mathscr{S})$ are the functional covariates, $\beta_1,\dots,\beta_P$ are the functional coefficients in $L^2(\mathscr{S} \times \mathscr{T})$, $\beta_0 \in L^2(\mathscr{T})$ is the functional intercept, and $\varepsilon_1,\dots,\varepsilon_n$ are the independent error terms with zero mean. The model can be specialized to a scalar-on-function regression if $y_i(t)$ is constant for all t, as in the work of Capezza et al. [3]. Capezza et al. [3] and Centofanti et al. [4] propose to estimate model (1) by applying multivariate functional principal component analysis to the functional covariates and response. After retaining a subset of the estimated principal components, an approximate multivariate model is obtained, which can be estimated through least squares. The esti-

mated model yields predictions of the response variable, then the prediction error on the response variable can be monitored through the FRCC, which, in the functional response case, is the set of Hotelling's T^2 and the squared prediction error (*SPE*) control charts calculated on the functional residuals. We refer to [3] and [4] for the definition of the two monitoring statistics. In the scalar response case, under normality assumption, the scalar prediction error can be monitored by using control limits based on quantiles of the t distribution. If at least one monitoring statistic is out of the control limits, then an OC alarm is issued. Capezza et al. [3] provide details on how to build contribution plots for fault detection in case an OC is raised.

The R package `funcharts` also implements a real-time monitoring of right-censored functional data where the right edge of the domain progressively moves right over time, as introduced by Capezza et al. [3] for the scalar response case. In fact, hastening the detection of an OC state of the process (before the entire acquisition of the profiles is available) becomes essential in many modern scenarios. We briefly describe below how real-time monitoring is implemented in the `funcharts` package, given a future observation observed in the interval $(0,t)$, where the functional domain is $\mathscr{T} = (0,T)$ and $t < T$. The FRCC is firstly built on the data set obtained by restricting all functional covariates and response in the reference data set used for model estimation to the interval $(0,t)$. Then, the Hotelling's T^2 and *SPE* monitoring statistics are calculated for a future observation to be monitored in real time. By repeating this procedure at several intermediate domain points t between zero and T, real-time evolution of the monitoring statistics is then obtained by means of a reference data set, i.e., a clean data set used to estimate the model and control chart limits.

3 A real-case study

In this section, we aim to demonstrate how the `funcharts` package can be used to build the FRCC in a real-case study on the SPM of CO_2 emissions in the shipping industry. The latter is an important topic because of the dramatic climate change in the last years and urges shipping companies to equip their fleet with multiple devices able to acquire high-frequency operational data about many variables. For each voyage of a ship connecting a departure and an arrival port, these data can often be modeled as profiles.

Data are courtesy of the shipping company Grimaldi Group. For confidentiality reason, the name of the ship, ports and GPS data are omitted and variables are scaled. The data refer to the navigation phase only and all profiles are functions defined on the same domain interval $\mathscr{T} = (0,1)$, which is the fraction of the total distance traveled by the ship at each voyage. The profile of the CO_2 emissions per mile are the quality characteristic of interest and the following four functional covariates are considered as covariates affecting the CO_2 emissions based on the experience of shipping managers, marine engineers and operators, namely the speed over ground,

the trim and the transverse and longitudinal wind components. For more details on the variable description we refer to [1, 5].

In the proposed application, we filter a single route that contains 300 voyages. After an energy efficiency initiative (EEI) performed on the ship, consisting mainly in a silicone foul release coat of the hull, a paint company as described in [5] guarantees a CO_2 emission reduction. In light of this, the reference data set can suitably include profiles related to 159 voyages pertaining to one year before the EEI. The following 141 voyages after the EEI can be then used for the Phase II monitoring.

In the following, we include the main results of the navigation data analysis. First, functional data are obtained from the data frame containing the original discrete data through the function `get_mfd_df`, which returns an object of the class `mfd` for multivariate functional data, provided by the `funcharts` package. After splitting the observations of the `mfd` object into functional response and covariates variables, each in turn split into before and after EEI observations, the function-on-function regression model is fit on the training data (before EEI) using the function `fof_pc`. Finally, based on the output object returned by the regression model and the new data (after EEI), the FRCC is obtained with the function `regr_cc_fof` and is plotted in Figure 1. Note that the monitoring statistics calculated on the before EEI data set are also plotted on the left hand side of the vertical dashed line. The FRCC shows a clear mean shift in the functional residuals since most of the observations collected after EEI are signalled as OC.

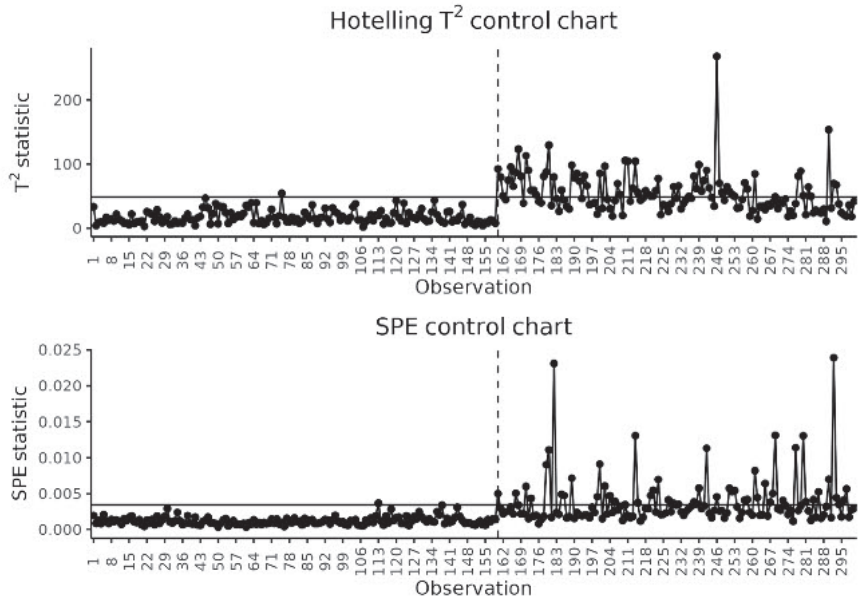

Fig. 1 FRCC used in the real-case study on the navigation data.

Finally, we briefly show how to apply real-time version of the FRCC on the navigation data set. We do not include the code for brevity, however, we report the most relevant result regarding the voyage n. 292, signaled as OC by the FRCC. We can notice that the SPE statistic goes very large in the central part of the domain, being able to anticipate the anomaly long before the end of the voyage.

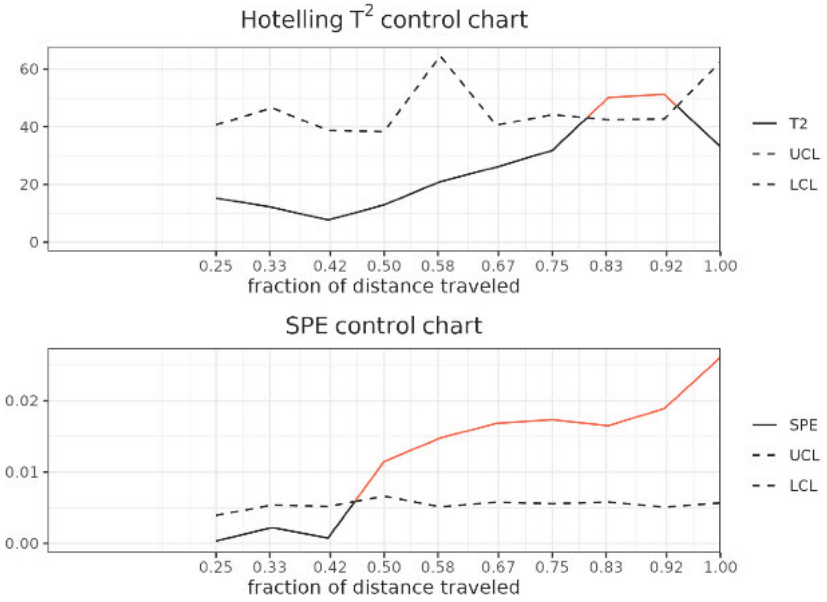

Fig. 2 Real-time FRCC used to monitor the Phase II voyage 292 in the navigation data set.

4 Conclusions

This article introduces the `funcharts` package for the statistical process monitoring (SPM) of multivariate functional data. In particular, it implements through R the recent methods of [3] and [4] and provides tools for building functional data, performing multivariate functional principal component analysis, building control charts for Phase II monitoring of shifts in the functional mean, allowing also the real-time monitoring for functional data with temporal domain. We demonstrate the package with a real-case study in the shipping industry on monitoring CO_2 emissions from navigation. The main added value of this R package is to make available and practically applicabile these novel statistical methodologies for complex data by marine engineers, even though the proposed methodologies are not limited to this

application and can be extended to all applications of SPM in presence of multivariate functional data.

Trend filtering for functional regression

Trend filtering per regressione funzionale

Federico Ferraccioli, Alessandro Casa and Marco Stefanucci

Abstract We propose a penalized approach for scalar on function regression. The method combines ideas from the trend filtering literature and regularization, allowing great flexibility and adaptivity to different degree of smoothness. The method leverages on a proper transformation of the functional predictor based on derivative operators of a certain degree. This allows to define an equivalent generalized lasso problem, that has some similarity to the spline basis approach, but removes the constraints on the locations of the basis. The perfomances of the methods are shown via experimental results.

Abstract *Si propone un approccio di stima penalizzata per regressione funzionale con risposta scalare. Il metodo combina idee provenienti dalla letteratura trend filtering e metodi di regolarizzazione, e permette una grande flessibilità e adattività a diversi gradi di regolarità. Il metodo sfrutta una appropriata trasformazione dei predittori funzionali basata sull'operatore derivata di un dato ordine. Questo permette di definire un problema equivalente in forma di stima lasso, il quale presenta alcune similarità all'approccio spline, senza però richiedere restrizioni sulle locazioni delle basi. Il comportamento del metodo proposto è valutato attraverso uno studio di simulazione.*

1 Introduction

Among the vast class of functional data analysis tools that had risen in popularity in the last decades, functional regression is certainly one of the core building blocks. It found use in spectroscopy, astrophysics and in general when the data are characterized by a temporal dimension. This setting can correspond to either functional predictors or functional responses (see Ramsay and Silverman [2005] for a thorough discussion on this topic).

In this work, we focus on regression models where a scalar response is predicted by means of a functional predictor. Let denote with $\{X_i(t), y_i\}_{i=1,\dots,n}$ the set of observed data, with $y_i \in \mathbb{R}$ being the response, and $X_i(t)$ the functional predictor. A classical formulation in this setting known as functional linear model is given by

$$y_i = \beta_0 + \int X_i(t)\beta(t) + \varepsilon_i \qquad i = 1, \dots, n. \tag{1}$$

Since we are dealing with an infinite-dimensional space of functions, regularization approaches are needed in order to obtain a meaningful and valid estimate of $\beta(t)$. There are two main strategies to address this problem. The first one represents $\beta(t)$ using a p-dimensional basis function, with p carefully chosen in order to effectively apply a regularization, while capturing the relevant features of $\beta(t)$. This lead to an ordinary least square problem, with p playing the role of the smoothing parameter. The second approach involves a penalized least squares estimation procedure to shrink variability in $\beta(t)$. Classical proposals for the penalty take the form of norm of a certain derivative of $\beta(t)$, e.g. $\int \beta(t)^{(d)}(t)^2 dt$, with $d = 2$ being a common choice. The estimation procedure is then recasted as a penalized regression problem, driven by a smoothing parameter λ. Both methodologies have different advantages in different scenarios. Nonetheless, they generates curves that do not adapt in case of different degree of smoothness. Moreover, when for certain regions of the domain $\beta(t) = 0$, the estimates they produce tend to be wiggly and not exactly linear or constant over any region.

Here we propose a flexible approach that is able to overcome these issues, bypassing the basis formulation but still obtaining interpretable estimates. Our proposal leverages on the trend filtering framework developed in Kim et al. [2009]. The idea is to define a proper transformation of the functional predictor $X(t)$ based on the derivative operator, that allows to define an equivalent generalized lasso problem [Tibshirani, 1996]. A similar approach is developed in James et al. [2009]. The proposed method has certain similarity to the basis approach, but removes the constraints on the locations of the basis.

In the next section we outline the methodology, while in Section 3 we show the performances of the proposed methodology via simulations. Section 4 is devoted to a discussion and possible extensions.

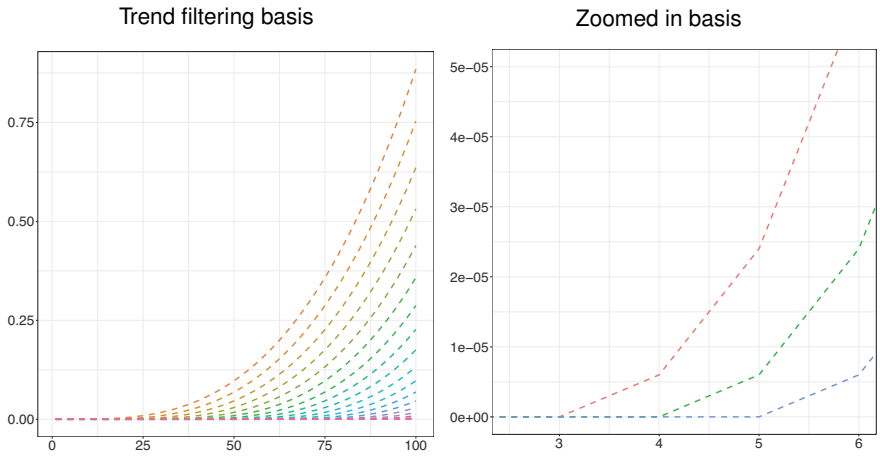

Fig. 1 On the left, the trend filtering basis functions of degree 3. On the right, the same basis are depicted more closely to show their behavior.

2 Methodology

The proposed approach borrows ideas from the classical penalized regression framework but it is rather different in nature. We start by introducing the notation and, afterwards, we discuss the differences and similarities with other methodologies.

Let assume we observe the functional predictors $X_i(t)$ at m distinct input points $(t_1,\dots,t_m)$. We denote by $\mathbf{X}$ the $n \times m$ dimensional matrix of functional predictors, and by $\boldsymbol{y}$ the n dimensional real-valued response vector. Let also $\boldsymbol{\beta} = (\beta(t_1),\dots,\beta(t_m))$ the m-dimensional vector of coefficients at the input points. In order to obtain a valid estimate for the infinite dimensional problem (1), we need to impose some restrictions on the coefficients $\boldsymbol{\beta}$. Here we propose to penalized the ℓ_1 norm of the derivative of $\boldsymbol{\beta}$. This allows to reduce the wiggliness of the estimates while simultaneously shrinking to zero the regions where the functional predictors have no effect on the response.

The resulting penalized least square estimation problem is then defined as

$$\underset{\boldsymbol{\beta}\in\mathbb{R}^m}{\arg\min} ||\boldsymbol{y} - \mathbf{X}\boldsymbol{\beta}||_2^2 + \lambda ||\boldsymbol{D}^{(k+1)}\boldsymbol{\beta}||_1 \tag{2}$$

where $\lambda > 0$ plays the role of smoothing parameter and $\boldsymbol{D}^{(i)}$ is the i-th order discrete difference operator.

For general k, the optimization problem in (2) does not have a straightforward solution, due to the complex penalty term. To solve this issue, we propose an equivalent generalized lasso formulation, based on the inversion of the derivative operator. More precisely, let us define $\mathbf{D} \in \mathbb{R}^{m\times m}$ the matrix

$$\mathbf{D} = \begin{bmatrix} \boldsymbol{D}_1^{(0)} \\ \vdots \\ \boldsymbol{D}_1^{(k)} \\ \boldsymbol{D}^{(k+1)} \end{bmatrix},$$

where $\boldsymbol{D}_1^{(i)} \in \mathbb{R}^{1\times m}$ denotes the first row of the i-th discrete difference operator $\boldsymbol{D}^{(i)}$, for $i = 1,\dots,k$ (by convention, $\boldsymbol{D}^0 = \boldsymbol{I}_m$). It is easy to show that the matrix $\mathbf{D}$ is invertible, with inverse $\mathbf{D}^{-1} = \mathbf{M}$ [see Appendix in Tibshirani, 2014]. We then define the vector of transformed coefficients $\boldsymbol{\alpha} = m^k/k! \cdot \mathbf{D}\boldsymbol{\beta}$. By substituting the expression for $\boldsymbol{\alpha}$ in (2), we obtain the equivalent optimization problem

$$\underset{\boldsymbol{\alpha}\in\mathbb{R}^m}{\arg\min} \left\| \boldsymbol{y} - \frac{k!}{m^k}\mathbf{X}\mathbf{M}\boldsymbol{\alpha} \right\|_2^2 + \lambda \sum_{j=k+2}^{m} |\alpha_j|. \tag{3}$$

Note that (3) takes the form of a lasso problem and can be solved using standard optimization procedures [Tibshirani, 1996].

The proposed formulation (3) has some similarity with locally adaptive regression splines. In particular, the matrix $\mathbf{M}$ takes the form of a basis matrix, where the basis functions are the falling factorial analogues of the truncated power basis in locally adaptive regression splines (see Figure 1). The main difference is that the proposed formulation allows for discountinuities in the derivatives of order $(1,\dots,k-1)$, while adaptive splines maintain continuous derivative. This is a major advantage in our methodology, since it allows to capture different degree of smoothness without introducing oscillatory behaviours in regions where $\beta(t)$ is linear or constant. A similar approach has been proposed in James et al. [2009], where the authors develop a flexible functional regression approach where they combine a classical spline basis formulation with a lasso penalty on the derivative of $\boldsymbol{\beta}$. This differs from our approach, since we do not use spline basis but we model directly the functional predictors.

3 Experimental results

In this Section we present a simulation study to investigate the performances of the proposed procedure. We start from model (1) and we define a function $\beta(t)$ with different degree of smoothness. More precisely, the function is a polynomial of order 3 but is characterized by a flat segment in the central region of the domain (see Figure 2). We set a sample size $n = 500$, with $m = 100$ equispaced input points. We generated 100 samples from model (1) with ε_i i.i.d. Gaussian noise terms with standard deviation 2. We estimated the model via coordinate descent using the `R` package `glmnet` [Friedman et al., 2010] with the order of the penalty set to $k = 0$.

Figure 2 shows the results for two different values of the smoothing parameter. The solid red line represents the true value of $\boldsymbol{\beta}$, while the shaded lines correspond to

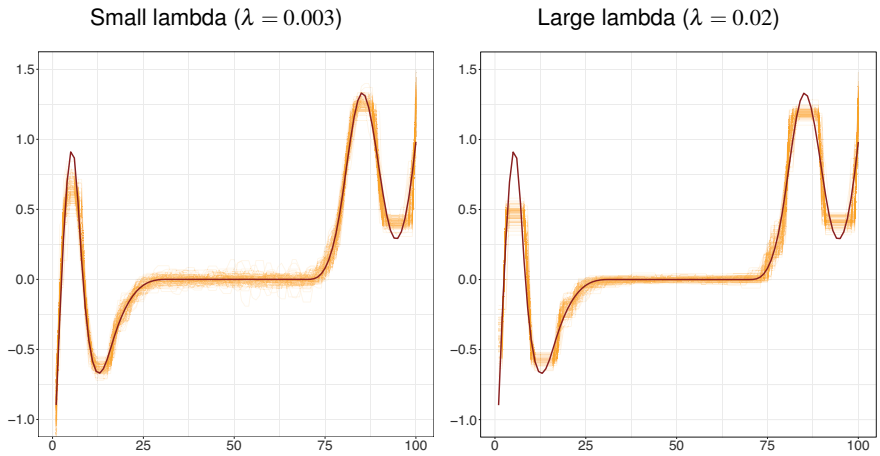

Fig. 2 Estimates for 100 samples from model (1); the solid red line represents the true function, while the background orange lines represent the estimates. Note that for small values of λ, the estimates follow more easily the peaks of the functions, while higher values lead to a more faithful reconstruction of the central regions at the cost of some oversmoothing in the peaks.

the 100 estimates. In both cases, the results look promising as the estimates not only perfectly capture the flat region in the middle of the domain, but also the high curvature peaks. It is worth noting how the choice of λ affects the results. For smaller values, the estimates follow more easily the peaks of the functions, but tend to exhibit more variability in the flat region. On the contrary, higher values of λ lead to a more faithful reconstruction of the central regions at the cost of some oversmoothing in the peaks. This is due to the form of the constraint which, penalizing the first derivative of the estimates, leads to a better estimation of zero-th order functions. We leave the study of higher order constraints to future work.

4 Discussion

We presented a generalization of the trend filtering approach for scalar on function regression. The methodology shows promising results and can be generalized in different ways. First, by imposing appropriate conditions on the functional inputs, we can extend the model to higher order derivatives or even to combinations of multiples derivatives. Given the convex form of the minimization problem, we can also consider alternative optimization procedure to improve the convergence. A possible direction could be given by the ADMM algorithms proposed by Ramdas and Tibshirani [2016]. Future works will also consider the introduction of covariates and the study of inferential procedures such as confidence intervals and hypothesis tests.

Conformal Prediction for Spatio-Functional Regression models

Conformal Prediction per modelli di regressione spazio-funzionale

Andrea Diana, Elvira Romano and Antonio Irpino

Abstract In this work we propose and show a general framework of distribution-free predictive inference for Spatio-Functional Regression models using Conformal Prediction techniques. In particular we focus on Geographically Weighted Regression (GWR) and Heteroskedastic Geographically Weighted Regression (HGWR) with two novel choices of non-conformity measures to compute simultaneous prediction bands.

Abstract In questo lavoro viene proposta e illustrata una generica procedura per fare inferenza non paramentrica su modelli di regressione spazio-funzionale utilizzando tecniche di Conformal Prediction (CP). In particolare l'attenzione viene posta sul modello di regressione geografico pesato (GWR) ed eteroschedastico (HGWR) con due nuove misure di non conformitá per calcolare bande di predizione.

Key words: functional data, spatial dependence, conformal prediction, regression model

1 Introduction

In this work we deal with regression models for spatio-fuctional data [5] and the problem of predictive inference. A crucial challenge for these models, like in classic functional data analysis methods, is quantifying uncertainty in prediction.

In Functional Data Analysis ([7],[9]), methods related to this framework consists in working on parametric bootstrapping techniques ([2], [4]), or in the application of dimensional reduction techniques to manage the naturally infinite dimensional problem ([1], [8]). More recent works are based on a novel approach to forecast by

Andrea Diana
University of Campania Luigi Vanvitelli, Caserta, Italy, e-mail: andrea.diana@unicampania.it

Elvira Romano,
University of Campania Luigi Vanvitelli, Caserta, Italy, e-mail: elvira.romano@unicampania.it

using Conformal Prediction (CP) ([6]). This last one overcome the previous literature since it is able to output either exact or valid prediction bands under minimal distributional assumptions.
The objective of the present work is to introduce a general framework for distribution-free predictive inference in Geographically Weighted Functional Regression (GWFR) and its heteroskedastic version using conformal inference. A prediction band for the functional response variable is proposed and two new non conformity measures are introduced. Prediction bands with locally varying length are defined, in order to adapt the approach in presence of heteroskedasticity in the data.

2 Spatially dependent Functional Regression models for geostatistical functional data

Geostatistical functional data $(X_{s_1}(t),\ldots,X_{s_i}(t),\ldots,X_{s_n}(t))$ are random functions $X_s(t)$ located in n points $(s_1,\ldots,s_i,\ldots,s_n)$ in $D \subseteq R^d$. Each function is defined on $T=[a,b] \subseteq R$ and is assumed to belong to a Hilbert space with the inner product $\langle X_{s_i}, X_{s_j}\rangle = \int_T X_{s_i}(t)X_{s_j}(t)dt$ [9]. For a fixed site s_i, it is assumed that the observed functions can be expressed according to the model: $X_{s_i}(t) = \mu_{s_i}(t) + \varepsilon_{s_i}(t), \quad i = 1,\ldots,n$ where $\varepsilon_{s_i}(t)$ are zero-mean residuals and $\mu_{s_i}(t)$ is the mean function.
For each $t, t \in T$, the random process is assumed to be second order stationary and isotropic: that is, the mean and variance functions are constant and the covariance depends only on the distance between sampling sites. It is assumed that the mean function is constant over D and that the semivariogram function $\gamma(h,t) = \gamma_{s_i s_j}(t) = \frac{1}{2}V(X_{s_i}(t) - X_{s_j}(t))$, according to [5], can be expressed by:

$$\gamma(h,t) = \gamma_{s_i s_j}(t) = \frac{1}{2}V(X_{s_i}(t) - X_{s_j}(t)) = \frac{1}{2}E\left[X_{s_i}(t) - X_{s_j}(t)\right]^2. \tag{1}$$

Let's suppose we want to predict a functional response variable $Y_s = \{Y_s(\tau), \tau \in T_1\}$ starting by K functional covariates $\chi_{s_i}(t) = [X_{s_{i,1}}(t),\ldots,X_{s_{i,K}}(t)]^T$. We can consider the geographically weighted regression (GWR) model [11] given by

$$Y_{s_i}(\tau) = \beta_0(\tau, s_j) + \sum_{k=1}^{K}\int_T X_{s_i,k}(t)\beta_k(t,\tau,s_j)dt + \varepsilon_{s_i}(\tau),\ i = 1,\ldots,n, \tag{2}$$

where the function $\beta_0(\tau, s_j)$ is the mean function at location s_j, $\beta_k(t,\tau,s_j)$ is the regression function for the $k-$th covariate at location s_j, and $\varepsilon_{s_i}(\tau)$ is a random error function at point s_i.

In this classical GWR model, the regression coefficients vary geographically and the variance of the error term is assumed fixed. The Heteroskedastic version of this model is obtained by assuming that the variance of the residual model depends on the spatial location. This can be illustrated by observing that local variability of the coefficients in the space may depend on different levels of the spatial variability.

In the HGWR the variance of the model ${\sigma^2}_{s_i}^{GWR}(t)$ is calibrated by replacing $\sigma^2(t)$ with $\sigma^2_{s_i}(t)$. By assuming that ${\sigma^2}_{s_i}(t)$ is a continuous function over the space, it can be estimated by a mean smoother. The final variance $\hat{\sigma}^2_{s_i}(t)$ replaces $\hat{\sigma}^2(t)$ to give

$$ {\sigma^2}_{s_i}^{GWR}(t) = var\{\hat{Y}_{s_i}(t) - Y_{s_i}(t)\} = \hat{\sigma}^2_{s_i}(t)[1 + S_{s_i}(t)] \tag{3} $$

The usual geographical weight at s_i is multiplied by the inverse of $\hat{\sigma}^2_{s_i}(t)$, where this second weighting term corrects for local heteroskedasticity, and resembles the weighted least squares (WLS) in MLR to stabilise a non-constant residual variance. The model has an iterative form, where at each iteration step, a re-weighted H-GWR fit is found.

Statistical inference on these models is strictly related on testing the variability of the coefficients and in constructing confidence interval by using bootstrapping procedures ([11]). In the following we introduce a conformal approach to construct prediction bands such to have finite sample validity, without assumption on the probability models.

3 Conformal Prediction for GWR and HGWR

Consider i.i.d. regression data $(\chi_{s_1}(t), Y_{s_1}(\tau)), \ldots, (\chi_{s_n}(t), Y_{s_n}(\tau)) \sim P$, where each $(\chi_{s_i}(t), Y_{s_i}(\tau))$ is a multivariate spatial functional stochastic process or a multivariate functional random field in $\mathscr{L}_2(T)^K \times \mathscr{L}_2(T_1)$, comprised of a response variable $Y_{s_i}(\tau)$ and a k−dimensional vector of features (or predictors, or covariates) $\chi_{s_i}(t) = (X_{s_i,1}(t), \ldots, X_{s_i,K}(t))$. The feature dimension K may be large relative to the sample size n (in an asymptotic model, K is allowed to increase with n). We are interested in predicting a new response $Y_{s_{n+1}}(\tau)$ from a new feature value $\chi_{s_{n+1}}(t)$, with no assumptions on P. Formally, given a nominal miscoverage level $\alpha \in (0,\, 1)$, a prediction band $C \subset \mathscr{L}_2(T)^k \times \mathscr{L}_2(T_1)$ based on $(\chi_{s_1}(t), Y_{s_1}(\tau)), \ldots, (\chi_{s_n}(t), Y_{s_n}(\tau))$ is such that

$$ \mathbb{P}(Y_{s_{n+1}}(\tau) \in C(\chi_{s_{n+1}}(t))) \geq 1 - \alpha, \tag{4} $$

where the probability is taken over the s_{n+1} i.i.d. draws $(\chi_{s_1}(t), Y_{s_1}(\tau)), \ldots, (\chi_{s_n}(t), Y_{s_n}(\tau), (\chi_{s_{n+1}}(t), Y_{s_{n+1}}(\tau))) \sim P$, and $C(\chi_s(t)) = \{Y_s(\tau) \in \mathscr{L}_2(T) :\ (\chi_s(t), Y_s(\tau)) \in C\}$ for a point $\chi_s(t) \in \mathscr{L}_2(T)^k$. The defined prediction bands have finite-sample (nonasymptotic) validity, without assumptions on P. These can be obtaining by defining the following algorithm of conformal prediction:

Algorithm of conformal prediction

Input: Data $(\chi_{s_i}(t), Y_{s_i}(\tau))$, $i = 1, \ldots, n$, miscoverage level $\alpha \in (0,1)$, Nonconformity measure $\mathscr{D}$, regression algorithm $\mathscr{A}$, points $\chi_{new}(t) =$

$\{\chi_{s_{n+1}}(t), \chi_{s_{n+2}}(t), \ldots\}$ at which to construct prediction band, and values $Y_{trial}(\tau) = \{Y_{s_{n+2}}(\tau), Y_{s_{n+2}}(\tau), \ldots\}$ to act as trial values
Output: Predictions band, at each element of $\chi_{new}(t)$
for $\chi_s(t) \in \chi_{new}(t)$ **do**
  for $Y_s(\tau) \in Y_{trial}(\tau)$ **do**
    $\hat{Y}_s(\tau) = \mathscr{A}(\{(\chi_{s_1}(t), Y_{s_1}(\tau)), \ldots, (\chi_{s_n}(t), Y_{s_n}(\tau)), (\chi_s(t), Y_s(\tau))\})$
    $R_{Y_s(\tau),s_i} = \mathscr{D}(\hat{Y}_s(\tau), Y_{s_i}(\tau))$, $i = 1, \ldots, n$ and $R_{Ys,s} = \mathscr{D}(\hat{Y}_s(\tau), Y_s(\tau))$
    $\pi(Y_s(\tau)) = \frac{1+\sum_{i=1}^{n} \mathbf{1}_{\{R_{Y_s(\tau),s_i} \leq R_{Y_s(\tau),s}\}}}{n+1}$
  end for

end for
Return $C_{conf}(\chi_s(t)), for\ each\ \chi_s(t) \in \chi_{new}(t)$

The regression algorithm $\mathscr{A}$ in our case is GWR and HGWR for geostatistical functional data. The non-conformity measures are two, an optimally weighted distance for functional data spatially dependent and a distance defined as a covex combination of the functional and the space dimension. $\mathscr{D}$ is an optimally weighted distance for functional data spatially dependent defined as in [10]

$$d_{\omega_s}\left(X_{s_i}(t), X_{s_j}(t)\right) = \sqrt{\int_T \omega_s(t)(X_{s_i}(t) - X_{s_j}(t))^2 dt} \tag{5}$$

where the weight ω_s satisfies $\omega_s \geq 0$ and $\int \omega_s dt = 1$. Using distance in 5, we consider weight functions including both the spatial and functional component. It is a generalisation of [3] to the spatial functional framework for two different spatial domains: the georeferenced and the directed network.
The spatio-functional smooth function is obtained by the following minimisation problem:

$$\omega_s(t) = argmin_{||\omega_s||=1} \frac{\sum_{1 \leq i < j \leq n} V(||\theta_{i,j})||^2_{\omega_s})}{\sum_{1 \leq i < j \leq n} [E(||\theta_{i,j})||^2_{\omega_s})]^2}; \tag{6}$$

with $\theta_{i,j}(t) = a_{i,j}X_i(t) - a_{j,i}X_j(t)$, where $a_{i,j}$ and $a_{j,i}$ are obtained starting from the structure of the spatial domain of interest. The coefficient $a_{j,i}$ is the element reflecting the spatial dependence among functional data and changes according to the spatial grid on which the functional data are observed. In our case, we choose a weight function depending on the spatial variability expressed by a trace-variogram function. Formally we define: $a_{i,j} = a_{j,i} = \hat{\gamma}(h_{i,j})$ where $\hat{\gamma}(h)$ is the estimated trace-variogramm. In alternative, $\mathscr{D}$ is a convex combination of classical functional distance and spatial distance.
An application on environmental studies shows main characteristics and advantages of both the proposed approaches.

Tourism and sport studies

Assessing satisfaction of tourists visiting Italian museums: evidence from the eWOM

Valutare la soddisfazione dei turisti che visitano i musei italiani: evidenze dall'eWOM

Daria Mendola and Valentina Oddo*

Abstract Museum visitors' satisfaction is a priority asset for those museums aiming at being competitive in the cultural tourism sector. In this study, evaluations by visitor-tourists, left in their reviews on museums on the TripAdvisor platform, are analysed. Through web scraping, we collected comments for twelve Italian museums left during the year 2019. The content analysis focussed on components of the tourists' satisfaction among Italian and foreign museum visitors, with emotional response, management, and exhibitions emerging as key concepts in museum's evaluation. Noticeably, some elements emerged as divisive: i.e., they appeared both among less and most satisfied tourist-visitors.

Abstract *La soddisfazione dei visitatori dei musei è un asset prioritario per quei musei che vogliano avere una posizione dominante nel turismo culturale. In questo studio vengono analizzate le valutazioni del visitatore-turista rilasciate come recensioni sulla piattaforma TripAdvisor. Attraverso il web-scraping, abbiamo raccolto i commenti su dodici musei italiani per l'anno 2019. La content analysis ha consentito l'esplorazione delle componenti di soddisfazione di visitatori italiani e stranieri. Le componenti emozionale, di management e le mostre hanno evidenziato un ruolo chiave. Sorprendentemente, alcuni elementi sono apparsi divisivi in quanto compaiono tra i principali motivi sia di soddisfazione che di insoddisfazione.*

Key words: Satisfaction, eWOM, Web-Scraping, Content Analysis, TripAdvisor.

1 Introduction

Cultural tourism is one of the main drivers of the Italian tourism flows and plays a crucial role in smoothing tourism seasonality [3]. Moreover, as from Ministry of Culture and Heritage data [9], richness of Italian artistic and cultural heritage is mainly concentrated in museums.

Museum managers have often to deal with the scarceness of funds and need to implement funding initiatives to meet conservation and maintenance costs. A recent trend is to base those strategies on visitors and their needs [4].

Satisfaction of visitors develops loyalty, increases museum reputation (e.g., through word-of-mouth among visitors), and is strictly linked to prospective revenues and funding opportunities [11]. Therefore, monitoring visitors' satisfaction provides museums with tools to plan competitive strategies, and to increase museums' attractiveness. Hence, the satisfaction of visitors is crucial to museums' survival over time.

Social media have dramatically changed the way the reputation of museums build itself. Visitors are currently able to exchange information, experiences, and emotions and communicate their satisfaction in a very easy and globally widespread way. At the same time, or consequently, social media have renewed the museum's approach to communication and marketing, besides revitalizing the learning, entertainment, and fundraising activities [1, 8].

In the last decade, user-generated content (UGC) has been gaining reliability for consumers, thus becoming an important input in their decision-making process, especially for the museum sector [8]. By producing UGC, e.g., via the so-called electronic word-of-mouth (eWOM), non-professional reviewers can influence stakeholders' opinions and share their views on products, services, and other commercial aspects. Museums' performances are continually affected by (and have real effects on) positive and negative eWOM, with a complex interplay still under-investigated. However, although studies using UGC for assessing tourism satisfaction are recently increasing, a relatively small number deal with museum visitors' satisfaction [1,11]. The relevance of opportunities raised by UGC and eWOM and the scarceness of studies on museums visitors' satisfaction through user-generated content were among the main motivations to undertake the present study.

This paper focuses on twelve Italian museums and their tourists-visitors' satisfaction, relying on comments left on the TripAdvisor platform during 2019 (the last year before the start of the pandemic crisis of the Covid-19 virus).

2 Data and Sample Selection

TripAdvisor (TA) is the largest travel site on the web which collects more than 860 million reviews. Through web-scraping, which is the process of extracting data from a website [5], it is possible to download visitors' reviews. Reviews are made by text

describing the visit and the museum facilities, refer to a specific year (the one of the visit), and are associated to an overall rating of the experience (on a 5-point scale).

We evaluated TA as a proper source for the aim of this study: it allowed us to study the attributes associated with the museum visitors' satisfaction by harvesting the information directly from the visitors.

In this study, we selected twelve museums[1] from six well-known Italian cultural tourism destinations, spread over the country: Turin, Venice, Florence, Rome, Naples and Palermo. For each city, museums were chosen from the top of TripAdvisor's ranking. The availability of an adequate number of tourists' comments for the year 2019 was also considered as a selection criterion.

Our target population is made up of comments left on the TA website. We restricted our analysis to those comments left by tourists who visited the twelve Italian museums in 2019. Given that the motivation of the trip/visit is unknown, we assumed as tourists those living outside the city where the museum is. The frame list obtained is made of 9,212 reviews. The frame population was stratified, first by the museum and then by the comment language. Particularly, two lists have been identified for each museum: one for reviews written in the Italian language and one for those in the English language. Hence, a probability sample of reviews (comments) for the twelve museums was drawn (n= 1,200).

3 Methods

The research aims were addressed via "content analysis" [6] and "word frequency analysis" [6, 10]. The former proved to be useful to detect areas of satisfaction and dissatisfaction with museums, gathering comments into nodes. The latter defines the main attributes that generate satisfaction or dissatisfaction by counting how many times a word is present in comments previously arranged by the overall museum experience rating. Hence, through the information collected, we assessed which concepts/words of the UGC are the most nominee in the museum evaluation.

In performing content analysis, we defined six *nodes*, that are logical containers where data is collected and coded following the specific core concept based on the existing literature [2]. Based on the existing literature [4,7], the following nodes have been defined:

1) Permanent and temporary exhibition: this category includes impressions related to exhibitions;

2) Museum management: this category highlights the visitor evaluation of museum management (ticket price, queue, marketing actions, etc.);

3) Staff: this category includes visitors' impressions of the staff competence (e.g., the front desk staff's ability to provide personalized information or the guides' competency in interpreting artworks);

[1] The selected museums are: *Egyptian Museum, Cinema Museum, Doge's Palace, Uffizi, Accademia Gallery, Vatican Museum, Castel S. Angelo, Borghese Gallery, Archaeological Museum, San Severo Chapel, Bourbon Tunnel, Norman Palace*.

4) No-core services: this category collects the impressions given to side-services (shops, cafes, restaurants, etc.);

5) Motivation: this category collects the reasons why the tourist-reviewer visited that museum (to spend time with family, to see a specific exhibition, etc.);

6) Emotional response: this category describes the visitors' feelings, their visit experience, and the assessments of the overall museum product.

The coding procedure (through the NVivo 12 software) worked on the assignment of parts of the comment's text to the specific node [2].

In addition, the word frequency analysis was useful to assess which attributes were more recurrent by the level of the overall rating that tourists gave to museums on the TripAdvisor platform.

Finally, coding of the 1,200 comments and their division according to the museum's final rating between the Italian and English samples gave us information on the opinion expressed by visitors on each specific node.

4 Results and Discussion

For the sake of brevity, this section reports content analysis results only on a selection of six major museums spread over all Italy. One hundred reviews (50 in Italian and 50 in the English language) were randomly drawn for each of the following museums: Turin Egyptian Museum and Venice Doge's Palace (Northern Italy), Florence Uffizi and Vatican Museum (Central Italy), Naples Archaeological Museum and Palermo Norman Palace (Southern Italy). For this comparison, the number of "references" (i.e., how many times an aspect has been mentioned in the overall comments) has been used. A chi-squared test for the homogeneity between the two linguistic groups of comments with respect to the node distribution was done on the pooled sample of the six museums. It assessed that there is no statistically significant difference between the two groups at 1% (χ^2=13.03, p-value=0.02). Table 1 shows the percentage distribution of references by node and museum, pooling together the two languages.

Table 1: *Percentage distribution of the number of references by node (column percentage by museum)*

Node	***Egyptian M.***	***Doge's Palace***	***Uffizi***	***Vatican M.***	***Archaeo-logical M.***	***Nor-man Palace***
Emotional response	30.65	32.14	30.85	29.29	30.6	38.81
Management	29.65	31.12	22.34	33.33	23.28	21.39
Exhibition	19.10	25.51	23.40	18.69	29.74	31.84
Staff	9.55	7.14	9.57	12.12	5.60	3.48
Motivation	7.54	1.02	8.51	3.54	8.62	3.48
No-core services	3.52	3.06	5.32	3.03	2.16	1.00
Total	100.00	100.00	100.00	100.00	100.00	100.00

Hence, the content analysis showed that, regardless of the museum, aspects most frequently mentioned in tourists' comments are those related to emotional response, management, and exhibitions.

When it comes to the word frequency analysis, Tables 2 and 3 show the most common (key)words (respectively in the Italian and the English language comments) mentioned in comments divided by rating.

Table 2: *Most common concepts found in Italian comments by rating (expressed in row percentage) assigned to the museum visit*

	Rating					
Keyword	*	**	***	****	*****	***n***
Visit	13.10	21.82	31.34	29.20	33.79	233
Guide	7.14	14.55	11.94	10.95	16.78	111
Tour	4.76	10.91	14.93	10.22	17.01	109
Exhibition	3.57	10.91	5.97	5.84	7.71	55
Queue (short)	1.19	0.00	2.99	7.30	8.16	49
Ticket (booked)	9.52	12.73	0.00	13.14	3.63	49
Queue (long)	19.05	9.09	11.94	4.38	1.13	40
Staff (bad service)	19.05	3.64	4.48	2.92	0.91	29
Staff (good service)	3.57	0.00	2.99	2.92	4.31	28
Ticket (expensive)	11.90	7.27	2.99	2.92	1.81	28
Audio guide	5.95	1.82	5.97	4.38	2.04	25
Crowded	0.00	7.27	1.49	1.46	1.59	14
Cafeteria	0.00	0.00	1.49	4.38	0.91	11
Shop	1.19	0.00	1.49	0.00	0.23	3
Total	100	100	100	100	100	784

Among Italian comments, the three more frequently reported sources of maximum dissatisfaction (one star) are, in decreasing order: the long queue, bad service from the staff and visits. Noticeably, "visit" is also the most frequently reported word in comments of most satisfied tourists (five stars), immediately followed by tour and guide. A similar ranking was found in English comments of most satisfied tourists: tour, visit, guide. While for the worst rating (one star), English comments focus on bad service from the staff, long queues, and tour.

In the end, the contribution of this paper was to assess the museum tourist-visitors' satisfaction via comments released on TripAdvisor. Although selection bias issues for web-based data are widely acknowledged in literature [1, 10, 11], among their advantages, is the possibility for managers to quickly and easily monitor the museum's performance very frequently and at a relatively low cost.

Further development of this study will regard the assessment of the post-pandemic period to investigate the evolution of visitors' experience.

COVID-19 pandemic and tourism demand: a comparison between Spain and Italy

La pandemia da COVID-19 ela domanda turistica: un confronto tra Spagna e Italia

Caterina Sciortino, Ludovica Venturella, Stefano De Cantis

Abstract Studies relating to the COVID-19 pandemic and its effects on tourism demand have been widely described in the literature. The main objective of this work is to quantify the drop in tourism demand, the drastic reduction in travel and changes in travel behavior. In order to undertake this task, a comparison between two important European countries is made: Spain and Italy. The impact of the pandemic on the tourism demand of residents was analyzed by using the two main surveys linked to tourism demand (*Viaggi e Vacanze in Italia e all'Estero* and *Encuesta de turismo de residentes*). Departing from an analysis of micro-data, an overview of the data obtained is also included in the work. The results demonstrate a significant reduction in demand with a consequent change in travel behavior.

Abstract *Gli studi relativi alla pandemia da COVID-19 e i suoi effetti sulla domanda turistica sono stati ampiamente descritti in letteratura. L'obiettivo principale di questo lavoro è quello di quantificare il calo della domanda turistica, la drastica riduzione dei viaggi e i cambiamenti nel comportamento di viaggio. Per fare questo, viene fatto un confronto tra due importanti paesi europei: Spagna e Italia. L'impatto della pandemia sulla domanda turistica dei residenti è stato analizzato utilizzando le due principali indagini legate alla domanda turistica (Viaggi e vacanze in Italia e all'estero e Encuesta de turismo de residentes). Partendo da un'analisi dei microdati, nel lavoro è inclusa anche una panoramica dei dati ottenuti. I risultati dimostrano una significativa riduzione della domanda con un conseguente cambiamento nel comportamento di viaggio*

Key words: Tourism demand; pandemic; microdata; Italy; Spain

1 Introduction

The outbreak of the COVID-19 pandemic occurred towards the end of 2019, convulsing the whole world and shifting social, political, and economic equilibria. Since the outbreak of the pandemic, many sectors in the economy began to collapse and, of these, tourism was one of the most affected.. Indeed, it can be said that the tourist sector has suffered a significant downturn in economic activity. According to the UNWTO (2021), international arrivals fell by 72% in the first ten months of 2020, compared with 2019. This drop determined a loss of US$ 935 billion in export revenues (UNWTO, 2021). The Covid-19 pandemic must be considered as a crisis of unprecedented proportions. Indeed, it is characterized by various features and implications unlike other economic or natural disasters (for example, SARS in 2002 or H1N1 in 2009, Skare et al, 2021,). As stated by ISTAT (2020), the cessation in tourist flows was one of the immediate effects of the pandemic crisis. According to DPCM (Prime Ministerial Decree) No. 19 of 25 March 2020, non-hotel accommodation was considered a dispensable part of the tourist economy while hotels could formally continue to operate (ISTAT, 2020).
Since the 1980s, there has been increasing growth in studies investigating the determinants of tourism demand and its changes (Jong, 2020). The academic community is also interested to understand the various factors determining the outbreak of the COVID-19 pandemic on tourism demand (Nguyen et al., 2020; Skare et al., 2021). For instance, Skare et al. (2021) have recognized the following as the most distinctive factors in this regard: geographic distance from ground zero (infection epicenter), the transmission rate and finally, media attention and the associated hysteria which can be considered more pertinent today. Furthermore, the literature regarding COVID-19 and tourism demand can be considered relatively heterogeneous (Schmude et al., 2021). There are several important issues related to this topic: air passenger demand (Gallego and Font, 2020), travel behavior when the pandemic can be said to have 'abated' (Ivanova et al., 2020) and the potential effects on lifestyle and travel in general (Wen et al., 2021).
Furthermore, as the pandemic has affected trends in international tourism demand, it is also important to study the effects of COVID-19 pandemic on national tourism and to understand how travel behaviour has changed. Indeed, according to Zhang et al. (2020) COVID-19 has modified travel behavior by reducing the willingness to travel, thereby increasing the desire to go from point A to point B by private means of transport and to nearer regions. In order to understand the effects of the COVID-19 pandemic on tourism demand, the aim of this paper is to investigate the domestic tourism demand in Italy and Spain between 2019 and 2020. Microdata from the *Trips and Holidays* survey relating to Italy and the *Encuesta de turismo de residentes* survey regarding Spain have been analysed. Various research questions were addressed in achieving this aim: quantifying the drop in the demand for tourism services in Italy and Spain (in terms of trips and excursions); and
understanding how travel behavior has changed in the 2019-2020 period in terms of domestic and foreign destinations, motivations, expenditure, accommodation choice etc.

2 Data processing and description

The analysis was conducted by considering the surveys relating to tourism demand, which had been conducted by ISTAT (in Italy) and INE (in Spain). A focus of the survey relating to the expenditure in Italian households is *Trips and Holidays*. The rationale for this focus is to collate information regarding the tourist movements of Italian residents. The survey is a quarterly, and the object of the research is the number and the features of trips made for holiday or work in Italy and abroad. The survey also includes information relating to the expenditure incurred. The sample comprises household members, which are selected either from a *municipal registry office-LAC* or via the *Anagrafe Nazionale della Popolazione Residente (National Registry Office of the Resident Population or ANPR)* of approximately 32,000 households in 540 Italian municipalities. The data are collected by means of a questionnaire, using the CAPI (Computer-Assisted Personal Interviews) methodology. The *Encuesta de Turismo de Residentes* survey provides monthly, quarterly and annual estimates of trips made by the resident population. Thereafter, the main features of the survey are collated, including expenses, socio-demographic characteristics, etc. The collection method used in this case is by means of telephone calls. The sample method makes reference to stratification criteria in terms of census sections. Microdata for 2019 and 2020 were downloaded from the ISTAT (2022) and INE (2022) websites; the data are included in Tables 1-5 below, considered in million.[1]

Table 1 Trips and Overnight stays in Italy and Spain (2019-2020)

(Millions, unless otherwise specified)

		2020			2019			percentage variation

3 Results

The total number of trips and overnight stays for domestic and outgoing trips in Italy and Spain are reported in Table 1. The total number of trips in the 2019-2020 period in Italy decreased by 47% (from 71.254 to 37.527 billion); the number of overnight stays also decreased (-43%). A similar result was observed for Spain: -47% regarding trips, -37% for overnight stays. The ratio between domestic and outgoing trips in Italy was 3:1 in 2019 and 10:1 in 2020. A consistency variation in outgoing trips, which was equal to -80%, was also observed. Moreover, 76% of the total recorded trips in Italy in 2019 were domestic. This percentage increased to 91% in 2020.
The ratio between domestic and outgoing trips in Spain was 8:1 in 2019 and 20:1 in 2020. The percentage variation in outgoing trips in the 2019-2020 period was -75%.

Furthermore, the percentage of domestic on total trips in Spain was approximately 90% for 2019 and 95% for 2020. Looking only at the domestic trips (Table 2), relating to Italy, the ratio between nights in hotel and non-hotel establishments is equal to 2:3 in 2019 and 1:2 in 2020.
Moreover, a diminution in nights spent in hotels of -36% was also observed. The percentage loss for Spain was approximately -58% with a ratio between nights spent in hotel and non-hotel establishments of 1:4 in 2019 and 1:8 in 2020. Table 3 regards expenditure that is, total expenditure, expenditure per trip, and expenditure per night. The authors of this paper also proposed a comparison between Italy and Spain for the 2019-2020 period regarding domestic and outgoing trips. And, considering total expenditure, it was observed that there was a similar decrease in the expenditure between Italy (-54%) and Spain (-56%). The highest decreases relating to the expenditure for trips abroad was -82% for Italy and -78% for Spain.
Table 4 details the motivations for trips and overnight stays. Personal motivations are classified as: *Pleasure* (Pleasure, leisure and holiday); *VFR* (Visiting friends and relatives); *Religious* (pilgrimage); and *Health* (treatment, including spas). Table 4 highlights a marked decrease in trips in Italy for personal and professional motivation (-45% and -68% respectively). And an observation of the four aforementioned categories reveals that the highest decrease was recorded in trips for religious reasons and pilgrimages with a decrease of 90%. It would appear that trips in Spain for personal motivation were most affected by the COVID-19 pandemic than trips for professional motivation (-48% and -42% respectively). Finally,Table 5 reports the number of excursions decreased considerably from 2020 to 2019 both in Italy (-48.5% from 80,021 million in 2019 to 41,194 million in 2020) and in Spain (-38.0% from 260.591 million in 2019 to 161.636 million in 2020).

4 Discussion and Conclusion

The COVID-19 pandemic has caused dramatic changes in societies worldwide, also impacting on the tourism industry, in turn inducing a substantial reduction in tourism demand. Utiilizing microdata [2] obtained from surveys relating to tourism demand in Spain and Italy, the aim of this paper has been to quantify the decrease in total trips but also to assess this decrease by considering different aggregates: travel behavior, excursion activity and, particularly, the decrease in terms of expenditure and the effects on tourism markets of these reductions (Plzáková and Smeral, 2021). This decrease concerns all tourism components: incoming and outgoing, hotel and non-hotel establishments, and varying motivations. However, a greater decrease was recorded in the outgoing component relating to hotels and in specific segments (religious trips). These changes in tourism trends during the COVID-19 pandemic derive from different reasons. Indeed, there are several determinants affecting travel decisions and, of these, it is possible to identify various travel constraints, such as: an intrapersonal constraint (a risk associated with 'health'), an interpersonal constraint

[2] However, the nature of this work is mainly descriptive and, it represents a preliminary analysis that will be overcomed through a methodological approach in which the change in tourism demand caused by COVID-19 will be analyzed.

(the absence of friends or relatives as travelling companions), and a structural constraint (social distancing) (Shin et al., 2022).

Only a partial answer to the original research question (to quantify the drop in tourism demand, the drastic reduction in travel and changes in travel behavior post-pandemic) is currently available with the preliminary 2021 data. On the one hand, the main issues of the pandemic concern its long-term effects and, specifically, a diminished degree of willingness to travel to long-haul destinations. Indeed, regional or national destinations (proximity tourism) are currently preferred. On the other hand, of note is the matter of a lasting change in tourism behavior: closer attention to non-hotel establishment solutions (typically smaller and more intimate), aspects relating to the health, and customer service. Changes in travel behavior have been highlighted by Jeon and Yang (2021), according to whom the COVID-19 pandemic has transformed and restricted tourist activities. In the post-pandemic, tourists may well prefer destinations offering safe spaces from the COVID-19 virus. Furthermore, many tourists will wish to avoid human contact with other tourists, investing their time in preventative measures. Changes in travel behavior post-pandemic are currently being extensively studied but it will only be possible to evaluate their impact and effects on the tourism market in the years to come.

A compositional analysis of tourism in Europe
Un'analisi composizionale del turismo in Europa

Francesco Porro

Abstract Tourism plays an important role in the economy of many European countries. For this reason many analyses have been performed to improve the understanding of such a relevant sector. In the literature many innovative statistical methodologies have been applied to tourism. In this paper the Decompositional Data (CoDa) approach is used for analyzing the touristic presence in Europe over the years 2016-2021. The considered time range also includes the last two years (2020 and 2021) affected by the COVID-19 pandemic.
Abstract *Il turismo gioca un ruolo importante nell'economia di molti paesi europei. Per questa ragione molte analisi sono state effettuate per migliorare la conoscenza di questo rilevante settore. In letteratura, molte innovative metodologie statistiche sono state applicate al turismo. In questo lavoro l'approccio basato su Dati Compositionali (CoDa) è utilizzato per analizzare la presenza turistica in Europa negli anni 2016-2021. Tale periodo comprende anche gli ultimi due anni (2020 e 2021) in cui l'emergenza sanitaria ha avuto un impatto molto rilevante.*

Key words: Aitchison geometry, Compositional Data, Hospitality, Logratio coordinates

1 Introduction

Since for many European countries, tourism is a very important economic sector, in the literature there are many statistical analyses on it. The (CoDa) methodology is a set of quite recent statistical techniques, that is getting more and more attention in the literature (cfr. [1] and [2]), and it begins to be successfully applied in many fields. An interesting review of many CoDa applications in tourism and hospitality

Francesco Porro
Dipartimento di Matematica
Università degli Studi di Genova, e-mail: francesco.porro@unige.it

can be found in [3]. In the following, after a brief recall of the main definitions, an application about the touristic presence in Europe over the years 2016-2021 based on the CoDa methodology is provided.

2 The Compositional Data (CoDa) methodology

The Compositional Data are multivariate observations where relative rather than absolute information is relevant. For this reason they represent a quantitative description of the parts of some whole. The basic definition in the CoDa methodology refers to the compositions.

Definition 1. A composition vector is a real-valued vector with all (strictly) positive components. A D-part composition is a class of equivalence which contains all the *compositionally equivalent* vectors in $\mathbb{R}^D$. Two compositions $\mathbf{x} = (x_1, x_2, \ldots, x_D)$ and $\mathbf{y} = (y_1, y_2, \ldots, y_D)$ are compositionally equivalent whenever there is a positive constant $c \in \mathbb{R}^+$ such that $\mathbf{x} = c \cdot \mathbf{y}$.

For dealing with equivalence classes, a representative of each class has to be selected. For sake of simplicity, usually in Compositional Data analysis, the vectors of proportions are chosen as representative elements, since their sum is equal to 1. The sample space for the equivalence classes is the D-part simplex $\mathbb{S}^D$, defined by:

$$\mathbb{S}^D = \{(x_1, x_2, \ldots, x_D) \in \mathbb{R}^D \ : \ x_i > 0 \ \forall i; \ \sum_{i=1}^{D} x_i = \kappa\}, \tag{1}$$

In formula (1), κ is an arbitrary constant. For further details on the D-part simplex, see [7], [5], [4] and the references therein.

Another important definition is about the *closure* of a composition.

Definition 2. Let $\mathbf{x} = (x_1, x_2, \ldots, x_D)$ be a the D-part composition. The closure (to κ) of $\mathbf{x}$ is a composition defined as:

$$\mathscr{C}(\mathbf{x}) = \left(\frac{\kappa \cdot x_1}{\sum_{i=1}^{D} x_i}, \frac{\kappa \cdot x_2}{\sum_{i=1}^{D} x_i}, \ldots, \frac{\kappa \cdot x_D}{\sum_{i=1}^{D} x_i} \right)$$

In the literature the so-called Aitchison geometry on the simplex has been introduced for analyzing compositional datasets in a suitable framework. More details can be found in [7] and in the reference therein.

In CoDa analysis, a dataset $\mathbf{X}$ is a sample consisting of n observations of D-part compositions $\mathbf{X} = (\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_n)'$, with $\mathbf{x}_i = (x_{i1}, x_{i2}, \ldots, x_{iD})$, $i = 1, 2, \ldots, n$. As described in [7], the standard statistical descriptive measures, based on the real Euclidean structure, should be used with attention in such a dataset, since they can lead to erroneous conclusions. To overcome this issue, the compositional approach suggestes an alternative set of descriptive measures based on the Aitchison geometry. In the following, just the most common two are presented.

Definition 3. For the compositional dataset $\mathbf{X}$, an indicator of central tendency is the closed geometric mean. This vector is called *center*, and it is defined by:

$$\text{cen}(\mathbf{X}) = \mathscr{C}(g_1, g_2, \ldots, g_D),$$

with g_j is the geometric mean of the n observations related to the j-th component of the vectors in $\mathbf{X}$:

$$g_j = \sqrt[n]{\prod_{i=1}^{n} x_{ij}},\ j = 1, 2, \ldots, D.$$

The dispersion level of a compositional dataset $\mathbf{X}$, is evaluated by the normalized variation matrix, defined by:

$$T^* = \begin{pmatrix} 0 & t^*_{12} & \cdots & t^*_{1D} \\ t^*_{21} & 0 & \cdots & t^*_{2D} \\ \vdots & \vdots & \ddots & \vdots \\ t^*_{D1} & t^*_{D2} & \cdots & 0 \end{pmatrix}, \quad \text{where } t^*_{ij} = var\left(\frac{1}{\sqrt{2}} \ln \frac{x_i}{x_j}\right).$$

By definition, the normalized variation matrix T^* is symmetric and its diagonal contains only zeros. A synthesis of the variability of a dataset by a single value, is the *Total Variance*, defined as follows.

Definition 4. The Total Variance of the compositional dataset $\mathbf{X}$ is a measure of its global dispersion. It is defined as

$$\text{TotVar}(\mathbf{X}) = \frac{1}{D} \sum_{i=1}^{D} \sum_{j=1}^{D} var\left(\frac{1}{\sqrt{2}} \ln \frac{x_i}{x_j}\right) = \frac{1}{D} \sum_{i=1}^{D} \sum_{j=1}^{D} t^*_{ij},$$

where the values t^*_{ij} are the entries of the normalized variation matrix T^*.

As the information convoyed by a composition is relative, an usual practice is to apply transformations, mapping the compositions into real vectors for exploiting the usual Euclidean structure. In the literature there are several transformations based on the logratios: the additive logratio (*alr*), the centered logratio (*clr*), and the isometric logratio (*ilr*). Unfortunately, an overview of these transformations is out of the scope of this paper: the interested reader can see [7] and [5], among others, for a detailed discussion. For the following analysis in this paper, it can just be reported that the *clr*-transformation is basically characterized by two important features: the first one is that it does not modify the number of parts, since a D composition is mapped into a vector in $\mathbb{R}^D$. The second one is that it preserves both the distances and the angles: for this reason, the Aitchison distance in the simplex of two compositions is equal to the distance of the corresponding transformed vectors in $\mathbb{R}^D$ (see [7] for details). This characteristic is very important in exploratory analyses based on metrics, like *clr*-biplots and ternary diagrams. The following one is the definition of the centered logratio transformation.

Definition 5. The centered logratio transformation (clr) of a D-part composition $\mathbf{x} = (x_1, x_2, \ldots, x_D)$ is given by

$$clr(\mathbf{x}) = \ln\left(\frac{x_1}{g_m(\mathbf{x})}, \frac{x_2}{g_m(\mathbf{x})}, \ldots, \frac{x_D}{g_m(\mathbf{x})}\right),$$

where $g_m(\mathbf{x})$ denotes the geometric mean of the D parts: $g_m(\mathbf{x}) = \sqrt[D]{\prod_{i=1}^{D} x_i}$.

Graphics are an important instrument for the visualization and the interpretation of data. The most common in Compositional Data analysis are the PCA biplots. The biplots are a representation of the data in dimension 2: they are based on the Single Value Decomposition (SVD) of the centered (or standardized) data matrix. In CoDa analysis, there are two basic kinds of biplots: the *form biplot*, which favours the display of the units, and the *covariance biplot*, which favours the display of the variables. More details on them can be found in [7], [6], and in [5].

3 Application

The data used for the application are provided by Eurostat, and they are available in the section *Industry, Trade and Services*[1]. The considered variable is "*Nights spent at tourist accommodation establishments*", and it is evaluated for all European countries in the time range between Jan-2016 and Nov-2021. There are no data for December 2021, because at the moment, the detection of such month is not yet available. In order to make the analysis more understandable, the original set of countries has been reduced, restricting the observed population to 12 countries: Finland (FIN), Germany (D), Greece (GR), Iceland (IS), Italy (I), Malta (MT), Netherlands (NL), Norway (NOR), Portugal (PT), Slovenia (SLO), Spain (E), and Sweden (SWE). The choice of the countries is motivated by the data availability, the geographic location and the population size. France and United Kingdom are not included because of the large amount of missing data, especially in the last two years (2020 and 2021). For the presence of missing data, also 8 compositions have been removed from the dataset. Since the considered variable is monthly detected, after the described data cleaning, the dataset can be seen as a compositional sample of 63 different 12-part compositions. In order to have a measure of central tendency, the Table 1 shows the sample center: there is a predominance of Germany (D), with the greatest value of the geometric mean equal to 0.267 over the sample period. The Table 2 reports the variation matrix of the dataset. The values in the last column (*Clr variances*) indicate that the maximum variability is associated with Greece (GR), and the Total Variance is equal to 1.426. In order to identify patterns in the data,

												Total Variance	1.426

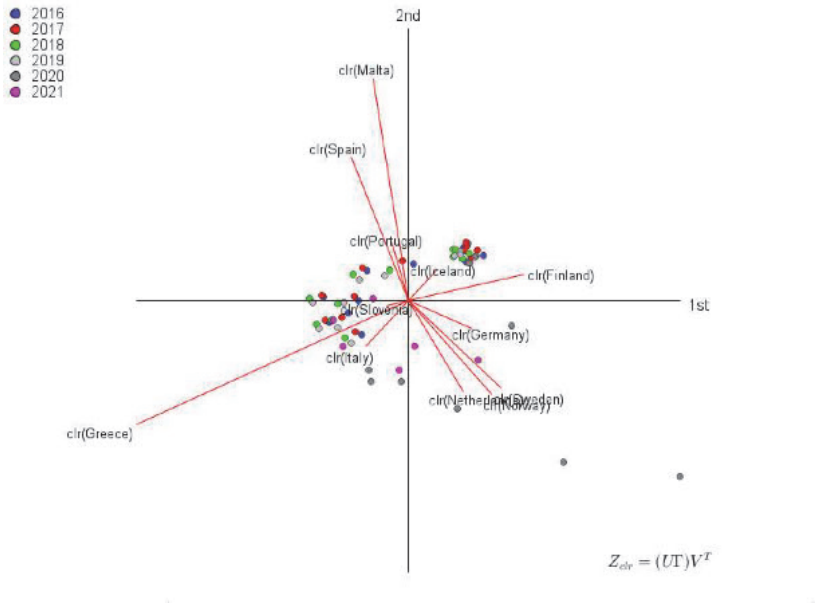

Fig. 1 The Covariance Biplot for the dataset of the 12 countries.

in Figure 1 has drawn the covariance biplot. The first two Principal Components can be considered quite representative of the dataset variability, since the first one explains the 53.33% of the total variance, and the second one bears the proportion of the cumulative explained variance to 80.84%. Following the interpretation rules of the compositional biplots, some remarks can be made from Figure 1.

- The first one regarding the interpretation of the Principal Components. The first Component divides the countries into two subsets: Malta, Spain, Portugal, Slovenia, Greece and Italy (on the left side) and the other countries, Iceland, Finland, Germany, Sweden, Norway and Netherlands (on the right side). This component seems thus related to a ”geographic” factor: on the left there are countries of South Europe, while on the right there are contries located in the North.
- The second Principal Component acts differently: it discriminates between Malta, Spain (at the top) and Greece, Netherlands, Norway and Sweden (at the bottom).
- The length of the rays (the segments joining each vertex to the center) shows that the smallest one is related to Slovenia, suggesting that the logratios of such country provide the smallest contribution to the total variability.

An analysis of the links (segments joining two vertices) is usually explanatory, since orthogonal links suggest a check of the corresponding logratios for zero correlation.

- The link Greece-Finland is (quite) orthogonal to any link with an extreme in the set {Malta, Spain, Portugal} and the other one in {Germany, Netherland, Sweden, Norway}.
- The sames happens for the links Italy-Finland, and Slovenia-Finland.
- The vertices of Sweden and Norway are very close: this means that the variances of the corresponding logratios are small, thus the ratios of their values are (quite) constant. For this reason, these two countries have a common behaviour, and eventually one can be discarded in further analyses.
- Since the projections of many points of the years 2020 and 2021 on each link are far from the projection of the center on the same link, it can be stated that the observations in these two years have a value of the logratio (corresponding to the link) very different from their average on the whole dataset. A reasonable motivation for this is the COVID-19 pandemic occurred exactly in those years.

Further findings can be obtained by the analysis of other plots (as ternary or De Finetti diagrams) and by using the Sequential Binary Partitions (SBP) with their related CoDa-dendrograms.

Improving administrative data quality on tourism using Big Data.

Migliorare la qualità dei dati amministrativi sul turismo attraverso l'uso dei Big Data.

Antonella Bianchino, Armando d'Aniello, Daniela Fusco.

Abstract National Statistic Institutes (NSIs) have used the Administrative Data for official statistics production for many years. However, they are characterized by typical errors of the source (e.g., coverage, delay in data registration) that could be solved by integrating other sources. The study shows how the use of Big Data can partially solve some of the errors. Particularly, the information about touristic accommodation obtained through web scraping, has been integrated with regional Administrative Data to improve the final quality assessment.

Abstract *L'uso dei dati amministrativi caratterizza da tempo le statistiche ufficiali degli Istituti di statistica. Tuttavia, essi si caratterizzano per tipologie di errore proprie della fonte (es. copertura, ritardi di registrazione) che possono essere risolti con l'ausilio di altre fonti. Lo studio dimostra come l'uso dei Big Data può intervenire nella risoluzione parziale di tali errori. In particolare, allo scopo di incrementare la qualità dei dati regionali sul turismo, questi sono stati integrati con le informazioni delle strutture ricettive presenti sul web.*

Introduction

The NSIs ordinarily use the Administrative Data (AD) sources for statistical purposes. By AD we mean the information produced by the Public Administration for administrative purposes which, processed by research institutes, become usable for statistical purposes. The rapid Information Technology (IT) development of Public Administrations (PA), which provides back structured and easily usable information on companies, institutions and individuals, made this integration process possible. However, non-sampling errors characterize the AD. For example, the time lag between the date of presentation of the deed and its reference period: the loss of information due to delay in updating the source and the presence of units cataloged with obsolete classifications. These aspects can reduce the informative power of administrative archives.

This study demonstrates how Big Data can improve the coverage of AD. Particularly we analyzed the Campania Region touristic accommodation affected by over coverage error. The activity status of the structures was evaluated using combining data: two AD sources (Rilevatore Turistico Regionale and Turismo Web), the Big Data source TripAdvisor and the Italian Business Register (Asia). The study shows the effect of the introduction of the Big Data source in the quality assessment of the integrated dataset.

The quality framework

1.1 Quality issues referred to different sources

Using a transformation function, the administrative objects are derived in Statistical units [10]; in this way the AD are aligned with statistical data firstly at the metadata level (through comparison and connection of definitions) and then at the data level. A mismatch between the statistical population of interest and the population identified by the administrative source may depend on several factors:

a) Definitional difference between the target population and the population covered by the administrative source.
b) Incorrect identification of statistical units.
c) Delays and / or missing administrative registrations.

The three factors cause coverage errors (over or under).
Where is possible, more administrative sources should be used. This would allow to reduce both the under-coverage error (by integrating sources that cover different portions of the population) and the over-coverage error (having the possibility of more information to establish which units correctly belong to the desired field of observation) [1].

For the quality assessment, Accuracy has a specific importance: for a long time, it was the main defining characteristic of the quality of a data product [3]. It represents the degree of closeness of computations or estimates to the exact or true values what the statistics were intended to measure. The bias and the variance of the estimates influence the accuracy of the final estimates. Theoretically, in multisource statistics, the use of additional sources should have a positive effect on the accuracy of the output, particularly on the coverage.

In this direction, Big Data play an important role. Big Data sources can generally be described as: "high volume, velocity and variety of data that demand cost-effective, innovative forms of processing for enhanced insight and decision making" [8]. In addition to generating new commercial opportunities in the private sector, Big Data are potentially a very interesting data source for official statistics, either for use on their own, or in combination with more traditional data sources such as sample surveys and administrative registers [4].

Among the differences between Big Data and traditional sources is the degree of control that NSIs have on the data acquisition and recording. In traditional surveys, NSIs can plan, design and carry out the acquisition procedures; for the use of administrative data sources, they may have agreements with the data providers [9]. Indeed, in a survey life cycle, coverage errors attain to the dimension of the representation line, i.e. to the target population or the set of units to be studied ("who") [6]. Instead, Big Data could not be representative of the whole population but just a fraction of it, which will probably have specific characteristics that differ from the broader population. In other words, the problem is similar to the one faced by studies dealing with non-probabilistic samples.

1.2 The sources quality evaluation

The administrative data quality assessment was done using the method proposed by Statistics Netherlands [5]. The AD sources used in the study had been evaluated using specific qualitative and quantitative indicators calculated on the three hyper-dimensions Source, Data and Metadata (table 1).

When Big Data sources are used, evaluation plays an important role [2]. Most of the specificities of Big Data are related both to its quick pace of change and in terms of the population covered. To evaluate the population coverage of touristic accommodation hubs, they are compared with Italian statistical institute (Istat) official statistics (table 2), used as benchmark. How table two shows, TripAdvisor has unit numbers similar to Istat data.

Methodology and results

The AD sources (Turismo Web and Rilevatore Turistico Regionale), the Big Data source (TripAdvisor) and the statistical source (Asia) are integrated applying the Fellegi-Sunter probabilistic model [7] combined with the deterministic model with

rules. Using the integrated dataset containing a new variable valorized by the presence of each unit in each source called SOURCE, a model finalized to establish the activity status of unit was built. The sources have been classified considering the reliability: the Business Register is the primary source for the quality building process; between the two AD sources, Turismo Web resulted the most reliable, according with the results show in paragraph 2.2; lastly, TripAdvisor is the least reliable concerning Big Data's typical errors. It was then attributed a score on each unit considering their presence in each source (variable SOURCE): Asia 0.45, Turismo Web 0.25, Rilevatore Turistico Regionale 0.20, TripAdvisor 0.10.

Summarizing the scores on each unit, the thresholds for the activity status of units have been defined as follows:

- More than 0.56: Active;
- Between 0.45 and 0.55: Eligible;
- Less than 0.44: Not eligible.

The results are shown in table 3. Considering Istat official data as a benchmark, the total difference with the Eligible units into the integrate Dataset is of 36%. In particular, the difference has been determined by the quantity of the structures in the province of Salerno, which, although decreased in number compared to the initial situation, is always twice the value found in the survey on the capacity of the accommodation facilities. This could depend on the presence of non-entrepreneurial managed structures that are not part of the Istat survey field of observation, but could be present in the integrated dataset with score equal to 0.45.

Salerno	6,395	1,289	2,952	2,154	5,106	2,255
Total	**13,274**	**3,436**	**4,827**	**5,011**	**9,838**	**7,185**

Conclusion

The results show how Big Data can be introduced in statistical productive processes as a partial solution to some administrative data limits. Particularly, they can contribute to reduce the AD time lag error and help the identification of closed accommodation. A step forward could be using Big Data as the main source, supplementing the administrative source. This would allow to identify the structures not yet registered due to delays in the registration of administrative acts by the PA.

The table 4 shows some quality indicators calculated on the integrated dataset. The coverage rate is calculated as the following ratio: (Not eligible units+(1-alpha) Units

solved)/(Units solved+Not solved units+alpha Not solved units). Units solved are the number of units which was possible determine the eligibility; Not solved units are the unknowing eligibility units; alpha is the ratio of not solved units that may be eligible (Eurostat suggests to set alpha=1).

The coverage rate for Campania region is +25.9% (over coverage), respect to +75.2% of over coverage obtained used only the AD sources. If the integrated register is used as a frame, it could be accepted. It's important to underline that probably the over coverage depends on different referring data of the sources. This limit could be overcome by running the model in an ordinary process.

Table 4: Integrated dataset quality indicators by province.

Province	***Coverage rate***	***Eligibility rate***	***Activity rate***
Caserta	15.5%	35.2%	49.3%
Benevento	19.8%	49.0%	31.3%

Geographical variations of socio-demographic issues

Elderly HCE and health care need: comparing spatially unexplained levels

Spesa e bisogno assistenziale delle popolazioni anziane: un confronto spaziale dei livelli non predetti

Irene Torrini, Laura Rizzi and Luca Grassetti

Abstract The increasing trend of HCE calls for a deeper evaluation of geographical variations of elderly expenditures for health services compared with their health care burden. Using 2019 data at the municipality level on the elderly population (65+) in Friuli-Venezia Giulia, we estimate Spatial Error Models for the total per-capita health expenditures and the percentage of individuals with high health care burden (classified into Resource Utilization Bands). The determinants of HCE and health care burden are investigated and the models' residuals are examined to derive health-economic scenarios of great relevance for policy-makers.

Abstract *La continua crescita delle spese assistenziali rende necessaria un'analisi geografica approfondita della spesa (quale proxy della domanda) e del bisogno assistenziale della popolazione anziana. Utilizzando i dati 2019 della popolazione anziana a livello comunale in Friuli-Venezia Giulia sono stati stimati Spatial Error Models per la media della spesa sanitaria pro-capite e per la percentuale di anziani con maggiore severità clinica (misurata attraverso la scala dei Resource Utilization Bands). I modelli hanno identificato quali sono i fattori predittivi delle variabili di studio, mentre i residui sono stati esaminati per trarre differenti scenari economico-sanitari di grande rilevanza per le scelte di politica economica e sanitaria.*

1 Aim and Background

The rise in health care expenditures (HCE) observed over the past 50 years is among the major concerns for the stability of public finances. This trend calls for continuous evaluation of health system efficiency, with unwarranted geographic variations in HCE widely assessed to identify under-use or over-use of services [15]. Shares of heterogeneity that are not explained by differences in the demographic structure of geographical units may, in fact, reflect inefficiencies. According to the existing literature, such unexplained variation is accounted for by differences in supply of services [6, 7, 4], socio-economic characteristics [5], technology [8, 11, 14], and policy makers' behaviour, political ideologies and contextual factors [13, 4].

In this paper, we investigate the heterogeneity at the municipality-level in health care burden and expenditures by comparing spatial patterns of unexplained shares of HCE and care need. The aim is the identification of the geographical units showing abnormal levels of HCE with respect to health care need or vice-versa.
We focus on the context of the Italian Region Friuli-Venezia Giulia (FVG) and the over-65 population. This subpopulation is characterised by severe health conditions, high care needs and, consequently, high health care expenditures. Several studies highlight the age-dependent nature of individual health care costs [12, 9]. They exhibit a J-shaped curve that increases slowly through adulthood and then exponentially after age 50 [1], with a large share of HCE taking place near the time of death [10, 16]. With a population average age of 47.31 years, a share of individuals over-65 equal to 29.08%[1] and a population that ranks as the second oldest in Italy, FVG represents the ideal setting for analyzing the elderly cohort.
By using administrative data at the municipality level, we analyse the per-capita total health care expenditures (total HCE hereafter) and the percentage of over-65 individuals with high health care needs accounting for their main determinants and the spatial correlation among disturbances. The sign and magnitude of models' residuals are then exploited to discuss the different health-economic scenarios.

2 Data Description

For our analysis, we use two datasets recording information on the over-65 population observed in the year 2019. The first one is drawn from the Health Care Information System (SISSR) of the Region Friuli-Venezia Giulia and provides information on age, gender, survival status, municipality of residence and individual health care expenditures covered by the public health care system for different types of services (hospital, outpatient, pharmaceutical and home care), aggregated into total health care expenditures (total HCE). The second dataset provides information on resource use by assigning each individual to an Adjusted Clinical Group (Johns Hopkins ACG System [2]). ACGs are mutually exclusive health status cate-

[1] Statistics drawn from the Health Care Information System of the Region Friuli-Venezia Giulia.

gories defined by morbidity, duration, severity, diagnostic certainty, aetiology, age, and gender [3]. Specifically, within each morbidity pattern, ACGs define clinical groups of individuals expected to require similar levels of health care resources. ACGs are combined into six Resources Utilization Bands (RUBs), where individuals with higher bands are expected to present higher clinical severity and consequently higher care needs, being more likely multi-morbid. We aggregate individual data at the municipal level and add to our dataset information on municipalities' socio-economic, health care supply and geographical characteristics, which may contribute to the territorial variation in expenditures and health care burden. They are obtained from, respectively, records of the National Institute of Statistics (ISTAT), the Italian Internal Revenue Service (*Agenzia delle Entrate*), and the Italian Ministry of Health.

3 Empirical Strategy and Results

The main aim of this analysis is to describe the spatial heterogeneity of total HCE, expressed in logarithm, and percentage of RUB equal to four or five (RUB_{45} hereafter) in the elderly population at the municipality level. Our approach is based on two stages. In the first step, we describe the behaviour of the two study variables through Spatial Error Models (SEMs). In the second step, we study the geographical patterns of the unexplained shares of elderly health care expenditure and burden across regional municipalities. The spatial models are estimated separately for the total HCE and the percentage of older adults with RUB_{45}. While spillover effects do not appear significant in preliminary analyses, the presence of unexplained similarities across elderly residing in neighbouring municipalities supports the introduction of spatial autocorrelation in the models' error component. Table 1 shows the results of statistically significant parameters[2]. One of the most interesting finding concerns the spatial autocorrelation in the error component, which is significant for HCEs but not for RUB_{45}. The different spatial pattern of unexplained shares of expenditures and health burden deserves further analysis, described in the next section.

To analyse the unexplained part of the geographical variation in our interest variables, we plot in Figure 1 the spatial distribution of unpredicted total HCE (left panel) and RUB_{45} (right panel). Green areas indicate municipalities where observed values are higher than the predicted (positive residuals - under-estimation), while red areas indicate the opposite scenario (negative residuals - over-estimation). In both cases, increasing colour tones correspond to increasing residuals' absolute values, while residuals near to zero are reported in white. This plot gives the first insight into the geographical pattern of unexplained levels of HCE and health care burden. For example, the mountainous area in the north-eastern part of the region presents relevant positive residuals for the percentages of RUB_{45} and negligible residuals for total HCE, pointing out the excess in the observed needs with respect to the pre-

[2] The coefficients of the disease dummies are omitted for space reasons.

dicted ones. This result does not correspond to a coherent excess in the observed expenditures. For the systematic comparison among all municipalities, we classify our geographical units according to the simultaneous concordance or discordance in the signs of the residuals of total HCE and RUB_{45}. We obtain four scenarios: municipalities with concordant over-estimated values, municipalities with concor-

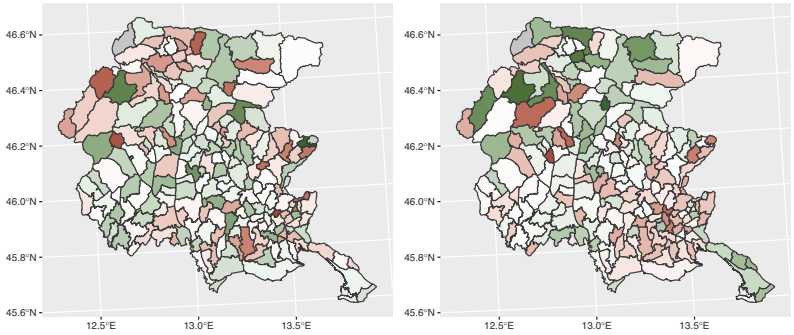

Fig. 1 Distribution of residuals at municipality level of the SEM model for total HCE (left panel) and RUB_{45} (right panel). The residuals shade from red (negative values) to green (positive values) identify over and under-estimated outcomes, respectively.

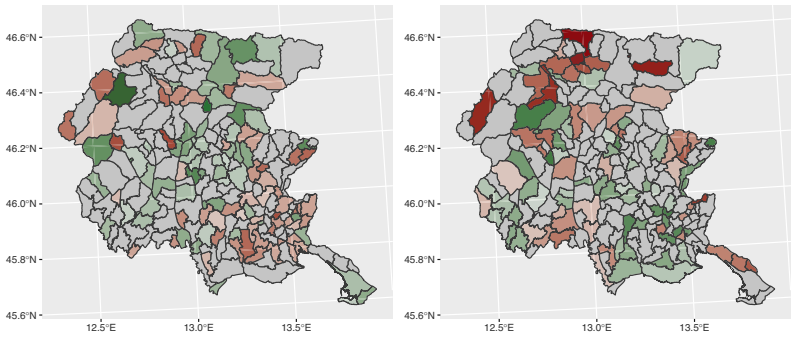

Fig. 2 Municipalities presenting concordant (left panel) and discordant (right panel) residuals. Red and green areas correspond to negative and positive total HCE residuals, respectively.

dant under-estimated values, municipalities with under-estimated HCE and over-estimated burden, and municipalities with over-estimated HCE and under-estimated burden. Figure 2 shows the spatial distribution of the scenarios with concordant (left panel) and discordant residuals (right panel). In both panels, red tones correspond to over-estimated HCE (hence, over-estimated RUB_{45} in the left panel and under-estimated RUB_{45} in the right panel), while green tones to under-estimated HCE (hence, under-estimated RUB_{45} in the left panel and over-estimated RUB_{45} in the right panel). Increasing colour tones correspond to an increasing joint magnitude of standardised residuals, measured through the Manhattan distance of the residuals coordinates from zero. The left panel indicates coherent patterns between expenditures and care needs. It points out several areas where the excess in observed HCE with respect to the estimated values is justified by a similar relationship between observed and estimated health care burden. A few cases present the opposite behaviour. The right panel is instead more relevant from a policy perspective, as it shows scenarios in which an excess in observed HCE is accompanied by under-estimated RUB_{45} or vice-versa. Such critical patterns require further investigations in each specific area in which they occur. In particular, the mountainous area in the northern part of the region is characterised by observed HCE lower than expected and an excess in the observed health burden, indicating partial coverage of the need for medical care. Similar situation is faced in the municipalities near the urban area of Trieste. In this city, instead, a concordance in the excess of observed HCE and burden is revealed. Finally, there are no critical scenarios in the other coastal municipalities and in plain or hilly areas.

4 Conclusions

In this work, we analyse the geographic variation in total HCE and health care burden at the municipality level by estimating two separate SEMs to account for spatial heterogeneity among unobserved factors. The geographical distribution of the residuals is then investigated to identify areas with inconsistent relationship between care needs and expenses, with particular remark for municipalities denoting partial coverage of the elderly need for medical care. Further developments concern the separated analysis of different kinds of health services (SUR spatial models) and time patterns (Panel spatial models).

Measuring sustainable development at the regional level. The case of Italy

Misurare lo sviluppo sostenibile a livello regionale. Il caso Italia

Marianna Bartiromo, Enrico Ivaldi[1]

Abstract The first objective of this work is to provide an innovative tool for sustainable development through the construction of a composite index. The second objective is to quantify the level of sustainable development achieved by Italian regions. Moreover, once the composite index has been constructed, the relationship between regional sustainable development and gross domestic product and the Gini index will be tested. The index of sustainable development will be constructed through a series of indicators made freely available by ISTAT through the method of Pena's Distance (DP2). The results of this study confirm the strong territorial gap present within the Italian Peninsula.

Abstract *Gli obiettivi di questo lavoro sono quello di fornire una chiave di lettura innovativa sullo sviluppo sostenibile attraverso la costruzione di un indice composito. Il secondo obiettivo è quello di quantificare il livello di sviluppo sostenibile raggiunto dalle Regioni italiane. Inoltre, una volta costruito l'indice composito si andrà a testare il rapporto tra lo sviluppo sostenibile regionale e il prodotto interno lordo e l'indice di Gini. L'indice di sviluppo sostenibile verrà costruito attraverso una serie di indicatori resi disponibili gratuitamente dall'ISTAT attraverso il metodo di Pena's Distance (DP2). I risultati di questo studio confermano il forte divario territoriale presente all'interno della Penisola italiana.*

Key words: Sustainable development, DP2, index

1 Introduction

Sustainable development represents one of the greatest challenges posed by globalization. Sustainable development consists in reconciling economic and social development with environmental protection, social equity and the rights of future generations. This orientation, expressed in the Bruntland Report (WCED, 1987), has the merit of having clarified the aspects on which global and national policies must focus. In particular, it highlighted the close relationship between economic, social and environmental development, proposing a holistic approach in which green sustainability is given central importance. In addition, the Report introduces the long-term perspective, the criterion of equity and inter- and intra-generational justice and, finally, the principle of efficiency in the use of natural resources. These principles have been translated into the rule of the balance of the three Es: Economic, Equity and Environment. Economic E is the ability to increase the gross domestic product per capita and improve competitiveness without affecting income and employment. Equity E, on the other hand, is the ability to increase human well-being in terms of security, nutrition, education and respect for fundamental individual freedoms. Finally, Environment E is the ability to provide resources, assimilate negative externalities and provide utility.
The objectives of this work can be outlined as follows:

1. to provide a new key to understanding sustainable development;
2. to quantify the level of sustainable development achieved by the various Italian regions;
3. to study the relationship between sustainable development, per capita GDP and the Gini index.

2 Material and Methods

Sustainable development, therefore, is a complex and multidimensional phenomenon. For this reason it has been necessary to use indicators capable of reading this complexity. To construct an aggregate composite index, data from the National Institute of Statistics (ISTAT) are considered, taking regional SDG values as a spatial reference.
The construction of the sustainable development index can be schematized as follows:

1. Preliminary survey of data availability and elimination of indicators that were clearly incomplete or manifestly unreliable. thanks to this phase, 98 indicators were selected that should ensure sufficient completeness of information (OECD, 2008);
2. a principal component analysis was then conducted using Varimax rotation (Kaiser,1958; Stevens, 1986). An explained variance level of 70% is considered significant (Pituch and Stevens, 2016).

3. Once the indicators had been chosen through Principal Component Analysis, it was possible to proceed to the elaboration of the index and then pursue the phases of normalization and weighting, and aggregation (OECD, 2008). The elaboration of the index was carried out using a non-compensatory index - the DP2 Distance - which is a parametric index since its formulation is based on the application of the linear regression model (Pena, 1977; Somarriba and Pena, 2009; Penco et al, 2020).
   The DP2 index provides the distance of each region from a reference base, which corresponds to the theoretical area that reaches the lowest value of the studied indicators, and it is defined for area j as follows:
   $DP2_j = \sum_{i=1}^{n} \left\{ \left(\frac{d_{ij}}{\sigma_i} \right) \left(1 - R^2_{i,i-1,i-2,\dots,1} \right) \right\}$ with i=1,…, n (area) e j=1,2,….,m (indicators)
   $d_{ij} = |x_{ij} - x^*_{ij}|$ = the difference between the value taken by the i-th indicator in area j and the minimum of the indicator in the least desirable theoretical scenario, i.e. the reference value of the X matrix.
   σ_I is the standard deviation of indicator I;
   $R^2_{i,i-1,i-2,\dots,1}$ is the squared multiple linear correlation coefficient in the linear regression of X_i on X_{i-1}, X_{i-2}, …, X_1 and indicates the part of the variance of X_i explained linearly by the X_{i-1}, X_{i-2}, …, X_1 indicators. This coefficient is an abstract number and is independent of the units of measurement of the various indicators.

The composite index obtained by applying the DP2 Index represents sustainable development at the Italian regional level. Higher scores represent situations of good "sustainable development" index compared to lower scores.

3 Results

The results obtained from the application of the method previously illustrated are as follows.
Overall, Emilia-Romagna (9.90) is the Region which has achieved the highest level of sustainable development in Italy. This is followed by Tuscany (9.56), Trentino-Alto Adige (9.14), Piedmont (9.13) and Umbria (8.50). Overall, the regions lagging furthest behind are geographically located in the South and they are: Basilicata (4.81), Campania (4.64), Puglia (4.06), Calabria (3.29) and Sicily (1.91). The results, therefore, converge towards a clear prevalence of central and northern Italy over the South in terms of achieving the best levels of sustainable development (Figure 1).

Figure 1: Results map for Sustainable development index

Emilia-Romagna	9.9
Tuscany	9.56
Trentino-Alto Adige	9.14
Piedmont	9.13
Umbria	8.5
Lombardy	8.48
Liguria	8.43
Marche	8.33
Friuli-Venezia Giulia	7.83
Abruzzo	7.76
Veneto	7.53
Lazio	7.43
Aosta Valley	7.41
Molise	6.78
Sardinia	5.34
Basilicata	4.81
Campania	4.64
Apulia	4.06
Calabria	3.29
Sicily	1.91

Once the sustainable development index was obtained and the results commented on, it was decided to test the link between the composite index, the regional Gross Domestic Product per capita (GDP per capita) and the Gini index to analyse the relationship between these variables.

In this work it was decided to use Kendall's tau-b coefficient, (Kendall, 1962). To better analyze the link between sustainable development, GDP per capita and the Gini index, it was decided to calculate the delta of Somers to understand the causal relationship between the variables. In fact, Somers' delta is a non-parametric index which allows to evaluate the asymmetric association between two ordinal variables (Somers, 1962). Between the independent variable of sustainable development and the dependent variable of GDP there is a positive concordance (0.547). This means that GDP positively influences levels of sustainable development. Regarding the relationship between the sustainable development index and GDP per capita ($\tau b = 0.550$, $p = 0.001$), it is observed that the levels of GDP per capita influence the levels of sustainable development. This means that regions that possess higher levels of GDP per capita also have high levels of sustainable development. Therefore, it can be understood how higher levels of wellbeing correspond to greater attention to sustainable development issues. On the other hand, as far as the Gini index is concerned, there is a negative concordance (-0.342), which means that the levels of sustainable development influence the levels of this indicator. ($\tau b = -0.349$, $p = 0.034$). This result shows how sustainable development is a solution in the fight against inequality: high levels of sustainable development, in fact, correspond to lower levels of inequality.

4 Discussion and Conclusion

To bridge the gap between North and South, the Ministry for the South and Territorial Cohesion adopted the so-called "Plan for the South 2030" at the beginning of 2020. This plan, in addition to reducing the gaps in the Italian peninsula between citizens and territories, wants to relaunch Italy in Europe, as the continuous and constant disinvestment in the South has done nothing but push the country back in the European Union rankings. The South 2030 Plan is structured around five missions: a) a South for young people; b) a connected and inclusive South; c) a South for the ecological turnaround; d) a South at the frontier of innovation; e) a South open to the world in the Mediterranean. As can be seen, these objectives are perfectly in line with both the goals of the 2030 Agenda and those of the European Green Deal. The year after the Plan for the South 2030 entered into force, the Italian government extended a new plan: the National Recovery and Resilience Plan (PNRR)(2021). The PNRR, as reported on the website of the Ministry of Economy and Finance "is part of the Next Generation EU (NGEU) program, the 750-billion-euro package, about half of which consists of grants, agreed by the European Union in response to the pandemic crisis. The total funds provided for the NGEU are around 248 billion euros, of which 26 billion are earmarked for the implementation of specific works and for the replenishment of resources from the Development and Cohesion Fund".

This measure aims to repair the economic and, above all, social damage caused by the pandemic crisis by helping to resolve Italy's structural weaknesses - including the strong territorial gap between North and South - and accompanying the country towards an ecological and environmental transition.

This study provides some relevant findings that can be summarized in the following propositions: first, a deep divide persists between the North-Central and the Southern regions of Italy. Southern regions tend to cluster systematically at the bottom of the rankings, unlike those in the North; second, regions where levels of sustainable development are higher show higher levels of GDP per capita and lower inequality; finally, lower levels of GDP per capita and higher levels of inequality may be obstacles to achieving higher levels of sustainable development.

The strength of this work lies in having created a composite index of sustainable development useful for measuring the levels of this phenomenon at the regional level. In fact, the complexity and multidimensionality of this phenomenon makes it very difficult and almost impossible to measure it (Gidding et al, 2002) and for this reason there are still few studies focused on the analysis of sustainable development at the regional level (Niemeijer, 2002; Salvati and Carlucci, 2014). In addition, the chosen method - the DP2 Index - allows the comparison of data over time. Therefore, it will be very interesting to repeat this study once the effects of the Plan for the South 2030 and the PNRR are visible so as to analyze regional differences as a result of the application of these policies. In terms of the critical aspects of this work, a major limitation is that of subjectivity in the choice of dimensions analyzed. However, sustainable development indices "remain invaluable in terms of their

ability to simplify complex measurement constructs, focus attention, and capture attention" (Booysen, 2002).
Finally, the results of this study only confirm the complexity of the sustainable development phenomenon and underscore the need for intervention especially in all those contexts with low levels of well-being and high levels of inequality.

Socio-economic deprivation and COVID-19 infection: a Bayesian spatial modelling approach

Deprivazione socio-economica e infezione da COVID-19: un approccio spaziale Bayesiano

Antonino Abbruzzo, Andrea Mattaliano, Alessandro Arrigo, Salvatore Scondotto, Mauro Ferrante

Abstract This paper aims to analyse the effect of socio-economic deprivation on COVID-19 incidence at the sub-urban level. Given the availability of information on monthly incidence rates from COVID-19 at census tract level for the two municipalities of Palermo and Catania (Italy), a Bayesian spatial model with zero-inflated binomial distribution is proposed. Results show an association between deprivation levels and incidence from COVID-19 in the two municipalities, also by controlling for the spatial structure of the territorial units. In the light of the results, health policy actions are needed, focusing interventions on the most deprived population groups.

Abstract *Il presente articolo ha l'obiettivo di analizzare l'effetto della deprivazione socio-economica sull'incidenza da COVID-19 a livello sub-comunale. Grazie alla disponibilità di informazioni sui tassi di incidenza mensili da COVID-19 a livello di sezione di censimento per i due comuni di Palermo e Catania (Italia), viene proposto l'utilizzo di un modello spaziale Bayesiano con distribuzione binomiale zero-inflated. I risultati mostrano un'associazione tra livelli di deprivazione e incidenza da COVID-19 nei due comuni, controllando per la struttura spaziale delle unità areali considerate. Alla luce dei risultati, si rendono necessarie azioni di politica sanitaria focalizzando gli interventi su segmenti di popolazione maggiormente a rischio.*

1 Introduction

The spread of SARS-CoV-2 has strongly impacted urban centres characterised by high population density. Consequently, pandemic containment policies have focused on the closure of some economic activities described by a higher risk of contagion and on interventions aimed at limiting mobility, by taking into account the spread of the infection at the regional and the sub-regional level. Indeed, recent studies conducted in the USA [1] and South America [2] have shown an association between the risk of COVID-19 infection and socio-economic conditions.

This work aims to analyse the relationship between socio-economic deprivation and incidence of COVID-19 cases in the two Sicilian municipalities of Palermo and Catania (Italy), at the intra-municipality level, by considering the spatial structure of the territorial units under analysis. To this aim, a hierarchical Bayesian model with zero-inflated binomial distribution for the number of cases in each area is proposed by using the integrated nested Laplace approximation (INLA).

2 Material and Methods

Aggregate monthly data on incident cases at the census tract level for the two major Sicilian municipalities of Palermo and Catania, from October 2020 to April 2021, has been made available by the Regional Epidemiological Observatory. The data include a variety of demographic, comorbidity-related, test-related and disease-specific variables that track the case's progression until its recovery or death. In this paper, we focus on the effect of socio-economic deprivation on COVID-19 incidence as measured by the deprivation index. This index is a composite indicator that considers five dimensions of deprivation, namely: the share of the population with at least primary level education, the proportion of unemployed people, the share of families with one parent and dependent offspring living together, the proportion of rented households, and the number of people by 100 m^2 at the census tract territorial level [3]. A categorisation of the deprivation index based on quantiles of the regional population has been used in this study. The collected data can be described as areal spatial data, where Y_i is a random aggregate value over an areal unit i with well-defined boundaries in D_i, defined as a countable collection of n-dimensional spatial units. Therefore, the data have a specific spatial structure that needs to be considered in the inferential process. Generally, spatial models are computationally demanding, given the complexity of the parameter space. The Integrated Nested Laplace Approximation (INLA) proposed by [7] is a computationally efficient algorithm designed for latent Gaussian models, which incorporates a vast and flexible class of models ranging from generalized linear mixed to spatial and spatio-temporal models. Example of application on disease mapping includes [4, 5, 6].

Let's consider a region of interest divided into n non-overlapping areas. Let $Y_i, i = 1, \ldots, n$, denote the number of cases in region i and assume that its distribution belongs to the exponential family, in which the linear predictor η_i can include terms

of covariates in an additive way,

$$\eta_i = \beta_0 + \sum_{k=1}^{n_\beta} \beta_k z_{ki} + \sum_{j=1}^{n_f} f^{(j)}(w_{ji}), \tag{1}$$

where β_0 is the overall intercept, $\mathbf{z} = (z_1, \ldots, z_{n\beta})$ are fixed covariates with linear effects $\{\beta_k\}$. The terms $\{f^{(j)}\}$ are used to represent specific Gaussian process. These latter terms can be accounted for by several statistical approaches, such as random (*iid*) effects, spatially or temporally correlated effects, smoothing splines, by varying the functional form of the $f(\cdot)$s. We consider the Besag-York-Mollie model to keep into account the spatial dependence.

Let $\boldsymbol{\theta} = (\theta_1, \ldots, \theta_{1+n_\beta+n_f}) = (\boldsymbol{\beta}, \mathbf{f})$ denote the vector of the model parameters, called latent field, and assume that the multivariate distribution belongs to a Gaussian Markov Random Field (GMRF), with zero mean and with a sparse precision matrix $Q(\boldsymbol{\psi})$, where $\boldsymbol{\psi}$ denotes a vector of hyperparameters, which are not necessarily Gaussian. A GMRF is simply a Gaussian with additional, conditional independence properties, meaning that x_i and x_j are conditionally independent given the remaining elements $x_{\{-ij\}}$ for quite a few $\{i, j\}$. In the Gaussian case, a practical consequence of conditional independence is that this results in zeros for pairs of conditional independence in the precision matrix. The main goal of the INLA-methodology is to obtain the marginal distributions for the elements of the latent field $p(\boldsymbol{\theta}|\mathbf{y})$ and the hyperparameters $p(\boldsymbol{\psi}|\mathbf{y})$, and use these to compute posterior summary statistics. This goal is achieved by exploiting the computational properties of the GMRF and the Laplace approximation for multidimensional integration, assuming the conditional independence of the observed variables $\mathbf{y}$ given the latent field $\boldsymbol{\theta}$ and the hyperparameters $\boldsymbol{\psi}$. For further details see [7, 8].

Besag–York–Mollié (BYM). The BYM is a discrete domain model used for describing count data per spatial unit [9]. The main idea is to borrow strength over neighbouring regions to get more reliable region-specific estimates. Due to inherent sampling variability, it is not recommended to inspect crude rates directly. We formulate a zero-inflated binomial model for the random variable Y_i, representing the number of cases in the region $D_i, i = 1, \ldots, n$. Moreover, the spatial component is assumed to follow a BYM distribution such that

$$Y_i \sim ZIBinom(\pi_i, N_i), \quad \text{logit}(\pi_i) = \beta_0 + \sum_{k=1}^{n_\beta} \beta_k z_{ki} + u_i, \quad u_i \sim BYM(\sigma_v^2, \sigma_\delta^2),$$

where N_i is the corresponding area population for the i-th spatial unit, z_{ki} are region level covariates (e.g. deprivation score, month). The random spatial process u_i is the sum of two independent Gaussian processes δ_i with variance σ_δ^2 and v_i with variance σ_v^2. In particular, for each region, the value of the v_i component depends on the average from the neighbouring regions

$$v_i | v_{\{-i\}}, \sigma_v^2 \sim N\Big(\sum_{j \in d_i} v_j / d_i, \sigma_v^2 / d_i \Big),$$

where d_i is the number of areas which share boundaries with the i-th one. Referring to the notation in Equation (1), $v_i = f^{(1)}(i)$ and $\delta_i = f^{(2)}(i)$ are two area-specific effects. The joint distribution for $\mathbf{v} = (v_1, \ldots, v_n)$ is a GMRF. Furthermore, the parameter δ_i represents the unstructured residual, modelled as

$$\delta_i | \sigma_v^2 \sim N(0, \sigma_\delta^2).$$

Inference for the latent field represented by $\boldsymbol{\theta} = [\boldsymbol{\beta}, \boldsymbol{u}]^T$ and the hyperparameters $\boldsymbol{\psi} = [\sigma_v^2, \sigma_v^2]^T$ can be carried out with INLA (see [8, Chapter 6] for further details).

3 Results

During the considered period, a total of 29492 cases in 1952 census tracts for the city of Palermo (total population 733780) and 11163 cases in 1484 census tracts in Catania (total population 329746) were observed. Due to lack of space, in Figures, 1 and 2 only maps for the deprivation index, and the percentage of cases in Palermo municipality are reported, respectively. Deprivation areas appear in peripheral areas, and a similar spatial distribution for the percentage of COVID-19 cases appears. After model estimation, performed by using the R-INLA package [7], in Table 1 the mean, standard deviation and quantiles (0.025,0.975) for the parameters β_j related to the linear predictor $\eta_i = \text{logit}(\pi_i)$, for the two municipalities of Palermo and Catania are reported, where π_i represents the probability of being a case in the area i. For both municipalities under analysis, a relationship between deprivation and risk of COVID-19 infection appears, with higher values of risk for areas with higher deprivation levels compared to less deprived areas. However, its effect seems to be much stronger in the case of Palermo municipality compared to Catania. By looking at the temporal effect, the risk of infection is, as expected, consistently higher in all the months, compared to the reference period (October 2020), with peak values observed in January and April 2021 for Palermo municipality and November 2020 and January 2021 in the case of Catania.

4 Conclusion

It is acknowledged that socioeconomic conditions strongly affects various health outcomes. This paper proposes an analysis of its effect on the risk of contagion by COVID-19 at the sub-urban level in two Sicilian municipalities. From a methodological perspective, the proposed approach allows for considering the spatial structure of the territorial units under analysis by using a computationally efficient algorithm. Similar to previous studies [1, 2], the results showed a positive association between socioeconomic deprivation, as measured by the deprivation index, and risk of infection by COVID-19. Nonetheless, the dynamic of such an association is

less clear. Lower cultural contexts may influence self-protection behaviour. Worst housing and working conditions may lead to overcrowded households and working environments where transmission is more likely, and suggested self-isolation procedures are challenging to follow. Consequently, health policy should consider the socioeconomic characteristics of the resident population and the area of residence in the development of infection control measures.

Applications in Economics

The measurement of Economic Security through relative indicators

La misura della Sicurezza Economica attraverso indicatori relativi

Alessandro Gallo, Silvia Pacei and Maria Rosaria Ferrante

Abstract Economic Security is a topic which focused the attention of many researchers in the past years. With the COVID-19 pandemic, the interest has been grown drastically because economic security influences the lives of many individuals and consequently the government's economic and political choices. In this framework the individual insecurity indicator proposed by Bossert and D'Ambrosio [1] it's a landmark, because of its useful analytical properties. We embrace their notion of economic insecurity and we propose relative security indicators starting by the absolute one they suggested. We compare the indicators in terms of analytical properties and in terms of applicability to European countries using the EU-SILC (2019) data-set.

Abstract *La Sicurezza Economica è un fenomeno che ha attirato l'attenzione di molti ricercatori negli ultimi anni. L'interesse per questo tema è cresciuto molto con l'arrivo della pandemia del COVID-19, poiché la sicurezza economica ha un impatto sulla vita degli individui e di conseguenza sulle scelte economiche e politiche di governi. In questo ambito, l'indicatore assoluto d'insicurezza economica suggerito da Bossert e D'Ambrosio [1] è considerato un punto di riferimento, grazie alle sue numerose proprietà analitiche. Supportando la loro idea di base per misurare l'insicurezza, in questo lavoro proponiamo nuovi indicatori relativi. Gli indicatori sono poi confrontati in termini di proprietà analitiche soddisfatte e in termini di applicabilità ai dati EU-SILC (2019) di alcuni paesi europei.*

Key words: Economic Insecurity, Well-Being Indicators, Index numbers...

1 Introduction

In the existing literature, there are few examples of Economic Insecurity Indicators, such as Hacker et al. [3], Osberg and Sharpe [4], Bossert and D'Ambrosio [1] and

Alessandro Gallo, Silvia Pacei, Maria Rosaria Ferrante
University of Bologna, Statistical Sciences Departement, via Belle Arti,
e-mail: alessandro.gallo20@unibo.it, silvia.pacei@unibo.it, maria.ferrante@unibo.it

Bossert et al. [2]. While few measures have been proposed there is some debate on which index is more adequate to measure a multi-faced issue as economic insecurity. Economic insecurity may be seen as the perception of insecurity experienced by the individuals, measured through the confidence with which individuals face future potential economic changes. Bossert and D'Ambrosio [1] gave a fundamental contribution to the literature with their insecurity indicator, continuing with the collaboration of Clark and Lepinteur in [2]. Their indicator's latest version is based on a weighted summation of absolute changes between the individual resource levels observed in consecutive years [2].
Considering $\mathbb{R}^{(T)}$ as the $(T+1)$-dimensional Euclidean space with component labeled $(-T,...,0)$, where 0 is the current period and $-T$ is the furthest period in the past and acknowledging that $x=(x_{-T},...,x_0)\in\mathbb{R}^{(T)}$ is an individual income stream and that the economic insecurity is evaluated only considering x, the indicator proposed by Bossert et al. [2] is given by:

$$AI^T(x)=l_0\sum_{\substack{t\in\{1,...,T\}\\ x_{-t}>x_{-(t-1)}}}\delta^{t-1}(x_{-t}-x_{-(t-1)})+g_0\sum_{\substack{t\in\{1,...,T\}\\ x_{-t}<x_{-(t-1)}}}\delta^{t-1}(x_{-t}-x_{-(t-1)}) \quad (1)$$

where δ is the inter-temporal weight, l_0 and g_0 are weights assigned to losses and gains and $AI^{(T)}$ (Absolute Indicator) is a function $AI^{(T)}:\mathbb{R}^{(T)}\to\mathbb{R}$ for each $t\in\mathbb{N}$, and $AI^T(x)=\langle AI^{(T)}\rangle_{T\in\mathbb{N}}$ is a measure of individual economic insecurity.
With this work, we give our contribution by proposing relative versions of the individual economic insecurity indicator in (1). We rather suggest considering relative change between resources stock, instead of the absolute variation, as we think that individuals are more likely to judge changes in their economic status in relative terms, being also used to relative salary increases. Therefore we think relative changes may allow to capture the real perceived individual security better. Moreover, indices based on relative changes have the advantages of being independent of the order of magnitude of the phenomenon considered and of the units of measurement, thus favoring the comparison between individuals and countries adopting different currencies. Section 2 shows relative economic security indicators and the respective analytical properties, in Section 3 an empirical application to EU-SILC(2019) is presented and in Section 4 we carry out conclusions and suggest further applications.

2 Relative indicators

In this section, two different indicators are proposed and compared with the AI. The first one considers the relative pair differences with respect to the further period. Considering the same environment as before, but acknowledging that $x=(x_{-T},...,x_0)\in\mathbb{R}^{(T)}-\{0\}$, the first proposal is formulated as follows:

$$RI^T(x) = g_0 \sum_{\substack{t \in \{1,...,T\} \\ x_{-(t-1)} > x_{-t}}} \delta^{t-1} \frac{x_{-(t-1)} - x_{-t}}{|x_{-t}|} + l_0 \sum_{\substack{t \in \{1,...,T\} \\ x_{-(t-1)} < x_{-t}}} \delta^{t-1} \frac{x_{-(t-1)} - x_{-t}}{|x_{-t}|} \quad (2)$$

where δ is the inter-temporal weighting parameter, l_0 and g_0 are weights assigned respectively to losses and gains, $RI^{(T)}$ is a function $RI^{(T)} : \mathbb{R}^{(T)} - \{0\} \to \mathbb{R}$ for each $t \in \mathbb{N}$, therefore $RI^T(x) = \langle RI^{(T)} \rangle_{T \in \mathbb{N}}$ is a measure of individual economic security, from now RI (Relative Indicator).
The second indicator we propose is a Logarithmic Relative indicator (LRI), where the relative change is obtained by applying the logarithm, as suggested in Törnqvist et al. (1985) [5], to the ratio between resources levels in two subsequent points in time, taking advantage of the useful properties of the logarithm.
Considering the same setup as before, with $x = (x_{-T}, ..., x_0) \in \mathbb{R}^{(T)}_{++}$, the $LRI^{(T)}$is a function $LRI^{(T)} : \mathbb{R}^{(T)}_{++} \to \mathbb{R}$ for each $t \in \mathbb{N}$. The security indicator $LRI^T(x) = \langle LRI^{(T)} \rangle_{T \in \mathbb{N}}$ is formulated as follows:

$$LRI^T(x) = g_0 \sum_{\substack{t \in \{1,...,T\} \\ x_{-(t-1)} > x_{-t}}} \delta^{t-1} \ln\left(\frac{x_{-(t-1)}}{x_{-t}}\right) + l_0 \sum_{\substack{t \in \{1,...,T\} \\ x_{-(t-1)} < x_{-t}}} \delta^{t-1} \ln\left(\frac{x_{-(t-1)}}{x_{-t}}\right) \quad (3)$$

where δ is the inter-temporal weighting parameter, l_0 and g_0 are weights assigned respectively to losses and gain.
In this indicator the relative pair differences are expressed as logarithm of the ratio and the relative difference is considered with respect to the logarithmic mean $L(x_{-t}, x_{-(t-1)})$ [5]:

$$\ln\left(\frac{x_{-(t-1)}}{x_{-t}}\right) = \frac{x_{-(t-1)} - x_{-t}}{L(x_{-t}, x_{-(t-1)})} \quad (4)$$

where $L(x_{-t}, x_{-(t-1)})$ is defined as [5]:

$$L(x_{-t}, x_{-(t-1)}) = \begin{cases} \frac{x_{-(t-1)} - x_{-t}}{\ln(x_{-(t-1)}/x_{-t})} & \text{for } x_{-(t-1)} \neq x_{-t} \\ x_{-t} & \text{for } x_{-(t-1)} = x_{-t}, \end{cases} \quad (5)$$

2.1 Properties

It has been proved that the two relative indicators satisfy some important properties. They both fulfill some properties considered also in [2], in particular *Gain-loss monotonicity*, which ensures that a gain in the further period is related to a higher level of security compared to a loss that occurred in the same period; *Homogeneity*, which establishes that if each value of an individual stream is multiplied by the

same constant, the security score remains unchanged; *Quasilinearity*, assures that it is possible to establish a link between streams of different lengths, and *Stationarity*, an important property when dealing with indicators adopting the geometric discounting. Moreover, LRI satisfied further useful properties: *Proximity monotonicity*, important to order the different individual streams and *Simmetry* [5], according to which inverting the ratio is equivalent to change the sign of the indicator, and necessary to prove that the LRI satisfies the *Proximity monotonicity* (while RI does not).

3 Application to Eu-Silc Data

To highlight the advantages offered by the indicators proposed, we estimate security indicators based on information produced by the EU-SILC (2019) survey, a widely used database to study poverty, inequality and social exclusion in EU member countries. We consider four different panels: from 2012 to 2016, from 2013 to 2017, from 2014 to 2018 and from 2015 to 2019. The variable used in the analysis is the equivalent disposable income at an individual level. Income values have been discounted to remove inflation. Streams of four years with three delays are considered and economic security scores are computed for all three indicators in all panels. As regards

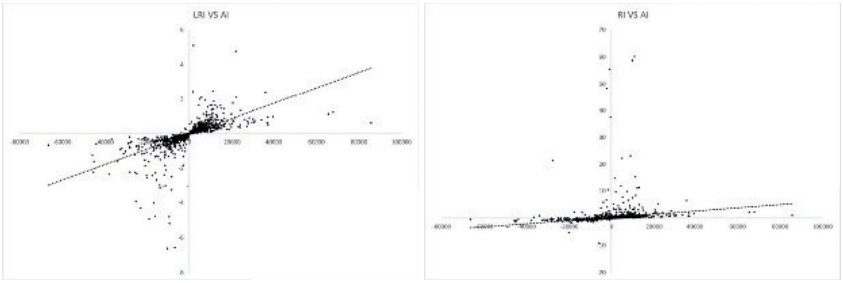

Fig. 1 Scatter-plots comparing relative indicators and the absolute one in 2019. On the left side the comparison among LRI and AI while on the right side among RI and AI. The X axis contains values from the AI and, the Y axis from the relative ones. In both graphs is shown the dotted interpolation line

the values used for the parameters included in the equations, we use the same values proposed in [2], therefore $\delta = 0.9, l_0 = 1$ and $g_0 = 15/16$. The AI is transformed into a security indicator by multiplying the scores times (-1), to carry out the comparison.

The correlation between LRI and AI appears high in the four periods considered (as an example the correlation coefficient is equal to 0.60 in 2019), while the correlation between RI and AI is much lower (0.04 in 2019). Scores obtained for the three indicators are compared in Figure 1. In the X-axis we put the AI scale, while in the

Y-axis the relative indicators ones. On the left figure, we see how dots allocate just on the first and the third quadrants, therefore individuals seen as insecure for the AI are classified in the same way from the LRI. On the other hand, dots look quite spread in the quadrants. This means that there are many cases where high values of security assigned by the AI coincide with much lower values of security according to the LRI and vice-versa. In the right figure, we see how the security allocation of the AI and the RI looks quite different. Dots are spread all over the X-axis in all four quadrants, confirming the lower correlation detected before.
To highlight the trend shown by the three indicators at an aggregate level, we calculate the weighted median of the individual scores. Figure 2 shows that results obtained from LRI are more coherent, at least on the median, with those obtained from AI. Hence LRI appears preferable to the RI as it satisfies more properties and is more coherent with AI, which has been already largely considered and applied in the literature.

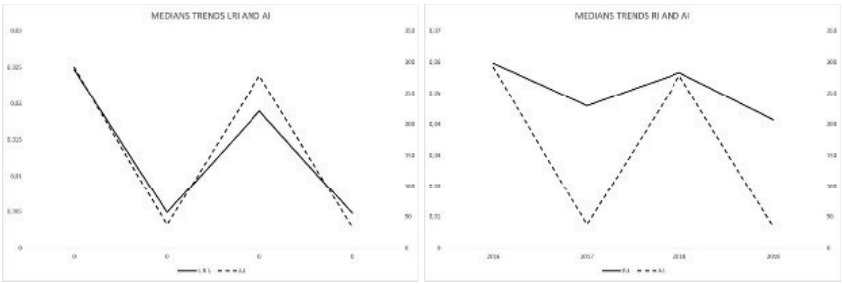

Fig. 2 Comparison between relative indicators weighted medians trends and the absolute indicator one.

Analyzing more in deep two indicators, LRI and AI, we notice that they lead to some differences in the "scores" calculated for the individuals in the sample. Taking individual scores from the year 2016 as an example, if we divide them into four quartile classes, we notice that 15% of the observations belong to different quartiles according to the two indicators. A sensible part of the observations belonging to different classes (45%) exchange from the third to the fourth class: differences regard above all high positive scores, that for the absolute indicator are close to median while for the relative indicator are close to the maximum and vice-versa. Finally, we use both LRI and AI to compare economic security in some European countries: Spain, Italy, Portugal, Greece, France, and the Netherlands. Figure 3 shows, as an example, results obtained from one synthetic indicator, the weighted median. The trends look comparable but, it's possible to notice how Spain and Portugal's trends in the AI diverge while in the LRI converge from 2016 to 2017. It is also notable how the countries' trends change rank order in two out of four years considered (2018 and 2019).

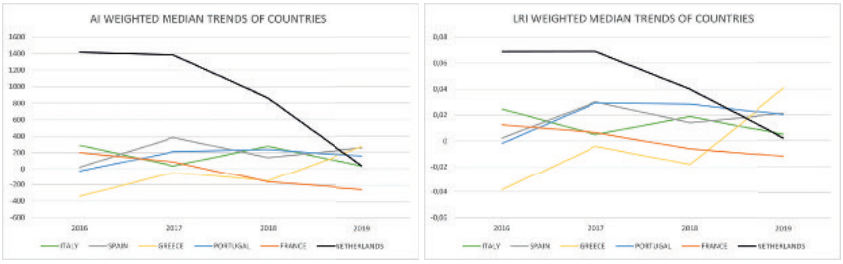

Fig. 3 Comparison between security indicators trends among different European countries.

4 Conclusions and further applications

In this work, two relative indicators of economic security are proposed and compared with the absolute one suggested by Bossert et al. [2]. Both are based on the use of relative change: in the RI it's applied by dividing the intertemporal difference of resource levels by the further period, while in the LRI is implemented by applying the logarithm to the ratio between resources levels in two subsequent points in time. Among these two relative indicators, the logarithmic version appears preferable: in terms of properties satisfied and in terms of consistency with the absolute indicators. Nevertheless, the logarithmic relative indicator rightly provides different results from the absolute indicator in some important cases, where considering a relative change amplifies or reduces the importance of the variation compared to the absolute change. The indicator suggested may be used to study the relationship between economic insecurity and other phenomena such as mental health, criminality and fertility.

A regional analysis of the efficiency by energy's producers in Italy

Un'analisi regionale dell'efficienza dei produttori di energia in Italia

Gianna Greca, Giuseppe Cinquegrana and Giovanni Fosco

Abstract The energy market in Italy is characterized by a competitive framework where regulatory Authority checks the conditions in which operate enterprises that produce, store, distribute and trade energy. The presence of government subsidies towards the energy's production Italian enterprises from two decades up now days in different ways (*Energy Account*, *Green Certificates*, *GRIN*) points out the issue if the efficiency of this industry was affected by these incentives. In this study we focus on the efficiency of the energy's production SMEs taking into account the territorial gap among the Italian Regions. An analysis on the impact of the subsidies to the energy's producers has been conducted regarding the efficiency of the industry on the basis of data collected (Source ISTAT, GSE).

Abstract Il mercato dell'energia in Italia è caratterizzato da un quadro competitivo in cui l'Autorità di regolamentazione verifica le condizioni in cui operano le imprese che producono, immagazzinano, trasmettono distribuiscono e commercializzano energia. La presenza di contributi pubblici alle imprese italiane di produzione di energia da due decenni ad oggi, con modalità diverse (Conto Energia, Certificati Verdi, GRIN), pone la questione se l'efficienza di questo settore sia stata influenzata da tali incentivi. In questo studio ci concentriamo sull'efficienza delle PMI produttrici di energia elettrica tenendo conto del divario territoriale tra le Regioni italiane. Sulla base dei dati raccolti (Fonte ISTAT, GSE) è stata condotta un'analisi sull'impatto degli incentivi ai produttori di energia sull'efficienza del settore.

1 Introduction

The framework of the Italian energy market is based on a competitive dimension regulated by law and monitored by the Italian Regulatory Authority for Energy, Networks and Environment (ARERA). The regulation involves the production, storage, distribution and trade of energy and regards enterprises different by size and industry activity. A relevant characteristic of the energy's production market is due to the fact that in Italy from two decades up to now days a frequent flow of government subsidies has been provided to the energy's producers.

With the exception of a few relevant multinational companies, the vast majority of enterprises that produce electric energy are SMEs and in this work we focus on them, in particular we conduct an efficiency analysis of these companies. In paragraph 1.1 we report a picture of the government subsides regarding *Energy Account* in the last two decades. In paragraph 2. a detailed description of data available for the analysis of the energy's producers (SMEs) and a formulation of the model used for the estimates have been presented. Government subsidies to energy producers

1.1 Government subsidies to energy producers

For plants that generate electricity through the conversion of solar energy, a specific incentive system called *Energy Account*, EC, has been provided for a period of twenty years that rewards the energy produced by photovoltaic systems with incentive rates. This mechanism, already provided for by Legislative Decree 387/2003, became operational following the entry into force of the interministerial decrees of July 28, 2005 and February 6, 2006 (I EA). The activity carried out by the GSE (*Gestore dei Servizi Elettrici*) consisted in the management and examination of the documentation sent by the responsible parties, in the monitoring of deadlines related to the obligations required by law and in the administrative management of the incentives related to the energy produced by the plants. The incentive was ruled by other decrees and in the following table 1 we report the amounts disbursed on *Energy Account* by decree and by year starting from 2007 up to 2020.

Table 1: Amounts disbursed on *Energy Account*, EA, by decree from 2007 up to 2019-2020, mil. Euro.

Decree	2007	2019	2020
I EA (issued in 2003-2005-2006)	17	71	80
II EA (issued in 2007)	2	2.903	3.005
III EA (issued in 2010)	…	581	599
IV EA (issued in 2011)	…	2.181	2.275
V EA (issued in 2012)	…	208	227
Total	**19**	**5.945**	**6.197**

Source: GSE

An other relevant mechanism of energy incentives is GRIN (Incentive Recognition Management) that allows you to take advantage of the incentives provided for by the D.M. 06/07/2012 for all the plants powered by renewable sources qualified to be subsided by Green Certificates up to 2015. Since 2016, the green certificate mechanism has been replaced by this new form of incentive. In this work we focus on GRIN mechanism in order to evaluate the impact of these subsides on the energy sector.

2 Data, Methods and Results

In order to estimate the efficiency of the energy's producers we have built a balanced panel of balance sheet data of energy producers, in particular SME's, from 2014 up to 2020 (source ISTAT). We report in the table 2.1 the number of units per size according to the employees in the activity 35.11 (NACE REV 2).

Table 2.1 : Number of units of the energy's producers by size included in the panel 2014-2020.

Size by employee	Number of units
Up to 9	3.819
10-49	85
50-249	6
Total	**3.910**

A territorial detail is available in the data base and in table 2.2 we report the distribution of energy's producers among the Italian macro territorial divisions.

Table 2.2: Number of units of the energy's producers by size included in the panel 2014-2020.

Size by employee	Number of units	Share % on Italy
North-Est	1.522	38.93
North-West	1.144	29.26
Center	611	15.63
South	470	12.02
Inlands	163	4.17
Total	**3.910**	**100**

The opportunity to use the territorial FRAME SBS (Source Istat), an integrated system of administrative and statistical data by local unit of each enterprise, and ENERDATA database (Source Istat) on economic-legal units that receive subsidies and/or buy and sell allowances[1], provide the tools to territorially explore the performance of energy producers.

[1] The "ENERDATA" database was built as part of the Istat thematic research Project "I meccanismi di incentivazione energetico-ambientale (Energy-environmental incentive mechanisms)". The database, integrating Istat and public data, collects information on the economic-legal units that, in the role of producers and/or users of energy, receive subsidies and/or buy and sell allowances (CO_2 allowances, Energy Efficiency Certificates, etc.) (Cfr. Greca G., Istat, Progetto di ricerca tematica "I meccanismi di incentivazione energetico-ambientale" and Greca G. (2021)).

In the model used to estimate the efficiency of energy producers, we consider a single output (Q) and two inputs: *labor* (L) and *capital* (K). The *total cost* depends on two prices: the price of the *labor* (p_w) and the price of the *capital* (p_r, *user cost of capital*). In order to estimate the cost function Cobb-Douglas, CB, we set a linear homogeneity condition, so the total cost and the price of capital are normalized with the price of labor.
In the following equation, the model considered is reported:

$$\ln\left(\frac{TC}{p_e}\right)_{i,t} = \alpha_i + \gamma_t + \delta_c + \beta_Q \ln Q_{i,t} + \beta_K \ln\left(\frac{p_r}{p_e}\right)_{i,t} + \beta_L \ln\left(\frac{p_w}{p_e}\right)_{i,t} + \beta_1 t + \beta_2 t^2 + U_{i,t} + V_{i,t}$$

$$U_{i,t} = \varphi_1 + \varphi_1 t + \varphi_2 t^2 + Z_{i,t}$$

$$U_{i,t} = \varphi_1 + \varphi_1 post_{2016} + \varphi_2 treated_i + \underbrace{\varphi_3 treated_i \cdot post_{2016}}_{\text{Treatment Effect}} + Z_{i,t}$$

TC= Total costs
p_e= energy price (based on the deflator of value added in energy activity)
p_r= capital price (depreciation plus financial charges / capital
p_w= average wage per employee (wages/ employees)
Q= value added at chained value (2015)
$\alpha_i,\ \gamma_t,\ \delta_c$ fixed effects: firm, year and municipality
t= trend
U= inefficiency term

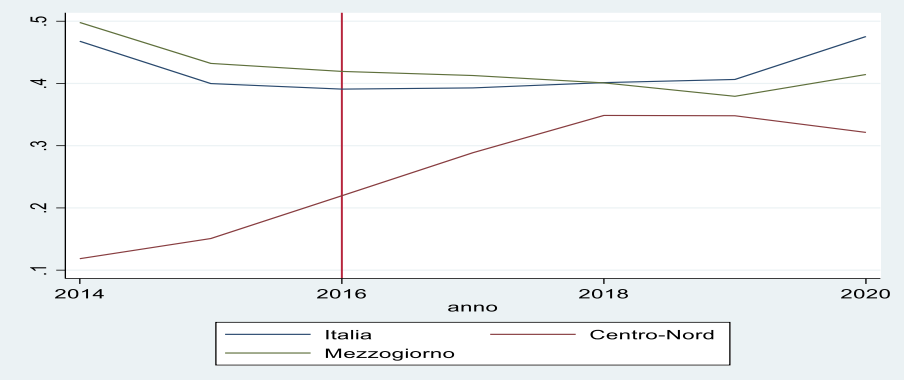
Source: our elaborations
All the variables considered have been deflated on regional level by the deflator of value added at chained value (2015) of the energy activity (NACE REV2). The analysis has been conducted on Small enterprises with only 6 units have more than 50 employees on the total of 3910 firms considered. The results of the estimation of the economic efficiency of energy's producers for a balanced panel from 2014 to 2020 have been reported in the table 2.3, where the control variable is the municipality. The northern firms that operate in the energy sector are less inefficient of the ones that are located in the South of Italy; in particular the regional origin affect the efficiency of the capital: the coefficient β_K is significant both Italy and Center-North and South (and Islands) but for the southern firms signals more inefficiency where it is equal to 0.10 as regards to 0.04 of the northern ones. On the side of output the coefficient β_Q is 0.95 in South and Island while it is 0.91 for the northern units.
In the Figure 2.1 we report the cost efficiency by Italian macro regions from 2014 to 2020, where it's pointed out that the energy's producers of southern regions are largely less efficient than the northern ones, but the gap has started to reduce from 2016.

Figure 2.1 Cost efficiency by Italian macro regions (Years 2014-2020).



Source: our elaborations
In a second step we identify the firms that receive GRIN subsidies in order to evaluate the impact of these incentives on the efficiency of the energy's producers by region and consider these units subjected to treatment. In particular these treated enterprises are 347 in 2016, 373 in 2017, 358 in 2018, 334 in 2019 and 294 in 2020. In the table 2.4 we report for a balanced panel from 2014 to 2020 the estimate of frontier cost of energy's producers considering a treatment for the firms that receive GRIN subsidies using DIFinDIF method to estimated the GRIN's policy effect.
In the table above, we implemented the same frontier cost but a different inefficiency cost model, which use the diff-in-diff method to estimate the GRIN subsidies' effect.

$$U_{i,t} = \varphi_1 + \varphi_1 post_{2016} + \varphi_2 trattati_i + \varphi_3 trattati_i \cdot post_{2016} + Z_{i,t}$$

In this different formulation of cost inefficiency, $post_{2016}$ is an indicator that defines years after the 2016. Whereas, *trattati* is an indicator that defines who takes GRIN subsidies. Thus, the interaction between these two variable indicator gives us the policy effect estimate φ_3.
The analysis with treated firms that receive GRIN subsidies shows that the incentives received do not improve the efficiency of energy's producers, rather the inefficiency increases both in terms of coefficient β_Q and of the one β_K and the southern firms is always worse than the northern ones considering these parameters. The regional gap is also clear looking at the figure

2.2 where it is reported cost efficiency by Italian macro regions with treatment for firms with GRIN incentives (Years 2014-2020). The firms in South and Islands decrease efficiency from 2015 to 2019 while the northern ones improve in that period. In 2020 all the areas show a large rebound.

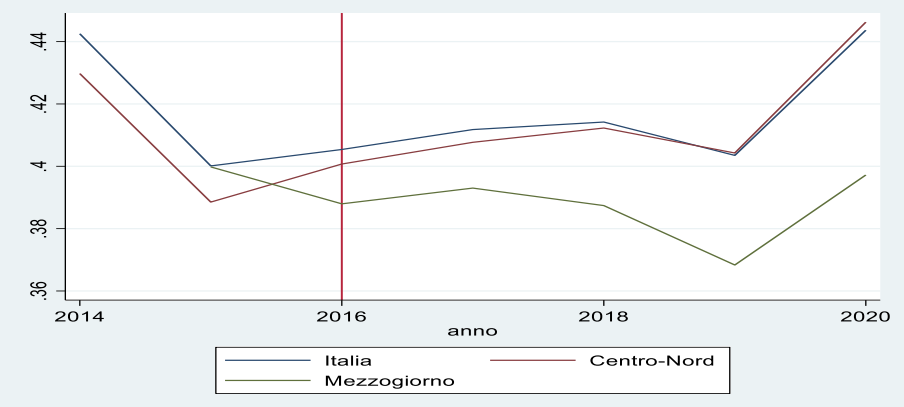
Figure 2.2 Cost efficiency by Italian macro regions with treatment for firms with GRIN incentives (Years 2014-2020).



Source: our elaborations

The results presented give some implications for the policy makers that decide to subside the energy's producers in order to check if this kind of incentives provide positive impact on the efficiency of the energy production sector. From Figure 2.1 we can see a convergence of the efficiency path between the Center-North and South (and Islands), but considering an analysis DIFinDIF with treatment of the firms that receive GRIN subsidies, we can conclude that this kind of incentives do not improve the efficiency of the energy's producers, anyway there is a differential impact on the Italian macro regions. In general the northern firms that operate in the energy sector are more efficient than the ones in the South and Islands as showed in Table 2.3 and in Figure 2.1, but the impact of GRIN subsidies show in Figure 2.2 a marked deterioration in the southern firms.

On Investigating Social and Financial Aspects of Cardano

Analisi degli Aspetti Sociali e Finanziari di Cardano

Stefano Vacca, Marco Ortu, Gianpaolo Zammarchi and Giuseppe Destefanis

Abstract The goal of this paper is to investigate the reasons and speculations surrounding the Cardano cryptocurrency (ADA) from two points of view: (I) opinion mining, analyzing the comments of expert users on the r/cardano subreddit; (II) financial, through the analysis and correlation of the price trend with the metrics extracted from Reddit. The main purpose of this study is to measure any cause-effect relationships between the social variables and the financial variables, in order to demonstrate whether it is possible to predict the price trend of the Cardano starting from the specialized discussions of the redditors, or if it is possible to predict the user behavior depending on the price trend in different periods.
L'obiettivo di questo lavoro è lo studio delle cause delle speculazioni che riguardano la criptovaluta Cardano (ADA), sotto due punti di vista: (I) l'opinion mining, analizzando i commenti di utenti esperti sul subreddit r/cardano; (II) finanziaria, attraverso l'analisi e la correlazione dell'andamento dei prezzi con le metriche estratte da Reddit; Lo scopo principale è quello di misurare eventuali relazioni di causa-effetto tra le variabili sociali e le variabili finanziarie, al fine di dimostrare se è possibile prevedere l'andamento dei prezzi del Cardano partendo dalle discussioni specialistiche dei redditors, oppure se è possibile prevedere il comportamento dell'utente in base all'andamento del prezzo in periodi diversi.

1 Introduction And Methodology

The analysis of cryptocurrencies price behaviours is one of the most discussed topics of the last few years on social media environments. In this study we focused our attention on Cardano (ADA), which is a proof-of-stake blockchain platform that, since January 2021, has seen a price increase from 15 euro cents on December 31st 2020 to the current 1.93 euro on September 23rd 2021 (+ 1271.55%). However, after the absolute peak of 2.42 euros reached on September 2nd, ADA suffered a price collapse until this analysis. The purpose of this work is to ascertain the existence of possible relationships between cryptocurrency market prices and social media [6] discussions in order to understand what topics have the potential to predict price movements. The first step was to retrieve the discussions comments from the social media platform *Reddit*, which has been shown to be one of the most valuable sources of information relating to cryptocurrency markets. Secondly, the occurrence of particular topics from social media content were evaluated, using dynamic topic modelling, that is an extension of Latent Dirichlet Allocation (LDA). Finally, a Hawkes model was implemented to identify hidden interactions between topics and cryptocurrency market prices. This family of statistical models is often used in economics analysis [2]. *Reddit* is an American social news aggregation, web content rating, and discussion website that reaches about 8 billion page views per month. It is built over multiples subreddits, where each subreddit is dedicated to the discussion of a particular subject and there are specific subreddits related to major cryptocurrency projects. We used the Pushift API[1] to extract comments from posts written on *r/cardano*, a subreddit with over 619,000 subscribers. The period considered runs from 1st July to 23rd September 2021, for a total of 72,090 comments extracted. Thanks to Natural Language Processing, Sentiment Analysis and Topic Modeling techniques, we extracted the following metrics: i) 10 topics using Latent Dirichlet Allocation; ii) 6 up and down VAD metrics, of which: 2 Valence metrics, 2 Arousal metrics and 2 Dominance metrics; iii) 6 price metrics that count the number of low, high and stable events derived by the common financial metrics, closing price minus opening price in the minute, and high price minus low price in the minute. Valence, Arousal and Dominance (VAD) represent conceptualized affective dimensions that respectively describe the interest, alertness and control a subject feels in response to a certain stimulus. Warriner et al. [7] has created a reference lexicon containing 14,000 English words with VAD scores for Valence, Arousal, and Dominance.

Topic Modeling. A topic model is a specific statistical model used to identify the abstract topics within a collection of documents. Topic modelling is a frequently used text-mining tool for discovery themes occurring within a corpus automatically, finding a distribution of words in each topic and the distribution of topics in each document. In this work, we used the *Latent Dirichlet Allocation* (LDA) [4], which is a popular unsupervised learning technique for topic modelling, introduced in 2003. This type of topic model assumes that each document contains multiple topics to different extents. It has been proven that the standard LDA model can not understand both the ordering of words within a document and the ordering of documents within

[1] https://github.com/pushshift/api

a corpus. For this reason, in 2006, an extension of this model was developed [3]. This LDA model extension is known as *dynamic topic model* and even if it still has no understanding of the order of words in a document, at least the order of documents in the corpus is accounted for.

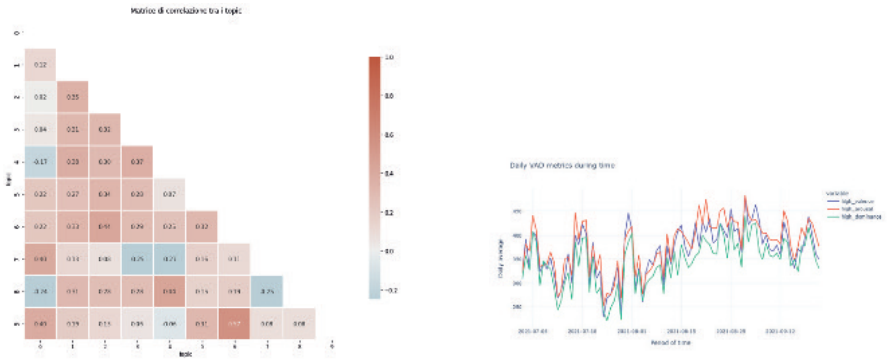
Topic	Keywords	Label	# comments
0	stake, pool, reward, ada, epoch	Staking & rewards	9932
1	question, answer, word, ask, dip	Uncertainty	4189
2	video, comment, link, watch, youtube	General Information	5030
3	fee, people, transaction, nice, invest	Trading and Smart Contracts	4404
4	project, cardano, people, think, know	Cardano Community Information	9036
5	ada, token, cardano, binance, nft	NFT & Investments	4017
6	buy, crypto, good, coin, ada	Pure Trading	8130
7	wallet, thank, yoroi, ledger, use	Stacking Wallets	9008
8	cardano, contract, smart, eth, ethereum	Smart Contracts & Crypto Market	12233
9	ada, year, pay, tax, hold	Crypto, Taxes & Law	6111

Table 1: Reddit Topics.

Table 1 shows the 10 topic extracted with the dynamic LDA along with the five top words, label and number of comments of each topic. Figure 1a shows the linear correlation between topics (that primarily indicates positive linear correlations, except for 6 out of 45 combinations). The highest correlation is between topics 6 (Pure Trading) and 9 (Crypto, taxes & law), with a positive correlation of 0.57. The highest negative correlation is instead between topic 4 (Cardano Community information) and topic 7 (Stacking wallets) with -0.27.
Figure 1b shows the daily trend of VAD metrics. The growing trend of all three metrics starting from August follows the increase in the ADA price. Financial data was extracted from Binance[2]. Each line of the dataset refers to the price trend with a frequency of 1 minute. We finally created six final metrics used in our model, they count the events of *low*, *high* and *stable* of price and volatility changes (delta of high minus low values).

Hawkes Model. The Hawkes process is a point process class [5], also known as a self-exciting counting process, in which the impulse response function explicitly depends on past events. In this type of process, the observation of an event causes the increase of the process impulse function. From a mathematical point of view, a point process is a Hawkes process if the impulse function $\lambda\left(t|H_t\right)$ of the process takes the form of Equation 1.

[2] https://www.binance.com/it/markets



(a) Correlation among topics

(b) VAD daily trend.

Fig. 1: Topics correlation and VAD metric trends.

$$\lambda\left(t|H_t\right) = \lambda_0(t) + \sum_{i:t_i<t} \phi\left(t - t_i\right) \tag{1}$$

In Equation 1, H_t represents the history of given past events, $\lambda_0(t)$ is a positive function that determines the basic intensity of the process and ϕ is another positive function known as *memory kernel*, since it depends on past events occurred before time t. Hawkes models can be used to identify dynamic interactions among a group of K processes. Once the Hawkes model is fitted, it will contain some weights representing the directional strength of any interaction between processes, interpreted as the expected number of events on a specific process resulting from an event on another process.

2 Main Findings

The goal of the analysis was to investigate and identify any cause-and-effect relationships between the social variables (the online world) and the financial variables of the cryptocurrency market (the financial world). Hawkes models made it possible to relate these two (apparently) unrelated worlds. Here the cause-and-effect relationships are intended as *predictive causality*, a particular case of Humean causality such as Granger causality [1], which could indeed be reconstructed through Hawkes models [2, 8]. In particular, we found: *i)* The relationships between the variables are self-excitement both before and after the event in which the price reaches its maximum (2nd September), with a loss of effect when the max_lag exceeds 24; *ii)* In the period leading up to the maximum point, the topic "trading and smart contracts" (Topic 3) causes increases in the delta_high_volatility metric where, on the contrary, the topic linked to uncertainty (Topic 1) generates a reduction; *iii)* From 3rd to 8th September the substantial price reduction (delta_volatility_low) generated a reduction in high volatility events, which in turn records a negative self-excitement relationship (-1.53). Figure 2 shows that there are self-excitement movements, with

slight mutual-excitement movements between the low delta price events towards other price metrics and topics.

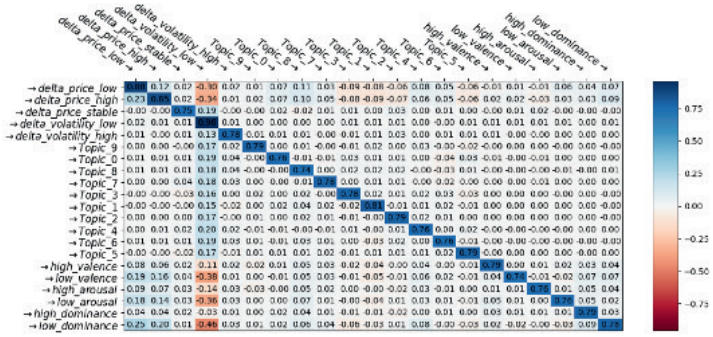


Fig. 2: Max_lag 24 for the entire considered period

The low volatility metric (delta_volatility_low) generates slight increases in all 10 topics, while a reduction in VAD metrics, but above all a reduction in financial metrics linked to high and low price reduction events. By reducing the number of days in the analysis, it is possible to note an important change in the behaviour of the matrix (Figure 3a). In fact, the diagonal of self-excitement disappears, in favour of important mutual-excitement recordings. The most important are those that link topic 3 (which deal with the themes of "trading and smart contracts") with the increase in price volatility (delta_volatility_high), while the topic linked to uncertainty (Topic 1) causes a reduction.
The coefficient matrix lights up differently (Figure 3b) considering the period 3-8 September 2021 (on 7th September the price settles down after the collapse occurred). In this case, events of high volatility suffer important effects, in particular due to the price reduction (delta_price_low) which generates the reduction together with itself (self-excitement effect with coefficient at -1.53). The low value of the comments also generates highly variable events, as well as the topic on NFTs and Trading (Topic 3 and Topic 5).

The purpose of this work was to identify the relationships between topic discussion occurrences on social media and Cardano (ADA) market price changes. To achieve this goal, dynamic topic modelling was first applied to social media content, and then a Hawkes model was used to decipher relationships between topics and cryptocurrency price movements. The results highlighted an interesting cause-effect (in the Granger causality sense) relationships between the social media metrics extracted from comments of domain expert redditors and the trend of ADA in two moments of price rise and fall. Also, the results show how social media plays an important role in these decentralized systems.

Combined permutation test on the effect of age of micro enterprises on the propensity to Circular Economy

Test di permutazione combinato sull'effetto dell'età di micro imprese sulla propensione all'Economia Circolare

Stefano Bonnini[1] and Michela Borghesi[2]

Abstract Circular Economy (CE) is emerging as a possible strategy that companies might adopt to engage with environmental sustainability challenges. An interesting hypothesis concerns the effect of companies' age on the propensity of micro enterprises to undertake CE activities. Among the main difficulties in testing this hypothesis, are the multidimensional nature of the concept of CE, the small number of observations and the unbalanced sample sizes, typical situations of the empirical studies on this topic. We propose a solution based on a combined permutation test. Through a Monte Carlo simulation study, we investigate the power of this test. Finally, we consider a case study concerning Italian companies in the metal sector.

Abstract *L'Economia Circolare (CE) sta emergendo come una possibile strategia che le aziende di tutte le dimensioni potrebbero adottare per consentire loro di affrontare le sfide della sostenibilità ambientale. Un'ipotesi interessante riguarda l'effetto dell'età delle aziende sulla propensione delle micro imprese a intraprendere attività di CE. Tra le principali difficoltà nel verificare questa ipotesi, vi sono la natura multidimensionale del concetto di CE, le piccole dimensioni campionarie e lo sbilanciamento delle stesse, tipiche situazioni degli studi empirici sull'argomento. Proponiamo una soluzione basata su un test di permutazione combinato. Attraverso uno studio di simulazione Monte Carlo, indaghiamo sulla potenza di questo test. Infine consideriamo un caso studio riguardante aziende italiane nel settore della produzione e lavorazione dei metalli.*

1 Introduction

This paper deals with a multivariate two-sample test on proportions, based on the comparison of two multivariate Bernoulli distributions. For instance, it may be of interest to compare the propensity to Circular Economy (CE) of young and old companies. "Propensity to CE" is a multidimensional concept that concerns a set of attitudes and behaviors on the part of enterprises. The response represents presence or absence of such attitudes or behaviors, hence its components are dichotomous variables and the underlying probability distribution is a multivariate Bernoulli.

The aim of CE is to reduce the resources escaping from the circle so that the system functions in an optimal way. One goal of CE is to keep the added value in products for as long as possible and eliminate waste. When a product has reached the end of its life, resources are kept within the economy so that they can be productively be used again to create further value [7].

According to the existing literature, small-and-medium-sized enterprises are lagging behind on this topic. Many authors indicate that older firms are better to be involved in CE activities [1]. However, empirical studies specifically devoted to very small enterprises, the so-called micro enterprises, typical of the economic systems of several countries, including Italy, are missing. The published works usually suffer from some methodological limitations. In particular, they do not consider the multivariate nature of the response, they ignore the existence of confounding factors (firm size when testing the effect of age and vice-versa, economic sector, etc.), they use inferential methods not valid for small samples, they do not deepen the reliability of the results in case of unbalanced sample sizes.

The main goal of this work is to propose a two-sample permutation test for multivariate Bernoulli variables in order to investigate the relationship between propensity to CE and companies' age, overcoming the mentioned limitations of the current literature. The proposed method is valid also for directional alternatives and small samples. We investigate the power behaviour of the test through a simulation study. Furthermore, we contribute to the empirical literature on CE, applying the test to a case study concerning Italian micro enterprises in the metal sector.

Section 2 focuses on the presentation of the problem and on the methodological proposal. Section 3 is dedicated to the simulation study and Section 4 to the application problem. Section 5 includes results and concluding remarks.

2 Testing problem and methodological solution

Let us consider a multivariate test on proportions for two independent samples, where the multivariate response consists of q binary components, with $q \geq 2$. For the sake of simplicity, when a binary variable takes value 1 we symbolically denote the event a success. H_0 is the equality of the vectors of the q proportions of successes in population 1 and population 2 or, equivalently, the equality of the q marginal probabilities of success. For instance, the null hypothesis consists in the equality of

the proportions of young and old circular companies, according to q different points of view. We focus on the one-sided test because more challenging from the methodological point of view and more interesting in the applications. The adaptation of the procedure to the two-sided alternative is trivial. Hence, the alternative hypothesis H_1 is that the proportions of successes in population 2 are greater than those in population 1 (e.g. the propensity to be circular of young firms is less than that of old firms).

The general problem can be defined as follows, according to the union/intersection approach

$$\begin{cases} H_0: \bigcap_{k=1}^{q} (X_{1k} =^d X_{2k}) \\ H_1: \bigcup_{k=1}^{q} (X_{1k} <^d X_{2k}) \end{cases}$$

where X_{jk} is the Bernoulli random variable that takes 1 in case of success (e.g. circularity of a firm) in the j-th population according to the k-th partial aspect and 0 otherwise. The k-th partial null hypothesis is equivalent to $P(X_{1k} = 1) = P(X_{2k} = 1)$, whilst the k-th partial alternative hypothesis can be written as $P(X_{1k} = 1) < P(X_{2k} = 1)$. H_0 is true if all the partial null hypotheses are true. H_1 is true if at least one partial alternative hypotheses is true. When a partial alternative hypothesis does not hold, the corresponding partial null hypothesis is true. Each vector of q values observed on a statistical unit (e.g. firm) is supposed to be realization of the q-variate random variable $(X_{j1}, \dots, X_{jq})$ where $j = 1$ or $j = 2$ depending on whether the statistical unit belongs to sample 1 or sample 2 respectively. One crucial difficulty of such a problem is the need to take into account the dependence structure of the q marginal Bernoulli variables. This problem cannot be easily solved within a parametric approach.

The proposed solution is based the approach of Combined Permutation Tests (CPTs) [2]. CPTs consist of a family of nonparametric tests, suitable for problems that can be broken down into partial tests, robust and powerful in particular (but not only) for small sample sizes. For the application of this test, the independence with respect to units can be relaxed in favor of the exchangeability condition [5]. The solution is based on the application of q partial permutation tests on proportions. Each of them consists of testing the k-th partial null hypothesis versus the k-th partial alternative hypothesis with the difference between the proportion of sample 2 and sample 1 as a test statistic. The dependence between the partial tests in the null distribution is implicitly considered by permuting the rows of the dataset or equivalently by randomly assigning the observed row-vectors of q values to sample 1 and sample 2. For the general problem, a suitable combination of the q partial tests, based on the application of a function ψ on the partial p-values, can be used as a test statistic: $T_\psi = \psi(l_1, \dots, l_q)$, where l_k $(k = 1, \dots, q)$ is the p-value of the k-th partial test. We take into account the combining function of Fisher and Tippett, $T_F = -2\sum_{k=1}^{q} \log(l_k)$ and $T_T = \max_k(1 - l_k)$ respectively.

3 Simulation study

The power of the proposed test is assessed through Monte Carlo simulations. We consider different settings, according to the sample sizes n_1 and $n_2 = u \cdot n_1$ where $u = n_2/n_1$ is the unbalance ratio. For each setting, 1000 datasets with $q = 5$ response variables, are randomly generated. The vectors of success probabilities are $\theta_j \mathbf{1}_q$, $j = 1,2$, where θ_1 and $\theta_2 = \theta_1 + \delta$ are scalars taking values in the interval $(0,1)$ and $\mathbf{1}_q$ is a vector of q elements equal to 1. After the generation from the q-variate normal distributions $\mathcal{N}_q(\mathbf{0}, \boldsymbol{\Sigma})$, data are dichotomized according to θ_1 and θ_2. Let z_{ik} be the value of the i-th statistical unit and k-th variable generated from the normal distribution, the dichotomous value from the Bernoulli distribution of parameter θ_j is attained according to the following rule: $w_{ik} = 1$ if $z_{ik} \leq z_{1-\theta_j}$ and 0 otherwise, where $z_{1-\theta_j}$ represents the quantile of the standard normal distribution with cumulative probability equal to θ_j. The elements of $\boldsymbol{\Sigma}$ in the main diagonal, i.e. the variances σ_{kk}, $k = 1, \dots, q$, are set to 1, and the covariances (or equivalently the correlations) are assumed to be constant: $\sigma_{ks} = \rho$, $k \neq s$. We set $\theta_1 = 0.3$ and $\rho = 0.3$. In the null hypothesis $\delta = 0$ whilst in the alternative $\delta = 0.05$. For the computation of the p-values under H_0, instead of considering the exact permutation distribution, for computational convenience, we randomly generate 1000 permutations and compute approximate p-values according to the Conditional Monte Carlo approach [5]. The significance level of the simulations is α=0.05.

Table 1 reports the rejection rates of the permutation tests with the combinations of Fisher and Tippet. In both the cases the rates tend to be less than 0.05 and, when this is not true, they are very close to α. This conclusion holds for any sample size, it is valid for both balanced and unbalanced case and for any unbalance ratio. Hence, we can conclude that both the combined tests are well approximated.

Table 1: Rejection rate under H_0 with q=5, ρ=0.3, θ_1=0.3 and α=0.05

n_1	u	*Fisher*	*Tippett*	n_1	u	*Fisher*	*Tippett*
20	0.1	0.053	0.049	20	2	0.048	0.052
40		0.040	0.041	40		0.042	0.040
60		0.052	0.052	60		0.044	0.043
80		0.052	0.048	80		0.037	0.037
100		0.050	0.044	100		0.048	0.044
20	0.5	0.047	0.036	20	10	0.045	0.042
40		0.050	0.052	40		0.052	0.030
60		0.049	0.040	60		0.043	0.051
80		0.052	0.048	80		0.037	0.047
100		0.054	0.053	100		0.055	0.056
20	1	0.043	0.050				
40		0.047	0.046				
60		0.055	0.048				
80		0.046	0.052				
100		0.047	0.044				

Table 2 shows the rejection rates under the alternative hypothesis. It is evident that the power increases as the sample size increases and therefore the test is consistent. Since the rejection rates under H_1 are always greater than α, then the test is unbiased. The power increases with the unbalance ratio. Hence, the larger n_2 with respect to n_1, the higher the capacity of the test to recognize that the true hypothesis is $\theta_1 < \theta_2$. In all the considered settings Fisher's function seems to provide a combined test more powerful than Tippett's function.

4 Application problem

The combined permutation test based on Fisher's function was applied to original data collected with the CATI method in January 2020. The survey involved Italian small and medium enterprises. We focused on the metal sector to avoid confounding effects due to sector heterogeneity and because this sector, more than others, lends itself to the CE. In fact metals are inherently recyclable, as they retain their utility for multiple product lifecycles and also for the versatility in favor of their reuse. For this reason, metal sector has always operated according to an approach of recovery, recycling and reuse [3]. Specifically, we analysed the interesting case, not much explored so far, of micro enterprises, i.e. firms with less than 9 employees [1]. We are in presence of small samples: 4 young and 32 old firms, with a balance ratio of 8.

The goal is to answer the following research question: "Is the propensity towards CE of younger firms lower, within the category of micro firms?". The responses are 6 binary variables that correspond to the following actions, chosen according to [6]: (1) innovations aimed at reducing the use of materials; (2) innovations aimed at

reducing the emitted waste; (3) innovations aimed at reuse of waste in its production cycle; (4) innovations aimed at transferring waste to other companies, which use them in their own production cycle; (5) innovations aimed at changing the design of the products in order to maximize their recyclability; (6) investments in R&D aimed at reducing the environmental impacts of production.

The p-value of the test is 0.266. It indicates no significance at α=0.05. Hence, there is not empirical evidence to reject the hypothesis of null effect of firm age.

5 Results and conclusions

The combined permutation test on the proportions of multivariate dichotomous variables is powerful, flexible because distribution-free, unbiased and consistent. This methodology is suitable also for small samples and its power depends also on the extent and the direction of the unbalance. The combination of Fisher is always preferable to that of Tippett. The application of the test to original sample data concerning Italian micro enterprises in the metal sector does not bring empirical evidence in favor of the hypothesis that the propensity towards CE is increasing function of age.

Comparison of Two Different Approaches to Measure Economic Access to Food and Insecurity: an Application to Mexican data

Comparazione di due approcci per valutare l'insicurezza alimentare: un'applicazione sui dati ENIGH in Messico

Stefano Marchetti, Luca Secondi and Adrian Vargas-Lopez

Abstract The UN SDG 2 establishes the achievement of food security by 2030. The pandemic has exacerbated inequalities and what was primarily a problem of emerging countries now also characterizes developed countries. Measuring economic access to food properly is an important issue to be addressed to allow a constant official monitoring of the phenomenon. By using the Mexican National Survey of Household Income and Expenditure data, the aim of this paper is to assess the convergence between a qualitative assessment of food insecurity and an indicator of economic access to food obtained from Household Budget Surveys, usually carried out in several countries. As the first analyses suggest, when quality assessment of food insecurity is difficult to obtain, the food access economic indicator can be used instead to support data driven policy decisions.

Abstract *L'SDG 2 stabilisce il raggiungimento della sicurezza alimentare entro il 2030. La pandemia ha aumentato il livello di disuguaglianza anche nei Paesi sviluppati con situazioni di marginalità sociale che includono l'insicurezza alimentare. Si rendono necessarie misure appropriate per il monitoraggio della capacità di soddisfare i bisogni primari di alimentazione. In questo lavoro utilizziamo i dati di indagine messicani, per valutare la convergenza tra una misura di insicurezza alimentare qualitativa basata su domande specifiche e una quantitativa basata sulla spesa per alimenti. Come confermato dalle prime analisi, la misura quantitativa, più facilmente ottenibile dalle indagini correnti degli uffici nazionali di statistica in*

Key words: food expenditure, qualitative assessment, SDG 2

1 Introduction

The UN Sustainable Development Goals have set clear targets on global poverty, hunger and malnutrition to be achieved by 2030, which have prompted academics and policy-makers to identify and define useful strategies and measures as well as proper methods to assess drivers effectively. Specifically, SDG 2 foresees the reduction of food insecurity by reducing chronic hunger, defined as situation that exists when people lack access to sufficient amounts of nutritious food for an active and healthy life as measured by the Prevalence of Undernourishment (PoU), in accordance with SDG Indicator 2.1.1 ([1]).

Food insecurity is a complex problem, manifesting as obesity and malnutrition in addition to extreme hunger and starvation ([2]) and it is commonly defined as *"having at all times, physical, social and economic access to sufficient, safe and nutritious food that meets dietary needs and food preferences for an active and healthy life"* ([3]).

Food insecurity and the related notion of economic access to food may appear to refer exclusively to developing countries, but in actual fact it is a phenomenon that was also present in developed and affluent countries ([4]) including Europe ([5]) and more generally OECD countries, even before the outbreak of Covid-19 pandemic even if the pandemic has exacerbated inequality, with almost 811 million people faced hunger in 2020, according to figures by the Food and Agriculture Organization of the United Nations.

In this perspective a correct and proper measurement of this phenomenon is essential. Focussing on measuring economic access to food and (in)security both qualitative scales and indicators based on the household income expenditure have been proposed. However, these measures have been used as alternatives or as single dimensions within a multidimensional perspective capturing availability, access, utilization and stability of food.

However, since in developed countries it is the task of official statistics to conduct the survey on household consumption by collecting household expenditures for different categories of expenditure (i.e. the so-called Household Budget Surveys, HBSs) it would be good to investigate to what extent measures based on data of an economic nature (income or consumption) are aligned with qualitative measures and scales that are already well explored and widely developed, instead, in emerging countries.

The statistical robustness and correspondence of information and classification between different approaches may in fact allow for the extension of the use of HBSs (but also surveys on income) for further purposes that go beyond or, even better,

complement the analyses that have so far been conducted on poverty in general, expanding them towards the analysis of poverty and food insecurity.

In this study, we focus on Mexico and specifically on the National Survey of Household Income and Expenditure (ENIGH) carried out every two years by the National Institute of Statistics and Geography (INEGI). We aim to compare two measures of food insecurity. The first is based on the ENIGH set of questions to measure food insecurity from a qualitative perspective. The latter is based on household consumption expenditures - and specifically household consumption expenditure on food - that is also surveyed in ENIGH. Therefore, the possibility of referring to a double perspective within the same survey has motivated us to explore the statistical reliability of these two approaches in measuring a unique phenomenon.

2 Data and Method

The National Survey of Household Income and Expenditure (ENIGH) is a representative sample survey conducted in Mexico every two years with the general aim of providing stakeholders with a statistical overview of income and expenses behaviour of households in terms of their amount, origin and distribution.

For our analysis we use the ENIGH 2018 wave, which involves a national sample of 87,826 housing units. INEGI uses a stratified, two-stage design, where the secondary units are the households and the primary units are municipalities, while stratification is done according to geographic characteristics.

Within the Mexican ENIGH survey the food insecurity issue is assessed through the use of the Latin American and Caribbean Food Security Scale (ELCSA) by taking advantage of 6 questions where families signal if during the past three months they had access to a limited variety of food, whether they skipped a meal, if they had eaten less than they thought they should, if they ran out of food, if they felt hungry but did not eat, and if they had not eaten for a whole day. These questions are asked twice if in the household there are children (i.e., individuals younger than 18). The second time, respondents answer for the infants living in the dwelling ([6]).

The severity of food insecurity is constructed by the number of questions that people answer affirmatively. When households without children answer "Yes" to 5-6 questions, they are Severely Insecure. If they answer 3-4 questions affirmatively, they are Moderately Insecure; 1-2 questions, Mildly Insecure; and, 0 questions, Secure. Similarly, each threshold is built for households with children. In Mexico we estimated 60.3% of people is food secure, while 39.7% are not. In particular 19.3% are mildly insecure, 12.1% are moderately insecure and 8.3% are severely insecure. There are about $49,670,000$ persons who are not food secure. Figure 1 shows the proportions of persons by severity of food insecurity according to the ELCSA scale divided by households with and without children. We can observe that households with children show a higher level of food insecurity, highlighting the difficulties of such households to afford adequate nutrition.

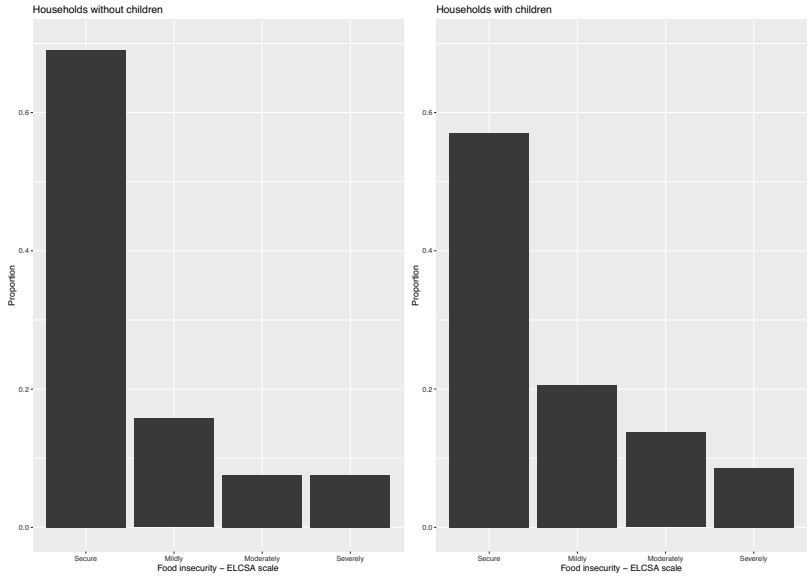

Fig. 1 Proportions of people living without (left) and with (right) children by ELCSA food insecurity scale. Source: ENIGH 2018 data.

The ENIGH surveys also information about household consumption expenditure, used to obtain the share of food expenditure and a proxy indicator of the food (in)security ([1]). Let x_i be the total expenditure and y_i the food expenditure for household i, then the share of food expenditure at household level is simply defined as $SF_i = y_i/x_i$. According to the Integrated Food Security Phase Classification (IPC, 2021), we use a four-group classification: i. no food insecurity if $SF < 40\%$, ii. mild food insecurity if $40\% \leq SF < 50\%$, iii. moderate food insecurity if $50\% \leq SF < 70\%$ and iv. severe food insecurity if $SF \geq 70\%$. We estimated at national level 48.3% of persons being food secure, 23.5% being mildly food insecure, 24.4% being moderately food insecure and 3.8% being severely food insecure. According to this measure, about $64,675,000$ persons are not food secure. The picture obtained is a little bit different from the previous one, and seems to emphasize more the food insecurity phenomenon. We show in figure 2 the proportions of persons living in the different food (in)security conditions, classified by persons living with or without children. Using this measure, the difference between households with and without children are minimal, with a bigger proportion of food severely insecure for person living without children.

Both the food insecurity measures are estimated using the Horwitz and Thompson expansion estimator. Standard error are obtained using Taylor approximation and are considered small at national level.

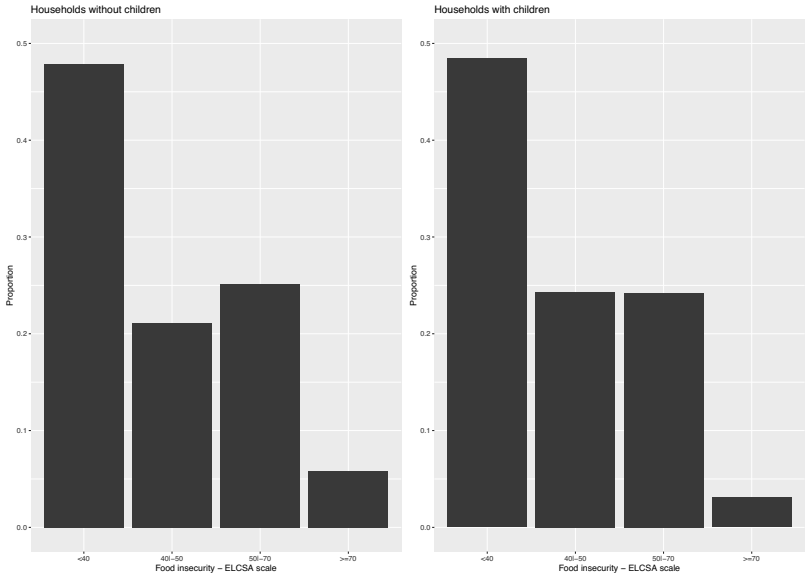

Fig. 2 Proportions of people living without (left) and with (right) children by IPC food insecurity scale. Source: ENIGH 2018 data.

3 Discussion on the comparison between food insecurity measures

In this section we compare the food insecurity measure obtained from the ELCSA scale and from the IPC scale. The first is based on specific questions aimed at investigating about properly nutrition, the latter is based on the consumption expenditure, usually surveyed in many countries.

The two measures are dependent according to the Pearson χ^2 test for contingency table with the first and second-order Rao-Scott corrections (p-value $< 2.2e-16$) ([7]). Even if we carry out the test within regions the result does not change. We also carry out a regression model to assess the relation between the *SF* and the food insecurity on the quality ELCSA scale and some controlling variables (presence of children, regions and urban/rural area). The average *SF* is significantly different among secure, mild insecure, moderately insecure and severe insecure categories.

Although the two measures are dependent there are some differences. Figure 3 visualizes the cross classification of food insecurity level between ELCSA and IPC scale. Firstly, it is reasonable that persons classified severely, moderately or mild insecure on the IPC scale can be secure according to the ELCSA scale, this mean that a very large amount of resources are used for nutrition. What need further investigations are those persons who are secure on IPC scale (i.e. $SF < 40\%$) while mildly, moderately or severely insecure according to ELCSA scale. Indeed, these

persons devote less than 40% to consumption expenditure for food, but they have difficult to have an adequate nutrition level.

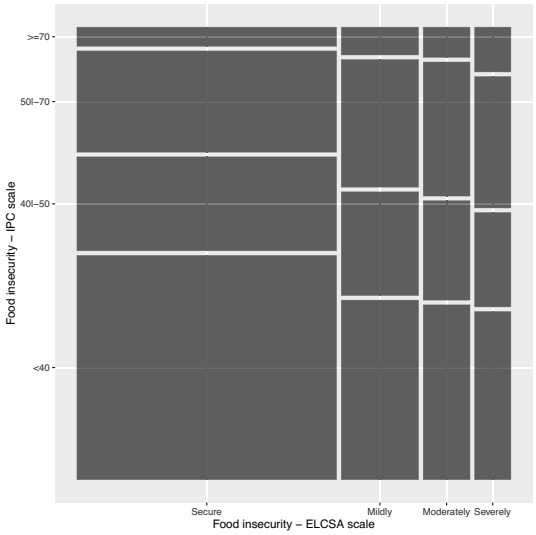

Fig. 3 Cross classification of food insecurity level between ELCSA and IPC scale. Source: ENIGH 2018 data.

We can conclude that the IPC based scale emphasizes more the problem than ELCSA scale, but exclude persons that have not access to sufficient nutrition. Future works will investigate on these issues.

Image analysis and visual methods

Bias correction of the maximum likelihood estimator for Emax model at the interim analysis

Correzione per distorsione della stima di massima verosimiglianza del modello Emax nell'analisi ad interim

Caterina May and Chiara Tommasi

Abstract The Emax model is a dose-response model commonly applied in clinical trials, agriculture and environmental experiments. We consider a two-stage adaptive design for collecting "optimal" data for estimating the model parameters. At the first stage (interim analysis) a locally D-optimum design is computed to get a sample of independent observations and to produce a first-stage maximum likelihood estimate (MLE). At the second stage, the first-stage MLE is used as initial parameter-value to determine another D-optimum design and then to collect the second-stage observations.
The first-stage estimate influences the quality of the data gathered at the second stage, where a large number of observations can be collected. In real life problems, instead, the sample size of the interim analysis is usually small; therefore, the first-stage MLE should be precise enough even if based on few data. From this consideration, our guess is that if we improved the behaviour of the first-stage MLE through a bias correction, then the D-optimal design determined at the second stage would produce better experimental points. In this study we provide the analytic expression of the first-order bias correction of the MLE in the Emax model.
Abstract *Il modello Emax è un modello di risposta alla dose comunemente usato negli esperimenti clinici, agricoli e ambientali. In questo lavoro consideriamo un disegno adattivo a due stadi per raccogliere dati "ottimali" al fine di stimare i parametri del modello. Al primo stadio (analisi ad interim) viene calcolato un disegno localmente D-ottimo per raccogliere un campione di osservazioni indipendenti e ottenere una stima di massima verosimiglianza (SMV). Al secondo stadio la SMV di primo stadio viene usata come valore inziale del parametro per determinare un secondo disegno D-ottimo e raccogliere le osservazioni di secondo stadio a par-*

tire da quest'ultimo disegno sperimentale. Tali osservazioni dipendono quindi dalle risposte precedenti.
La stima di primo stadio influenza la qualità dei dati al secondo stadio. Nei problemi reali la dimensione campionaria dell'analisi ad interim è di solito bassa, quindi la SMV di primo stadio sarrebbe opportuno fosse precisa anche se basata su un campione piccolo. La nostra idea è quindi quella di migliorare la SMV di primo stadio correggendone la distorsione, così che il disegno D-ottimo al secondo stadio sia migliore. In questo lavoro determniamo l'espressione analitica al primo ordine della distorsione della SMV di primo stadio dei parametri del modello Emax.

Key words: maximum likelihood estimator, interim analysis, small sample, bias correction, D-optimality, two-stage adaptive design, Emax model

1 Introduction

The *Emax* model is well-characterized in the literature and it is frequently used for dose-response designs in clinical trials, as well as in agriculture and in environmental experiments (see, for instance, [3] and [2]). It has the form $y = \eta(x,\theta) + \varepsilon$ where y denotes a response at the dose $x \in \mathscr{X} = [a,b]$, $0 \le a < b$; $\theta = (\theta_0, \theta_1, \theta_2)^T$ is a vector of unknown parameters; ε is a Gaussian random error; the nonlinear mean response is

$$\eta(x,\theta) = \theta_0 + \theta_1 \frac{x}{x+\theta_2}. \tag{1}$$

In equation (1), θ_0 represents the response at the dose zero; θ_1 is the maximum effect attributable to the drug; and θ_2 is the dose which produces the half of the maximum effect.

In this study, to collect observations that provide a precise estimation of θ, we consider a two-stage adaptive design. By the fact, sequential adaptive designs are quite common in clinical trials. More specifically, assume that a guessed value $\tilde{\theta} = (\tilde{\theta}_0, \tilde{\theta}_1, \tilde{\theta}_2)^T$ for θ is available, for instance from an expert opinion. At the first stage (or interim analysis) we take $n_1 < n$ observations according to a locally D-optimal design

$$\xi_1^*(\tilde{\theta}) = \arg\max_{\xi \in \Xi} |M(\xi;\tilde{\theta})|,$$

where $\xi = \begin{Bmatrix} x_{11} & \cdots & x_{1M_1} \\ \omega_{11} & \cdots & \omega_{1M_1} \end{Bmatrix}$ denotes a design, which is defined as a finite discrete probability distribution over $\mathscr{X}$, Ξ is the set of all possible designs and

$$M(\xi;\theta) = \int_{\mathscr{X}} \nabla\eta(x,\theta)\nabla\eta(x,\theta)^T d\xi(x), \tag{2}$$

is the information matrix of ξ. Moreover $\nabla\eta(x,\theta)$ denotes the gradient of the mean response $\eta(x,\theta)$ with respect to θ (see for instance, [8] or [1] as references in op-

timal design of experiments). The design $\xi^*(\tilde{\theta})$ is said locally optimal because it depends on a guessed parameter value $\tilde{\theta}$ due to the non-linearity of $\eta(x,\theta)$. Since a D-optimal design minimizes the generalized asymptotic variance of the MLE for θ, it should improve the precision of the parameter estimates. Let $\hat{\theta}_{n_1}$ be the first-stage MLE based on the n_1 observations gathered during the interim analysis. At the second stage, the available data information can be used to improve the choice of the experimental points. Therefore, $n_2 = n - n_1$ additional responses are collected according to another locally D-optimal design, $\xi_2^*(\hat{\theta}_{n_1})$, where $\hat{\theta}_{n_1}$ is used in (2) instead of $\tilde{\theta}$.

The final MLE is computed employing the whole sample of $n = n_1 + n_2$ data, which are dependent because the second-stage data depend on the first-stage responses through $\hat{\theta}_{n_1}$. In [9] and in [10] the theoretical properties of this final MLE are described.

The sample size of the interim analysis is usually small and thus $\hat{\theta}_{n_1}$ might be affected by the bias which converges to zero as n increases to infinity. On the other hand, the second-stage D-optimal design depends on $\hat{\theta}_{n_1}$ and at this stage a larger number of observations are collected. If these n_2 responses are observed at bad design points (or in bad proportions), they might produce an unreliable final MLE. On the other hand, if we improve the behaviour of the first-stage MLE through a bias correction, then the D-optimal design determined at the second stage should produce better experimental points. In Section 2 we provide the analytic expression of the first-order bias correction of the MLE in the *Emax* model.

2 Simulations of MLEs efficiencies and first order bias correction

As explained in the introduction, we need to understand how the MLE at the first stage influences the D-optimal design at the second stage. From the analytical expression of the locally D-optimal design ξ_D^* for the *Emax* model (provided by [7]):

$$\xi_D^*(\theta) = \xi_D^*(\theta_2) = \begin{Bmatrix} a & x^*(\theta_2) & b \\ 1/3 & 1/3 & 1/3 \end{Bmatrix}, \tag{3}$$

where the interior support point is

$$x^*(\theta_2) = \frac{b(a+\theta_2) + a(b+\theta_2)}{(a+\theta_2) + (b+\theta_2)}, \tag{4}$$

we have that the second stage D-optimal design depends only on θ_2.

The behaviour of $x^*(\theta_2)$ when $[a,b] = [0,150]$ is plotted in Figure 1. Let θ_2^t denotes the "true" value of θ_2. From Figure 1 we can note that the derivative of $x^*(\theta_2)$ is a positive decreasing function of θ_2 and thus the effect on $x^*(\theta_2)$ is larger for the values $\theta_2 < \theta_2^t$.

The following theorem provides the expression for the bias of the first stage MLE of θ_2, which is herein denoted by $\hat{\theta}_{n_1,2}$.

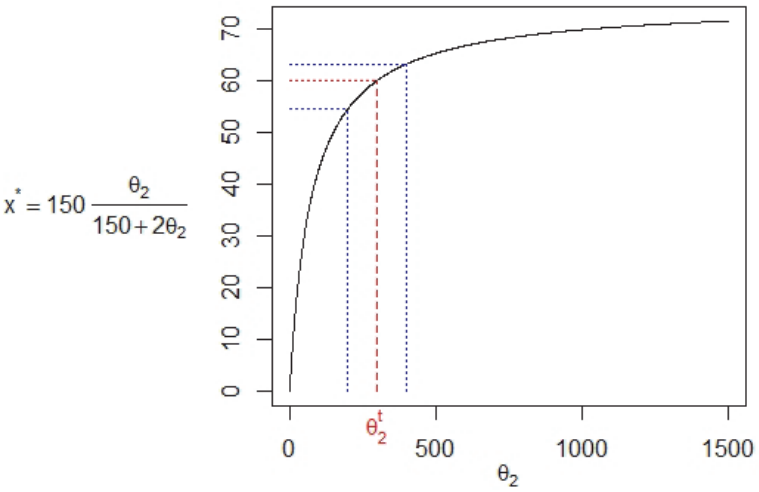

Fig. 1 D-optimum middle dose $x^*(\theta_2)$ for the Emax model

Proposition 1. *Let $\theta_{2,0}$ be a nominal value for θ_2. If n_1 first stage observations are taken according to the local D-optimal design (3), with equal numbers treated at the experimental points a, $x^*(\theta_{2,0})$ and b, then the bias of the first stage MLE of θ_2 is*

$$E(\hat{\theta}_{n_1,2} - \theta_2) = \frac{b_2(\theta)}{n_1} + O(n_1^{-2}),$$

where $b_2(\theta) > 0$ is given by

$$\begin{aligned} b_2(\theta) = & \frac{1}{(a-b)^4\theta_1^2\theta_2^2(a+\theta_{2,0})^2(b+\theta_{2,0})^2} \\ & \cdot\big\{3\sigma^2(a+\theta_2)^2(b+\theta_2)^2[2ab+(a+b)\theta_{2,0}+\theta_2(a+b+2\theta_{2,0})]^2 \\ & [3ab(a+b)+(a^2+10ab+b^2)\theta_{2,0}+3(a+b)\theta_{2,0}^2 \\ & +2\theta_2(a^2+ab+b^2+3(a+b)\theta_{2,0}+3\theta_{2,0}^2)]\big\}. \end{aligned} \tag{5}$$

Proof. Cox and Snell (1968) introduced the $O(n^{-1})$ formula for the bias of the MLE in the case of n observations not being identically distributed. Cordeiro and Klein (1994) proposed a matrix expression for this bias, which is herein specialized for the Emax model and the D-optimal design $\xi_D^*(\theta_{2,0})$. Calculations are available by the authors upon request.

This result justifies the fact that, when $\theta_{2,0} < \theta_2^t$ the fixed procedure (that consists in collecting all the n observations according to the initial (first-stage) D-optimal design) seems to have a worst performance than a two-stage design; in facts, $\hat{\theta}_{n_1,2}$

has a positive bias and thus it takes (on average) larger values, and thus we expect that $x^*(\hat{\theta}_{n_1,2})$ is closer to $x^*(\theta_2^t)$ than $x^*(\theta_{2,0})$ does.

3 Conclusions

In this paper we have presented the idea of improving the two-stage adaptive design proposed in [9] by introducing a bias correction. An analytic form of the first-order bias correction under the Emax model has been provided. We also justify the non-symmetric performance of the adaptive procedure in comparison with a fixed one, that results from the simulations in [9].

As a future work, we aim to apply the bias correction to the two-stage procedure in order to investigate its possible improvement. We aim at exploring also other types of bias corrections, in particular the ones obtained by modifying the score function (see, for instance, [11]).

Visual and automated methods in digital microscopy to evaluate fungal colonisation on plant roots

Metodi visivo ed automatizzato per valutare la colonizzazione di funghi nelle radici di piante in microscopia digitale

Ivan Sciascia[1], Andrea Crosino[1] and Andrea Genre[1]

Abstract The vast majority of studies investigating arbuscular mycorrhizas (AM) and their applications in agriculture require a precise quantification of the intensity of root colonisation. Here we propose a novel semi-automated approach to quantify AM fungal root colonisation based on digital image analysis comparing three methods: i) visual quantification ii) image thresholding, iii) machine learning. We recognize machine learning as a very promising tool for accelerating, simplifying and standardizing this critical step in analyzing AM of interest to applied and basic science.

Abstract *La grande maggioranza degli studi sulle micorrize arbuscolari (AM) e la loro applicazione in agricoltura richiede una precisa quantificazione dell'intensità della coloniszazione della radice. Proponiamo un metodo semiautomatico per quantificare la coloniszazione da funghi AM basata sull'analisi delle immagini digitali confrontando tre metodi: i) quantificazione visiva, ii) sogliatura di immagini, iii) machine learning. Riconosciamo il machine learning come metodo molto promettente per accelerare, semplificare e standardizzare la quantificazione della coloniszazione delle radici con AM, di interesse nella scienza applicata e di base.*

Introduction

Arbuscular mycorrhizas (AM) are widespread plant endosymbioses that develop between Glomeromycotina fungi and the roots of the majority of plant species, including most crops. The symbiosis benefits extend to both partners by improving plant mineral absorption, tolerance to biotic and abiotic stresses and fitness, while rewarding the fungal symbionts with carbohydrates compounds derived from photosynthesis process, such as sugars and lipids (Rich et al. 2017). The main applied benefit of AM could be in low-input farming. A critical step in all studies on AM is the precise quantification of root colonisation by AM fungi (Ferrol and Lanfranco 2020). However, molecular analyses based on the quantification of fungal sequences in total root DNA or arbuscule-specific markers in total root RNA extracts are still outnumbered by direct microscopic quantification of the intraradical fungal structures after histochemical staining (McGonigle et al. 1990; Novero et al. 2002). In an attempt to improve the spread, repeatability, and reliability of root colonisation measurements, we here present a semi-automated approach based on digital imaging and different types of image processing techniques and compared it to the commonly used visual method developed by Trouvelot et al (1986). We designed a semi-automated algorithm to generate quantitative indexes of root colonisation deriving from either image thresholding using ImageJ, or based on machine learning analyses (Arganda-Carreras et al. 2017) using the commercial software Zeiss Intellesis (Volkenandt et al. 2018). Our analyses identify machine learning as a promising alternative approach to visual quantification of AM fungal root colonisation.

Materials and methods

To quantify the extent of AM fungal root colonisation, we acquired two sets of images of mycorrhizal and not mycorrhizal roots stained with 0.1% methylene blue in lactic acid. Quantitative AM fungal colonisation was measured based on the frequency and abundance of fungal structures following Trouvelot et al. (1986) as described in Volpe et al. (2020) considering it as the i) visual method. The images were acquired with CI-L fitted with a 4x / 0.10 WD30 objective or Leica DMA500 fitted with a PLAN4x/0.10 objective. The fungal structures were stained blue while the plant tissues and cells remained transparent or light blue. As ii) image thresholding we use ImageJ framework: a color image can be represented by three components: red, green and blue (RGB) and the shades of each color can be represented by $2^8 \rightarrow [0,255]$ bit, thus using one byte (1byte = 8 bits) for each color. A threshold value can be applied to an image: if we have a gray-toned image or on a single RGB channel in the form $2^8 \rightarrow [0,255]$ we can collect the area size of the pixels which are in the range between minimum and maximum threshold according to the function:

$$S = \left\{ \begin{array}{c} a \quad if\ i_{xy} \leq s \\ b\ otherwise \end{array} \right\}$$

Considering the last approach as iii) machine learning, we tested an image analysis procedure, based on machine learning, using Zeiss Zen Intellesis application (Carl Zeiss Microscopy GmbH Jena, Germany) (Nesbit et al. 2021). Unlike image segmentation by intensity thresholding, image analysis by machine learning extracts features of images that are then used for classification. Machine learning is a branch of artificial intelligence that solves tasks using algorithms that are capable of learning from experience (training), without being explicitly programmed for a specific task. Differently from the intensity thresholding based approach, the method we used in this analysis was based on the neighborhood pixel characteristics that were subsequently classified based on description vectors. Zeiss Intellesis can apply a number of machine learning tools called basic features. In this study, we used basic feature 25, which achieves digital image segmentation by applying a number of filters based on 25 parameters derived from Gaussian, Gabor and Hessian filtering.

Results

After applying segmentation macro to all our images, a set of quantitative values was obtained corresponding to the supposed colonised area (darkest pixels) and the total root section area (as isolated from the image background).
The ratio between the colonised and total root area in an image was used as threshold (t) index and represents the intensity (I) of root colonisation:

$t = \frac{mycorrhized\ area}{total\ area} * 100$

In Figure 1, we summarize the fit of the t-index of each visually classified intensity class (1-6) describing x-y axis between visual classification (x) and the t index (y) and in Table 1 we perform ANOVA with pairwise comparisons between visually classified intensity class inferred by t-index.

Table 1. ANOVA Pairwise (I-J) correlation analyses of the root colonisation intensities as inferred by the t-index in the visual categories. Statistics with pairwise post hoc multiple comparisons (Bonferroni method).*Mean difference is significant at 0.05 level.

4 Discussion

The present study evaluated the reliability of two semi-automated image analysis methods in comparison to visual scoring (Trouvelot et al., 1986) to evaluate root AM quantification (Vierheilig et al. 2005). Contrast thresholding uses the gradient of pixel brightness (inversely related to cotton blue staining) as an indicator of fungal presence. Quantification of root colonisation intensity by contrast thresholding resolved the six root colonisation intensity classes, as used for visual scoring, and can, therefore, be considered reliable for rapidly screening root samples A few critical aspects should anyway be considered. One major limitation of the thresholding method is the variability of brightness range between images: different dyes, optical setups, root translucence and the presence of additional microorganisms (such as bacteria, algae, endophytic fungi, invertebrates) especially in field samples, that cannot be discriminated from fungal structures simply based on pixel brightness. In addition, the method is strongly affected by image background noise and the utilized magnification. Lastly, the segmentation process can only be set *ex ante*, by changing the setting of the macro without any possibility for subsequent intervention by the user. The machine learning-based procedure of the Zeiss Zen Intellesis turned out to be the most efficient. It allows for discrimination among the different fungal structures, such as hyphae, arbuscules and vesicles, during the manual training phase to generate a model that the software then applies to all analysed samples. This approach also resolved the six classes of intensity and achieved the best correlation with manual colonisation scoring. Importantly, training phase was relatively short (it requires 50 minutes overall) and turned out to be effective, even when using a limited number of images (10 images). Lastly, the use of machine-learning allowed reliable discrimination between fungal structures, such as intra- and extraradical hyphae, and arbuscules, something that contrast thresholding of images could not resolve. A critical factor for accurate machine learning-based root colonisation level assessments is that the software is trained by an expert. The analysed

images of the training phase are saved in a reference folder and can be shared for verification by other researchers and even re-use. This opens a new perspective for data reproducibility. Experts can share their expertise with the entire research community by simply sharing the images. Furthermore, the training file can become a common resource for reference and, thereby, make the detected intensity by AM fungi more uniform and repeatable. The current model of machine learning could be extended so that it cannot only assign samples to mycorrhization intensity classes, but also reliably discriminate between root colonisation by arbuscules, vesicles, hyphal coils and so forth. At present, the commercial nature of the software hampers the modification of the image analysis algorithm, which could, however, be overcome as shown by Evangelisti et al. (2021). A simple increase in the number of images used for training might be sufficient to refine the efficiency of machine learning to discriminate among different fungal structures. Indeed, considering the method recently published by Evangelisti et al. (2021) was described to reliably discriminate among fungal structures (arbuscules, hyphae, and vesicles). It would be extremely interesting to investigate the possibility to merge the two algorithms in an attempt to develop a more powerful tool for image analysis that could make quantification of root colonisation by AM fungi more reproducible and allow discrimination of root colonisation and a detailed identification of intraradical fungal structures.

From satellite images to road pavement type: an object-oriented classification approach

Dalle immagini satellitari al tipo di pavimentazione stradale: un approccio di classificazione orientato agli oggetti

Arianna Burzacchi, Matteo Landrò and Simone Vantini

Abstract This research aims at developing an innovative supervised classification method for road pavement which recognizes surface type of road segments starting from satellite images. Roads of unknown surface are labelled as *paved* or *unpaved* by means of new algorithms developed in the field of Object-oriented Data Analysis and using open-source software and data. The proposed approach is proven to be accurate, low-cost, and can be straightforwardly extended from the single case study of Greater Maputo to other cities.

Abstract L'obiettivo di questa ricerca è sviluppare un metodo innovativo di classificazione supervisionata per la superficie di manto stradale a partire dalle immagini satellitari delle strade. La ricerca si inserisce nell'ambito della Object-oriented Data Analysis e fa uso di software e dati open-source per classificare il tipo di pavimentazione stradale come pavimentato (*paved*) o sterrato (*unpaved*). La metodologia proposta risulta essere accurata, a basso costo e scalabile, facilmente replicabile dal caso studio della Grande Maputo all'analisi di altre città.

1 Introduction

Road infrastructure conditions could be very informative for road maintenance, route planning and transport operations [4, 11]. However, road network databases rarely include the information on road pavement status, especially in developing countries. Within this context, the research aims at developing an automatic classification method for road pavement surfaces using an object-oriented approach.

While much research on image-based pavement classification aims at detecting pavement distress [e.g. 10], only few related studies have addressed surface type classification. Common data sources are panoramic images from private databases and Google Street View imagery, which however lack in most developing countries [2], while further analysis is performed by means of feature-based extraction and classification methods [e.g. 6, 12] and neural networks [e.g. 11].

The proposed method works with open-source and always available data, namely Google Earth satellite images [3] and map features exported from the OpenStreetMap (OSM) road network [8]. Among all OSM attributes, the classification algorithm considers the road surface type, indicating whether a road is *paved* or otherwise *unpaved* [9].

The object-oriented approach is preferred to pixel-based methods since it was proven to be more accurate and high-performing [5, 7, 13]. Indeed, object-oriented image-based algorithms take into account both spectral information of each pixel and features of pixel distribution, such as shape and size. In this study, "objects" to be considered are groups of street pixels in the RGB space, extracted from each image and used as sample units of the classification algorithm.

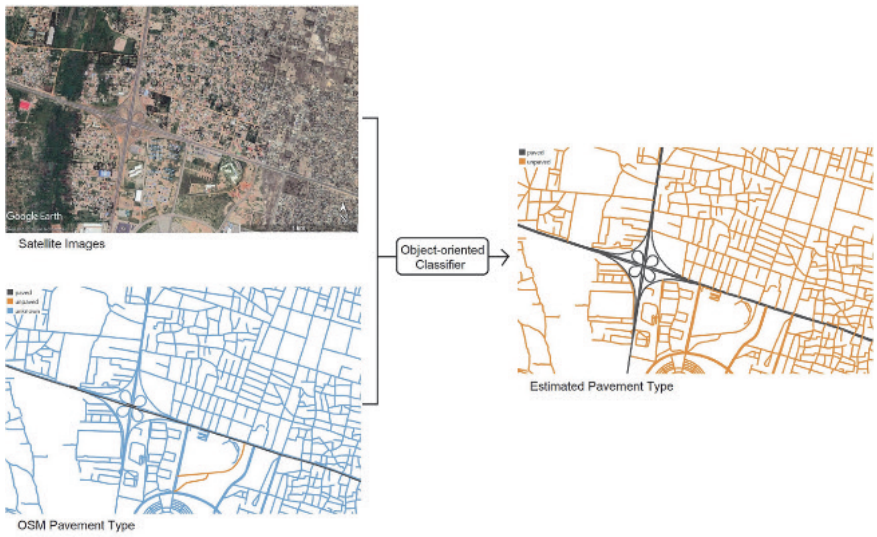

Fig. 1 Input data (left) and output pavement classification (right) of the object-oriented classifier.

2 Outline of the methodology

The first part of the study focuses on street pixel extraction from satellite images. Most images of the dataset portray both street surface and additional objects, such as vehicles, vegetation and buildings. For this reason, a two-step filtering phase is needed to remove uninformative pixels from each image. In the first step, the shade of covering vegetation is identified to set a threshold on pixel darkness. Then, dark pixels associated to vegetation are removed. During the second step, street pixels are identified by means of DBSCAN with properly-tuned parameters. The density-based method DBSCAN is chosen among other clustering algorithm due to the peculiar shape of pixel distributions in the RGB space, namely pixels of streets, buildings and vehicles form distinct clusters connected by background noise.

The following part of the research aims at building an object-oriented classification algorithm for road pavement. Street pixel clusters are input instances of a k-nearest neighbours algorithm which labels roads of unknown surface based on the k most similar pixel clusters of known surface. More formally, each street pixel object is considered as a random sample from a multivariate distribution and, given a distance among probability distributions, the k closest distributions are found and used for classification.

In this second part, the focus is on the choice of the best mathematical embedding for the object-oriented approach. Four metrics between multivariate distributions are compared by evaluating classification performance and computational time of k-NN. Moreover, data are transformed from RGB to alternative colour spaces to investigate which is the most suitable for this application.

The third part of the research focuses on the choice of proper frequency thresholds for k-NN classification. Considering the real-world context of application of the proposed algorithm, misclassification and uncertainty costs are assigned to possible outcomes of k-NN. Then, thresholds are chosen through the minimization of the total predicted cost.

Finally, road type information is exploited to improve the classification of road pavement surface. Road type is an additional attribute provided by OSM to measure the importance of roads in road network systems [9]. The proposed methodology is slightly modified to incorporate this information. The neighbour research, which was previously performed on the set of all streets, is now restricted to the set of streets which have the same typology of the one to be classified.

3 Application and main results

The proposed classification algorithm is applied to the case study of Greater Maputo, in Mozambique. The dataset comprises cropped and filtered raster images of 53 240 road segments and their OSM attributes, and accounts only 5% roads of known pavement surface. Starting from known surface roads, the algorithm predicts pavement surface of the remaining 95%.

The method shows an overall classification error of 7.8% on the test set, which decreases to 5.5% when the street type attribute is included in the model. A detailed description of the method and its application can be found in [1].

Valid inference for group analysis of functionally aligned fMRI images

Inferenza valida per l'analisi di gruppo di immagini fMRI allineate funzionalmente

Angela Andreella, Riccardo De Santis, and Livio Finos

Abstract Functional magnetic resonance imaging (fMRI) data require preprocessing steps before statistical analysis. Multi-subjects fMRI studies are complicated: the brain's anatomical and functional structure varies across subjects. Anatomical alignment does not capture the functional variability across subjects; the functional alignment is then applied. Generally, group analysis on functionally aligned fMRI data refers to between-subject classification. We propose an inference group analysis arguing that using functional aligned images based on Procrustes transformation does not affect type I error.

Abstract *I dati di risonanza magnetica funzionale (fMRI) necessitano di fasi di pre-elaborazione prima dell'analisi statistica. Gli studi fMRI multi-soggetto sono complessi: la struttura anatomica e funzionale del cervello varia tra i soggetti. L'allineamento anatomico non cattura la variabilità funzionale tra i soggetti, si applicano dunque metodi di allineamento funzionale. Generalmente, ci si riferisce ad analisi di classificazione quando si parla di studi multi-soggetto su dati allineati funzionalmente. In questo lavoro proponiamo un'analisi di gruppo inferenziale sostenendo che utilizzare immagini allineate funzionalmente tramite metodi basati sulla trasformazione di Procuste non influisce sull'errore di tipo I.*

1 Introduction

Functional Magnetic Resonance Image (fMRI) is the most used technique to study the neural underpinnings of human cognition. The brain activation is expressed in the correlation between the sequence of cognitive stimuli and the sequence of measured blood oxygenation levels (BOLD). In reaction to neural activity, changes in brain hemodynamics impact the local intensity of the magnetic resonance signal, i.e., the voxel intensity (single volume elements). The voxel expresses statistically significant neural activity if the correlation computed is statistically significant concerning an inactive region null hypothesis. However, when group analysis is performed, many problems arise.

First, brain activity is not functionally nor anatomically aligned across subjects since brains' anatomical and functional structures vary across subjects, even in response to identical sensory inputs. Anatomical normalization (e.g., [13]) fixes the anatomical misalignment; but it fails to capture the functional variability across subjects. Second, analyzing group activation means performing several statistical tests equal to the number of voxels (i.e., roughly $200,000$ statistical tests). It leads to multiple testing problems, and family-wise error rate must be controlled.

In this paper, we proposed a method that simultaneously resolves the functional misalignment and gains power in group analysis inference without affecting the type I error. The functional alignment is done by the ProMises model [2] which can be seen as a procedure that sorts the null hypotheses based on a priori information. The brain images' functional alignment can be described as a sorting criterion independent from the test statistics, making the inference on aligned data completely valid. This procedure is not new in the literature; some methods use, for example, previous findings in similar experiments or the total variance of the variables if central location tests are used [5].

The outline of the paper is as follows. Subsect. 2.1 introduces the ProMises model [2], while Subsect. 2.2 shows the group analysis procedure in fMRI data. The valid inference using functionally aligned data is described in Subsect. 2.3. Finally, the ProMises model is evaluated by performing a group-level inference, analyzing task-related fMRI data in Sect. 3. The entire code used in this work is available in [3].

2 Methods

2.1 ProMises model

Let $\{X_i \in \mathbb{R}^{n\times m}\}_{i=1,\dots,N}$ a set of matrices to be aligned and $M \in \mathbb{R}^{n\times m}$ the shared unknown matrix. The ProMises model uses similarity transformation [7], i.e., scaling, rotation/reflection, and translation, to map $\{X_i \in \mathbb{R}^{n\times m}\}_{i=1,\dots,N}$ into a common reference matrix M. The model is defined as follows:

$$X_i = \alpha_i(M + E_i)R_i^\top + 1_n^\top t_i \tag{1}$$

where E_i is the random error matrix with a normal matrix distribution [8] $E_i \sim \mathscr{MN}_{nm}(0, \Sigma_n, \Sigma_m)$, R_i is the orthogonal matrix parameter with a von Mises-Fisher distribution [4] (i.e, $f(R_i) \sim C(F,k)\exp(kFR_i)$ with $F \in \mathbb{R}^{m\times m}$ location parameter, $k \in \mathbb{R}^+$ regularization parameter and $C(F,k)$ normalizing constant), α_i is the scaling parameter and t_i is the translation parameter with 1_n a n-dimensional vector of ones. The maximum a posteriori estimates for the sets $\{R_i\}_{i=1,\dots,N}$ and $\{\alpha_i\}_{i=1,\dots,N}$ equal

$$\hat{R}_i = \{U_i V_i^\top\}_{i=1,\dots,N}; \quad \hat{\alpha}_{i\hat{R}_i} = \frac{||\Sigma_m^{-1/2}\hat{R}_i^\top X_i^\top \Sigma_n^{-1/2}||_{\mathrm{F}}^2}{\mathrm{tr}(D_i)} \quad \forall i \in \{1,\dots,N\}, \tag{2}$$

where $||\cdot||_{\mathrm{F}}$ is the Frobenius norm, and $U_i D_i V_i^\top$ is the singular value decomposition of $X_i^\top \Sigma_n^{-1} M \Sigma_m^{-1} + kF$. For further details about the estimation process, see [2].

2.2 Group-level analysis

Let consider the set $\{X_i \in \mathbb{R}^{n\times m}\}_{i=1,\dots,N}$. After the X_i matrices' functional alignment (e.g., using the ProMises model explained in Subsection 2.1), the first-level analysis (i.e., subject-level analysis) is performed to find significant activation in the set of m voxels for each subject under the null hypothesis of no activation. Therefore, we consider for each subject i the following model:

$$X_i = DB_i + ZG_i + E_i \tag{3}$$

where $D \in \mathbb{R}^{n\times p}$ and $Z \in \mathbb{R}^{n\times q}$ are fixed matrices, $B_i \in \mathbb{R}^{p\times m}$, $G_i \in \mathbb{R}^{q\times m}$ and $B_i = B + U_i$, $G_i = G + g_i$ with B is the true matrix of fixed effects of interest, G of fixed nuisance effects. $[U_i^\top | g_i^\top] \sim \mathscr{MN}(0, \Sigma_m, \Sigma_{pq})$ is the matrix of random effects.

We have now a set of N matrices $\{\hat{B}_1, \dots, \hat{B}_N; \hat{B}_i \in \mathbb{R}^{p\times m}\}$, which for example describes the difference between the neural activation during two stimuli recorded in the voxel $k \in \{1,\dots,m\}$ of the subject i. The one-sample t-test [11] is generally performed to study the group's mean activation due to the difference between the neural activation during two stimuli:

$$T = \frac{\hat{\mu}}{\hat{\sigma}/\sqrt{N}}, \tag{4}$$

where $\hat{\mu} = \sum_{i=1}^N \hat{B}_i/N$ is the sample mean between-subjects with $\hat{\mu} \in \mathbb{R}^{p\times m}$, and $\hat{\sigma} = \frac{1}{N-1}\sum_{i=1}^N (\hat{B}_i - \hat{\mu})^2$ is the sample variance between-subjects with $\hat{\sigma} \in \mathbb{R}^{p\times m}$. Therefore, we have one local test T_k for each voxel/null hypothesis $H_0^k : \mu_k = 0$ against the two-sided alternative hypothesis.

In the ProMises model (1) we assume M equals for all subjects, while in (3) the mean effect is subject-specific, that is $M_i = DB_i = DB + DU_i = M + DU_i$. The

additional random matrix DU_i must be then inserted in (1). However, $\mathbb{E}(U_i) = 0$ by definition, and $\mathbb{E}(M_i) = M$. We assume that under H_0 the random effect involved in B_i is null (i.e., these terms does not impact the estimation process of R_i).

2.3 Valid Inference

Here, we propose a theorem that ensures the validity of inference using functionally aligned data.

Theorem 1. *Let consider the p-values p_k related to the statistical test T_k, where $k \in M = \{1, \dots, m\}$. If the ProMises model defined in Subsection* (2.1) *is valid, then:*

$$\Pr(p_k \leq \alpha \mid \hat{R}_i, \hat{\alpha}_i) = \alpha, \quad \forall k \in S \tag{5}$$

where $S \subseteq M$ is the set of true null hypotheses, α is the significance level, and $\hat{R}_i$ defined as (2)*.*

Proof. Let assume that the the ProMises model defined in Equation (1) is valid, then we have:

$$X_i = \alpha_i(M_i + E_i)R_i^\top = \alpha_i(DB_i + ZG_i + E_i)R_i^\top. \tag{6}$$

W.l.o.g. we assume the set $\{X_i\}_{i=1,\dots,N}$ to be column-centered matrices. Write $H_Z = Z(Z^\top Z)^{-1}Z^\top$, so $\hat{B}_i = (D^\top(I - H_z)D)^{-1}D^\top(I - H_z)X_i$. The ProMises model becomes $X_i = \alpha_i(ZG_i + E_i)R_i^\top$ under H_0. It is now easy to see that the $\hat{B}_i \mid \hat{R}_i, \hat{\alpha}_i$ is normal zero-centered under H_0 like $\hat{B}_i$ with variance Σ. In addition, the information involved in the estimation of R_i and B_i are orthogonal (i.e., $\mathbb{E}((ZG_i + E_i)^\top(I - H_z)\hat{X}_i) = tr(\Sigma_n^\top(I - H_Z))\Sigma_m^\top$ which is independent of D and other subjects's information, and $X_{j \neq i}$ are independent of $(I - H_z)X_i$ by definition). This implies that also the statistical test $T \mid \hat{R}_i, \hat{\alpha}_i$ defined in (4) is normal zero-centered and finally $\Pr(p_k \leq \alpha \mid \hat{R}_i, \hat{\alpha}_i) = \alpha \; \forall k \in N$.

Theorem 1 assures the validity of the group analysis inference when data functionally aligned by the ProMises model are used instead of the raw data. In the next section, we apply the ProMises model to fMRI images and then we perform one-sample t-tests for each voxel to analyze the group mean activation. The gain in power is notable if the functionally aligned data are used instead of the raw ones.

3 Application

3.1 Data

The auditory data collected by [12] are analyzed, available at `https://openneuro.org/datasets/ds000158/versions/1.0.0`. The study consists

of neural activation of 218 subjects passively listening to vocal, i.e., speech, and nonvocal sounds. We randomly select 18 subjects.

We preprocess the data using the FMRIB Software Library (FSL) [10] using a standard processing procedure. For further details about the experimental design and data acquisition, please see [12]. We perform a higher-level analysis ROI, i.e., group-subject analysis [11], considering the superior temporal gyrus (STG) as ROI, which is well known to be involved in auditory processing [6]. The STG was extracted from the Harvard Oxford cortical structural atlas (`http://fsl.fmrib.ox.ac.uk/fsl/fslwiki/Atlases`). The matrices are then composed of 310 rows (time points/stimuli) and 10233 columns (voxels). The ProMises model is implemented in [3] based on the programming language Python [14] according to the PyMVPA package [9].

3.2 Results

Using the ProMises model, we found notable results for group analysis of fMRI data. The left panel of Figure 1 illustrates the one-sample t-tests (4) computed using the images aligned by the anatomical alignment [13] and by the ProMises model. The right panel of Figure 1 shows the empirical cumulative distribution function of these one-sample t-tests. The ProMises model returns a set of t-tests 85.85% higher in mean (in absolute value) than the t-tests computed using anatomical alignment. In the case of equivalent t-tests, the percentage would equal 50%.

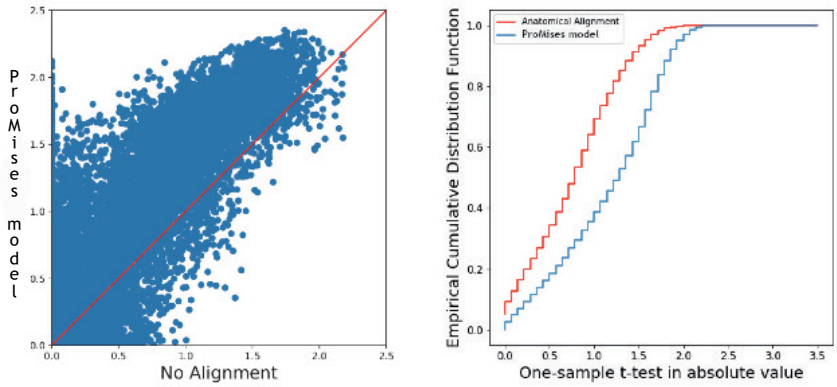

Fig. 1 Left panel: Scatter plot of the one-sample t-tests in absolute value considering the fMRI images of 18 subjects aligned by anatomical alignment (x-axis) and the ProMises model (y-axis). **Right panel**: Empirical Cumulative Distribution Function of one-sample t-tests in absolute value considering the fMRI images of 18 subjects aligned by anatomical alignment (red line) and the ProMises model (blue line).

4 Discussion

In this manuscript, we evaluated the ProMises model in the context of group-level inference analysis of fMRI data. We proved the validity of the inference if functionally aligned data are used instead of the raw ones (where only the anatomical registration is performed). The information used in the ProMises model to estimate the orthogonal matrix parameter can be seen as prior information used to sort the statistical tests in the group analysis. Finally, we showed an interesting application where the one-sample t-tests at the group level using data aligned by the ProMises model illustrate higher absolute values than the one-sample t-tests computed using data aligned by the anatomical alignment.

Topological persistence for astronomical image segmentation

Segmentazione di immagini astronomiche mediante strumenti topologici

Ceccaroni, R., Brutti, P., Castellano, M., Fontana, A. and Merlin, E.

Abstract The fast evolution of telescope technologies is making possible the collection of a massive wide variety of data. In our era, a tool that automates information extraction from astronomical images is essential. Within this broad task, image segmentation plays a key role and classical edge-based detection algorithms are not well-suited to deal with astronomical images because they typically lack a clear-cut boundary structure.
Thus, to effectively tackle this task, it is mandatory to develop dedicated tools.
The main goal of this work is to design and test a new, unsupervised segmentation method strongly based on Topological Data Analysis (TDA) techniques. Thanks to tools like persistent homology and persistence diagrams, in fact, it is possible to identify the connected components of abstract objects, like an image, and then put them to use in order to compute a sensible segmentation.
Abstract La rapida evoluzione delle tecnologie dei telescopi sta rendendo possibile la raccolta di un'ampia varietà di dati. Nella nostra era è essenziale uno strumento che automatizza l'estrazione di informazioni dalle immagini astronomiche. All'interno di questo ampio compito, la segmentazione dell'immagine gioca un ruolo chiave. Gli algoritmi classici sono basati sul rilevamento dei bordi e non sono adatti per le immagini astronomiche poiché in quest'ultime gli oggetti non hanno dei confini ben definiti.

Pertanto, per affrontare efficacemente questo compito, è stato necessario lo sviluppo di strumenti adeguati.
L'obiettivo principale di questo lavoro è progettare e testare un nuovo metodo di segmentazione non supervisionato fortemente basato sulle tecniche di analisi dei dati topologici (TDA). Grazie a strumenti come l'omologia persistente e ai diagrammi di persistenza, infatti, è possibile identificare le componenti connesse di oggetti astratti, come un'immagine, ed utilizzarle per calcolare una segmentazione apprezzabile.

Key words: Topological data analysis, Persistence diagram, Image segmentation, Astronomical imaging

1 Introduction

Modern astronomy has made relevant strides in the last 60 years with increasingly advanced technologies. Since 1965, a growing number of space telescopes have been launched into Earth orbit. In the same years, Willard Boyle and George E. Smith invented the Charge-Coupled Device (CCD) [7]. This electronic detector is still used today and marks the transition from analog to digital technology. Thanks to this device, it is possible to capture digital images and store precise and rigorous information about astronomical objects.

Not so long ago, the James Webb Space Telescope (JWST) was successfully launched. It is intended to succeed the Hubble Space Telescope. Other space telescopes will be launched into orbit in the coming years. Among them, there is Euclid: a visible to near-infrared space telescope currently under development by the European Space Agency (ESA).

Like observation, the analysis of astronomical images has also undergone improvements. Initially, objects were identified and classified by eye. Today, in the Big Data era, the need for time-saving and accurate tools to detect and analyze objects in images dominated by observational noise has significantly increased.

In this work, we present a new tool aimed at the so-called *image segmentation* which is part of the detection step: in the segmentation process, the significative (i.e., above the noise level) pixels of the digital image are univocally assigned to the sources, defining their extension. This new tool is based on TDA. In particular, we use persistent homology. [9, 5, 3, 12].

2 Materials and Methods

In the following part we firstly provide details of used data. Then, we describe our segmentation algorithm (TIS). Finally the metrics used to compare the outputs are analysed.

2.1 Data

We test the source-detection algorithms on simulated data. The simulated image (Figure 1) has a size of $25,000 \times 25,000$ pixels. It was produced using the software Galsim [11] and it is a simulation for Euclid. The image simulates a realistic scenario in which there are overlapping galaxies: a deep wide-field observation like the one obtained with Euclid's VIS filter. Of this image is known the ground truth.

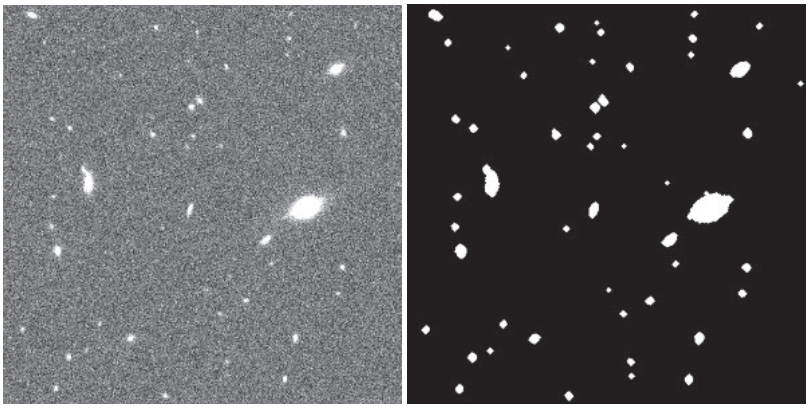

Fig. 1: On the left is a patch of size 500×500 of of the simulated image, on the right the segmentation using TIS.

2.2 Topological Image Segmentation

In this section, we present the segmentation algorithm for astronomical images based on persistent homology. The astronomical image I together with its *RMS*-map are the inputs. As output, we would get the segmented image S_I, in which each object is identified with an integer (*id*). A catalog containing all the relevant information about each object we found is also generated.

2.2.1 Pre-Processing

Before calculating persistent homology, the image is cleaned. Denoising is done to reduce the noise in the image. The thresholds are calculated and, thanks to the map *RMS*, the damaged pixels are masked.

As a first step, the noise in the image I is reduced by using one of the denoising methods described in [10]. By default, Gaussian Smoothing is used. The window size depends on σ and is $\lfloor 8\sigma + 1 \rfloor$. If $\sigma < 1/4$ then the window has fixed size 3×3. From the convolution, we get $I_{denoise} \coloneqq (G_\sigma \star I)$.

The second step involves estimating the background (bkg) of I that can be executed by taking the median of the values of I. By default $bkg \coloneqq 2.5\ median - 1.5\ mean$.

At this point, a $mask \coloneqq (I_{denoise} - bkg) > t \cdot RMS$ is generated, where t is a parameter, default set at $t = 2$. Then $mask$ is dilated with a $d = 5$ default parameter. The values of the $I_{denoise}$ image are normalized in $[0,1]$. The 0 value is assigned to the damaged pixels using $mask$. Then, we get $I_{pre-process} \coloneqq \text{MinMaxScaler}(I_{denoise}) \cdot mask$.

2.2.2 Persistent Diagram

The next step is the calculation of persistent homology [4] from $I_{pre-process}$. The 0-dim persistence diagram is calculated. The implementation used is called *Cubical Ripser* and is described in [8]. The result is stored in a $(n,6)-$array, where n is the number of objects. Each row consists of

$$\begin{array}{|cccccc|} \hline birth & death & x_1 & y_1 & x_2 & y_2 \\ \hline \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ \hline \end{array}$$

where (x_1, y_1) is the location of the birth of the object and (x_2, y_2) is the location of the death of the object in the image $I_{pre-process}$. For further computational details see [9, 5, 1, 8].

At this point, the persistence diagram is filtered to separate topological features from noise using clustering or persistent entropy. The values of $lifetime = birth - death$ are calculated. By default, a k-means is applied with $k = 2$ on the values $\log(lifetime)$. Filtering returns only the indices ($idxs$) of the objects to be analyzed during segmentation.

2.2.3 Segmentation

For each index returned by the filtering, a temporary image $I_{temp} \coloneqq (death \leqslant I_{pre-process} \leqslant birth)$ is generated. In this binary image, we identify the connected

components and select the component that contains (x_1, y_1). This is our segmentation of the object. We have to repeat these steps for all indexes to gain the segmentation of the entire image S_I.

2.3 Metrics

For the comparison of segmentations, we use the metrics proposed in [6]. For *matching detections* we define *detection recall (completeness)* as the proportion of detected objects and *detection precision (purity)* as the proportion of segments matchable to real objects. We use *F-score* as the harmonic mean of precision and recall. For *evaluating areas*, assume that the ground truth segmentation consists of N objects, $\{R_1, \ldots, R_N\}$, with their corresponding areas $\{A_1, \ldots, A_N\}$, whereas the test segmentation is composed by M objects, $\{T_1, \ldots, T_M\}$, with areas $\{a_1, \ldots, a_M\}$. We then define the Under-Merging error (UM) as

$$UM = \sum_{j=1}^{M} \frac{\big(A_k - (T_j \cap R_k)\big)(T_j \cap R_k)}{A_k},$$

where k is the index such that R_k maximise $T_j \cap R_k$ for each test object T_j, and we define the Over-Merging error (OM) as

$$OM = \sum_{k=1}^{N} \frac{\big(a_j - (T_j \cap R_k)\big)(T_j \cap R_k)}{a_j},$$

where j is the index such that T_j maximise $T_j \cap R_k$ for each test object R_k. In the end, we defined an Area score $= 1 - \sqrt{OM^2 + UM^2}$, which combines the two to give a single, overall score.

3 Results

In this section, we report the results obtained in comparing the segmentation output by TIS and SExtractor [2], a well-established and reliable segmentation tool in astronomy. The results were obtained using patches of 500×500 pixels of the simulated image as samples.

Figure 2 shows the range of F-scores produced by TIS and SExtractor using their default settings. For SExtractor, it is notable that the scores have a smaller interquartile range. Overall, focusing on median scores, we see that TIS is performing better than SExtractor with a median score of 0.58, while SExtractor achieves a median score of 0.42. TIS showed a higher variability also in Area scores. However, we see the strongest performance from TIS, with a median score of 0.76. The weakest performance was produced by SExtractor, with a median score of 0.37.

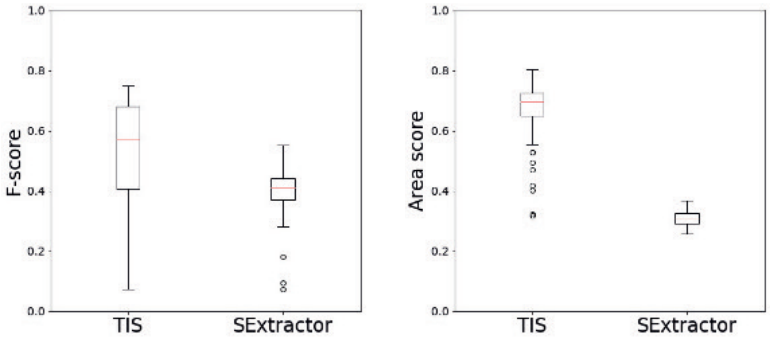

Fig. 2: On the left the F-scores comparison, on the right the Area scores comparison

In conclusion, the proposed TDA based segmentation methods is relatively simple and effective, showing performance on simulated images that are comparable to (if not better than) those obtained by a broadly adopted tool like SExtractor. Going forward, a broader and more in depth comparison is surely needed.

Statistical assessment and empirical estimation

Confidence regions for optimal sensitivity and specificity of a diagnostic test

Regioni di confidenza per sensibilità e specificità ottimali di un test diagnostico

Gianfranco Adimari, Duc-Khanh To and Monica Chiogna

Abstract We propose new methods that provide approximate joint confidence regions for the optimal sensitivity and specificity of a diagnostic test, fixed by the Youden index criterion. Such methods are semiparametric and overcome limitations of alternative approaches available in the literature. Our proposal is based on empirical likelihood pivots and covers two situations: binormal model and binormal model after the use of Box-Cox transformations. In the last case, we show how to use two different transformations, for the healthy and the diseased subjects.

Key words: Empirical likelihood, Box-Cox transformation, Youden index, ROC analysis, bootstrap calibration

1 Introduction and background

The accuracy of a diagnostic test can be assessed by its receiver operating characteristic (ROC) curve. The test result can be dichotomized at a specified cutpoint. Given the cutpoint, the sensitivity is the probability of a true positive, i.e., the probability that the test correctly identifies a diseased subject. The specificity is the probability of a true negative, i.e., the probability that the test correctly identifies a non-diseased subject. When one varies the cutpoint throughout the entire real line, the resulting pairs (1 − specificity, sensitivity) form the ROC curve (see Pepe[1], as general reference). Let X denote the result of a continuous diagnostic test for a non-diseaded subject and Y the result of the test for a diseaded subject. We as-

Monica Chiogna
Department of Statistical Sciences "Paolo Fortunati", University of Bologna, Via Belle Arti, 41; 40126 Bologna, Italy. e-mail: monica.chiogna2@unibo.it

sume, without loss of generality, that high test values indicate high likelihood of disease. Then, for a given cutpoint τ, the sensitivity and the specificity of the test are $\theta(\tau) = \Pr(Y > \tau) = 1 - F_Y(\tau)$ and $\eta(\tau) = \Pr(X \leq \tau) = F_X(\tau)$, respectively, where $F_X(\cdot)$ denotes the cumulative distribution function of X and $F_Y(\cdot)$ the cumulative distribution function of Y. In practice, for the purpose of making diagnosis, that is, classifying a subject as either diseased or healthy, a diagnostic threshold is required. In order to select an "optimal" diagnostic cutpoint, there exists a variety of approaches. Among them, the one based on the Youden index [2], J, is certainly the most popular. The Youden index is the maximum of the sum of sensitivity and specificity minus one, i.e., $J = \max_\tau J(\tau)$, with $J(\tau) = \theta(\tau) + \eta(\tau) - 1$. The corresponding optimal cutpoint, τ^+ say, is the value that maximizes $J(\tau)$, i.e., the cutpoint that has the largest value in the associated sum of sensitivity and specificity. Clearly, sensitivity and specificity at the optimal cutpoint τ^+ are relevant measures for the diagnostic ability of the test.

Actually, the ROC curve of a new diagnostic test is unknown, being unknown (at least partially) the distributions of the test results, for both diseased and non-diseased populations. Hence, the statistical evaluation of the discriminatory ability of the test is obtained by making inference about its ROC curve and other quantities of interest, such as optimal thresholds and associated sensitivities and specificities. Generally, inference is based on data from some suitable sample of patients for which the disease status can be exactly assessed by means of a so-called gold standard test (GS). When an optimal threshold is estimated from data of both diseased and healthy samples, the corresponding estimated sensitivity and specificity are correlated, and joint inference is necessary to take into account such a correlation. Methods to built joint confidence regions for sensitivity and specificity at the optimal cutpoint based on the Youden index are proposed by Bantis et al.[3] and Yin and Tian[4]. Both works deal, in particular, with parametric (or semi-parametric) methods for the binormal model. When the hypothesis of normality is not adequate, in both articles it is suggested to resort, when possible, to a single Box-Cox transformation. The main limits of such methodologies are: (i) the related confidence regions have (or derive from regions that have) elliptical shape, because they are based on the asymptotic normality of appropriate estimators or pivots; (ii) when the normality of the biomarker does not meet, application of Box-Cox transformations is considered, but limited to a single transformation for both populations.

We propose new methods that provide approximate joint confidence regions for the sensitivity and specificity of a test, corresponding to the optimal cutpoint fixed by the Youden index criterion. They are based on empirical likelihood pivots, so give rise to likelihood-type regions that have no predetermined constraints on the shape and are automatically range respecting. The proposal covers binormal model and binormal model after the use of Box-Cox transformations. Importantly, in the second case, we show how to use two different transformations, for the healthy and the diseased subjects.

Background Let $x_1, \ldots, x_m$ be a random sample from X, i.e., the test results from m non-diseased patients, and $y_1, \ldots, y_n$ a random sample from Y, i.e., the test results from n diseased patients. The true disease status of each patient is assumed to

be ascertained by a GS test. Let $\hat{F}_X$ denote the empirical distribution function based on $x_1,\ldots,x_m$ and $\hat{F}_Y$ the empirical distribution function based on $y_1,\ldots,y_n$. Hence, for a fixed value t, $\hat{F}_X(t) = (1/m)\sum_{i=1}^{m} I(x_i \le t)$, where $I(\cdot)$ denotes the indicator function. Recall that we consider a continuous diagnostic test and that, for a fixed threshold τ, $\theta = \theta(\tau) = 1 - F_Y(\tau)$ and $\eta = \eta(\tau) = F_X(\tau)$. Adimari and Chiogna[5] define the empirical likelihood [6] statistic

$$\ell(\theta,\eta,\tau) = 2m\left\{\hat{F}_X(\tau)\log\frac{\hat{F}_X(\tau)}{\eta} + \left[1-\hat{F}_X(\tau)\right]\log\frac{1-\hat{F}_X(\tau)}{1-\eta}\right\} + 2n\left\{\hat{F}_Y(\tau)\log\frac{\hat{F}_Y(\tau)}{1-\theta} + \left[1-\hat{F}_Y(\tau)\right]\log\frac{1-\hat{F}_Y(\tau)}{\theta}\right\},$$

for $\theta \in (0,1)$, $\eta \in (0,1)$, $\tau \in \mathscr{T}$, where $\mathscr{T} = \left[\max\{x_{(1)},y_{(1)}\}, \min\{x_{(m)},y_{(n)}\}\right)$, and $x_{(i)}$, $i = 1,\ldots,m$, and $y_{(j)}$, $j = 1,\ldots,n$, denote the order statistics from the samples. When $\tau \notin \mathscr{T}$, then $\ell(\theta,\eta,\tau) = +\infty$. The Authors prove that, under very weak conditions, for each triplet τ_0, $\theta_0 = 1 - F_Y(\tau_0)$ and $\eta_0 = F_X(\tau_0)$ of true parameter values, when $\min\{m,n\} \to +\infty$ and $\lim m/n$ is finite and not zero, $\ell(\theta_0,\eta_0,\tau_0) \xrightarrow{d} \chi^2_2$, where χ^2_2 indicates the chi-squared distribution with 2 df. Then, such result can be used to construct non-parametric confidence regions for a pair of parameters, for example (θ_0,η_0), when the third remaining parameter is fixed: the set $\mathscr{R}_\alpha = \{(\theta,\eta) : \ell(\theta,\eta,\tau_0) \le c_\alpha\}$, where $\alpha \in (0,1)$ and c_α is such that $\Pr(\chi^2_2 > c_\alpha) = \alpha$, is a confidence region with nominal coverage probability $1-\alpha$ for the pair (sensitivity, specificity), at a fixed cutt-off τ_0. Regions obtained by $\ell(\theta,\eta,\tau_0)$ retain all good features of empirical likelihood confidence regions, whose shape and orientation is determined only by the data, and are range respecting.

2 The proposed method

Let τ^+ be the true optimal cutpoint based on the Youden index approach, and let θ^+ and η^+ be the corresponding values of sensitivity and specificity. If τ^+ was known, the pivot $\ell(\theta^+,\eta^+,\tau^+)$ could be used directly to build approximate confidence regions for (θ^+,η^+). In practice, τ^+ is unknown and must be estimated from the available data. Let $\hat{\tau}^+$ be a suitable estimator for τ^+. By resorting to the plug-in method, we can consider the quantity $\ell(\theta^+,\eta^+,\hat{\tau}^+)$, where an estimate replaces an unknown value. Unfortunately, such a replacement is not untroublesome. Indeed, the standard χ^2 approximation is no longer applicable in such a case. It is well known in the literature that when estimated entities enter in an empirical likelihood pivot, this has an asymptotic distribution which is a linear combination of independent χ^2_1 random variables (see, for example, Hjort et al.[9]), whose coefficients are (unknown) eigenvalues of a suitable 2×2 matrix. Since accurate estimation of such coefficients can be somewhat challenging, in the following we resort to the bootstrap calibration and apply it to the distribution of $\ell_*(\theta^+,\eta^+) = \ell(\theta^+,\eta^+,\hat{\tau}^+)$. This allows us to obtain estimates of the quantiles of the distribution of $\ell_*(\theta^+,\eta^+)$, which we will use to define the desired confidence regions.

Binormal model In some situations it is reasonable to assume that the diagnostic test has normal distribution, in both populations of healthy and diseased subjects. Let $X \sim N(\mu_x, \sigma_x^2)$ and $Y \sim N(\mu_y, \sigma_y^2)$. To formalize the assumption that the values of the test are positively associated with the disease status, we impose hereafter that $\mu_y > \mu_x$. For the binormal model, the optimal threshold provided by the criterion based on the Youden index can be obtained analytically and results to be

$$\tau^+ = \frac{\mu_x((\sigma_y/\sigma_x)^2-1) - (\mu_y-\mu_x) + (\sigma_y/\sigma_x)\sqrt{(\mu_y-\mu_x) + ((\sigma_y/\sigma_x)^2-1)\sigma_x^2 \log((\sigma_y/\sigma_x)^2)}}{(\sigma_y/\sigma_x)^2-1}.$$

When variances are equal, i.e. $\sigma_x^2 = \sigma_y^2$, then $\tau^+ = (\mu_x+\mu_y)/2$. Then, by the plug-in principle, a consistent estimator of τ^+ can be obtained by substituting in the above expressions the empirical counterparts $\bar{X} = (1/m)\sum_{i=1}^m X_i$, $\bar{Y} = (1/n)\sum_{i=1}^n Y_i$, $S_x = \sqrt{(1/(m-1))\sum_{i=1}^m (X_i-\bar{X})^2}$ and $S_y = \sqrt{(1/(n-1))\sum_{i=1}^n (Y_i-\bar{Y})^2}$ of μ_x, μ_y, σ_x and σ_y, respectively. Observe that the resulting $\hat{\tau}^+$ estimator is, essentially, the maximum likelihood estimator of τ^+.

Let $\Phi(\cdot)$ denote the cumulative distribution function of the standard normal. Given the observed data $x_1, \ldots, x_m$ and $y_1, \ldots, y_n$, we compute the estimate $\hat{\tau}^+$ and the corresponding optimal estimated sensitivity $\hat{\theta}^+ = 1 - \Phi((\hat{\tau}^+ - \bar{y})/S_y)$ and specificity $\hat{\eta}^+ = \Phi((\hat{\tau}^+ - \bar{x})/S_x)$. To conveniently calibrate $\ell_*(\theta^+, \eta^+)$ we resort to a simple bootstrap procedure:

1. use parametric bootstrap to get B bootstrap samples $\{x\}_b$ and $\{y\}_b$, for $b = 1, \ldots, B$, of sizes m and n, respectively;
2. add to each bootstrap sample the extremes (min and max) of the corresponding original sample, so as to obtain "enlarged" bootstrap samples of size $m+2$ and $n+2$, respectively;
3. compute $(\bar{x}_b, \bar{y}_b, S_{xb}, S_{yb})$, $\hat{\tau}_b^+$ and $\ell(\hat{\theta}^+, \hat{\eta}^+, \hat{\tau}_b^+)$ from the b-th pair of (enlarged) bootstrap samples, where $\hat{\theta}^+$ and $\hat{\eta}^+$ are the estimates obtained from the original data and the empirical distributions are taken from bootstrap samples;
4. get the estimate $\hat{c}_\alpha$ as the sample quantile of order $1-\alpha$ from the values $\ell(\hat{\theta}^+, \hat{\eta}^+, \hat{\tau}_b^+)$, $b = 1, \ldots, B$.

Then, the set $\mathscr{R}_\alpha = \{(\theta^+, \eta^+) : \ell_*(\theta^+, \eta^+) \leq \hat{c}_\alpha\}$, is a confidence region, with nominal coverage probability $1-\alpha$, for the optimal pair (sensitivity, specificity), corresponding to the Youden index criterion. In the above presented bootstrap procedure, at step 2, we "enlarged" bootstrap samples in order to reduce effects of the so-called convex hull problem, i.e., to reduce the probability that $\ell(\hat{\theta}^+, \hat{\eta}^+, \hat{\tau}_b^+)$ may be not finite. Moreover, we process only (enlarged) bootstrap samples whose averages respect the fixed order ($\mu_y > \mu_x$).

Normal models after Box-Cox transformations Suppose now that distributions of X and Y cannot reasonably be considered normal. Moreover, assume that $X > 0$ and $Y > 0$, with probability 1. In such a situation, Box-Cox transformations can help to achieve normality and are frequently used in ROC studies [3, 7]. However, to the best of our knowledge, papers available in the literature discuss, in this regard, a single transformation for the test results, both for healthy and diseased subjects. Although this approach has the advantage of leaving the ROC curve un-

changed (due to its invariance property with respect to increasing monotonic transformations), it can be inappropriate in cases where the two distributions of X and Y are very different from each other. In the following, we show how a more general approach involving two different transformations may be used.

Let

$$X^{(\lambda_1)} = \begin{cases} \frac{X^{\lambda_1}-1}{\lambda_1} & \lambda_1 \neq 0 \\ \log(X) & \lambda_1 = 0 \end{cases} \qquad Y^{(\lambda_2)} = \begin{cases} \frac{Y^{\lambda_2}-1}{\lambda_2} & \lambda_2 \neq 0 \\ \log(Y) & \lambda_2 = 0, \end{cases}$$

the transformed test results. The parameters defining the transformations are denoted by λ_1 and λ_2. Our proposal starts from the following observation. Since the optimal threshold τ^+ meets the relation

$$\begin{aligned} \tau^+ &= \arg\max_{\tau} [F_X(\tau) - F_Y(\tau)] = \arg\max_{\tau} [\Pr(X \leq \tau) - \Pr(Y \leq \tau)] \\ &= \arg\max_{\tau} \left[\Pr\left(X^{(\lambda_1)} \leq \tau^{(\lambda_1)}\right) - \Pr\left(Y^{(\lambda_2)} \leq \tau^{(\lambda_2)}\right) \right], \end{aligned}$$

where $\tau^{(\lambda_1)}$ and $\tau^{(\lambda_2)}$ are the transformed values of a same generic threshold τ, the double transformation leaves the optimal values of sensitivity and specificity unchanged. Moreover, $\theta^+ = 1 - \Pr\left(Y^{(\lambda_2)} \leq \tau^{+(\lambda_2)}\right)$ and $\eta^+ = \Pr\left(X^{(\lambda_1)} \leq \tau^{+(\lambda_1)}\right)$. Clearly, in the transformed scales, such optimal values match with two different threshold values.

$$\begin{aligned} \ell(\theta^+, \eta^+, \hat{\tau}^+) = {} & 2m \left\{ \hat{F}_X^{(1)}(\hat{\tau}_1^+) \log \frac{\hat{F}_X^{(1)}(\hat{\tau}_1^+)}{\eta^+} + \left[1 - \hat{F}_X^{(1)}(\hat{\tau}_1^+)\right] \log \frac{1 - \hat{F}_X^{(1)}(\hat{\tau}_1^+)}{1 - \eta^+} \right\} \\ & + 2n \left\{ \hat{F}_Y^{(2)}(\hat{\tau}_2^+) \log \frac{\hat{F}_Y^{(2)}(\hat{\tau}_2^+)}{1 - \theta^+} + \left[1 - \hat{F}_Y^{(2)}(\hat{\tau}_2^+)\right] \log \frac{1 - \hat{F}_Y^{(2)}(\hat{\tau}_2^+)}{\theta^+} \right\}, \end{aligned} \tag{1}$$

which is infinite when $\hat{\tau}_1^+$ is out of the range of the sample from $X^{(\hat{\lambda}_1)}$, or $\hat{\tau}_2^+$ is out of the range of the sample from $Y^{(\hat{\lambda}_2)}$. Observe that now the pivot in (1) depends on three estimated nuisance parameters: $\hat{\lambda}_1$, $\hat{\lambda}_2$ and $\hat{\tau}^+$.

In order to obtain confidence regions for the pair (θ^+, η^+), we propose the following algorithm. Given the observed data $x_1, \ldots, x_m$ and $y_1, \ldots, y_n$, we firstly compute the estimates $\hat{\lambda}_1$ and $\hat{\lambda}_2$. Then, using transformed data $x'_1, \ldots, x'_m$ and $y'_1, \ldots, y'_n$, say, we obtain sample means and standard deviations $\bar{x}'$, $\bar{y}'$, S'_x, S'_y, and maximize, with respect to τ, $\Phi\left(\frac{\tau^{(\hat{\lambda}_1)} - \bar{x}'}{S'_x}\right) - \Phi\left(\frac{\tau^{(\hat{\lambda}_2)} - \bar{y}'}{S'_y}\right)$ to get $\hat{\tau}^+$. Next, we can get the estimates $\hat{\theta}^+ = 1 - \Phi\left(\frac{\hat{\tau}_2^+ - \bar{y}'}{S'_y}\right)$ and $\hat{\eta}^+ = \Phi\left(\frac{\hat{\tau}_1^+ - \bar{x}'}{S'_x}\right)$. Finally, we use bootstrap calibration:

1. get B parametric bootstrap samples $\{x'\}_b$ and $\{y'\}_b$, for $b = 1, \ldots, B$, of sizes m and n, respectively;
2. add to each bootstrap sample the extremes (min and max) of the corresponding original (transformed) sample, so as to obtain "enlarged" bootstrap samples;
3. from the b-th pair of (enlarged) bootstrap samples, compute $(\bar{x}'_b, \bar{y}'_b, S'_{xb}, S'_{yb})$, $\hat{\tau}_b^+$, $\hat{\tau}_{1b}^+$, $\hat{\tau}_{2b}^+$ and $\ell(\hat{\theta}^+, \hat{\eta}^+, \hat{\tau}_b^+)$, using (1) where $\hat{\theta}^+$ and $\hat{\eta}^+$ are the estimate obtained from the original (transformed) data;

4. get the estimate $\hat{c}_\alpha$ as the sample quantile of order $1-\alpha$ from the values $\ell(\hat{\theta}^+, \hat{\eta}^+, \hat{\tau}_b^+)$, $b = 1, \ldots, B$.

The set $\mathscr{R}_\alpha = \{(\theta^+, \eta^+) : \ell_*(\theta^+, \eta^+) \leq \hat{c}_\alpha\}$, is the searched confidence region with nominal coverage $1-\alpha$. In the bootstrap procedure, we process only (enlarged) bootstrap samples whose averages respect the order between the averages of the original (transformed) samples. As an example, Table 1 gives some results of a large simulation study conducted to evaluate the finite sample behaviour of our confidence regions.

Table 1 Simulation results for Log Normal distributions: empirical coverages (over 10000 Monte Carlo replications) for some values of m, n, θ^+ and η^+. $B = 1000$ and $\alpha = 0.1, 0.05, 0.01$.

On the sensitiveness to the memory parameter in the network of tennis

Sensitività del parametro di memoria in una rete dei giocatori di tennis

Alberto Arcagni and Vincenzo Candila and Rosanna Grassi

Abstract In the recent paper of Arcagni et al. (2022), the use of network theory has been introduced in tennis to forecast the winning probabilities of male and female players. The main advantage of the proposed approach is the ability to capture the evolution of each players' ability, even when a set of players is not playing at the time of the matches under consideration. The approach of Arcagni et al. (2022) makes use of the Bonacich centrality computed on the network of players. Such a network is weighted with the number of wins-losses and it has a (decreasing) weight for the matches played far in the past depending on a fixed "memory" parameter. In the present paper, we aim at verifying the sensitiveness of the memory parameter to a grid of values. Surprisingly, the good performances of the approach proposed by Arcagni et al. (2022) are largely preserved, independently of the chosen memory parameter.

Abstract *Nel recente lavoro di Arcagni et al. (2022), l'uso della teoria delle reti è stato introdotto nel tennis per prevedere le probabilità di vittoria di giocatori maschili e femminili. Il maggiore vantaggio dell'approccio proposto è l'abilità di catturare l'evoluzione delle abilità di ciascun giocatore, anche quando un insieme di giocatori non sta giocando al tempo delle partite in esame. L'approccio di Arcagni et al. (2022) utilizza la Bonacich centraility ottenuta sulla rete di giocatori. Tale rete è pesata con il numero di vittorie-scofitte e ha un peso (decrescente) per le partite giocate nel passato, peso che dipende da un parametro di memoria fisso. Nel presente lavoro, si mira a verificare la sensitività del parametro di memoria*

nei confronti di una griglia di valori. Sorprendentemente, le buone performance dell'approccio proposto da Arcagni et al. (2022) sono consistentemente preservate, indipendentemente dalla scelta del parametro di memoria.

Key words: Networks, eigenvector centrality, tennis, sensitiveness, memory parameter, forecasting.

1 Introduction

Recently, Arcagni et al. (2022) introduced the use of the network theory in the sport forecasting literature, with the aim of predicting more accurate and precise rating scores in tennis. In their contribution, Arcagni et al. (2022) take advantage of the network theory to calculate (and daily update) the ratings of the entire set of players, and not limited to the players involved in the matches of the day under investigation. The ratings are obtained through the Bonacich centrality (Bonacich and Lloyd, 2001), which comes out from the eigenvector decomposition of the weighted adjacency matrix, that is the cumulative matrix of wins-losses of the whole network of players. The rates for players at day t depend on the past wins-losses, under a fixed temporal aggregation, which attributes a decreasing weight to the matches played further in the past. In their original contribution, Arcagni et al. (2022) define α as the "memory" parameter, and adopt a fixed configuration for such a parameter. The aim of the present contribution is to verify the sensitiveness of the memory parameter to different values, by means of a calibration procedure across a grid of values.

The rest of paper is structured as follows. In Section 2, the calibration procedure for the memory parameter is described. Section 3 is devoted to the empirical analysis. Conclusions follow.

2 Network approach for players ratings

As in Arcagni et al. (2022), let i and j denote two players among the n different available players. Moreover, let t denote the time at which the matches between the players are disputed, where t_0 is the time of the first match available. Let $\mathbf{W}_t$ be the weighted adjacency matrix, defined as follows:

$$\mathbf{W}_t = \sum_{t^* \in [t_0, t]} f(t^*, t, \alpha) \cdot \mathbf{L}_{t^*}, \tag{1}$$

where $\mathbf{L}_{t^*}$ is the $n \times n$ binary matrix consisting of wins-losses at time $t^* \in [t_0, t]$. The weighting function $f(\cdot)$ in Eq. (1) depends on the memory parameter α and it is expressed as:

$$f(t^*,t,\alpha) = \left(1+\frac{t-t^*}{\alpha}\right)^{-1} \text{ with } t^* \in [t_0,t], \alpha > 0. \quad (2)$$

Note that:

$$\lim_{\alpha\to+\infty} f(t^*,t,\alpha) = 1 \,\forall t \text{ and } t^* \in [t_0,t],$$

meaning that larger values of α assign the same weight to all the matches. Starting from the weighted adjacency matrix in (1), the measure of the strength of all the players at time t is obtained through the Bonacich centrality (Bonacich and Lloyd, 2001). More in detail, it is the principal eigenvector (Horn and Johnson, 2012) of the matrix $\mathbf{W}_t$. The advantage of such approach is that if a player does not play, his/her score depends on the memory of function f, but it is also captured by the network context. In fact, if the player i stops playing, the network approach also captures the variations of the whole set of players.

The main contribution of the present work is to verify the sensitiveness of the scores to different values of α. In the original paper, Arcagni et al. (2022) have set the memory parameter α equal to 365 days, that is, the matches played one year before have a weight of one half. In the cited article, this solution provided excellent results: the scores have been able to forecast consistently better the winning probabilities compared to several popular approaches. However, setting $\alpha = 365$ may be too restrictive. Therefore, we allow the parameter α to vary from 1 to 1460 days. In the case of the limit of α to infinity, all the matches, even those played many years ago, have the same weight.

3 Empirical analysis

The data used in this work were downloaded from the site `www.tennis-data.co.uk`, which provides a large number of statistics concerning the match results of the professional tennis players. This archive has recently been used also by Angelini et al. (2022) and Baker and McHale (2017), among others. The period under investigation spans from July 4, 2005, to November 22, 2020. Only matches involved in the Masters 1000 and Grand Slams are considered. In the first step of the analysis, the *clean* function of the R package 'welo' (Candila, 2021), has been executed. The remaining matches are 14,170, for a total of 470 male players.

The full sample was divided into two non-overlapping periods: a training sample (from 2005 to 2015, consisting of 10,029 matches) and a testing sample (from 2016 to 2020, that is, 4,141 matches). The training sample was used to calculate the centrality-based scores. Once obtained the scores, for all the different memory parameter values adopted, we use the logit regressions as in Arcagni et al. (2022) to compute the winning probabilities. These logit regressions consider as covariates the centrality-based scores of the players. Finally, the Mean-squared-errors (MSE) and Log-loss scores are calculated. The averages of the MSE and Log-loss scores are reported in Figures 1 and 2, respectively. Interestingly, the pattern of the MSE

and Log-loss scores are very similar, reaching a minimum for $\alpha = 91.25$. But, it is worth noting that all the losses here used appear to be quite stable to the grid of α values considered. Only when the the memory parameter is very high, then the losses consistently increase.

4 Conclusions

The choice of the memory parameter in the weighting function (2) does not significantly alter the resulting MSE and Log-loss averages, except when the memory parameter is set to be extremely large. In this case, the weighting function attributes great importance to old matches and, consequently, the network is not flexible enough to catch changes in players abilities.

Two-part model with measurement error
Modello a due parti con errore di misura

Maria Felice Arezzo, Serena Arima, and Giuseppina Guagnano

Abstract In many applications, there are positive-valued phenomena which show a very high frequency at zero. One major difficulty with this type of data is that the existence of a point-mass at zero makes common distributions unsuited for modeling the data. To cope with these difficulties, some models have been developed. A popular example is the two-part model in which two stochastic models are assumed: the first governs whether the response variable is zero or positive an the second, conditional on its being positive, models the level. We extend the two-part model to cope with measurement error on the dependent variables of both stochastic parts. This situation is common in many applied works.

Abstract *In molte applicazioni la variabile di interesse assume valori positivi con una frequenza molto alta di valori nulli. Una delle principali difficoltà con questo tipo di dati è che l'esistenza di una massa a zero rende le distribuzioni comuni inadatte per la modellazione dei dati. Per far fronte a queste difficoltà, sono stati sviluppati alcuni modelli. Un esempio è il modello in due parti in cui vengono assunti due modelli stocastici: il primo determina se la variabile di risposta è zero o positiva e il secondo, condizionatamente al primo, ne modella il livello. Estendiamo il modello a due parti tenendo conto dell'errore di misura sulle variabili dipendenti di entrambi i modelli stocastici. Questa situazione è comune in molti lavori applicati.*

1 Introduction

In many fields, real phenomena with positive values often show a very high frequency at zero. This kind of data can be represented by semi-continuous variables, which are combination of a point-mass at zero and a positive skewed distribution.

One major difficulty with this type of data is that the existence of a point-mass at zero makes common distributions, such as the gamma, unsuited for modeling the data. To cope with these difficulties, the two-part model has been proposed. In it, two stochastic models are assumed: the first, by means of an additional binary variable, governs whether the response variable is zero or positive and the second, conditional on its being positive, models the level.

Also in many applied works, variables are flawed with measurement error. This could easily happen, for example, during an interview if the respondent misunderstands the question.

We extended the two part model to consider two types of measurement errors: the first affects the binary variable that governs whether the response variable is zero or positive, and the second is on the positive part of the response variable.

In the literature, a mismeasurement on a continuous variable is called measurement error while it is called misclassification when it affects a categorical variable. When the fallible variable is continuous, the two dominant error models are the Berkson's [1] and the classical [3]. In the first one, the error-prone observed value is fixed while the true unobservable variable is random and its random structure is specified conditionally on the former. In the classical approach the error-prone variable is specified as a function of the true one with the error component inserted in a multiplicative or additive form and independent from the true variable.

Let us introduce some notation on the measurement error models used in our work. Let Y^O be the fallible/error-prone binary variable and y^O be the observed value. The misclassification model, which specifies the behaviour of Y^O given the true unobserved value $Y^T = y^T$, is characterized by the misclassification probability:

$$P(Y^O = y^O | Y^T = y^T). \tag{1}$$

Following [4], we set the misclassification probabilities $\alpha_1 = P(Y^O = 0|Y^T = 1)$ (the probability of false negative) and $\alpha_0 = P(Y^O = 1|Y^T = 0)$. (the probability of false positive). Since Y^T is random, if we specify the distribution of $Y^O|Y^T$, it follows that:

$$P(Y_i^O = 1) = (1-\alpha_1)\pi_i + \alpha_0(1-\pi_i) = \pi_i(1-\alpha_0-\alpha_1) + \alpha_0 \tag{2}$$

where $\pi_i = P(Y_i^T = 1)$. Such a probability can be estimated as a function of covariates through a generalized linear model.
When we deal with a continuous variables W, the classical error model in the multiplicative and additive form respectively is:

$$W_i^O = \begin{cases} W_i^T \cdot \xi_i, & \xi_i \sim \log N(\mu, \sigma_\xi^2) \\ W_i^T + \xi_i, & \xi_i \sim N(\mu, \sigma_\xi^2) \end{cases} \qquad \text{with } \mu = 0 \tag{3}$$

where μ is usually null and W^T (or its logarithm) can be specified as a linear function of some predictors. In the proposed model, see section (2), we generalize the distribution of ξ_i, admitting $\mu \neq 0$ and specific for each unit.

2 The proposed model

Let us consider a semi-continuous random variable W, whose observability depends on a binary variable Y: when $Y_i = 1$, we observe a positive value for W_i; otherwise, when $Y_i = 0$, we have $W_i = 0$. Referring to the two-part model: in the first part, we have to specify a binary choice model for the probability of observing a positive-versus-zero outcome and then, in the second part, a regression model is fit for the positive outcome *conditional* on a positive outcome. Under this framework, let us initially assume that there is no measurement error in any of the response variables (the true W and Y coincide with the observable ones). Let us denote themwith W^T and Y^T, the probability of a positive response as $P(W_i^T > 0|\boldsymbol{Z}_i) = P(Y_i^T = 1|\boldsymbol{Z}_i) = \pi_i$, and the conditional distribution of the positive responses as $g(W_i^T|W_i^T > 0, \boldsymbol{X}_i)$, where Z and X are two sets of possibly overlapping explanatory variables.

The two-part model has the following mixture p.d.f. [2] and likelihood:

$$f\left(W_i^T\right) = (1-\pi_i)I(Y_i^T = 0) + \pi_i g(W_i^T|Y_i^T = 1, \boldsymbol{X}_i) \tag{4}$$

$$L(\beta,\theta) = \underbrace{\left[\prod_{Y^T=0}(1-\pi_i)\cdot\prod_{Y^T=1}\pi_i\right]}_{L_1(\boldsymbol{\beta})}\cdot\underbrace{\left[\prod_{Y^T=1}g(W_i^T|Y_i^T=1,\boldsymbol{X}_i)\right]}_{L_2(\boldsymbol{\theta})} \tag{5}$$

where β and θ are vectors of parameters that govern the binary and the continuous part respectively, and $I(Y_i^T = 0)$ is an indicator function such that it equals 1 if $Y_i^T = 0$ and 0 otherwise; it is motivated by the fact that when $Y_i^T = 0$, the density of W^T collapses to a unit probability mass.

More precisely, $L_1(\beta)$ is the likelihood of a standard binary regression model and the corresponding link function is usually specified as probit or logit. $L_2(\theta)$ refers to the regression model for the continuous variable W^T, usually involving gamma or log-Normal distributions. We model L_1 with a probit link and L_2 as a log-Normal regression dealing with the following two-part model:

$$\text{Part one:} \qquad P(W_i^T > 0|\boldsymbol{Z}_i) = P(Y_i^T = 1|\boldsymbol{Z}_i) = \pi_i = \Phi(\boldsymbol{Z}_i\boldsymbol{\beta}) \tag{6}$$

$$\text{Part two:} \qquad \log(W_i^T) = \boldsymbol{X}_i\boldsymbol{\theta} + u_i, \quad u_i \sim N(0;\sigma_u^2) \tag{7}$$

where $\Phi(\cdot)$ is the standard normal c.d.f.

Suppose, now, that both variables W and Y may be affected by measurement errors, so we have the observable Y_i^O and W_i^O and the true Y_i^T and W_i^T. We assume that the measurement error that affects the observable W^O acts in a multiplicative way as in the first line of equation (3), so that $\log(W^O) = \log(W^T) + \varepsilon$, with $\varepsilon = \log(\xi)$. When we admit the possibility of measurement error for W and Y, we can no longer refer only to the p.d.f. of the true W as in (4), but we need to consider the observability of W^O and define its p.d.f.:

$$f\left(\log(W_i^O)\right) = \sum_{j=1}^{4} \psi_{ji} \cdot g_j\left(\log(W_i^O)\right) \tag{8}$$

where the weights are defined as:

$$\begin{aligned}
\psi_{1i} &= P(Y_i^O = 0, Y_i^T = 0) = (1-\alpha_0)\cdot(1-\pi_i) \\
\psi_{2i} &= P(Y_i^O = 1, Y_i^T = 1) = (1-\alpha_1)\cdot\pi_i \\
\psi_{3i} &= P(Y_i^O = 1, Y_i^T = 0) = \alpha_0\cdot(1-\pi_i) \\
\psi_{4i} &= P(Y_i^O = 0, Y_i^T = 1) = \alpha_1\cdot\pi_i
\end{aligned} \tag{9}$$

and the conditional densities in equation (8) are:

$$\begin{aligned}
g_1\left(\log(W_i^O)\right) &= f\left(\log(W_i^O)|Y_i^O = 0, Y_i^T = 0\right) = 1 \\
g_2\left(\log(W_i^O)\right) &= f\left(\log(W_i^O)|Y_i^O = 1, Y_i^T = 1, \boldsymbol{X}_i\right) \\
g_3\left(\log(W_i^O)\right) &= f\left(\log(W_i^O)|Y_i^O = 1, Y_i^T = 0\right) \\
g_4\left(\log(W_i^O)\right) &= f\left(\log(W_i^O)|Y_i^O = 0, Y_i^T = 1\right) = 1
\end{aligned} \tag{10}$$

The density g_2 represents the main contribution in explaining $\log(W^O)$, but its weight ψ_2 tends to zero as α_1 goes to 1.

The density g_3 does not depend on the covariates $\boldsymbol{X}$ because $W_i^T = 0$ when $Y_i^T = 0$; hence it only refers to the erratic component ε. Its weight ψ_3 increases as α_0 gets higher. As a last step, we model Y_i^O and $\log(W_i^O)$ as:

$$P\left(Y_i^O = 1|Z_i\right) = \alpha_0 + (1-\alpha_0-\alpha_1)P\left(Y_i^T|Z_i\right) \tag{11}$$

$$\log(W_i^O) = \boldsymbol{X}_i\boldsymbol{\theta} + (u_i + \varepsilon_i) \tag{12}$$

where $\boldsymbol{X}_i$ is the row vector containing all information for the i-th individual. The first part of the model (i.e. equation 11) is consistent with equation (2). For the second part, coherently with (7), we assume a normal distribution for ε, $\varepsilon_i \sim N(\mu_i, \sigma_\varepsilon^2)$, and consequently for the global error component $u_i + \varepsilon_i = v_i \sim N(\mu_i, \sigma_v^2)$. Furthermore, we assume that u_i and ε_i are uncorrelated. It's important to stress that the above specification extends the classical measurement error model, allowing each unit to

have a different expected value μ_i. In other words, the measurement error may act with a different intensity for each population unit. We model the expected value as a function of individual characteristics: $\mu_i = h(\boldsymbol{X}_i^* \boldsymbol{\gamma})$, with $\boldsymbol{X}_i^*$ row vector. For the sake of simplicity, we just consider a linear function $\mu_i = \boldsymbol{X}_i^* \boldsymbol{\gamma}$. Admitting a varying μ_i implies that the conditional densities g_2 and g_3 must be conditioned to $\boldsymbol{X}_i^*$. Since $\log(W_i^O)$ and μ_i are both specified as linear functions of the predictors, to avoid any problem of identifiability of the parameters $\boldsymbol{\theta}$ and $\boldsymbol{\gamma}$, we assume that the sets of covariates X and X^* do not overlap.

The contribution of the $i-th$ unit to the likelihood is:

$$L_i(\boldsymbol{\beta}, \boldsymbol{\theta}, \boldsymbol{\gamma}, \alpha_0, \alpha_1) = \{(1-\alpha_0) \cdot (1-\pi_i) + \alpha_1 \cdot \pi_i\}^{(1-y_i^O)} \tag{13}$$
$$\cdot \left\{(1-\alpha_1) \cdot \pi_i \cdot N(\boldsymbol{X}_i \boldsymbol{\theta} + \boldsymbol{X}_i^* \boldsymbol{\gamma}; \sigma_v^2) + \alpha_0 \cdot (1-\pi_i) \cdot N(\boldsymbol{X}_i^* \boldsymbol{\gamma}; \sigma_\varepsilon^2)\right\}^{y_i^O}$$

where $N(\boldsymbol{X}_i \boldsymbol{\theta} + \boldsymbol{X}_i^* \boldsymbol{\gamma}; \sigma_v^2)$ and $N(\boldsymbol{X}_i^* \boldsymbol{\gamma}; \sigma_\varepsilon^2)$ are the densities g_2 and g_3 in equation (10) respectively. In the following, for the sake of brevity and to highlight the dependency on the parameters, we denote them as $g_2(\boldsymbol{\theta}, \boldsymbol{\gamma})$ and $g_3(\boldsymbol{\gamma})$.

3 Simulation study

We present the finite sample performances of the proposed model and compare them to the classical probit/ols two part model via Monte Carlo simulations. We assumed the following generating model for the error-free dependent variables:

$$\Pr\left(Y^T | Z_1, Z_2, Z_3\right) = \Phi\left(\beta_0 + \beta_1 Z_1 + \beta_2 Z_2 + \beta_3 Z_3\right) \tag{14}$$
$$\log W^T = \theta_0 + \theta_1 X_1 + \theta_2 X_2 + u \tag{15}$$

where $\Phi(\cdot)$ is the c.d.f of a standard normal. The covariates are generated as follows: Z_1 is log-normal with zero mean and unit variance, X_2 and Z_2 are binomial with $p = 1/3$, X_1 and Z_3 are uniformly distributed over the unit interval. To generate the observed (i.e. error-prone) binary variable, Y^O, we define the misclassification matrix based on equation (1) and we sample accordingly. Finally, the mismeasured continuous part is generated as in equation 12 allowing $\mu_i = \gamma X_4$, with $X_4 \sim Mult_4(p_1 = 0.01; p_2 = 0.06; p_3 = 0.33, p_4 = 0.60)$.

Across simulations we fixed: $\theta^T = (10, 0.8, -0.5)$, $\beta^T = (-1, 0.2, 1.5, -0.6)$, $\sigma_u^2 = 2$ and set the remaining parameters according three scenarios: 1) $\alpha_0 = \alpha_1 = 0.05; \sigma_\varepsilon^2 = 3; \gamma = -0.2$, 2) $\alpha_0 = 0.05; \alpha_1 = 0.20; \sigma_\varepsilon^2 = 3; \gamma = -0.2$ and 3) $\alpha_0 = \alpha_1 = 0.20; \sigma_\varepsilon^2 = 3; \gamma = -0.2$. We repeat each simulation scenario 100 times with samples of size $n = 5,000$. In table 1 we report the results.

For the binary part of the model, even in the case of a small amount of misclassification ($\alpha_0 = \alpha_1 = 0.05$), ordinary probit produces estimates that are biased by 14-22%. As expected, the problem worsens as the amount of misclassification

Table 1 Empirical mean and standard errors, over 100 simulated data sets, of the parameter estimates based on the proposed model and the two-part model.

Note: The standard error of the simulation results are reported in italic.

grows. Conversely, the proposed model provides more accurate estimates, in terms of mean squared errors, for all levels of misclassification.

For the continuous part, the results of the proposed model are very encouraging since the estimates of all parameters are trustworthy. These results hold for all simulations scenarios (all tables are available upon request). Although satisfactory, the estimates of γ and σ_v^2 showed some variability in the accuracy when $\sigma_\varepsilon^2 = 3$.

Statistical assessment of practical significance

Valutazione statistica della significatività pratica

Andrea Ongaro, Sonia Migliorati, and Enrico Ripamonti[1]

Abstract Traditionally, common testing problems are formalized as precise null hypotheses representing an idealized situation such as absence (vs. presence) of a treatment effect. However, in most applications the real purpose of the analysis is to assess evidence in favor of a practically relevant effect more than simply determine its presence. We have proposed a sufficiently general approach to the problem of establishing the practical significance of obtained results. This entails the derivation of *ad hoc* procedures for modifying commonly employed tests to make them suitable for appropriate interval null hypotheses. Herein we describe how the problem of the assessment of practical significance could be dealt with in our proposed framework, in case of a sample from a Normal population.

Abstract *Tradizionalmente i problemi di verifica di ipotesi sono formalizzati in termini di ipotesi nulle precise che rappresentano una situazione idealizzata indicante l'assenza (vs. presenza) di un effetto del trattamento. Tuttavia, nella maggior parte delle applicazioni il vero scopo dell'analisi è valutare la significatività pratica di un effetto più che semplicemente determinarne la presenza. Abbiamo proposto un approccio sufficientemente generale al problema di stabilire la significatività pratica. Ciò comporta la derivazione di procedure ad hoc per modificare i test di uso comune al fine di renderli idonei ad appropriate ipotesi di tipo intervallare. In questo contributo descriviamo come affrontare il problema della significatività pratica secondo la nostra prospettiva, considerando il caso studio di un campione da una popolazione Normale.*

1. Introduction

In applications, most common statistical testing problems are formulated as precise null hypotheses. This is the case, for example, of widespread null hypotheses such as "a certain treatment or explanatory variable is ineffective" or "two or more treatment effects are identical". Very often, however, the real objective of the analysis is to assess whether the effect is large enough to be of practical or substantive significance for the problem at hand rather than simply establishing its presence/absence. For instance, two different drugs can be equivalent from a clinical point of view without having an identical effect.

It follows that the null hypothesis should be more properly formulated as an interval null hypothesis, including all practically irrelevant departures from the precise null. The use of a precise null hypothesis seems justified only if it can be considered as an accurate approximation of the real interval one (see [1] for discussion). However, this is not the case in the commonly encountered context of moderate or large data sets, where even a very small departure from the precise null can be detected (leading to rejection) due to the high power of the test. To appreciate how severely misleading results based on precise null formulation can be, consider the following simple but representative example.

Let X be a vector of i.i.d. observations from a Normal r.v. with unknown mean μ and known variance σ^2. Suppose to test the hypothesis that μ is not substantially different from μ_0. The standard practice is to test the precise null hypothesis $H_0^*: \mu = \mu_0$ vs. $H_0^*: \mu \neq \mu_0$. Let us indicate with $\bar{X}$ the sample mean, t the observed value of the test statistic $T = \sqrt{n}|\bar{X} - \mu_0|/\sigma$, and Φ the standard Normal distribution function. One would then reject H_0^* when the standard p-value $p^* = P_{\mu_0}(T \geq t) = 2(1 - \Phi(t))$ is sufficiently low.

Consider now the more realistic interval hypothesis $H_0: |\mu - \mu_0| \leq \delta$. The corresponding p-value can be shown to be

$$p = p_\delta(t) = sup_{|\mu-\mu_0|\leq\delta} P_\mu(T \geq t) = 2 - [\Phi(t - \delta_{st}) + \Phi(t + \delta_{st})],$$

where $\delta_{st} = \delta\sqrt{n}/\sigma$ expresses the departure in terms of sample mean standard deviation. The validity of the precise hypothesis approximation can be established by choosing t so that the real evidence $p_\delta(t)$ is fixed at a given level (e.g. 0.05) and then comparing this level with p^* as δ_{st} varies (see Figure 1). Remarkably, p^* can be considered approximately correct (less than 10% error) only if δ_{st} is very small (less than 0.1 - 0.2), drastic differences between p and p^* (p^*being about one half p) occurring for δ_{st} ranging from 0.4 to 0.6. Finally, values of δ_{st} in the interval (1, 1.1) lead to a p^* about 1/10 p. In fact, p^* can be proved to decay exponentially fast as δ_{st} diverges, for fixed $p_\delta(t)$.

The implication is that p^* becomes substantially smaller than p, even for moderate n and small δ values. For example, for a departure as small as $\delta/\sigma = 0.05$, the approximation is accurate only for $n \leq 25$; for a less extreme departure of $\delta/\sigma = 0.5$ a 50% error is obtained even when $n = 1$, n =4 already producing a 90% error.

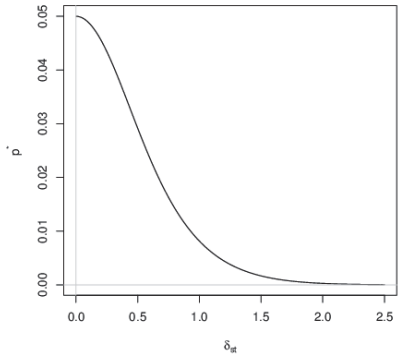

Figure 1. p^* as a function of δ_{st} with $p_\delta(t) = 0.05$.

The distinction between statistical and practical significance is well known in the literature, and it has been, and still is, the subject of animated debates on the usefulness of significance testing in many applied fields [2,3]. More recently an issue of the *American Statistician* devoted to the *p*-value debate has also touched upon this topic (e.g. see [4] and [5]).

Herein we adopt an interval null hypothesis formulation of the problem, which entails two types of inherent difficulties. From a methodological standpoint, the construction of tests for interval null hypotheses in general contexts is not trivial as only tests for precise null hypotheses (in the following standard tests, ST) are implemented and available. Moreover, from a practical point of view, the choice of the threshold δ is often a difficult task in some applied contexts. In [6] a general and unifying method addressing these problems has been put forward. Here we illustrate the method focusing on its application to the simple but very representative Normal case. In the next section we briefly review the general approach.

2. A general framework to test interval null hypotheses

The basic idea of our methodology is to properly modify commonly used precise null hypotheses ST tests. Let $\{T \geq k\}$ be the rejection region of the ST for a given statistic T. In presence of nuisance parameters ψ, its level under the interval null hypothesis can be excessively large (equal to 1) for any fixed k. This is because, typically, the distribution of T does not depend on ψ only under the precise null hypothesis, and T may become very large or even diverge under the interval null hypothesis.

To solve this problem, we let the threshold of the rejection region depend on data, so that it can account for changes in the distribution of T due to changes in ψ. The new threshold is obtained by suitably estimating $k_\alpha(\delta, \psi)$, which represents the α level ST threshold for known ψ. Specifically, we propose two solutions:

1. *Plug-in Test* (PIT): ψ is replaced in $k_\alpha(\delta, \psi)$ with some point estimate $\hat{\psi}$;

2. *Confidence Interval Test* (CIT): $k_\alpha(\delta, \psi)$ is maximized over an arbitrary confidence interval (at level $1-\gamma$) for ψ.

The main advantage of the PIT is its simplicity and good expected behavior for large sample size. However, the attained level is not guaranteed to coincide with the nominal level. The advantage of the CIT is that it can be shown to have a completely general and simple level, namely $\alpha+\gamma$. Consequently, the desired level α is guaranteed in this case by simply choosing an $(\alpha-\gamma)$ level threshold (with $\alpha > \gamma$).

As for the problem of determining the threshold δ, no general automatic rules can be given, since this problem typically relies on a careful context-dependent evaluation. In specific fields reference values may be identified, e.g. see [7]. In other, more difficult cases, we suggest focusing on those departure values which are crucial to assess practical significance. Therefore, we look for the minimum information on δ needed to reach a conclusion with a certain level of evidence. To this end we propose to derive the value δ'_α, defined as *the largest departure δ to be rejected at level α*. In this way, to decide about practical significance (at level α) it is only required to decide whether δ'_α is a relevant or not.

To allow an easy implementation of all proposed procedures, we suggest using a graphical tool, called *significance curve*. This curve is made up of *p*-values for the interval null hypothesis as a function of δ. Thus, it directly provides the degree of evidence against all possible specifications of the interval null hypothesis. Any value δ'_α is readily available by finding the δ value making the curve equal to α.

3. Practical significance in the Normal case

We now illustrate our procedure in the context of a Normal population. When the variance is known, the ST reject region $\{T \geq k\}$ is suitable for the interval null hypothesis. In the notation of Section 1, the test statistic $T = \sqrt{n}|\bar{X} - \mu_0|/\sigma$ is stochastically increasing in $|\mu - \mu_0|$. Therefore a size α threshold $k_\alpha(\delta)$ for the hypothesis $H_0: |\mu - \mu_0| \leq \delta$ can be shown to exist unique and can be obtained by numerically solving the equation

$$p_\delta(k) = sup_{|\mu-\mu_0|\leq\delta} P_\mu(T \geq k) = 2 - [\Phi(k - \delta_{st}) + \Phi(k + \delta_{st})] = \alpha.$$

The value δ'_α can be determined considering that the null hypothesis is rejected iff the *p*-value $p_\delta(t) \leq \alpha$. As $p_\delta(t)$ can be shown to be increasing and continuous in δ, then δ'_α can be computed by solving the equation $p_\delta(t) = \alpha$. Thus δ'_α can be graphically evaluated by plotting the significance curve, i.e. the *p*-value $p_\delta(t)$ as a function of δ or, more conveniently, of δ_{st} (see Figure 2).

This curve promptly provides a clear and complete picture of the information contained in the data: roughly speaking, a strong evidence is present against departures smaller than 0.67 ($p \leq 0.01$), a moderate one against departures between 0.67 and 1.36 ($0.01 \leq p \leq 0.05$), and so on. Notice that, even for moderate *n*, $p^* =$

0.0027 is likely not to be evidence of practical significance: there is evidence at, say, 0.01 level iff a departure $|\mu - \mu_0|$ equal to $0.067\sigma/\sqrt{n}$ is thought to be relevant.

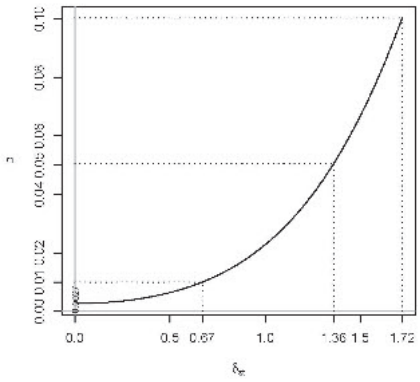

Figure 2. The significance curve with t=3 ($p^* = 0.0027$)

The situation is more involved in case of unknown variance σ^2. For the precise hypothesis $H_0^*: \mu = \mu_0$ the ST is the usual t-test with size α^* rejection region: $R^* = \{|T| \geq t_{n-1;1-\alpha*/2}\}$, where $T = \sqrt{n}(\bar{X} - \mu_0)/S$, S^2 is the sample (unbiased) variance, and $t_{\upsilon,\beta}$ is the β quantile of a Student's t distribution with υ degrees of freedom. In this case the ST $\{|T| \geq k\}$ cannot be used for the interval null hypothesis, as its size can be shown to be equal to 1 for any $k \geq 0$. This is because the distribution of T can be shown to be continuous and stochastically increasing in $\sqrt{n}|\mu - \mu_0|/\sigma$, diverging to infinity when $\sqrt{n}|\mu - \mu_0|/\sigma \to \infty$. Therefore, the probability of $\{|T| \geq k\}$ tends to 1 when $\sigma^2 \to 0$ (if $\mu \neq \mu_0$), for any given k. However, were σ^2 known, a size α threshold $k_\alpha(\delta, \sigma^2)$ can be determined. Specifically, this threshold can be obtained as solution of the equation:

$$p_{\delta,\sigma^2}(k) = P_{\delta,\sigma^2}(|T| \geq k) = 1 - V_{n-1,\frac{\sqrt{n}\delta}{\sigma}}(k) + V_{n-1,\frac{\sqrt{n}\delta}{\sigma}}(-k) = \alpha$$

where $V_{\upsilon,ncp}$ is the non-central Student's t distribution function with υ d.f. and non-centrality parameter *ncp*.

The PIT is obtained by replacing σ^2 with its estimate S^2, which leads to the rejection region $\{|T| \geq k_\alpha(\delta, S^2)\}$. Here the significance curve is given by $p_{\delta,S^2}(t)$ viewed as a function of δ, from which the value δ'_α can be deducted.

Let us now focus on the CIT. The usual two-tailed $(1-\gamma)$ level CI for σ^2 is $[(n-1)S^2/c_{n-1;1-\gamma/2}, (n-1)S^2/c_{n-1;\gamma/2}]$, where $c_{\upsilon;\beta}$ is the β quantile of a Chi-square distribution with υ d.f.. *As* $k_\alpha(\delta, \sigma^2)$ can be shown to be decreasing in σ^2, an α level CIT is given by

$$\{|T| \geq k_{\alpha-\gamma}(\delta, S^2_{inf}\},$$

where $S_{inf}^2 = (n-1)S^2/c_{n-1;1-\frac{\gamma}{2}}$, and the corresponding significance curve takes form $p_{\delta,S_{inf}^2}(t) + \gamma$.

A peculiar feature of the present context is that large values of $|T|$ are associated with large values of $k_\alpha(\delta, S^2)$, being S^2 negatively correlated with $|T|$ and $k_\alpha(\delta, S^2)$ decreasing in S^2. Thus, both tests can be expected to be conservative. Indeed, when $|\mu - \mu_0| = \delta$ the simulated probability of rejection of the PIT is always less than α, being increasing in σ^2. Moreover, the limit of this probability when $\sigma^2 \to \infty$, can be proved to be α, which can thus be considered the exact size of the test. It is shown by simulation that values close to α are already obtained for moderate σ^2 values ($\delta/\sigma \leq 1/4$ for *n*=30) with improving performances as *n* increases.

The CIT exhibits a similar behavior, but with size $\alpha - \gamma$ and a (sometimes relevant) lower first kind error probability.

Interestingly, in this context it is possible to compare the two test performances. Given that in this example both tests have level α, the PIT is preferable as, being by construction more liberal, it can be expected to attain higher power than the CIT. Notice that in general this comparison is not possible, as there is no guarantee that the PIT has level α. Indeed, the PIT was found to be rather liberal in other settings.

4. Conclusion

We have illustrated how our general approach can be rather easily implemented in the Normal case producing sensible results even when nuisance parameters are present. Many other noteworthy cases are covered by our methodology, encompassing the Student's *t*, Chi-square, and Snedecor's *F* type of tests, as well as null hypotheses concerning multidimensional parameters. Our proposal can be applied in many scientific areas involving use of tests and precise hypotheses testing, like medicine, psychology, ecology [8].

Autoregressive and mixed effects models

Asymptotic Properties of the Nonlinear Least Squares Estimator in HE-HAR Models

Proprietà asintotiche dello stimatore dei minimi quadrati non lineari in modelli HE-HAR

Emilija Dzuverovic, Edoardo Otranto

Abstract We examine the properties of nonlinear least squares (NLS) estimator for a nonlinear extension of the class of heterogeneous autoregressive (HAR) models for realized covariance (RC) matrices. The Monte Carlo (MC) experiments verify the asymptotic properties of the OLS for multivariate HAR specifications, used as a benchmark. Then we replicate the experiment to verify the same properties for the Hadamard exponential (HE)-based HAR extensions, establishing the convergence of regular HAR coefficients in all cases, while the asymptotic normality of the NLS estimates is uniquely confirmed for the "HE_vech-HAR" specification with log-transformed RC series. The only persistent but relatively narrow asymptotic bias is evident for the "HE" parameter estimate. We submit models in MC exercises to several sensitivity checks and show the robustness of corresponding results.

Abstract *In questo lavoro esaminiamo le proprietà dello stimatore dei minimi quadrati non lineari (NLS) per una estensione della classe di modelli autoregressivi eterogenei (HAR) per matrici di covarianza realizzata (RC). Tramite esperimenti Monte Carlo (MC) verifichiamo le proprietà asintotiche dello stimatore dei minimi quadrati per il modello base HAR multivariato. Ripetiamo poi lo stesso esperimento per verificare le stesse proprietà per il modello Hadamard Exponential (HE)-HAR, stabilendo la convergenza dei coefficienti tipici dell'HAR in tutti i casi, mentre la normalità asintotica è ottenuta in modo univoco solo per la specifica "HE_vech-HAR" con le serie RC trasformate logaritmicamente. E' evidente la presenza di una (leggera) distorsione per lo stimatore del parametro "HE". Vengono realizzati diversi esperimenti MC per verificare la robustezza dei risultati sotto varie ipotesi distribuzionali.*

Keywords: HAR, Hadamard exponential matrix, Monte Carlo, nonlinear least squares, realized covariances.

1 Introduction

The covariance matrix of asset returns is a central input to asset pricing, portfolio allocation and risk management decisions. Over recent decades, considerable research by statisticians and econometricians has been devoted to modelling, estimating and forecasting variance-covariance matrices. The majority of introduced models assume that variances and covariances of asset returns are assessable conditional upon the past information, i.e., multivariate GARCH (MGARCH) models (Bauwens et al. (2006)), or treat them as inherently latent quantities, i.e., multivariate stochastic volatility (MSV) models (Asai et al. (2006)).

Emilija Dzuverovic, University of Messina, Italy; email: edzuverovic@unime.it.

Edoardo Otranto, University of Messina, Italy; email: edoardo.otranto@unime.it.

In contrast, the recent preferable realized covariance method adopts high-frequency data to allow for accurate estimation of the variances and covariances of low-frequency returns (e.g., Andersen et al. (2003), Barndorff-Nielsen and Shephard (2004), Barndorff-Nielsen et al. (2008, 2011)). As volatility becomes essentially "observable", it can be modelled directly, rather than being treated as a latent variable. However, realized covariance (RC) models generally face several challenges, and the most prominent contain ensuring the positive definiteness of the covariance forecasts coupled with the dimensionality issue. The latter implies the rapid increase in the number of parameters with the cross-sectional dimension that has a potential pronounced impact on the statistical efficiency of the estimation and could even render the model estimation unfeasible. Hence, the RC modelling framework calls for parsimonious yet flexible parameterizations, capable of capturing complex serial dependencies observed in realized variances and covariances.

Among the high-frequency data (HFD)-based models, the multivariate extensions of the Heterogeneous Autoregressive (HAR) Model (Corsi, 2009) are widely employed (e.g., vech-HAR Model (Chiriac and Voev (2011), HAR-DRD Model (Oh and Patton (2016)). This class of models originally inspired by the Heterogenous Market Hypothesis of Müller et al. (1993) and the asymmetric propagation of volatility between long and short horizons appears capable of capturing the commonly recognized long memory property of realized covariances via simple linear regression structures.

Nevertheless, in the face of the emphasized curse of dimensionality issue, an easy-to-implement framework contains the adoption of the scalar versions of HAR-based models. This implies that all variances and covariances, or correlations obey the same dynamics, an assumption that is obviously highly restrictive. In this regard, using the element-by-element Hadamard exponential (HE) function of the matrix, the asset pair-specific and time-varying impact coefficients of the lagged realized variances and covariances, or correlations, could be defined, adding great flexibility in the dynamics via a single parameter (Bauwens and Otranto (2020, 2022)).

A practical advantage of the HAR family of models is the straightforward estimation via OLS. By incorporating the so-called "HE" extension (Bauwens and Otranto (2020, 2022)), the nonlinear LS (NLS) could be adopted. Thus, great computational advantages in terms of simplicity, stability and cost potentially arise on behalf of flexible and parsimonious HE_HAR models compared to all other maximum likelihood (ML)-based RC models. It has therefore been natural to ask if the convincing NLS method would generate (at least asymptotically) unbiased, efficient and normally distributed estimators. The approach taken to provide a reliable and empirically valid answer to this question contains the extensive Monte Carlo (MC) simulation experiment.

The rest of the paper is organized as follows. Section 2 introduces the HAR-based framework adopted for MC experiments; Section 3 provides a brief discussion on empirical results and gives some concluding comments.

2 Framework

2.1 vech-HAR Model

The study began with the aim to validate the theoretically established asymptotic properties of the HAR OLS estimates (e.g., McAleer and Medeiros (2008), Hwang and Shin (2014)). We consider the vech-HAR Model (Chiriac and Voev (2011)):

$$\text{vech}(C_t) = (1 - \alpha_D - \alpha_W - \alpha_M)\text{vech}(\overline{C}) + \alpha_D\text{vech}(C_{t-1}) + \alpha_W\text{vech}(\overline{C}_{t-1:t-5}) + \alpha_M\text{vech}(\overline{C}_{t-1:t-22}) + \varepsilon_t,$$

where vech(.) is the operator that stacks the lower triangular portion of its matrix argument as a vector, regressors are the averages of the past RC matrices, $\overline{C}$ is the sample mean of the RC series and α's are scalar parameters. Finally, ε_t is a vector of disturbances.

We consider two alternative specifications for the distribution of ε_t, i.e., Normal, applying the log transformation to realized covariances (Bauer and Vorkink (2011)), and the Wishart distribution (e.g., Golosnoy et al. (2012), Bauwens et al. (2012)). These hypotheses ensure the positive definiteness of RC series. For ease of notation, we indicate the resulting models by "log vech-HAR" and "vech-HAR Wishart".

2.2 HE_vech-HAR Model

However, the adoption of the scalar vech-HAR Model requires imposing a very strong assumption, i.e., all the variances and covariances obey the same dynamics. Bauwens and Otranto (2022) suggest a way of adding great flexibility in the model dynamics while preserving the parsimonious parameterization, i.e., via a single additional parameter, using the Hadamard exponential (HE) function of the matrix.

In practical terms, let us consider again the simple scalar vech-HAR Model (Chiriac and Voev (2011)), where each daily RC matrix is specified as a linear function of lagged daily, weekly and monthly covariances. Bauwens and Otranto (2022) suggest replacing, e.g., the scalar impact coefficient α_D of lagged daily RC on the current RC matrix by $\alpha_D\exp(\varphi\text{vech}(P_{t-1} - J_m)$, where φ is the parameter and P_{t-1} is the lagged realized correlation matrix. Thus, if φ differs from zero, the impact coefficient becomes both asset pair-specific and time-varying.

The adoption of lagged correlations in the impact parameter can be justified by the strong evidence that volatilities and correlations move together (e.g., Andersen et al. (2001)). As such, we expect the transfer of volatility clustering phenomenon to correlations as well. During turbulent periods, the correlations increase, but the level of persistence of such an increase can be distinct across asset pairs. Hence, by adding a dependence of the impact coefficient on lagged correlations, we are able to account for the volatility clustering effect on realized covariances that differs across asset pairs and changes through time.

The vech-HAR Model with the "HE" extension could be estimated by NLS. In this regard, we investigate the asymptotic properties of the HE_vech-HAR NLS estimates generated via the Gauss-Newton algorithm. Again, we consider both the realized covariances in log form (Bauer and Vorkink (2011)) and Wishart generated ones (e.g., Golosnoy et al. (2012), Bauwens et al. (2012)). Moreover, we examine the NLS properties under the recently proposed conditional Matrix F distribution for RC matrices (e.g., Opschoor et al. (2018), Vassallo et al. (2021)). For ease of notation, we indicate resulting models by "log HE_vech-HAR", "HE_vech-HAR Wishart" and "HE_vech-HAR Matrix F".

2.3 HE_HAR-DRD Model

Given that the benchmark scalar HAR-DRD Model (Oh and Patton (2016)) imposes the sharp restriction that all the correlations follow the same dynamics, we introduce the "HE" extension to the specification of the realized correlation series R_t, such that:

$$\text{vech}(R_t) = (1 - \overline{\alpha}_{D,t} - \alpha_W - \alpha_M)\text{vech}(\overline{R}) + \alpha_D \exp(\varphi \text{vech}(R_{t-1} - J_m)) \odot \text{vech}(R_{t-1}) + \alpha_W \text{vech}(\overline{R}_{t-1:t-5}) + \alpha_M \text{vech}(\overline{R}_{t-1:t-22}) + \varepsilon_t,$$

where $\odot$ denotes the Hadamard product, φ is the "HE" parameter, $\overline{R}$ is the sample mean of the realized correlation series, J_m is the m x m matrix of ones with respect to the cross-sectional dimension m and $\overline{\alpha}_{D,t}$ is the average of the entries of $\alpha_D \exp(\varphi \text{vech}(R_{t-1} - J_m))$. Clearly, if φ differs from zero, the impact coefficient becomes asset pair-specific and time-varying.

Within this framework, we keep adopting the benchmark HAR Model (Corsi (2009)) in the first step for each individual realized variance.

Similarly to HE_vech-HAR, HAR-DRD model with the "HE" extension could be estimated by NLS. As follows, we examine the asymptotic properties of HE_HAR-DRD NLS estimates generated via the Gauss-Newton algorithm. Based on the outcomes of initial asymptotic estimations, we simulate only "HE_HAR-DRD Wishart" Model.

3 Discussion

Both the linear and nonlinear HAR processes discussed above are simulated for the cross-sectional dimension m = 3 with sample sizes T = 1000, 3000, 5000, 10000, 50000. Then, the OLS/NLS estimates are computed for the parameters with the replication number N = 1000, coupled with the sample means of 1000 estimates and respective standard deviations. Finally, we check the asymptotic normality via the Jarque-Bera test (Jarque and Bera (1981)).

Based on the MC replication outcomes, we verify the consistency and asymptotic normality of the OLS estimates for the benchmark multivariate HAR specifications, i.e., "log vech-HAR" with(out) covariance targeting and "vech-HAR Wishart", with the full convergence of parameters attained at the sample size T = 10000 and steadily reducing standard deviations as the sample size grows. Furthermore, the asymptotic normal distribution of all estimated coefficients is confirmed simultaneously with the consistency evidence. E.g., Table 1 reports the results for the "log vech-HAR" Model.

Considering the Gauss-Newton NLS estimates, we establish the convergence of the regular HAR parameters in each HE_vech-HAR specification, i.e., "log HE_vech-HAR", "HE_vech-HAR Wishart" and "HE_vech-HAR Matrix F", with the consistency of the coefficients on log-transformed lagged RC validated even at the sample size T = 5000 coupled with the confirmation of the "normality" hypothesis on all parameters. Conversely, in each model, the remaining "HE" parameter estimate is featured by the relatively narrow asymptotic bias around the absolute 2%. E.g., Table 2 reports the results for the "log HE_vech-HAR" Model.

On the other hand, the NLS for the nonlinear HAR-DRD specification, i.e., "HE_HAR-DRD Wishart", generates inconsistent and non-Gaussian estimates, with the average absolute 1.5% asymptotic bias on conventional HAR parameters and rather pronounced "HE" term bias up to -10%.

Finally, we submit the models in the MC exercises to several sensitivity checks and show the robustness of corresponding results.

Table 1: $N = 1000$ "log vech-HAR" with the covariance targeting estimates.

Parameter/Sample Size	T = 1000	T = 3000	T = 5000	T = 10000	T = 50000
$\alpha_D = 0.45$					
Sample Mean	**0.45**	**0.45**	**0.45**	**0.45**	**0.45**

Note: The table reports the sample mean of the 1000 NLS estimates of each "log HE_vech-HAR" parameter with the corresponding standard deviation in parenthesis, coupled with the percentage absolute bias (at sample sizes $T = 1000, 3000, 5000, 10000, 50000$). It also shows the p-value of the Jarque-Bera test for each coefficient and respective sample size, where the entries in boldface indicate the failure to reject the null hypothesis of "normality" at the 5% significance level.

Given the breadth of the HAR modelling framework and their widespread adoption in the context of accurate RC matrix forecasting, these results provide a valuable extension to existing ones in the literature and immediate practical implications. However, an avenue we have not explored in this study is building up the alternative flexible but still parsimonious multivariate HAR extensions subject to the NLS estimation. E.g., incorporating the smooth transition structure within the MHAR framework to explicitly account for the asymmetric behaviour of realized variances and covariances (see e.g., McAleer and Medeiros (2008), Qu et al. (2016)). Hence, it remains completely an open empirical question whether the consistency and asymptotic normality of the NLS could be confirmed for the upcoming nonlinear HAR models for RC matrix, which arguably reflect the interesting topics for further research.

The full set of MC experiments with the corresponding results is available upon request.

A note on testing for threshold non-linearity in presence of heteroskedasticity in time series

Una nota sui test per non-linearità a soglia in presenza di eteroschedasticità

Simone Giannerini and Greta Goracci

Abstract In this note we study the behaviour of an asymptotic test for linearity against the threshold autoregressive moving average model in presence of conditional heteroskedasticity. We recall the relevant asymptotic theory both under the null and the alternative hypotheses for a supremum Lagrange Multiplier test statistic in presence of *i.i.d.* errors. By means of a small simulation study we show that when the innovations follow a GARCH process the size of the test can be severely biased and we discuss possible solutions to the problem.

In questa nota studiamo il comportamento di un test per la non linearità di tipo autoregressivo-media mobile con soglia, in presenza di eteroschedasticità. Introduciamo la teoria asintotica di riferimento, sia sotto l'ipotesi nulla sia sotto l'ipotesi alternativa, per la statistica test basata sui moltiplicatori di Lagrange quando gli errori sono i.i.d.. Per mezzo di uno studio di simulazione mostriamo poi che, quando gli errori seguono un processo GARCH, allora l'ampiezza del test può risultare fortemente distorta e discutiamo possibili soluzioni al problema.

Key words: Threshold autoregressive moving-average models, Lagrange multiplier test, Linearity testing, heteroskedasticity, GARCH models

1 Introduction

The problem of testing for threshold non-linearity in time series has received much attention since the seminal works of Chan [5] [6]. Among the contributions, in [10] a stochastic permutation scheme is used to derive the null distribution of the test statistics, whereas in [8] the validity of the bootstrap has been proved. Also, in [13] and [9] an extension of the test to threshold autoregressive moving average models (TARMA) is presented. Tests for unit-root against the alternative hypothesis of a stationary threshold process have been discussed in [3],[11], [4], [7].

In all the abovementioned works, the innovation process is assumed to be *i.i.d.*. To some extent, the behaviour of such tests in presence of conditional heteroskedasticity has been studied in [14], that discuss testing for a TAR process with ARCH-type innovations, whereas [12] introduce tests for TMA with GARCH-type innovations. To the best of our knowledge, there are no studies on the asymptotic behaviour of the general ARMA versus TARMA test when the innovation process presents conditional heteroskedasticity.

In this paper we revisit the general framework of asymptotic testing for threshold ARMA effects introduced in [9] and present a Monte Carlo study where we show that such test can be severely biased in presence of heteroskedastic innovations. The paper is structured as follows: in Section 2, we describe the sup Lagrange Multiplier test statistic (sLM*), recall its asymptotic distribution and the consistency of the associated test. In Section 3, we present a simulation study on the size of the sLM* test in presence of conditional heteroskedasticity, whereas in Section 4 we offer some discussion and possible solutions to the problem.

2 The test and its asymptotics

Let the time series $\{X_t : t = 1,\dots,n\}$ follow the threshold autoregressive moving-average model (TARMA(p,q)) defined by the difference equation:

$$X_t = \phi_0 + \sum_{i=1}^{p} \phi_i X_{t-i} - \sum_{j=1}^{q} \theta_j \varepsilon_{t-j} + \varepsilon_t + \left(\varphi_0 + \sum_{i=1}^{p} \varphi_i X_{t-i} - \sum_{j=1}^{q} \vartheta_j \varepsilon_{t-j} \right) I(X_{t-d} \leq r).$$

The innovations $\{\varepsilon_t\}$ follow a *i.i.d.* process with zero mean and finite variance σ^2; p, q and d are known positive integers and indicate the autoregressive order, the moving-average order and the delay parameter, respectively. Moreover, $I(\cdot)$ is the indicator function and $r \in \mathbb{R}$ is the threshold parameter. For notational convenience, we abbreviate $I(X_t \leq r)$ by $I_r(X_t)$. Let $\phi = (\phi_0, \phi_1, \dots, \phi_p)^\intercal$, $\theta = (\theta_1, \dots, \theta_q)^\intercal$, $\varphi = (\varphi_0, \varphi_1, \dots, \varphi_p)^\intercal$ and $\vartheta = (\vartheta_1, \dots, \vartheta_q)^\intercal$. Moreover we define:

$$\eta = (\eta_1^\intercal, \eta_2^\intercal, \sigma^2)^\intercal \quad \text{with} \quad \eta_1 = (\phi^\intercal, \theta^\intercal)^\intercal \quad \text{and} \quad \eta_2 = (\varphi^\intercal, \vartheta^\intercal)^\intercal.$$

The true parameters have a subscript zero, e.g. η_0, $\eta_{0,1}$, θ_0, ... Also, we assume η_0 to be an interior point of the parameter space.

We test whether a TARMA(p,q) model provides a significantly better fit than the linear ARMA(p,q) model by developing a Lagrange multiplier test statistic. Let $\mathbf{0}$ be the vector with all zeroes, hence the system of hypotheses becomes:

$$\begin{cases} H_0 & : \eta_{0,2} = \mathbf{0}, \\ H_1 & : \eta_{0,2} \neq \mathbf{0}, \end{cases}$$

Under H_0, the time series follows a linear ARMA(p,q) model:

$$X_t = \phi_{0,0} + \sum_{i=1}^{p} \phi_{0,i} X_{t-i} - \sum_{j=1}^{q} \theta_{0,j} \varepsilon_{t-j} + \varepsilon_t. \tag{1}$$

We rely upon the following assumptions:

A1. Let $\phi(z) = 1 - \phi_1 z - \phi_2 z^2 - \cdots - \phi_p z^p$ and $\theta(z) = 1 - \theta_1 z - \theta_2 z^2 - \cdots - \theta_q z^q$, then $\phi(z) \neq 0$ and $\theta(z) \neq 0$ for all $z \in \mathbb{C}$ such that $|z| \leq 1$ and they do not share common roots. Moreover, $\{X_t\}$ is ergodic and invertible both under H_0 and under H_1.

A2. ε_t has a continuous and strictly positive density f on the real line and $E\left[\varepsilon_t^4\right]$ is finite.

A3. The density f of ε_t is absolutely continuous with derivative f' and $\int \left(f'(x)/f(x)\right)^2 f(x)\,dx < \infty$.

The Gaussian log-likelihood, conditional on the initial values $X_0, X_{-1}, \ldots$, is given by

$$\ell_n(\eta, r) = -\frac{n}{2}\ln(\sigma^2 2\pi) - \frac{1}{2\sigma^2}\sum_{t=1}^{n} \varepsilon_t^2(\eta, r)$$

$$\varepsilon_t(\eta, r) = X_t - \left\{ \phi_0 + \sum_{i=1}^{p} \phi_i X_{t-i} - \sum_{j=1}^{q} \theta_j \varepsilon_{t-j}(\eta, r) \right\} - \left\{ \varphi_0 + \sum_{i=1}^{p} \varphi_i X_{t-i} - \sum_{j=1}^{q} \vartheta_j \varepsilon_{t-j}(\eta, r) \right\} I_r\left(X_{t-d}\right)$$

and the q initial values are set to zero. Consider the following first and second partial derivatives of $\ell_n(\eta, r)$:

$$\frac{\partial \ell_n(\eta, r)}{\partial \eta_2} = -\frac{1}{\sigma^2}\sum_{t=1}^{n} \varepsilon_t(\eta, r)\frac{\partial \varepsilon_t(\eta, r)}{\partial \eta_2};$$

$$\mathscr{I}_n(\eta, r) = \begin{pmatrix} \mathscr{I}_{n,11}(\eta) & \mathscr{I}_{n,12}(\eta, r) \\ \mathscr{I}_{n,21}(\eta, r) & \mathscr{I}_{n,22}(\eta, r) \end{pmatrix} = \begin{pmatrix} -\frac{\partial^2 \ell_n(\eta, r)}{\partial \eta_1 \partial \eta_1^\intercal} & -\frac{\partial^2 \ell_n(\eta, r)}{\partial \eta_1 \partial \eta_2^\intercal} \\ -\frac{\partial^2 \ell_n(\eta, r)}{\partial \eta_2 \partial \eta_1^\intercal} & -\frac{\partial^2 \ell_n(\eta, r)}{\partial \eta_2 \partial \eta_2^\intercal} \end{pmatrix}.$$

We write $\partial\hat{\ell}_n(r)/\partial\eta_2$ and $\hat{\mathscr{I}}_n(r)$ to refer to $\partial\ell_n(\eta,r)/\partial\eta_2$ and $\mathscr{I}_n(\eta,r)$ evaluated at the restricted maximum likelihood estimator of η. The test statistic is:

$$T_n = \sup_{r\in[r_L,r_U]} T_n(r), \tag{2}$$

where

$$T_n(r) = \left(\frac{\partial\hat{\ell}_n(r)}{\partial\eta_2}\right)^{\intercal}\left(\hat{\mathscr{I}}_{n,22}(r) - \hat{\mathscr{I}}_{n,21}(r)\hat{\mathscr{I}}_{n,11}^{-1}\hat{\mathscr{I}}_{n,12}(r)\right)^{-1}\frac{\partial\hat{\ell}_n(r)}{\partial\eta_2}.$$

Both under H_0 and H_1, the asymptotic distribution of T_n is a functional of a Gaussian process. Hence, define $\{\xi(r),\ r\in\mathbb{R}\}$ to be a centered Gaussian process with covariance kernel

$$\Sigma(r_1,r_2) = \Lambda_{22}(r_1\wedge r_2) - \Lambda_{21}(r_1)\Lambda_{11}^{-1}\Lambda_{12}(r_2),$$
$$\text{where } \Lambda_{ij}(r) = E\left[\frac{1}{\sigma_0^2}\left(\frac{\partial\varepsilon_t(\eta_0,r)}{\partial\eta_i}\right)\left(\frac{\partial\varepsilon_t(\eta_0,r)}{\partial\eta_j}\right)^{\intercal}\right].$$

In order to assess the behaviour of the test under the alternative hypothesis, let $\mathbf{h} = \left(h_{10},h_{11},\cdots,h_{1p},h_{21},\cdots,h_{2q}\right)^{\intercal}\in\mathbb{R}^{p+q+1}$ be a vector of constants and r_0 a fixed scalar; we consider the sequence of alternatives $H_{1,n}$ specifying that X_t satisfies the following difference equation:

$$X_t = \phi_{0,0} + \sum_{i=1}^{p}\phi_{0,i}X_{t-i} - \sum_{j=1}^{q}\theta_{0,j}\varepsilon_{t-j} + \varepsilon_t + \left[\frac{h_{10}}{\sqrt{n}} + \sum_{i=1}^{p}\frac{h_{1i}}{\sqrt{n}}X_{t-i} - \sum_{j=1}^{q}\frac{h_{2j}}{\sqrt{n}}\varepsilon_{t-j}\right]I_{r_0}(X_{t-d}).$$

The next theorem contains the main results.

Theorem 1. *Let $\{\xi(r),\ r\in\mathbb{R}\}$ be defined as above. Then it holds that:*

(i) under H_0 and Assumptions A1 and A2, T_n converges weakly to

$$\sup_{r\in[r_L,r_U]}\xi(r)^{\intercal}\left(\Lambda_{22}(r) - \Lambda_{21}(r)\Lambda_{11}^{-1}\Lambda_{12}(r)\right)^{-1}\xi(r).$$

(ii) under $H_{1,n}$ and Assumptions A1 – A3, T_n converges weakly to

$$\sup_{r\in[r_L,r_U]}(\xi_r+\gamma_r)^{\intercal}\left(\Lambda_{22}(r) - \Lambda_{21}(r)\Lambda_{11}^{-1}\Lambda_{12}(r)\right)^{-1}(\xi_r+\gamma_r),$$

where $\gamma_r = \left\{\Lambda_{22}(\min\{r,r_0\}) - \Lambda_{21}(r)\Lambda_{11}^{-1}\Lambda_{12}(r_0)\right\}\mathbf{h}$.

(iii) under $H_{1,n}$ and Assumptions A1 – A3, as $\|\mathbf{h}\|\to\infty$, the test statistic T_n has power approaching 100%.

3 Finite sample behaviour in presence of heteroskedasticity

In this section, we study the finite sample performance of the sLM* test in presence of GARCH innovations. The length of the series is $n = 100, 200, 500$ and z_t, $t = 1, \ldots, n$ is generated from a standard Gaussian white noise. The nominal size of the test is $\alpha = 5\%$ and the number of Monte Carlo replications is 1000. The critical values of the test are taken from [1] and the threshold is searched from percentile 25th to 75th of the sample distribution. We simulate from the following ARMA$(1,1)$-GARCH$(1,1)$ model:

$$\begin{aligned} X_t &= \phi_1 X_{t-1} + \theta_1 \varepsilon_{t-1} + \varepsilon_t. \\ \varepsilon_t &= (a_0 + a_1 \varepsilon_{t-1}^2 + b_1 h_{t-1})^{1/2} z_t. \end{aligned} \tag{3}$$

where $\phi_1 = (-0.8, -0.4, 0, 0.4, 0.8)$ and $\theta_1 = (-0.5, 0.0, 0.5)$. We combine these with the following parameters for the GARCH specification: $(1,0,0)$ (case A), $(a_0, a_1, b_1) = (1, 0.1, 0.8)$ (case B), $(1, 0.8, 0.1)$ (case C), so as to obtain 15 different parameterizations. Note that Case A corresponds to the case of *i.i.d.* errors (no GARCH effect) and is taken as a reference. The results are presented in Table 1. Clearly, when the errors are *i.i.d.* (Case A), the size of the test converges to the correct nominal 5% size as the sample size increases. However, in presence of GARCH-type errors this is not the case. In particular, for Case C, the size bias gets worse with increasing sample sizes.

Table 1 Empirical size at nominal level $\alpha = 5\%$ for the ARMA(1,1)-GARCH(1,1) process of Eq. (3) for sample sizes 100, 200, 500. The Case A corresponds to a ARMA(1,1) with *i.i.d.* errors.

4 Conclusions

The results of the simulation study clearly show that disregarding the heteroskedasticity can produce a substantial bias in the size of tests for threshold effects in time series. Different remedies to this problem can be adopted. A first, naive, option would be to perform a preliminary test for the presence of (conditional) heteroskedasticity prior to testing for threshold effects. Obviously, this is a suboptimal solution since the overall significance level of the tests should be adjusted, which is most likely unfeasible since there are no available results on the dependence between the relevant statistics. A second approach would be to adopt a bootstrap scheme that is robust against heteroskedasticity, such as the wild bootstrap. Unfortunately, as also discussed in [8], there are major technical difficulties with proving the validity of the wild bootstrap in this framework. A third, more natural, approach would be to include the GARCH terms directly in the specification of the auxiliary model associated to the supLM statistic of Eq. (2). This latter approach is the subject of ongoing investigations [2].

The Conditional Autoregressive Wishart-$\mathscr{G}$ Model

Il Modello Wishart-$\mathscr{G}$ Autoregressivo Condizionale

Massimiliano Caporin and Marco Girardi

Abstract We propose a new distribution for modelling realised covariances of financial assets, obtained as the product of a scalar component distributed as a unit-mean inverse gamma and a matrix component following a Wishart distribution. We adopt an autoregressive moving average structure for the expected value of the resulting distribution. The aim of the model is to capture a common factor within the assets and to separate it from the *idiosyncratic* conditional covariance dynamic.

Abstract *Proponiamo una distribuzione innovativa per modellare la covarianza realizzata di strumenti finanziari, ottenuta come prodotto di una componente scalare con distribuzione gamma inversa a media unitaria e una componente matriciale che segue una distribuzione Wishart. Utilizziamo una struttuta autoregressiva a media mobile per il valore atteso della distribuzione risultante. Il fine del modello è di identificare un fattore comune tra gli asset e di separarlo dalla dinamica della covarianza condizionata idiosincratica.*

Key words: conditional autoregressive model, realised covariance, common factor, portfolio allocation, index tracking

1 Introduction

Conventional approaches for multivariate modelling and forecasting of covariances of asset returns are based on low-frequency data and model matrices either given past observations, such as multivariate GARCH models [1], or treat them as an un-

observed stochastic process, such as multivariate stochastic volatility models [6]. More recently, realised measures from high-frequency data have proven to be a valuable tool in this field. A renowned approach is the Conditional Autoregressive Wishart (CAW) model by [3], generalising the Wishart Autoregressive (WAR) model by [4] with an autoregressive moving average structure for the mean of the Wishart distribution, allowing both lagged covariance matrices and lagged predictions of the covariance to contribute to the prediction.

In this work we propose a novel multivariate distribution for realised covariance modelling and forecasting, obtained as the product of a Wishart distribution and a scalar component following a unit-mean inverse gamma. The resulting distribution allows to identify a common factor of risk amongst the assets that can be removed to focus the attention on the residuals, which we refer to as the *idiosyncratic covariance dynamic*. The common factor is initially modelled as the conditional mean of a Multiplicative Error Model (MEM), and then realised covariances are filtered from this mutual element and endowed with a CAW-like structure for prediction. The model accounts for symmetry and positive definiteness of the covariance matrices and is estimated by maximum likelihood.

2 The $\mathscr{G}$ density

Let X be a unitary-mean inverse gamma random variable with shape parameter $-\alpha$ and $\mathbf{Y}$ be a Wishart random variable with n degrees of freedom and scale matrix C/n, that is

$$f_X(x) = \frac{x^{\alpha-1}}{(-\alpha-1)^{\alpha}\Gamma(-\alpha)} \exp\left(\frac{\alpha+1}{x}\right), -\alpha, x > 0, \tag{1}$$

and

$$f_{\mathbf{Y}}(\mathbf{y}) = \frac{(n/2)^{nm/2} \mid \mathbf{y} \mid^{(n-m-1)/2} \exp(-\frac{n}{2} Tr(C^{-1}\mathbf{y}))}{h(n,m) \mid C \mid^{n/2}}, \tag{2}$$

where m is the dimension of $\mathbf{Y}$ and $h(n,m) = \pi^{m(m-1)/4} \prod_{j=1}^{m} \Gamma(n/2 + (1-j)/2)$. The densities of $\mathbf{\Omega} = X\mathbf{Y}$ and $\mathbf{Z} = \delta\mathbf{\Omega}$, where δ is a scalar, are provided by Theorem 1 and Corollary 1, respectively.

Theorem 1. *Let X be a unitary-mean inverse gamma random variable and $\mathbf{Y}$ be a Wishart random variable with n degrees of freedom and scale matrix C/n, then $\mathbf{\Omega} = X\mathbf{Y}$ follows a $\mathscr{G}(\alpha, C, n)$ density, that is,*

$$f_{\mathbf{\Omega}}(\boldsymbol{\omega}) = \frac{(n/2)^{nm/2} \mid \boldsymbol{\omega} \mid^{(n-m-1)/2} \Gamma(nm/2 - \alpha)}{h(n,m) \mid C \mid^{n/2} (-\alpha-1)^{\alpha}\Gamma(-\alpha)} \times \\ \times \left(\frac{n}{2} Tr(C^{-1}\boldsymbol{\omega}) - (\alpha+1)\right)^{\alpha - nm/2}. \tag{3}$$

Proof. The density of $\mathbf{\Omega}$ is given by

$$f_{\mathbf{\Omega}}(\boldsymbol{\omega}) = \int_{R_+} f_{x\mathbf{Y}}(\boldsymbol{\omega}) f_X(x)\,\mathrm{d}x, \tag{4}$$

where the scale transformation $x\mathbf{Y}$ follows a Wishart with expected value xC. Thus, Eq. 4 becomes

$$\begin{aligned} f_{\mathbf{\Omega}}(\boldsymbol{\omega}) = & \frac{(n/2)^{nm/2} \mid \boldsymbol{\omega} \mid^{(n-m-1)/2}}{h(n,m) \mid C \mid^{n/2} (-\alpha-1)^{\alpha}\Gamma(-\alpha)} \times \\ & \times \int_{R_+} x^{\alpha-1-nm/2} \exp\Big(x^{-1}\Big(-\frac{n}{2}Tr(C^{-1}\boldsymbol{\omega}) + (\alpha+1)\Big)\Big)\,\mathrm{d}x. \end{aligned} \tag{5}$$

The solution of this kind of integral is provided by [5] in section 3.326 at page 337. Integrating Eq. 5 by substitution using $x = y^{-1}$, we get

$$\begin{aligned} f_{\mathbf{\Omega}}(\boldsymbol{\omega}) = & \frac{(n/2)^{nm/2} \mid \boldsymbol{\omega} \mid^{(n-m-1)/2} \Gamma(nm/2-\alpha)}{h(n,m) \mid C \mid^{n/2} (-\alpha-1)^{\alpha}\Gamma(-\alpha)} \times \\ & \times \Big(\frac{n}{2}Tr(C^{-1}\boldsymbol{\omega}) - (\alpha+1)\Big)^{\alpha-nm/2}, \end{aligned} \tag{6}$$

which is a $\mathscr{G}(\alpha, C, n)$ density. □

Corollary 1. *Let $\mathbf{\Omega} \sim \mathscr{G}(\alpha, C, n)$ and δ be a scaling factor, then $\delta\mathbf{\Omega} \sim \mathscr{G}(\alpha, \delta C, n)$.*

Proof. Let $\mathbf{Y} \sim W(C,n)$, where C is the expected value of $\mathbf{Y}$, and A is a square matrix of dimension m, then $A\mathbf{Y}A' \sim W(ACA', n)$. If we apply the scale transformation δ to the Wishart density $\mathbf{Y}$, and we define $A = diag(a_1, \ldots, a_m)$ with $a_i = \sqrt{\delta}$, $i = 1, \ldots, m$, then $\delta\mathbf{Y} = A\mathbf{Y}A' \sim W(\delta C, n)$, and, by Theorem 1, the density of $\mathbf{Z} = \delta\mathbf{\Omega}$ is

$$\begin{aligned} f_{\mathbf{Z}}(\mathbf{z}) = & \frac{(n/2)^{nm/2} \mid \mathbf{z} \mid^{(n-m-1)/2} \Gamma(nm/2-\alpha)}{h(n,m) \mid \delta C \mid^{n/2} (-\alpha-1)^{\alpha}\Gamma(-\alpha)} \times \\ & \times \Big(\frac{n}{2}Tr\big((\delta C)^{-1}\mathbf{z}\big) - (\alpha+1)\Big)^{\alpha-nm/2}, \end{aligned} \tag{7}$$

which is a $\mathscr{G}(\alpha, \delta C, n)$ density. □

2.1 Dynamics of δ_t

The aim of this item is to extract a common factor amongst the securities, so the first step is to define how to model the elements of the covariance matrix in a way that allows to sort mutual and specific components. If we denote with $v_{ij,t}$ the generic ij element of the realised covariance matrix, we can express it with a multiplicative

model $v_{ij,t} = \lambda_t \sigma_{ij,t}$, where λ_t is a common factor for the elements in the matrix while $\sigma_{ij,t}$ is an element-specific factor assuming either positive or negative values. Then, the estimate of λ_t is

$$\tilde{\lambda}_t = \left(\prod_{ij \in \mathbf{S}} | v_{ij,t} | \right)^{\frac{2}{m(m+1)}}, \tag{8}$$

where $\mathbf{S}$ is the set of ij combinations of the elements in the lower triangular part of the realised covariance matrix, including the elements on the main diagonal. The scalar δ_t is modelled as the conditional mean of the Multiplicative Error Model (MEM) by [2], using $\zeta_t = T\tilde{\lambda}_t / \sum_{i=1}^{T} \tilde{\lambda}_i$ as source of information to ensure $\mathbb{E}[\delta_t] = 1$, that is

$$\delta_t = (1 - \theta_1 - \theta_2) + \theta_1 \delta_{t-1} + \theta_2 \zeta_{t-1}. \tag{9}$$

According to [7], the parameters of Eq. 9 can be estimated with a GARCH software by taking $\sqrt{\zeta}$ as dependent variable and setting the mean to zero.

2.2 Dynamic of C_t

The conditional mean of $\mathbf{Y}$ is endowed with an autoregressive moving average process resembling the CAW model by [3]. This model allows the predicted covariance matrix to depend on lagged covariance matrices as well as on their lagged predictions. A CAW of order (p,q) expresses C_t as

$$C_t = \mathbf{C}\mathbf{C}' + \sum_{i=1}^{p} \mathbf{A}_i C_{t-i} \mathbf{A}_i' + \sum_{j=1}^{q} \mathbf{B}_j \mathbf{Z}_{t-j} \mathbf{B}_j', \tag{10}$$

where $\mathbf{C}$ is a lower-triangular matrix, and $\mathbf{A}_i, \mathbf{B}_i$ are parameter matrices. The structure guarantees the symmetry and positive definiteness of the conditional mean C_t without imposing parametric restrictions on $(\mathbf{C}, \mathbf{A}_i, \mathbf{B}_i)$. In order to limit the number of parameters being estimated, $\mathbf{A}_i$ and $\mathbf{B}_i$ can be defined as diagonal matrices, and the intercept can be expressed as a function of the model long-run covariance obtained as follows. Let vec$(\cdot)$ denote the operator that stacks all columns of a matrix into a vector, and let vech$(\cdot)$ and ivech$(\cdot)$ denote respectively the operator that stacks the lower triangular portion (including the diagonal) of a matrix into a vector and the one reversing this operation. Then, the vector representation of the CAW (p,q) is

$$c_t = c + \sum_{i=1}^{p} \mathscr{A}_i c_{t-i} + \sum_{j=1}^{q} \mathscr{B}_j z_{t-j}, \tag{11}$$

where $c_t = vech(C_t)$, $z_t = vech(\mathbf{Z}_t)$, $c = vech(\mathbf{C}\mathbf{C}')$, and $(\mathscr{A}_i, \mathscr{B}_j)$ are $k \times k$ matrices, with $k = m(m+1)/2$, obtained as

$$\mathscr{A}_i = L_m (\mathbf{A}_i \otimes \mathbf{A}_i) D_m, \quad \mathscr{B}_j = L_m (\mathbf{B}_j \otimes \mathbf{B}_j) D_m, \tag{12}$$

where L_m and D_m denote the elimination and duplication matrices such that $vec(X) = D_m vech(X)$ and $vech(X) = L_m vec(X)$. The unconditional mean is given by

$$\mathbb{E}[z_t] = \left(I_k - \sum_{i=1}^{max(p,q)} (\mathscr{A}_i + \mathscr{B}_i) \right)^{-1} c, \tag{13}$$

and the covariance targeting variant is therefore

$$C_t = \tilde{c} + \sum_{i=1}^{p} \mathbf{A}_i C_{t-i} \mathbf{A}_i' + \sum_{j=1}^{q} \mathbf{B}_j \mathbf{Z}_{t-j} \mathbf{B}_j', \tag{14}$$

where $\tilde{c} = ivech(c)$. We adopt an analogous approach for modelling the conditional mean of $\mathbf{Y}$, using diagonal parameter matrices with $p = 1$, $q = 1$ and covariance targeting. Additionally, $\mathbf{Z}_{t-1}$ is replaced by $\mathbf{Z}_{t-1}/\zeta_{t-1}$, since realised covariances are filtered by the terms used for the common factor estimation. The parameters in Eq. 14 are estimated by maximum likelihood.

3 Empirical Analysis

We use high-frequency data at 1-minute level (390 daily observations) of the 26 assets of the Dow Jones Industrial Average (DJIA) which have always been included in the index in the period of analysis. The realised covariance matrices are computed as $RCOV_t = \sum_{i=1}^{I} r_{t,i} r_{t,i}'$, where $r_{t,i}$ is the vector of percentage log-returns for the i-th 1-minute interval of the t-th trading day. The sample period is 2 January 2003 to 24 June 2020 with a total of 4400 trading days.

We want to show that δ_t can be seen as a proxy for market variance, so we fit the model to the full sample of daily realised covariances and compare the results with the DJIA variance, computed with an EGARCH(1,1), and realised variance. The correlation of the common factor with the DJIA variance is above 0.9, meaning that δ_t well represents market movements. This close relation is also shown in Fig. 1 where δ_t is plotted with the DJIA realised variance (rescaled for comparison, since δ_t is constructed to have unit-mean).

Another way of displaying the crucial role of δ_t is to focus on its relevance within the conditional mean. Fluctuations in the covariance matrix are mostly captured by the common factor, which promptly adapts to sudden market changes, while residual movements are explained by the elements in C_t. This is clearly observable in periods marked by extreme instability such as the 2008 financial crises and the recent pandemic. When considering the median value of the off-diagonal elements of $RCOV_t$ and C_t, it can be noticed that C_t has a marginal effect on the overall conditional mean $\delta_t C_t$, having a correlation of just 0.02 with the median of the off-diagonal elements of realised covariances as well as of conditional means.

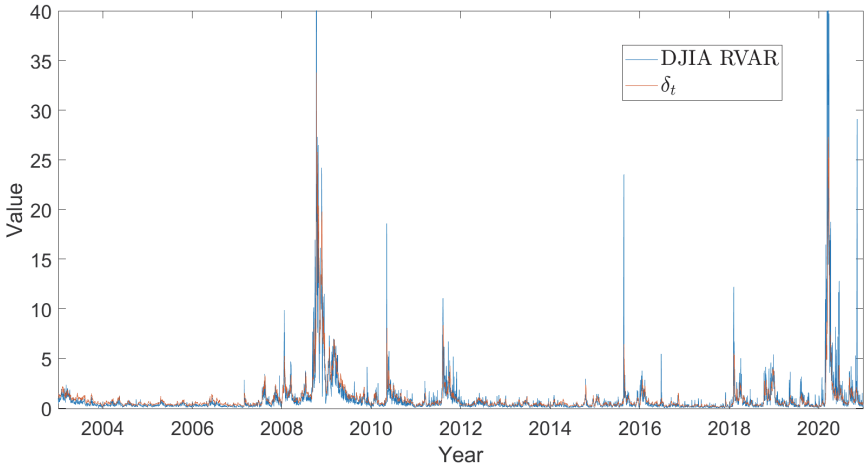

Fig. 1 Common factor and DJIA realised variance

4 Conclusions

In this work we propose a conditional autoregressive model for realised covariances using a novel distribution that identifies a common factor among the assets with the remarkable property of accurately tracking market variability. The model can be exploited to isolate the effect of the common factor and operate on the remaining component only for asset allocation applications, for instance in market risk tracking and hedging.

Semi-parametric generalized linear mixed effects models for binary response for the analysis of heart failure hospitalizations

Modelli lineari generalizzati ad effetti misti semi-parametrici per risposta binaria per l'analisi di ospedalizzazioni per scompenso cardiaco

Alessandra Ragni, Chiara Masci, Francesca Ieva, Anna Maria Paganoni

Abstract In this work, we propose a semi-parametric mixed effects model for binary response with an Expectation Maximization (EM) algorithm for the parameters estimation and we apply it to an administrative database of Lombardy Region (Italy) related to patients hospitalised for hearth failure between 2000 and 2012 within different hospitals. The semi-parametric assumption provides the random effects of the model to be distributed according to a discrete distribution with an (a priori) unknown number of support points, inducing an automatic clustering of the higher level units (in our application, hospitals). This modelling induces hospitals within the same cluster to share the same random effects.

Abstract *In questo lavoro, proponiamo un modello ad effetti misti semi-parametrico con risposta binaria, con un algorithmo con tecnica EM per la stima dei parametri e lo applichiamo ad un dataset amministrativo della Regione Lombardia (Italia), relativo ad ospedalizzati per scompenso cardiaco tra il 2000 e il 2012 in diversi ospedali. La semi-parametricità risiede nell'assunzione di una distribuzione discreta degli effetti random del modello, con un numero (a priori) sconosciuto di punti di supporto, inducendo così un clustering delle osservazioni relative al livello più alto della gerarchia (nella nostra applicazione, gli ospedali). Con tale modello, gli ospedali nello stesso cluster condividono lo stesso effetto random.*

1 Introduction

In this work, we intend to propose an innovative model called *Semi-Parametric Generalized Linear Mixed-effect Model* (SPGLMM), aiming at identifying sub-populations inside a hierarchical data structure, where groups within the same sub-population share the same random effect.

More in details, a clustering of the groups at the highest level of hierarchy is automatically performed by the algorithm by assuming the random effects of the Generalized Linear Mixed effects Model (GLMM) to be distributed as a discrete distribution with an a-priori unknown number of support points, creating an association between the group and the sub-population to which it belongs to; this is the novelty of the SPGLMM and in such assumption lies the non-parametricity of the algorithm. Semi-parametric mixed-effects models have been already proposed in the literature, but only for continuous and multinomial responses [1, 2]. SPGLMM generalizes this approach for binary and other responses in the exponential family (such as Poisson,...). A suitable Expectation Maximization (EM) algorithm for the parameters estimation is provided and, in order to test the proposed method, different simulations are performed.

In addition, an application to a real data case is presented. We apply SPGLMM to data retrieved from the administrative databases of Lombardy Region (Italy), related to patients hospitalized for Heart Failure (HF) between 2000 and 2012 [3, 4]. HF is a major and growing public health issue, characterized by high costs, steep morbidity and mortality rates [5]. Despite the advances in the understanding the pathophysiology of chronic HF and the improvement of therapy, HF mortality and morbidity rates remain high [6]. The analysis focuses on discovering sub-populations of hospitals which differently affect patients hospitalizations, with the aim of getting insights on the effects the different hospitals treatments have on the HF patients.

2 Semi-parametric generalized linear mixed effect model

Given $i = 1,...,N$ groups, GLMMs are generally defined such that, conditioned on the random effects $\mathbf{b_i}$ in the i^{th} group, the dependent variable $\mathbf{y_i}$ (n_i-dimensional vector) in the i^{th} group is distributed according to the exponential family with its expectation, being related to the linear predictor $\mathbf{X_i}\beta + \mathbf{Z_i}\mathbf{b_i}$ via a link function $g(\cdot)$:

$$g(E[\mathbf{y_i}|\mathbf{b_i}]) = \mathbf{X_i}\beta + \mathbf{Z_i}\mathbf{b_i} \quad \text{for} \quad i = 1,...,N$$

where $\mathbf{X_i}$ and $\mathbf{Z_i}$ are, respectively, the $[n_i \times (P+1)]$ and $[n_i \times (Q+1)]$ matrices of fixed and random covariates in the i^{th} group; β is the $(P+1)$-dimensional vector of fixed coefficients and $\mathbf{b_i}$ the $(Q+1)$-dimensional vector of random coefficients in the i^{th} group.

In the parametric framework, the random coefficients $\mathbf{b}$ are assumed to be normally distributed: $\mathbf{b} \sim N(\mathbf{0}, \Sigma_{\mathbf{b}})$.

In our semi-parametric approach, we assume $\mathbf{b}$ to follow a discrete distribution, called P^*, with an a-priori unknown number of support points. More in details, P^* is a discrete distribution with M support points $(\mathbf{c_1}, ..., \mathbf{c_M})$ for $M \leq N$, where each $\mathbf{c_l} \in \mathbb{R}^{Q+1}$, $l = 1, ..., M$, corresponds to the l^{th} subpopulation. The number of discrete masses M is not chosen a-priori, but it is estimated together with the other parameters of the model. The interpretation is that each group i ($i = 1, ..., N$) is assigned with a certain probability w_l to a sub-population l with parameter values $\mathbf{c_l}$ allowing to identify a latent structure among the groups. The distribution of the random effect coefficient $\mathbf{b_i}$ is the following:

$$\mathbf{b_i} = \begin{cases} \mathbf{c_1} & p(\mathbf{b_i} = \mathbf{c_1}) = w_1 \\ ... & \\ \mathbf{c_M} & p(\mathbf{b_i} = \mathbf{c_M}) = w_M \end{cases} \qquad \sum_{l=1}^{M} w_l = 1, \qquad w_l \geq 0$$

3 The EM algorithm for SPGLMM

The algorithm is inspired by the one proposed in *Azzimonti et al. (2013)*[7] and consists in the computation of the *expected log likelihood* and its maximization with respect first to random effects and then to fixed effects, in an iterative framework. More in details, the maximization of the following quantity is performed:

$$(\beta^{up}, \mathbf{c_1}^{up}, ..., \mathbf{c_M}^{up}) = \underset{\beta, \mathbf{c_l}}{\operatorname{argmax}} \sum_{i=1}^{N} \sum_{l=1}^{M} \mathbf{W_{il}} logL(\beta, \mathbf{c_l} | \mathbf{y_i})$$

where $L(\beta, \mathbf{c_l} | \mathbf{y_i}) = p(\mathbf{y_i} | \beta, \mathbf{c_l}) = \prod_{j=1}^{n_i} f(\mathbf{y_{ij}}, g(E[\mathbf{y_{ij}} | \mathbf{c_l}])$, being $f(\cdot)$ the density function of the response, and $\mathbf{W_{il}} = \frac{w_l p(\mathbf{y_i} | \beta, \mathbf{c_l})}{\sum_{k=1}^{M} w_k p(\mathbf{y} | \beta, \mathbf{c_k})} = \frac{p(\mathbf{b_i} = \mathbf{c_l}) p(\mathbf{y_i} | \beta, \mathbf{c_l})}{p(\mathbf{y_i} | \beta)} = p(\mathbf{b_i} = \mathbf{c_l} | \mathbf{y_i}, \beta)$.

It is possible to divide the maximization in two substeps:

1. Computation of $\mathbf{c_l}^{up}$, given β computed at previous iteration, as

$$\mathbf{c_l}^{up} = \underset{\mathbf{c_l}}{\operatorname{argmax}} \sum_{i=1}^{N} \mathbf{W_{il}} logL(\beta, \mathbf{c_l} | \mathbf{y_i}) \quad \text{for} \quad l = 1, ..., M$$

2. Computation of β^{up}, given $\mathbf{c_l}$ computed at the previous step, as

$$\beta^{up} = \underset{\beta}{\operatorname{argmax}} \sum_{i=1}^{N} \sum_{l=1}^{M} \mathbf{W_{il}} logL(\beta, \mathbf{c_l} | \mathbf{y_i})$$

The weights can be updated as $w_l^{up} = \frac{\sum_{i=1}^{N} \mathbf{W_{il}}}{N}$, which corresponds to the sample mean over the N groups of the l^{th} population; therefore, the estimation of the coefficients $\mathbf{b_i}$ of the random effects for each group is obtained as follows:

$$\tilde{\mathbf{b}}_\mathbf{i} = \mathbf{c}_{\tilde{\mathbf{l}}} \quad \text{where} \quad \tilde{l} = \underset{l}{\text{argmax}}\, \mathbf{W}_{\mathbf{il}} \text{ for } i = 1, ..., N$$

Finally, the support reduction of the discrete distribution stands on two criteria:

- two points $\mathbf{c_l}$ and $\mathbf{c_k}$ closer than a fixed threshold D collapse to a unique point $\mathbf{c}_{\mathbf{l,k}} = \frac{\mathbf{c_l}+\mathbf{c_k}}{2}$ with weight $w_{l,k} = w_l + w_k$;
- points with a weight w lower than a fixed threshold $\tilde{w}$ or not associated to any subpopulation are removed; when one or more mass points are deleted, the remaining weights are reparametrized in such a way that they sum up to 1.

4 SPGLMM for binary response and simulation study

In the simulation and in the case study, we focus on the case of a binary response variable. In such family of models, the link function $g(\cdot)$ is assumed to be the *logit* link. If we assume the random coefficients $\mathbf{b}$ to follow the discrete distribution P^* described in Section 2, the SPGLMM formulation for observation j in group i is the following:

$y_{ij}|\mathbf{c_l} \sim Ber(\pi_{ijl})$ for $i = 1, ..., N$, $j = 1, ..., n_i$ and $\pi_{ijl} = \mathbf{E}[y_{ij}|\mathbf{c_l}] = P(y_{ij} = 1|\mathbf{c_l})$

$$\eta_{ijl} = logit(\pi_{ijl}) = log\Big(\frac{\pi_{ijl}}{1-\pi_{ijl}}\Big) = \sum_{h=1}^{P} x_{ijh}\beta_h + \sum_{k=0}^{Q} z_{ijk}c_{lk}$$

$$p(\mathbf{y_i}|\beta, \mathbf{c_l}) = \prod_{j=1}^{n_i} \frac{exp\{y_{ij}\eta_{ijl}\}}{1+exp\{\eta_{ijl}\}} \quad \text{and} \quad L(\beta, \mathbf{c_1}, ..., \mathbf{c_M}|\mathbf{y}) = \sum_{l=1}^{M} w_l \prod_{i=1}^{N} p(\mathbf{y_i}|\beta, \mathbf{c_l}).$$

To validate the estimation algorithm proposed, we perform a simulation study: we consider $I = 10$ groups of data, where each group contains $n_{i=1,...,I} \sim U(70, 100)$ and we induce the presence of three subpopulations. We implement three different Data Generating Processes (DGP) each of them based on models including one fixed covariate $\mathbf{x_i} \sim N(\mathbf{0}, \mathbb{1}_{n_i})$, with the following differences: DGP A based on a **model A** having both random intercept and random covariate, DGP B based on a **model B** having only a random covariate, DGP C based on a **model C** having only a random intercept. The random covariate, when present, is distributed as $\mathbf{z_i} \sim N(\mathbf{0}, \mathbb{1}_{n_i})$. Table 1 reports the mathematical formulation of the three models. The thresholds D and $\tilde{w}$, described at the end of Section 3, are set to 1 and 0.05, respectively. Table 2 shows, for each of the three models, the coefficients (fixed and random) simulated and estimated by the algorithm, respectively in the upper and lower part of the table, in 100 runs of the algorithm.

model A	**model B**	**model C**
$\begin{cases} \eta_i = c_{01} + c_{11}\mathbf{z_i} + \beta_0\mathbf{x_i} & i=1,2 \\ \eta_i = c_{02} + c_{12}\mathbf{z_i} + \beta_0\mathbf{x_i} & i=3,...,7 \\ \eta_i = c_{03} + c_{13}\mathbf{z_i} + \beta_0\mathbf{x_i} & i=8,9,10 \end{cases}$	$\begin{cases} \eta_i = \beta_0 + c_{01}\mathbf{z_i} + \beta_1\mathbf{x_i} & i=1,2 \\ \eta_i = \beta_0 + c_{02}\mathbf{z_i} + \beta_1\mathbf{x_i} & i=3,...,7 \\ \eta_i = \beta_0 + c_{03}\mathbf{z_i} + \beta_1\mathbf{x_i} & i=8,9,10 \end{cases}$	$\begin{cases} \eta_i = c_{01} + \beta_0\mathbf{x_i} & i=1,2 \\ \eta_i = c_{02} + \beta_0\mathbf{x_i} & i=3,...,7 \\ \eta_i = c_{03} + \beta_0\mathbf{x_i} & i=8,9,10 \end{cases}$

Table 1 The three simulated models: A, B and C.

	model A			model B			model C	
	$\mathbf{c_0}$	$\mathbf{c_1}$	β_0	β_0	$\mathbf{c_0}$	β_1	$\mathbf{c_0}$	β_0

5 An application to the heart failure hospitalizations in Lombardy Region

Data were supplied by Regione Lombardia (Italy) - Healthcare Division [3] within the research project described in *Mazzali et al.* [4]. Hospital discharge forms with HF-related diagnosis codes were the basis for identifying HF hospitalizations as clinical events, or episodes. In patients experiencing at least one HF event, we selected hospitalizations for causes related to cardiocirculatory pathologies (Clinical Classifications Software for ICD-9-CM codes [8] greater or equal than $'96'$ and less or equal than $'117'$). Moreover, we included in the analysis only patients who didn't leave the study before its end (except for death) and didn't change hospital at different hospitalizations. Our variable of interest is the binary variable that tells us whether a patient had at least a secondary hospitalization in the 365 days after the first one. We selected hospitals that received at least two patients (≥ 2) and in which at least a patient had a secondary hospitalization; this choice was performed because, for each hospital, the SPGLMM requires a logistic regression to be fitted on the fixed covariates of the patients cured in such hospital: both the classes need to be present.

Collected data include 60813 patients (51.54% females, mean$\pm$sd age 75.33 ± 12.06, median age 78, range $18-105$) hospitalized in 218 structures. Each hospital received on average$\pm$sd 278.95 ± 372.33 different patients. We built the model as follows: for each patient, the sex and the normalized number of comorbidities out of the twenty most significant (e.g. dementia, coagulopathy, hypertension, psychosis, arrhythmia,...), recorded at the first hospitalization, were set as fixed covariates; a random intercept for the hospital has been considered. Multiple runs, with different D, were performed.

With $D = 0.2$, the SPGLMM identified six groups with numerosities 27, 113, 1, 12, 57 and 4; in addition, 4 hospitals were not assigned to any of the groups. We report the obtained fixed coefficients and the correspondent p-value computed through likelihood ratio test: $\beta_{\text{Sex}} = -0.2166$ (p-value$= 2.97 \cdot 10^{-22}$), $\beta_{\text{NComorbidities}} = 0.0395$ (p-value$= 4.09 \cdot 10^{-5}$) and random intercept for the six groups:

$$\begin{cases} c_{0i} = -0.7081 & i = 1,...,27 \\ c_{0i} = -0.7605 & i = 28,...,140 \\ c_{0i} = -0.2897 & i = 141 \\ c_{0i} = -2.3994 & i = 142,...,153 \\ c_{0i} = -1.3446 & i = 154,...,210 \\ c_{0i} = -0.7495 & i = 211,...,214 \end{cases}$$

6 Discussion and further developments

The simulation results reported in Section 4 show that the proposed SPGLMM, for different random effects and fixed covariates, well performs in the individuation of the simulated groups. The study shows that the preliminary results obtained by the application of the SPGLMM algorithm to the heart failure hospitalizations, performing a clustering on the hospitals, provide informative insights on their characteristics; such result could in future support decision policies. Different numbers of subpopulations were detected for different thresholds D.

Developments of this work include the analysis of the selection of the best threshold D and other methods for the evaluation of the providers (i.e. sets of hospitals) performances, such as their profiling, outlier detection or the computation of the PVRE (Percentage of Variation due to Random Effects). Further goals also concern the application of SPGLMM to integer outcomes such as a Poisson or a Zero Inflated Poisson where the number of hospitalizations, for a certain patient in a certain amount of time after the first hospitalization, is the response.

Issues in Data science

`etree`: Classification and Regression With Structured and Mixed-Type Data in `R`

`etree`: *Classificazione e Regressione Con Dati Strutturati e Misti in* `R`

Riccardo Giubilei, Tullia Padellini, Pierpaolo Brutti

Abstract As data continue to grow in complexity, so does the need for models and methods that directly account for their non-trivial structure because any simplification may induce loss of information. Energy Trees have been recently proposed following this principle as a unifying and statistically sound framework for classification and regression with structured and mixed-type covariates. In this work, we provide an illustration of `etree`, which is the R package where Energy Trees are implemented. We describe its origin, structure, main function, and other important features, such as methods for plotting and making predictions. The package currently covers functional data and graphs as structured covariates. However, thanks to its modular infrastructure, any other type of variable can be easily included.

Abstract *Con l'aumentare della complessità dei dati, cresce anche la necessità di avere modelli in grado di gestirne la struttura in quanto l'eventuale semplificazione può causare perdita di informazione. Seguendo questo principio, gli Energy Trees sono stati proposti recentemente come framework unificante e statisticamente rigoroso per fare classificazione e regressione con covariate di tipo strutturato e misto. In questo lavoro, presentiamo* `etree`*, ovvero il pacchetto R in cui gli Energy Trees sono implementati. Ne descriviamo le origini, la struttura, la funzione principale, e altre caratteristiche importanti, come ad esempio i metodi per costruire grafici e fare previsioni. Al momento, il pacchetto prevede l'utilizzo di dati funzionali e grafi come covariate strutturate. Tuttavia, grazie alla sua infrastruttura modulare, ogni altro tipo di variabile può essere facilmente integrato.*

1 Introduction

Structured data objects such as functions, graphs, images, or time series are constantly growing in quantity and need of being analyzed. However, arbitrary simplifications, often resulting in loss of information, are usually required to apply standard statistical techniques. Energy Trees are a new statistical learning model that adequately accounts for the possibly non-trivial structure of the variables. More precisely, the model provides a unifying and statistically sound framework for classification and regression with structured and mixed-type data.

Energy Trees are a recursive binary partitioning model with piecewise constant fits. They are built starting from Conditional Trees [3] and replacing standard permutation tests with Energy tests of independence [7] from the Energy Statistics framework [6]. This choice allows for testing the association between variables defined in spaces that are not necessarily Euclidean, and not necessarily equal.

At each step of Energy Trees iterative procedure, an Energy test of independence is performed between the response variable and each of the J covariates. If the test of global independence (defined as the intersection of the J tests of partial independence) is not rejected at the specified significance level, the recursion is stopped; otherwise, the covariate most associated with the response in terms of p-value is selected for splitting. When the covariate is traditional, an Energy test of independence is performed for each possible split point, and the one yielding the strongest association with the response is chosen. When the selected covariate is structured, Energy Trees provide two alternative strategies: 1) transform the structured selected variable into Euclidean vectors through coefficient expansion, and then apply any splitting technique that works with numerical variables; 2) use distance-based clustering methods such as Partitioning Around Medoids (PAM) [5].

Energy Trees are implemented in R package `etree`, which is publicly available at `https://github.com/ricgbl/etree`. In this work, we briefly describe `etree`'s origin, structure, main function, and other important characteristics. Finally, we draw some concluding remarks and sketch directions for future work.

2 Package overview

R package `etree` is built upon `partykit` [4], which is the package where Conditional Trees are implemented. The new package attempts to follow `partykit` design principles, exploiting the rich and flexible infrastructure for objects of class `"constparty"`. However, Energy Trees are designed to work with structured and mixed-type variables, hence their implementation requires more flexibility and some further adjustments. First, the fundamental data structure is generalized from the `data.frame`s used in `partykit` to `list`s. A new class of objects, `"etree"`, allows defining characteristic methods. Energy tests of independence substitute permutation tests, and both splitting strategies are implemented. Additionally, specific handling is provided for each type of covariate considered in the package. The es-

sential exported functions are three: etree() (the main function), plot(), and predict(). The package also features about two dozens original internal functions and several modified versions of partykit internal functions.

The current version of etree covers functional data and graphs as structured covariates. However, thanks to a well-established and modular infrastructure, almost any other case can be easily implemented.

3 Main function

The main function in R package etree is the homonym etree(), which allows fitting an Energy Tree by simply specifying the response variable, the set of covariates, and possibly some other parameters. The function is specified in the same way regardless of the task type: the choice between classification and regression is automatically made depending on the nature of the response variable.

The function etree() is defined through the following call, where default values for arguments that admit one are included:

```
etree <- function(response,
                  covariates,
                  weights = NULL,
                  minbucket = 5,
                  alpha = 0.05,
                  R = 1000,
                  split_type = 'coeff',
                  coeff_split_type = 'test',
                  p_adjust_method = 'fdr')
```

The arguments of etree() can be shortly explained as follows:

- response: response variable, an object of class "factor" or "numeric" (for classification and regression, respectively);
- covariates: set of covariates, in the form of a list where each element is a different variable;
- weights: optional numeric vector of case weights;
- minbucket: minimum number of observations that each terminal node must contain;
- alpha: nominal level controlling the probability of type I error in the Energy tests of independence used for variable selection;
- R: number of replicates in every Energy test of independence;
- split_type: splitting method used when the selected variable is structured. Either "coeff" for coefficient expansion, or "cluster" for clustering;
- coeff_split_type: method to find the split point for the chosen component when the selected variable is structured and split_type = "coeff". Either "test", where Energy tests of independence are used, or "traditional", to employ Gini index for classification and RSS for regression;

- `p_adjust_method`: multiple-testing adjustment method for p-values, which can be set to any of the values provided by `stats::p.adjust()`. Default is `"fdr"` for False Discovery Rate.

The function `etree()` returns the full-grown fitted tree as an object of class `"etree"`. Methods for printing, plotting, and predicting with objects of this class are included in the package and explained in Section 5.

4 Distance and coefficient expansion techniques

When using Energy Trees, covariates can be in principle of any kind. A useful distinction is between traditional variables, including numeric and nominal, and structured ones, such as functions and graphs. Each type of covariate requires an appropriate distance, which is always necessary to compute the test statistics in the Energy tests of independence employed for variable selection. It is also needed by structured covariates when using the clustering approach to splitting. Additionally, structured covariates necessitate a proper technique for coefficient expansion when choosing that method for splitting.

Here, the types of covariates under consideration are four: numeric, nominal, functions, and graphs. Tables 1 and 2 include `etree` default choices of distance and coefficient expansion techniques, respectively, and the corresponding R functions used to implement them. Note that these choices can be easily changed to reflect personal preferences or application-specific needs, and that new types of variables can be quickly added.

Table 1 Choices of distance and corresponding functions for the four types of covariates available in the package.

	Technique	**R function**
Numeric	Euclidean	`stats::dist()`
Nominal	Gower	`cluster::daisy()`
Functional	L^2-norm	`fda.usc::metric.lp()`
Graphs	Edge Difference [2]	`NetworkDistance::edd()`

Table 2 Choices of coefficient expansion techniques and corresponding functions for the two types of structured covariates available in the package.

	Technique	**R function**
Functional	Cubic B-splines	`fda.usc::optim.basis()`
Graphs	Shell distribution [1]	`etree::graph_shell()`

5 Other functions

Fitted Energy Trees can be plotted by calling `plot()` on the `"etree"` object returned by `etree()`. Specifically, `etree` offers a `plot()` method for `"etree"` objects that is a modified version of the `partykit` one for the `"constparty"` class. Basic elements have been mostly kept intact from the original version. On the other hand, in `etree`, inner nodes are colored differently based on the splitting variable's type. Additionally, split points are on the edges, as in `partykit`, only for traditional variables, or for structured covariates when `split_type = "coeff"`; otherwise, the size of the corresponding kid node is displayed.

In `etree`, predictions are given by the `predict()` method for `"etree"` objects. When the `newdata` argument is not specified, `predict()` returns the fitted values for the response; otherwise, it computes predictions for the observations in the test set provided with `newdata`. The only step required to obtain both these types of results is as easy as calling `predict()` on the fitted Energy Tree returned by `etree()`, and possibly adding `newdata`. Then, the `etree` version of `predict()` automatically identifies the `split_type` used for fitting, and reacts accordingly. If `newdata` is provided and `split_type = "coeff"`, coefficient expansion is applied to the structured covariates contained in the test set, and, subsequently, splits are induced and predictions are made based on the rules established in the fitting procedure; when `split_type = "cluster"`, the distances between the medoids coming from fitting and the observations in the test set are calculated, and, subsequently, splits and predictions are obtained by assigning the new observations to the closest medoid at each split.

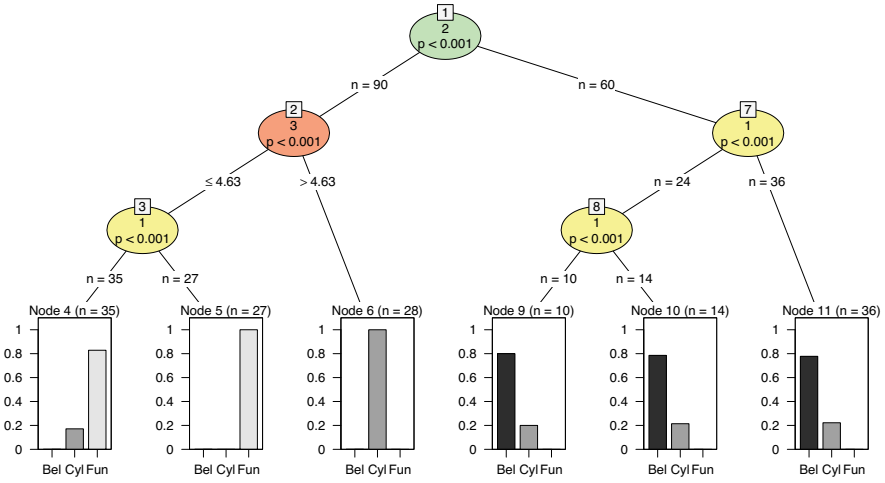

Fig. 1 Example plot of an Energy Tree fitted with `split_type = "cluster"` on a simulated classification dataset.

6 Concluding remarks and future work

The aim of this work is to illustrate R package `etree` for Energy Trees. Despite the complexity that Energy Trees potentially have to deal with, the interface and the functionalities for users are kept as simple as possible. The rich infrastructure of `partykit` has been embedded and generalized, enabling further possibilities. However, much room is left for improvement.

The graphical compartment should be enhanced, possibly using `ggplot2` and `ggparty` package to provide fancier and dynamic plots. A procedure for missing values handling through surrogate splits should be considered. The computational complexity could be improved in many ways: using faster versions of PAM, such as CLARA and FastPAM, for clustering; further optimizing the internal functions; compiling the package's underlying processes in C. Finally, `etree` is expected to implement any methodological development within the Energy Trees framework, which may include the introduction of new types of structured covariates and the case where also the response variable is structured.

Deep Learning framework for ungrouping coarsely aggregated vital rates.

Un modello di deep learning per disaggregare tassi raggruppati in classi.

Andrea Nigri

Abstract The aim of this study is to develop a versatile methodology for ungrouping vital rates leveraging deep learning algorithms based on neural networks.
Abstract Lo scopo di questo studio è quello di sviluppare una metodologia versatile per disaggregare dati demografici usando algoritmi di deep learning basati sulle reti neurali.

Key words: Ungrouping, Vital Rates, Deep Neural Network.

1 Introduction

The monitoring of changes and inequality among populations is a prime aim to assess population dynamics and social and public policies. Thus reliable predictions of age-specific vital rates are crucial in demographic studies. Data deficiency usually refers to incomplete or misreported information such as age exaggeration and age heaping, in both death and population data. Despite single age-specific data being desirable, ages are commonly grouped in bins of 5 years in most cases. This is the case of demographic data, which are followed by a broad or open-ended age class for older ages. Several methods have been proposed for the disaggregation problem about historical data and data from developing countries that lack functional systems of vital registration ([9]; [13]; [8]; [12]). Using countries from the Human Fertility Database (HFD), [8] derived age-specific fertility rates from abridged data comparing 10 different methods. The authors concluded that the modified Beers method ([3]) provided the best fit. Similarly, [12] using schedules observed in the HFD and in the US Census International Database (IDB), proposed a calibrated spline (CS) as a more accurate and flexible alternative to Beers interpolation method that requires more computation. Among mortality modeling, the main approaches aimed at ungrouping

Andrea Nigri

histograms or abridged life tables were based on parametric assumptions for the underlying distribution ([6]; [7]; [5]). For fitting a nonparametric density to binned data histosplines ([2]), kernel density estimators ([1]), and local likelihood estimation. One of the most prominent frameworks has been proposed by [11] whom developed a versatile method for ungrouping histograms based on the composite link model, with a penalty added to ensure the smoothness of the target distribution. Estimates are obtained by maximizing a penalized likelihood.
Nevertheless, estimations often require harmonizing, comparability, and coherence among countries and gender. Working on a single-gender population, the aforementioned models do not guarantee the latter properties, jeopardizing the comparability across time and among countries. Thus relying on coarsely grouped data may hinder accurate data analysis. Aiming at providing a more comprehensive perspective on the indirect age-specific vital rates estimation from grouped data, this paper introduces a multi-population (countries and genders) approach for splitting the abridge demographic rates. The model leverages deep learning algorithms based on deep neural networks (DNN) to uncover age-specific vital rates.
The proposed model represents an advance in mortality modeling, offering the advantage of an indirect and complementary way to approximate death rates specific for age. It can be valuable in contexts where population-level mortality studies are hindered by financial or time constraints, for national registries that do not support the open data system.

2 Method

In this section, I will describe the DNN model used to derive the country-specific ungrouped death rates by age and time. Let $\mathbf{M^{(1)}} = \log(m_{a^{(1)},t})_{a^{(1)} \in A^{(1)}, t \in T}$ be a matrix with death rates for single ages, where rows denote age and columns calendar years, and $\mathbf{M^{(5)}} = \log(m_{a^{(5)},t})_{a^{(5)} \in A^{(5)}, t \in T}$ the matrix with grouped death rates in 5 years age classes. We set $A^{(1)} = \{0, 1, ..., 100\}$, $A^{(5)} = \{0, 1-4, 5-9, ..., 100-110\}$ and $T = \{t_1, t_2, ..., t_n\}$. Then, for an DNN architecture composed of three hidden layers $k = 3$, the theoretical relationship defining the matrix $\mathbf{M^{(1)}}$ given the vector of 5-years age grouped rates $\mathbf{M^{(5)}}$ is represented by:

$$\mathbf{M^{(1)}} = f^{(3)}(\mathbf{W^{(3)}}(f^{(2)}(\mathbf{W^{(2)}} f^{(1)}(\mathbf{W^{(1)}}\mathbf{M^{(5)}} + \mathbf{b^{(1)}}) + \mathbf{b^{(2)}}) + \mathbf{b^{(3)}}), \qquad (1)$$

where $f^{(k)}$ is the activation function, $W^{(k)}$ is the matrix of weights, and $b^{(k)}$ is the bias used to control the triggering value of the activation function. Thus, $f^{(1)}(\mathbf{W^{(1)}}\mathbf{M^{(5)}} + \mathbf{b^{(1)}}) = \mathbf{H^{(1)}}$ is the first hidden layer that accepts the vector $\mathbf{M^{(5)}}$ as input.

The DNN model is based on a training algorithm that involves an unconstrained optimisation problem aiming to minimise the prediction error. The idea is to adjust the weights of the network connections to minimise a measure of the difference between the actual and the desired output ($\mathbf{M^{(1)}}$ and $\hat{\mathbf{M}}^{(\mathbf{1})}$), respectively, known as the loss function $\mathcal{L}$. Here, I present a simple example of how to extend the DNN

model for the multiple populations case. Consider the case in which the full Human Mortality Database (HMD) is used to train a model and then to predict the single age-specific mortality profile. I still model the functional relationship between coarsely binned data and single-year age grouped rates, as numerical inputs and outputs. Thus, I extend the framework to the multi population model by adding other demographic features, such as country, year and sex, using what is known as embedding layer, that ([10]) allows a low-dimensional representation learning, mapping categorical variables into a vector space. In the present study I deal with the following variables:

$$c \in \mathcal{C} = \{\text{Italy,..,Russia}\}; g \in \mathcal{G} = \{\text{Male, Female }\}; a \in \mathcal{A} = \{0,..,110\}; t \in \mathcal{T} = \{1990, ..., 2015\}. \tag{2}$$

Embedding layers map these features into real-valued vectors, where for instance $z_C(c)$ is the new representation of countries. Therefore, $i = (c,g,a,t) \in I = \mathcal{C} \times \mathcal{G} \times \mathcal{A} \times \mathcal{T}$ might be considered the categorical features space. Once embedding vectors have been defined for each categorical variable, all variables, categorical and not, are concatenated into a single feature vector: $x_{\mathbf{M}^{(5)},i} = (\mathbf{M}^{(5)}, z_I(i))$, which is used as input to the sub-neural network (previously described) in order to predict the ungrouped death rates in year t, at age a for country c gender g related to levels of observed coarsely binned data.

2.1 Implementation

Let $\left\{\log(m_{a^{(5)},t})\right\}_{t=t_0}^{t_s}$, for $t_0 < t_s$, be the country-specific observed grouped death rates. Then, each series is split into a train-validation set and a test set, where the first one is used for fitting the model's parameters, while the second one to test the model's prediction and calculate the error. Specifically, the time frames 1970-2000 is used as a train-validation set, according to the 80%-20% splitting rules. The best DNN setting during the training phase is used to obtain predictions in the test phase which takes place on the time frames 2001-2015.

Hence, let t_τ, with $t_0 < t_\tau < t_s$, be the calendar year corresponding to the last realization in the training-validation set. The values of $\log(m_{a^{(5)},t})$ over the period (t_0, t_τ), $\left\{\log(m_{a^{(5)},t})\right\}_{t=t_0}^{t_\tau}$, represent the input for train-validation, while the corresponding output is $\left\{\log(\hat{m}_{a^{(1)},t})\right\}_{t=t_0}^{t_\tau}$. The values of grouped death rates over a subsequent period, $\left\{\log(m_{a^{(5)},t})\right\}_{t=t_\tau+1}^{t_s}$, represent the input for test, while the corresponding output is $\left\{\log(\hat{m}_{a^{(1)},t})\right\}_{t=t_\tau+1}^{t_s}$. Thereby, denoting ψ_{nn} as a composition of functions defined on the basis of the NN architecture, the model can be described by:

$$\left\{\log(\hat{m}_{a^{(1)},t})\right\}_{t=t_\tau+1}^{t_s} = \psi_{nn}\left(\left\{\log(m_{a^{(5)},t})\right\}_{t=t_\tau+1}^{t_s} \middle| \hat{W}\right) \tag{3}$$

where $\left\{\log(\hat{m}_{a^{(1)},t})\right\}_{t=t_\tau+1}^{t_s}$ is the matrix of death rates in single year age group, in the test set obtained by ψ_{nn}, that involves the NN weights $\hat{W}$ estimated during the network training.

3 Results

I consider historical mortality data collected by the [4] for all available countries and both genders. Aiming to assess the multi population model robustness and consistency toward the historical data, I carry out an out-of-sample test by using 30 years for training-validation (1970-2000) and the remaining years (2001-2015) are used for model forecasting/test. I now validate the DNN model forecasting performance using illustrative applications. These examples are dedicated to investigating whether the approaches can capture (a) regular and irregular trends over time (b) dynamics of age-specific mortality improvements. The analysis includes numerical and graphical representations of the goodness of fit. To assess the models' accuracy, I calculate the Root Mean Square Error (RMSE) and Mean Absolute Error (MAE) on the out of sample period, which in the present analysis corresponds to 2001-2015 time window. Despite the DNN estimations derived from the DNN training on the whole HMD, here, for brevity's sake, I provide results for only six countries in table 1. Overall, the DNN provides remarkable accuracy.

Table 1: Out-of-sample test: MAE and RMSE for DNN, by country and gender.

Country	**Male**		**Female**	
	MAE	RMSE	MAE	RMSE
Australia	0.083	0.120	0.106	0.168
Denmark	0.126	0.223	0.150	0.247
Italy	0.067	0.103	0.0836	0.120
Japan	0.072	0.095	0.106	0.127
Russia	0.074	0.093	0.083	0.104
USA	0.06	0.075	0.068	0.081

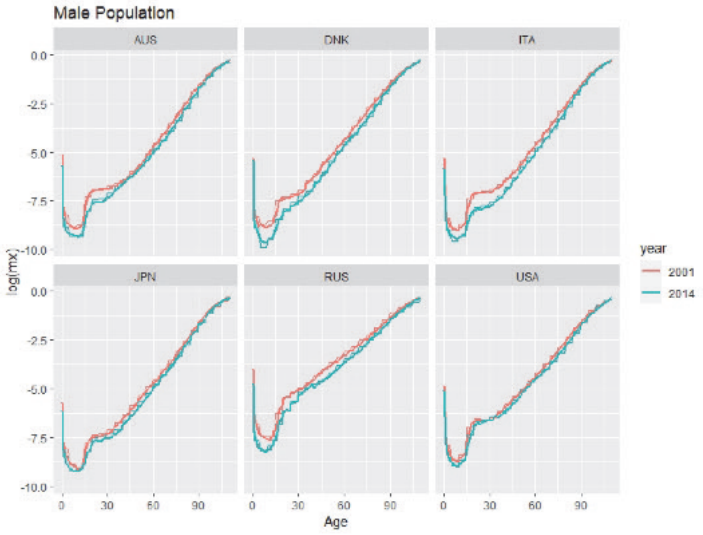

Fig. 1: Estimated ungrouped mortality rates, by countries for 2001, 2014 based on training period 1970-2000. The stepped-line refers to the observed rates collected in 5-year age groups. Solid lines are the DNN reconstructed ungrouped death rates

4 Discussion

This manuscript contributes to the current literature on the demographic methods for ungrouping vital rates. I propose a Deep Neural Network framework to ungroup death rates from rates collected in 5-year age groups, using a multi population approach. This method represents an advance among mortality modeling, indeed the model could be used to estimate vital rates for single ages in regions or subpopulations where present information is lacking but past data are available or from surrounding countries or populations.

Inside the metaverse: analysis of the state of the art and development of a new usage approach based on quality and ethics

Dentro il metaverso: analisi dello stato dell'arte e sviluppo di un nuovo approccio di utilizzo basato su qualità ed etica

Vito Santarcangelo[1], Emilio Massa[1], Saverio Gianluca Crisafulli[1], Antonio Ruoto[1], Angelo Lamacchia[1], Alessandro D'Alcantara[1], Alessandro Verderame[1], Massimiliano Giacalone[2]

Abstract The paper analyses, starting from the first coining of the term, the state of the art related to the technologies and possible approaches of the metaverse, with particular focus on the potentialities expressed by blockchain-based metaverses and their criticalities. The paper then discusses in detail the concept of tokens, in order to explain the dynamics of regulation of ownership and transactions within the metaverse, up to the exposition of the revolutionary concept of ethical metaverse, object of industrial patent, based on the concepts of quality and social responsibility in a Benefit Impact (BIMPACT) Assessment perspective.

Abstract *Il paper analizza, partendo dalla prima coniazione del termine, lo stato dell'arte relativo alle tecnologie e ai possibili approcci del metaverso, con focus particolare alle potenzialità espresse dai metaversi basati su blockchain e alle relative criticità. Il lavoro tratta dunque nel dettaglio il concetto di token, al fine di spiegare le dinamiche di regolamentazione della proprietà e delle transazioni all'interno del metaverso, fino ad arrivare all'esposizione del rivoluzionario concetto di metaverso etico, oggetto di privativa industriale, basato sui concetti di qualità e di responsabilità sociale in ottica Benefit Impact (BIMPACT) Assessment.*

Key words: metaverse, blockchain, smart contract, NFT, SFT, token, digital twin, ar cloud, virtual reality, augmented reality, IPFS, ethics, quality, metavalue, CSR, BIMPACT

1 Introduction

One of the current trends in the technologic world is linked to the concept of metaverse, an innovative digital interactive experience. The term metaverse was coined by Neal Stephenson in Snow Crash (1992) [1], the sci-fi cyberpunk book described as a kind if virtual reality shared through internet, where you are represented in 3D by your own avatar and where everyone can create everything they wish; as a prototypical form of metaverse we can consider Second Life, a MUVE (multi-user virtual environment) born in 2003 where it is possible, logging in through your own digital avatar, to explore a virtual world, to interact with other users, to join activities and to create or exchange goods and services [2].

Even if the technology available during the development of Second Life allowed a quite good interaction with other users thank to the maturity of internet-related technology and to a good digital reproduction of real places thanks to graphic engines, several mechanics of real life were missing, making the title tend more towards a video game and less towards a virtual reality or metaverse. The first difference with the current metaverse was the lack of digitization of the natural right of ownership, that includes the artificial creation of scarcity, of the uniqueness, of the value, of a currency and other features that bring with them some technical challenge, and has been overcome thanks to blockchain technology; the second one, on the other hand, concerned the perception and immersion in the digital environment and the fruition of such contents, which has been bridged thanks to the evolution of hardware devices for the fruition of digital contents such as VR viewers, different sensor devices and new software technologies such as AR or AI [3]. The evolution of the concept of metaverse is therefore linked to all the mentioned technologies that allow to virtualize the features of reality and make all its virtual aspects more immersive and real.

The aim of this paper is to carry out a state-of-the-art analysis on metaverse technologies and approaches, highlighting their potentials and limitations, clarifying the concept of token (regulation of ownership and transactions in the metaverse) and introducing a revolutionary concept of ethical metaverse based on the concepts of quality and social responsibility (evolution of the BIMPACT metric defined by B Lab [19]).

2 Technologies of the metaverse

The concept of metaverse in recent years is destined to evolve into the coexistence of real and virtual contents, overcoming the concept of gamification of virtual environment (simple implementation in computer graphics of a non-real environment). In order to enable this vision, a digital model of the physical/real world is needed, where immersive 3D technologies, such as VR and AR, can add those digital interactions that can create an infinite set of real-world based experiences [4]. The real world-based metaverse involves the possibility of creating

simulations and interactions with the reality around us, going beyond what is possible in Second Life. To make this evolution of metaverse possible, three new technologies are fundamental: Digital Twin, AR Cloud and Virtual Reality. Digital Twin is a 3D technology able to create a digital model of an entity that exists in the real world, in order to interface it through information layers, sensors and IoT systems. A Digital Twin allows to acquire real-time information from the physical model to interact with it through digital systems [5]. The AR Cloud, also known as spatial computing, is an augmented reality technology implemented in the cloud, capable of adding information layers to the real world, creating hybrid environments in which one can simultaneously use traditional tools, augmented reality and virtual reality, with the particularity that the digitally generated contents are persistent, since the data are tracked with respect to the physical environment and stored in the cloud, and are always accessible by every user in the metaverse [6]. An example is the digital platform Spatial, a well-known AR collaboration tool. Virtual Reality is the one that can guarantee the highest level of immersion and presence in the digital experience, replacing the view of the real world with a digitally produces scene that can represent a duplicate of the real world or places from a totally imaginary universe [7]; it can be used through special devices, such as visor, and in combination with the Digital Twin and the AR Cloud it provides the flow from the real world to the virtual world.

By exploiting the various potentials of these technologies, it is possible to implement the real/virtual worlds of the metaverse.

3 Metaverse and blockchain

Another technology that characterises the metaverse is the blockchain [18]. If a gaming metaverse (Minecraft, Roblox) unites multiplayer dynamics with the possibility for the users to create contents [8], a blockchain metaverse (Decentraland, The Sandbox) allows its users to own properties just like in the real world; it is possible using the blockchain technology and in particular using the smart contracts, through which it is possible to create digital currencies (token) and collection of assets (NFTs and SFTs) describing their behavior and characteristics, making them customizable, guaranteed by the decentralized blockchain network and independent of the single platform hosting a metaverse, thus visualizing a reality with more similar features to the one we know but richer and without limits [9].

The tokens of the metaverse are the basis for the functioning of virtual worlds and are mainly divided into three categories. The Governance Tokens, similar to shares, is basically a digital asset that allows token owners to vote and to take decisions that will influence the future of the protocol to which the token corresponds. System Tokens, which are needed to perform actions within the system, such as selling and buying in internal marketplaces and developing new functions, and whose value is essentially linked to the dynamics of the metaverse. Finally, NFTs (non-fungible tokens), which are unique digital objects whose

transaction/ownership is recorded on the blockchain. NFTs have played a key role in enabling the market for digital resources, that would have been reproducible without the possibility of recognizing their actual ownership otherwise. An NFT can for instance be a work of art, as well as a real estate property [10].

Most of the metaverses use one or more standards for their tokens, that allows to describe the functions and the events that the smart contract can implement [11]. The most used standards are ERC-20 for the fungible tokens, ERC-721 for the non-fungible tokens (NFT) and finally ERC-1155 for semi-fungible tokens (SFT), i.e. having the functionality of ERC-20 and ERC-721 to obtain the property of semi-fungible token. The blockchain is therefore used to record transactions and allows token holders to exchange them without any restriction. However, it does not allow the asset corresponding to the registered NFT/SFT to be saved within the transaction, limiting itself to a unique information on the same. In this regard, is introduced the IPFS (Interplanetary File System) protocol, which allows to decentralize data storage where instead of pointing to a URI, one points to a content hash [12]. This information is unique, immutable, and always accessible. All transactions are regulated by smart contracts: from buying and selling activities, to commercial agreements, to private agreements, everything goes through the writing of a smart contract whose nature is absolutely unchangeable and conditioned in time to the rules established in the contract itself, ensuring fairness and security between the parties involved [13].

A blockchain metaverse bases its success on participation, it has an autonomous and independent economic system whose main resource is land, a real estate property that allows it to give place and shape to its virtual activities, characterized by a real estate market that fully reflects the logic of operation typical of real estate, with areas/properties that are worth more than others. The properties of a metaverse are NFTs that can be traded on platforms such as OpenSea. All meta-verses are characterized by the presence of avatars, constructions, vehicles and objects of any nature, without limits in terms of creativity; these resources, defined as assets, can be created and sold in the form of NFTs and constitute an essential engine for the economy of the metaverse [14]. Each metaverse is therefore characterized by its own creative style, and from this technological infrastructural complexity/variety we derive the different interpretations/definitions that characterize the metaverse. The winning metaverse will therefore be the one equipped with a highly dynamic, technological and quality infrastructure, that is flexible to the various demands of the market and of its users. The concept of quality of the metaverse is particularly important, as it is closely related to its user experience and compliance, i.e. to the technologies used to guarantee a high level of UX (user experience), which can be calculated by considering aspects of usability and sentiment analysis feedback, together with strict compliance with mandatory regulations (lawfulness of the actions that can be carried out through the metaverse), personal data, commercial/industrial secrecy and intellectual property managed through it. These parameters represent, in fact, the main criticalities of the metaverse that open up important analysis scenarios to be addressed.

4 Prospects for an ethics-based metaverse: an experimental quality model

As mentioned in the previous paragraph, the development of the metaverse will most likely depend on the level of trust of the users [15], trust that cannot be consolidated and based on mere gamification and economic logic [16].

For this reason, in this paragraph we introduce a model of experimental development of an ethical metaverse that aims to enhance the territorial experience in order to raise awareness of the geography, products and customs of a territory, using the metaverse as an international showcase by putting in place value actions based on ethics and not on economic values, on what we could therefore define as "metavalues" related to ethics and know-how, which can then allow those who make ethics their goal, in reality and in the metaverse, to be able to interact more and distinguish themselves by virtue [17].

A valoristic dimension that rewards those rich in virtues, and allows business or interactions to develop only if in real life or in the metaverse itself, models of social responsibility or scientific progress and dissemination are followed. Engaging in the real dimension by achieving scores in a BIMPACT key, proving service activities, and contributing to the progress of the community in a technical-scientific perspective thanks to the development of new technology therefore represents a dimension of meritocratic enhancement of the ethical metaverse through the production of meta-values. A mathematical formulation of the concept of metavalue can be expressed by the sum of the contributions of two weighted (Θ,τ) integrals calculated on two-time intervals of reference t1 and t2, which integrate the temporal trends over time of actions of social responsibility (csr) and know-how (kh) carried out in reality (ar) or in the metaverse (av). The trends are therefore user behavioural functions that represent the tokens of user actions in the metaverse and map their actual certified actions in the real world.

$$mvl = \theta \int_{t1}^{t2} (ar_{csr}(t) + ar_{kh}(t))dt + \tau \int_{t1}^{t2} \left(av_{csr}(t) + av_{kh}(t)\right) d(t)$$

The core of this model is based on the fundamental concept of metavalue. Metavalue is the coinage of this ethical metaverse and is a function of the level of ethics expressed in the real world and/or in the metaverse, as well as the know-how that can be expressed through work tables, training provided and publications certified in a smart contract perspective in the metaverse or by intellectual property and scientific publications that can be obtained in an OSINT perspective or from institutional databases (e.g. UIBM, SIAE). Technology transfer thus becomes proof of know-how and commitment to the progress of science and technology. Then, metavalue is obtained considering in a fiscal year (t1,t2) the benefit investments (from fiscal balance) and BIMPACT score adding the contribution know-how (number of patents granted and papers' citations in that year). The value obtained is combined by score calculated by metaverse. This virtuous metaverse becomes a source of quality and an example of best practice, with a view to the social responsibility of the individual and of the company.

5 Conclusion

This work aims to provide a synthetic representation of the metaverse complexity, its potential, some of its criticalities and a possible model from a quality and ethical perspective. This shows how this tool can represent a new trend for developers in the IT world, on a par with operating systems to be adapted to the required purposes. It is therefore possible to imagine specific productive metaverses based on Industry 4.0, investment metaverses to create a network of investors, companies and consultants from all over the world, and also possible applications for the improvement of culture, research into healthcare (through research teams and hospitals working together in real-time synergy in the metaverse) and for geopolitical purposes and institutional management of relations thanks to easier sharing of virtual experience.
