Statistics and indicators for the recovery and resilience plan

The prominence of statistical information for the monitoring and effective implementation of the NRRP

La centralità dell'informazione statistica per il monitoraggio e l'efficace attuazione del PNRR

Andrea Petrella

Abstract In this short contribution I discuss three areas of interest where an improvement in the statistical domain is likely to provide the highest returns in terms of effective implementation and social inclusiveness of the NRRP: (i) monitoring; (ii) transparency; (iii) ex-post evaluation.

Abstract *In questo breve contributo discuto tre ambiti in cui un miglioramento nel campo statistico potrebbe fornire i maggiori benefici in termini di efficacia nell'attuazione e inclusione sociale del PNRR: (i) monitoraggio; (ii) trasparenza; (iii) valutazione d'impatto.*

Key words: NRRP, monitoring, policy evaluation

The Italian NRRP encompasses an ambitious set of reforms and investments, with the aim to spur post-pandemic recovery and to increase the resilience of the economy to future shocks. The arrangements made with the European Commission for a timely implementation of the Plan place a great emphasis on performance, measured as the capacity to meet pre-determined qualitative and quantitative goals (so-called 'milestones' and 'targets'). This represents a challenge – and possibly a good practice for the future – for Italian Public administration that is traditionally more inclined to monitor spending rather than attainments. In this context, data infrastructures and high-quality statistical information will be key to pursue the goals of the Plan. Here I will briefly discuss three areas of interest where an improvement in the statistical domain is likely to provide the highest returns in

[1] Andrea Petrella, Bank of Italy; email: andrea.petrella@bancaditalia.it

terms of effective implementation and social inclusiveness of the Plan: (i) monitoring; (ii) transparency; (iii) ex-post evaluation.

Monitoring is the area where most advancements have already been done. As a matter of fact, the orientation to monitoring is intrinsic in the design of the NRRPs that provide for a continuous supervision of the different achievements planned for each project. The variety in the number of interventions, governance layers and implementing bodies make this task extremely complex. This is the reason why the design of a monitoring system for the NRPP has been one of the foremost endeavour in the first year of application of the Plan. The Regis system realized by the State General Accounting Department is the IT infrastructure intended to collect data on the progress of each NRPP project, based on the information flows fed by the responsible administrations. On top of that, it keeps track of firms or other subjects having a contract awarded, links several external data sources to perform cross-validation checks, and also embeds a module to monitor the progress of spending for each intervention. Regis is definitely an ambitious infrastructure, whose contents are being progressively populated as the implementation phase of the NRRP gains momentum. However, the richness of the statistical information it can provide crucially relies on the responsible administrations' capacity to feed data on project advancements in a timely and accurate manner. For this reason, all interested parties should be aware of the importance of a high quality reporting, be provided with harmonized guidelines and have dedicated resources allocated to this task. Regis has especially been designed to monitor NRPP projects, but it may prospectively represent the primary monitoring instrument for all public spending initiatives. This will most probably be the case for the projects financed by the National Complementary Plan, whose implementation timeline has been designed according to the principles inspiring the NRRP. For all other initiatives outside the NRRP boundary, this might require a cultural switch within Italian Public administration toward a more performance-oriented planning.

Given the complexity of the NRRP framework and the richness of the statistical information collected for monitoring purposes, granting a transparent and effortless data access to the wider public is essential to guarantee an inclusive implementation of the Plan, to push forward the accountability of responsible administrations and to promote ex-ante analyses on the expected impact of each investment line. The website ItaliaDomani is intended to be the virtual platform through which information is channelled to the public. It has detailed sections describing the structure of the Plan and the contents of the planned interventions, and has recently launched a new open data section where information is released in a standardized and machine-readable format. At this time, the open data section still needs to be populated with valuable contents, though. In particular, real-time implementation data for each investment is an area where the greatest advances in transparency might be attained. To this aim, a greater integration with the Regis infrastructure might be pursued, designing automated routines that extract information and release them in open data format, of course respecting the relevant statistical confidentiality and personal data protection issues. Another area in which a greater information

standardization would favour transparency is the one of tender notices, which are highly heterogeneous in nature. At the moment, ItaliaDomani acts as a searchable repository for tenders, but the comparability between them is limited by the fact that the information is still unstructured and essentially textual.

Finally, let me stress that monitoring does not typically coincide with evaluation, and a timely implementation of projects does not necessarily imply their effectiveness. Whilst it is essential to deliver projects on time in order to receive the European funds as scheduled, the ultimate interest of both policymakers and the public is that NRPP measures have an impact on the relevant variables on which they are intended to act. As a matter of fact, the milestones and targets agreed upon with the European Commission hardly ever entail indicators of impact (for example, an increase in the graduation rate), while most of the times they concern procedural attainments (for example, the number of scholarships awarded). This is because the latter category of indicators is more directly verifiable than the former, which take considerably more time to materialize. Most importantly, in order to assess impact, it is first necessary to assess causality, which requires suitable data to perform a counterfactual econometric analysis. A rigorous impact evaluation exercise is not only relevant to assess the effectiveness of NRPP projects per se, but also to learn from past experiences, in order to better calibrate future policies. Of course, the evaluation phase of the NRPP measures is distant in time, as we have to wait for the complete rollout of each intervention and the full deployment of their effects. Nonetheless, it is important to figure out now what are the statistical challenges for future evaluation exercises, in order to start planning the necessary actions to take. Two issues should be tackled with greater priority. First, to perform counterfactual analysis it is crucial to have a control group, while the monitoring process is inclined to only record the "treated" units, meaning the firms or entities that receive funds or that are awarded a contract. To build a suitable control group it is instead essential to also record the units that applied but were not selected among the recipients or the contractors. The Regis system has the technical means to coherently process and store this data; it is notwithstanding necessary to activate the related information flows. Second, counterfactual techniques typically leverage on large datasets at the individual level to perform their impact evaluation analyses. Hence, for each variable of interest whose evolution we are interested to measure at the aggregate level, it would be important to observe the contribution of each elementary unit. In principle, the increased availability of administrative microdata makes this task relatively easy. However, on one hand, the necessity to link together the various data sources calls for an increased cooperation between the institutions owning proprietary data; on the other hand, suitable data management infrastructures are needed to handle such high-dimensional information. In recent years, some valuable experiences have been carried out it this direction. The wish is that we can build on them to face the challenges posed by the evaluation of the NRPP.

Big Data Analytics in mobile cellular networks as enabler for innovative statistics to evaluate the effects of Recovery and Resilience Plan actions

L'Analisi dei Big Data delle reti radiomobili cellulari come abilitatore di statistiche innovative per valutare l'effetto delle azioni del Piano di Ripresa e Resilienza

Andrea Zaramella[1], Dario Di Sorte[2], Denis Cappellari[3], Bruno Zamengo[4]

Abstract – The large deployment of packet-switched communication paradigm and the continuous growth of mobile phone services and usage, together with the pervasive deployment of network coverage, have made wide area mobile networks a valuable source of an extreme amount of data. The analytics of this time-space big-data can indeed be an innovative way to explore several insights on subscriber behaviour, presence and flows, while being strictly compliant with the GDPR requirements. In this paper we specifically focus on the tourism framework and put forward new algorithms and KPIs to investigate dynamics which can be overlooked by the official statistics. This should allow to be more effective/efficient to plan/monitor NPRR projects, the goal of which is to improve the touristic offer.

Abstract – *L'ampia diffusione del paradigma di comunicazione a commutazione di pacchetto e la continua crescita dei servizi e dell'utilizzo della telefonia mobile, insieme alla diffusione pervasiva della copertura del segnale, hanno reso le reti mobili geografiche una preziosa e immensa fonte di dati referenziati nel dominio del tempo e dello spazio. L'analisi di questi big-data è uno strumento innovativo per esplorare comportamenti, presenze e flussi degli utenti, in conformità assoluta ai requisiti di privacy del GDPR. In questo articolo ci concentriamo specificamente sul turismo e presentiamo nuovi algoritmi e KPI per indagare dinamiche che possono sfuggire alle statistiche ufficiali, con l'obiettivo di essere più efficaci/efficienti nella pianificazione/monitoraggio dei progetti PNRR in ambito offerta turistica.*

1 Introduction

The big-data generated by cellular mobile networks may open new perspectives of analysis about users' behaviour, presence and flows in several area analysis related to the tourism and transport/mobility sectors. In Vodafone, the platform to collect and elaborate raw data to quickly calculate insights is called Vodafone Analytics.

Mobile network big-data can help to better understand the behavior of visitors, their movement independently of overnight stays, their preferences (coast lovers, country lovers, explorers), co-visits, the trajectory of their movements. These analyses can be carried out also for specific segments of users (gender, age, nationality, residence). Also, it is also possible to perform cluster analysis to identify experience tourist areas (e.g., wine territory, spa locations) outside the main and classic paths, to proactively know and quantify new trends (e.g., bike tourism), to describe over and under tourism phenomenon, to measure the seasonal adjustment of tourism request. The analytics of big data can be useful to be more effective and efficient to both design and monitor projects as a function of the mobility of people; historical data (up to 18 months backwards), the low-latency and high frequency of data refresh (near-real-time) are precious planning and monitoring instruments. In the framework of the Italian NRRP (National Recovery and Resilience Plan), a field of application of Vodafone Analytics is the area of actions related to tourism, especially those related to the attractivity of *villages and small historical centers* ("borghi"). Similar applications can also be found in the NRRP missions relevant to mobility and transport (sustainable mobility) and ecological transition. Also, some analyses can be carried out to study some aspects crossed to several sectors such as, for instance, the measure of *ecological footprint* of tourists in a geographical area, correlated to presence, mobility and means of transport.

In the following Sections, we first introduce of the main concepts related to big data in cellular mobile networks, then we give an overview of the basic definitions of tourism statistics and map them within the mobile data algorithms. Finally, we describe a case study of the municipality of Padova to show how Vodafone Analytics can integrate the official statistics to give additional interesting insights into the mobility of tourists outside the municipality where they spend the night.

2 Mobile phone Big-Data

The ability of the Vodafone Analytics big data platform to collect (time, space) data from the field and immediately elaborate them depends on:

Space granularity: the density of mobile radio cells is paramount in guaranteeing the supply of reliable data. Vodafone can rely on 200.000 network cells; within densely populated areas the diameter of a cell can be reduced to a few hundred meters, and even to a smaller dimension if a dedicated network coverage to specifically cover certain locations (e.g., malls, stadiums, train stations, airports);

Time granularity: the sampling frequency of phone/SIM position (i.e., the cell is connected to) is of the utmost importance to enable the profiling process together with an accurate analysis. Vodafone can rely on a high frequency sample that guarantees presence notifications thanks to the monitoring of raw data from all the packet-switched interactions between phones and the network (calls, messaging,

notifications, data connections, app interactions etc). A phone can be sampled up to more than one thousand time per day, and this represents a proxy of continuity;

Network coverage extension: the Vodafone mobile network is widely recognized for its quality and strength throughout the whole national territory with a percentage of population (i) covered by 2G close to 100% and (ii) covered by 4G close to 99%;

Customer base: Vodafone counts 23 million of human Italian SIMs which generate a number of raw time-space data in the order of tens of billions;

Privacy by design: Vodafone Analytics services are designed according to the principles of privacy-by-design in compliance with GDPR rules (n. 05/2014, Working Group ex Art. 29) and all data are irreversibly anonymized and aggregated. Vodafone Analytics aims at studying the behaviour of homogeneous groups of people and not the behaviour of the single user. Finally, thanks to a proprietary calibration algorithm, the number of people in a cluster is projected to the entire universe of users and not only those connected to the Vodafone mobile network.

3 Tourism Case Study

Here below the classic definitions of tourism statistics:

- visitor: traveller taking a trip to a main destination outside his/her usual environment, for less than a year, for any main purpose (e.g., business, leisure) other than to be employed by a resident being and is classified as:
  - *tourist* (or overnight visitor), if the trip includes an overnight stay;
  - *same-day visitor* (or excursionist), if the trip does not include a night.

Through Vodafone Analytics it is possible to qualify travellers, visitors, tourists and same-day visitors by observing the most active area during the night:

- prevailing night area: this information approximates the location of the overnight stay of the tourist and corresponds to the coverage of the prevailing network cells where the Italian SIM is mainly registered during the night;
- telco home location (or phone residence): corresponds to the municipality where the Italian SIM has been registered more frequently in the past sliding window, typically 6-12 months long. This way Italian users can be disaggregated by region/province/municipality, based on the telephone residence. Also, as a first approximation, the residence of mobile phone users with a foreign SIM can be associated with the nationality of the SIM.

Thus, we can classify as tourists those users whose prevailing night area differs from their telco home location and as same-day visitors those who visit a municipality for at least 3 hours without having the phone residence there or nearby.

We now represent a trial carried out in the city of Padova, which is commonly recognized as a base of overnight stays for tourists visiting the Veneto region. ISTAT traditionally measures arrivals and nights spent in the territory through a census from recorded flows in official accommodation establishment, carried out on a monthly basis. What we want to study is the daily activity of tourists to Padova; where do they move during the holiday? We have considered all people spending a night in Padova in July 2021 and classified them as follows: (i) inhabitants of Padova and nearby, (ii) inhabitants of Veneto, (iii) Italians, (iv) Foreigners.

A subset of main results is shown in Fig.1. Fig.1a presents the geographical distribution of overnight stays of tourists in the area of Padova municipality. Fig.1b gives a visual representation of tourist mobility the day after their overnight stay in

Padova for both Italians and Foreigners. Fig.1c provides a quantitative description of the time they spend within and outside Padova municipality; a significant result is that a large percentage of daytime is spent outside Padova, with a strong presence, as expected, in Venice (Fig.1d). The behaviours of Italians and Foreigners are quite similar; this is the reason why they have been always represented together.

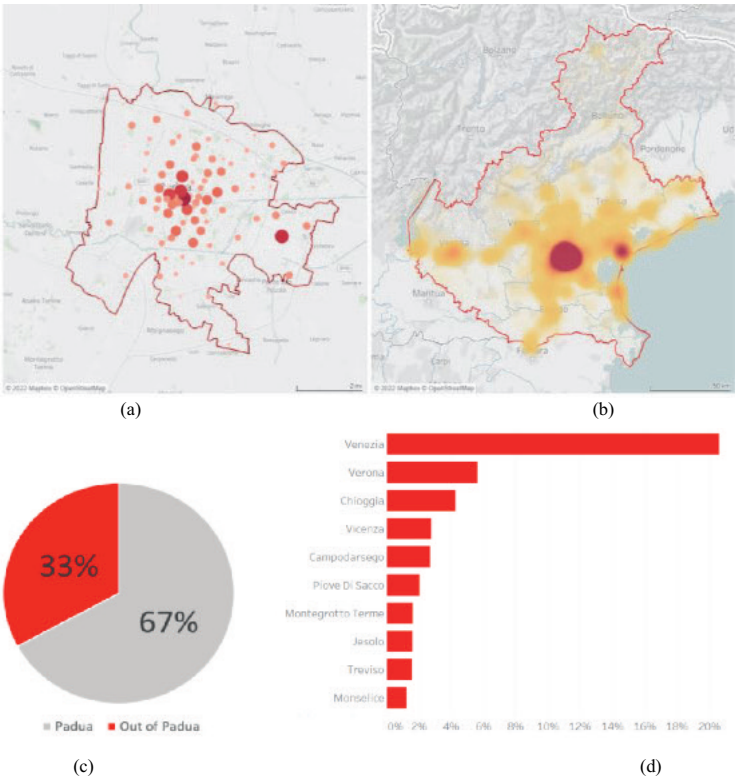

Figure 1: (a) Geographical distribution of overnight stays in Padova; (b) Mobility of tourists of Padova in Veneto region; (c) % daily time (8-22) spent within and outside Padova (d) ranking of municipalities visited by the tourists of Padova (% of total time outside Padova).

4 Conclusions

In this paper we have presented the capacity of mobile phone big data to deeply and promptly describe the behaviour of people on the territory with a high granularity on both time and space domain. NPRR is indeed a great opportunity to deeply investigate and deploy the analytical skills of big data generated near-real-time by mobile network operator for the accurate territorial monitoring. New perspectives of investigations, algorithms and KPIs can be opened in the framework of tourism, sustainable mobility, and ecological transition.

We have presented an application case in the touristic field to show how Vodafone Analytics metrics can support and complement traditional surveys to identify and quantify the presence of visitors in all the small municipalities and/or touristic destinations where there are no official accommodation establishments and the relevant data from survey/census.

Measuring the digital transition within the PA: proposals comparison

Misurare la transizione digitale nella PA: proposte a confronto

Susanna Traversa[1], Enrico Ivaldi[2]

Abstract
Although technological innovation is considered an important driver for economic recovery, interventions that are not accurately assessed against the current national scenario could increase the already existing territorial digital divide. In order to promote a fair and sustainable recovery in the course of this study, three indices of PA digitization are presented and compared, developed following the objectives W1.C1. "Digitization, innovation and security of PA" of the Italian RRF.
Abstract
Sebbene l'innovazione tecnologica sia considerata un importante driver per la ripresa economica, interventi non adeguatamente valutati rispetto all'attuale scenario nazionale potrebbero portare ad un aumento del digital divide territoriale già esistente. Al fine di promuovere una ripresa equa e sostenibile nel corso di questo studio vengono presentati e confrontati tre indici di digitalizzazione della PA, sviluppati in accordo con gli obiettivi W1.C1. "Digitalizzazione, innovazione e sicurezza della PA" del PNRR italiano.

Keywords: “eGovernment”, “Partially Ordered Set”, “Adjusted Mazziotta Pareto Index”.

Introduction

The challenges posed by COVID-19 have led to a break with the pre-2020 model of society, initiating a new phase characterised by extremely rapid and pervasive digital transition processes [4,5,19]. One of the areas most affected by digital implementation in recent years is the public sector. As emphasised by the European Institutions, the adoption of eGovernment processes represents an extremely strategic innovation opportunity for the Member States. The correct investment of European funds in the digital transition of the Italian Public Administration would therefore represent an opportunity for both social and economic recovery, in response to the criticalities that emerged during the pandemic. New forms of inequality - both social and industrial - due to the raising of barriers linked to weak digital infrastructure, a poor ability to reconvert business models and, above all, digital illiteracy that is still too present among the population, represent new challenges to be handled today [9,10,11,16,19]. For this reason, three different proposals for synthetic indices for assessing and monitoring the deployment of eGovernment models from a NUTS-2 perspective will be presented in this study. The possibility of having quantitative tools for the study of digitization over time represents a strategic opportunity for policymakers since the success of digital implementation policies represents for the states the possibility of strengthening their competitiveness, providing higher quality services to citizens while ensuring transparency and accountability, and reducing current and future costs [3,5,9,19].

Methodology

The methodological choice fell on the elaboration of two composite indices - i.e., aggregative approach – and a non-aggregative alternative using the Partially Ordered Set technique.
The first composite index hypothesis, referred to as $Digital_{min-max}$ was built by adopting the aggregation technique of Min-Max approach [13]. The second one, on the other hand, exploits a technique of aggregation that is becoming more and more widespread in the study of socio-economic phenomena, such as the Adjusted Mazziotta and Pareto Index ($AMPI^{+/-}$) technique, referred to in this study as $Digital_{AMPI^{+/-}}$ [14,15]. Among the reasons that led to the use of these two methods is the possibility, thanks to the choices made during their elaboration, to conduct the study of a phenomenon also from the point of view of its evolution over time. Although the use of aggregated indices is well consolidated and supported throughout the literature, this approach is not limitless. For this reason, an alternative synthesis method has been suggested employing the Partially Ordered Set – named as $Digital_{POSET}$ [6,7,8]. Among the strengths of $Digital_{POSET}$ is its great versatility of application, since it is suitable for studying qualitative, quantitative, and mixed variables, unlike aggregative methods [6,7,8,18]. In addition, since it does not require any aggregation and weighting of the variables, it avoids some of

the criticalities typical of composite the indicators, such as loss of information and the "flattering" effect concerning the incompatibilities that exist within a system of multi-dimensional variables.
For the construction of the non-aggregative index, one of the main issues in the $Digital_{POSET}$ analysis is the computational aspect. The study was therefore conducted by employing the statistical analysis software R and the CRAN package "parsec" [7]. Thanks to the graphical representation of the $Digital_{POSET}$ by the Hasse diagram, the cover relations between the individual profiles were re-constructed. Subsequently, the indicator was synthesized by exploiting the average rank method, which allows to obtain an order-preserved vector by calculating the average of the ranks assumed by each profile in a set of linear extensions of the original $Digital_{POSET}$ - i.e. $Digital_{POSET}$ subsets composed exclusively of comparable profiles (i.e. chains). Once the rankings were derived for each proposal, the results of the research were presented comparing their performance.

1.1 Selection of basic indicators

The variables used were selected through I.Stat database by a formative approach [1], and with the guidelines included by the Italian Government in the W1.C1 Mission of the RRF, dedicated to the "Digitalisation, innovation and security within the PA" [8]. Therefore, seven variables expressing the development of eGovernment were identified: (1) percentage of public institutions adopting cloud computing services to manage their data (CCS); (2) percentage of people aged 16-74 years who have used the Internet in the last 3 months and have basic digital skills (BDS); (3) percentage of institutions that have used all IT security measures (CS); (4) percentage of households with access to a broadband connection (BBC); (5) percentage of people (>14 years old) who contacted the PA in the last 12 months to obtain information through the internet (DS_I); (6) percentage of people (>14 years old) who interacted with the PA in the last 12months to download pre-filled forms through the internet (DS_PFF); (7) percentage of people (>14 years old) who have contacted the PA in the last 12months to send filled forms via the internet (DS_SM).

Discussion of the results

First of all, thanks to the cluster analysis carried out on the synthetic indices by the k-means method [17], a digital gap in terms of eGov adoption is evident. All three indices show that Sicily and Calabria are the most critical regions compared to the Italian context, with the 19th and 20th rankings, respectively. From the $Digital_{POSET}$ index perspective, however, a discrepancy appears between the two profiles, which are actually incomparable, as observed by studying the original data. Sardinia, Ligurian and Tuscany present distinctive features. While on the one hand the composite indexes place these three regions - two of which are in the center-

north - among those with medium digitalization performances, $Digital_{POSET}$ supplies more information. From the study of the non-aggregative index, in addition to the lack of comparability with any other profile, it's emerged also a great internal variability from the viewpoint of the range between which the ranks are assigned to the regions by the simulations of the final operation on the indicators, a correlation analysis between the three indices was carried out, using Kendall's aggregation coefficient ($\tau - b$) as a technique. After verifying the correct existence of the requirements for the use of Kendall's method, the results for the three indices were obtained. Through the function "corr.test()" implemented in R, an extremely positive correlation has been obtained in all three cases. Between $Digital_{AMPI^{+/-}}$ and $Digital_{min-max}$ for example, $\tau - b$=0.91 - showing a near-superposition between the two rankings. Lower is instead, although positive, $\tau - b$=0.87 calculated between $Digital_{min-max}$ and $Digital_{POSET}$. Finally, between $Digital_{AMPI^{+/-}}$ and $Digital_{POSET}$ there is a correlation $\tau - b$=0.78.
Although the values reported by the correlation index may suggest the choice between $Digital_{min-max}$ and $Digital_{POSET}$, it is necessary to consider the higher robustness obtained by the influence analysis test for the $Digital_{AMPI^{+/-}}$. Therefore, it is suggested that the final comparison between the latter aggregative technique and the $Digital_{POSET}$index should be the non-aggregative alternative.

Conclusions

In the light of what emerged during the analysis of the technical literature and from the considerations during the discussion of the results, we confirm the limitations linked to the use of synthetic indicators to the advantage of non-aggregative measures, which make it possible to understand the real variability that exists for a statistical unit, the existing relations of order between profiles without thinking about incompatibilities incurring a "flattening" risk in the interpretation of the results. Over the coming years, it will be necessary to update the datasets to continue checking the evolution of eGov systems at the NUTS-2 level, to understand the real state the art of government policies in terms of the digital transition.

Interpretability in functional clustering with an application to resistance spot welding process in the automotive industry

Interpretabilità nelle tecniche di clustering di dati funzionali mediante un'applicazione al processo di saldatura a resistenza per punti nell'industria automobilistica

Christian Capezza, Fabio Centofanti, Antonio Lepore, Biagio Palumbo

Abstract The functional clustering problem is recurrent in the Industry 4.0 framework with the ultimate goal to turn homogeneous cluster identification of profile data into a valuable interpretation of the phenomenon at hand. The concept of interpretability was recently addressed in functional cluster analysis by developing sparse methods able also to detect the portion of profile domain determining the cluster mean differences. This contribution aims to practically motivate the need for spreading sparse functional clustering methods in the industry through an application of the SaS-Funclust method proposed in [3] on the `ICOSAF` project functional data set which pertains to the automotive industry and contains observations of dynamic resistance curves, commonly recognized as the complete technological signature of the resistance spot welding process.

Abstract *Le tecniche di clustering di dati funzionali sono molto diffuse nel paradigma Industria 4.0 con l'obiettivo di interpretare il fenomeno in esame attraverso l'identificazione di sottogruppi omogenei dei segnali osservati. Il concetto di interpretabilità viene tradotto nell'ambito del clustering mediante lo sviluppo di metodi sparsi, in grado di identificare le porzioni di segnale che impattano maggiormente sulle differenze in media presenti tra i diversi gruppi identificati. Questo lavoro intende motivare la diffusione nell'industria di tecniche di clustering interpretabili, promuovendo l'uso del metodo SaS-Funclust proposto in [3] attraverso l'applicazione al dataset `ICOSAF` nell'ambito dell'industria automobilistica, che contiene osservazioni di curve di resistenza dinamica, comunemente riconosciute come firma tecnologica del processo di saldatura a resistenza per punti.*

Key words: Functional data analysis, Functional clustering, Sparse clustering, Interpretability

1 Introduction

The dramatic advances in computational power and technology have allowed scientists and practitioners in business and industry to acquire and store massive and complex data apt to be modelled as continuous random functions defined on a compact domain, which are usually, and hereinafter, referred to as *functional data*, *profile data* or simply *profiles*. However, the most common practice in industrial data analysis is to use any domain knowledge to extract univariate or multivariate attributes from observed profiles, even though this is markedly criticized as problem-specific, arbitrary, and risky of hiding useful information contained by the original profile. To circumvent this issue, the most natural idea is to cross-fertilize industrial best practices with functional data analysis (FDA) techniques [13, 7, 4, 8] and use or develop FDA methods to be directly applied on functional data as founding elements. This applies also to the so-called functional *clustering problem* in the unsupervised statistical learning setting, that is the identification of homogeneous subgroups (clusters) in a functional data set, without having specific knowledge about the true underlying clustering structure. The term *homogeneus* means that data falling in each group are more similar than those falling in different groups, with respect to a given similarity measure. As in any FDA problem, the intrinsic infinite dimensionality of functional data does not make the functional cluster analysis a mere extension of multivariate clustering. Classical overview of functional clustering methods can be found in [13, 4]. The functional clustering problem is recurrent in the Industry 4.0 framework where the quality characteristic of interest is often in the form of profile and has the ultimate goal to turn homogeneous cluster identification of profiles into a valuable interpretation of the process, or more in general, the phenomenon at hand.

The concept of *interpretability* is a broader issue to be faced in the development of insightful statistical approaches not only in business and industry but also in a large variety of applications such as medical sciences, law and justice. This concept was recently discussed during the ENBIS (European Network for Business and Industrial Statistics) Workshop "Interpretability for Industry 4.0" that was held at the University of Naples Federico II (Italy) on July 12-13, 2021 [9] and offered real-world industrial motivations and deep methodological insights on this topic [10]. Even though there is a lack of consensus about the rigorous definition, interpretability essentially refers to a profound cognitive process as the ability of a model or technique (or any element related to them, e.g., inputs, outputs, predictions) to support human decisions based on them [10]. This ability may have positive consequences on the acceptability of any proposed tool and its relative industrial deployment. Interpretability in functional clustering was recently addressed by developing *sparse* methods which are able to jointly cluster profiles and detect the portion of the profile domain that mostly determines the clustering, hereinafter referred to as *informative portion*. As in the multivariate setting, [6, 12, 11, 15], where some attributes could be completely noninformative to uncover the clustering structure of interest, sparse functional clustering methods [5, 14, 3] improve the interpretability of the solution, by imputing the presence of the clustering structure to the informative portion, as

well as its accuracy, because it avoids noninformative portions to possibly hide the actual clustering structure.

The paper aims to practically motivate the need for spreading sparse functional clustering methods in industry, by promoting the use of the SaS-Funclust method that was proposed in [3] and shown to outperform other methods already appeared in the literature before. SaS-Funclust is based on a functional Gaussian mixture model whose parameters are estimated by maximizing an objective function obtained by penalizing a log-likelihood function with roughness and functional adaptive pairwise penalties. The roughness penalty is introduced to impose some smoothness to the estimated cluster means, while the functional adaptive pairwise penalty identifies the informative portion by shrinking the means of separated clusters to some common values.

The remainder of the paper is as follows. Section 2 motivates the need for sparsity through a simulated numerical toy example. Section 3 applies the SaS-Funclust method to the `ICOSAF` project data set, which is a functional data set acquired during lab tests at Centro Ricerche Fiat (CRF) to characterize a resistance spot welding process in the automotive industryand openly available online [1]. A brief conclusion is presented in Section 4.

2 A simulated toy example

Figure 1 shows the cluster means estimated for a simulated data set, in which the real number of clusters is $G = 3$, by the SaS-Funclust method through the R package `sasfunclust` available on CRAN []. The informative portion of the domain for each pair of clusters is correctly recovered. The estimated cluster means are indeed pairwise fused over approximately the same portion of the domain as the true cluster means pairs. Note that, for the clusters whose true means are equal over $t \in (0.2, 1.0]$, the SaS-Funclust method identifies the informative portion of domain roughly in $[0.0, 0.2]$.

3 An application to resistance spot welding process in the automotive industry real-case study

Starting from the idea given by the simulated toy example of Section 2, in this real application we want to demonstrate the practical advantages of a sparse functional cluster analysis, in terms of interpretability. The `ICOSAF` project data set mentioned in the introduction contains 538 dynamic resistance curves (DRCs) acquired over a regular grid of 238 points equally spaced by 1 ms. DRC is recognized as the full technological signature in the resistance spot welding processes. Further details on this data set can be found in [2]. In this application, we focus on the DRCs estimated by means of the central differences method applied to the DRC values sampled each

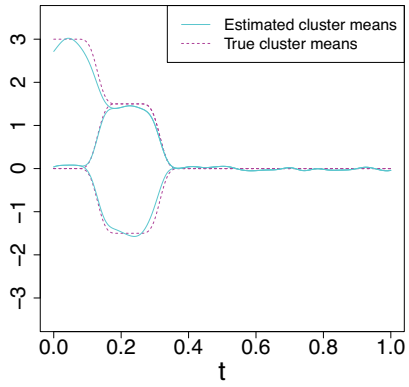

Fig. 1: True and estimated cluster means obtained through the SaS-Funclust method for a simulated data set in which the real number of clusters is $G = 3$.

2 ms. Figure 2 (a) shows the 538 functional observation of DRCs warped, without loss of generality, on the same compact domain $[0, 1]$, whereas Figure 2 (b) shows the corresponding derivative functions. In this setting, the aim of the analysis is to cluster DRCs and identify homogenous groups of spot welds that share common mechanical and metallurgical properties. Based on the considerations provided by [2] as well as on cluster number selection methods that are described for the SaS-Funclust and competing methods in [3], the number of clusters is set equal to $G = 3$. The estimated cluster mean of DRC derivative functions are displayed in Figure 2 (c), colored by cluster identified by the SaS-Funclust method. The same colours are used accordingly in Figure 2 (a) and (b), for graphical convenience. Even though at the first glance of Figure 2 the SaS-Funclust method seems to provide partitions that are similar to those obtained in [2] through the FPCA-based methods, the former clearly enables a more insightful interpretation of the results. The SaS-Funclust method is in fact able to effectively fuse cluster mean functions over noninformative portions of the DRC domain.

The mean function of DRC derivatives in clusters 1 and 3 are fused approximately from 0.5 to 1, due to comparable decreasing rate of the DRCs over these clusters. Instead, the mean of cluster 2 is fused with other cluster means between 0.8 and 1, only. Differences between mean functions of the three clusters are plainly visible in the first part of the domain. In particular, note that DRCs of cluster 2 show a smaller mean of the derivative function and reach their peaks (i.e., zeros of the first derivative) earlier than those of clusters 3 and 1. Roughly speaking, the plot in of Figure 2 (c) is a powerful support to display how the mean function behaviours differ over informative portions, as it allows practitioners to effectively filter out the focus of the analysis from the portions of domains where the estimated cluster mean functions are fused.

4 Conclusion

The advantages of the SaS-Funclust method, as a nice example of a sparse functional clustering method, are used to encourage the use of functional clustering methods in the industry, in place of traditional univariate or multivariate techniques. These in fact force practitioners to extract scalar attributes from quality characteristic naturally observed as functional data. The sparsity of the final solution induced by the functional adaptive pairwise fusion penalty of the SaS-Funclust method [3] allows pairs of cluster mean functions to be separated only over informative portions of profiles, or, in other terms, to be exactly equal over noninformative portions of the domain. In many applications, as in the `ICOSAF` project data set analyzed, such informative portions are very limited. In this case, a sparse clustering method may automatically improve interpretability. The specific application to the `ICOSAF` project data set identified homogenous groups of DRCs with different rate of change in the first part of the process alone. The identification of this behaviour, i.e., informative portion of DRC domain has been confirmed by CRF experts as a novel insight into the resistance spot welding process characterization which can naturally guide prac-

titioners to define, in a later stage of process learning, the most effective proxy of the final quality of spot welds produced.

Acknowledgements The authors acknowledge the CINECA award under the ISCRA initiative, for the availability of high performance computing resources and support. The present work was developed within the activities of the project ARS01_00861 "Integrated collaborative systems for smart factory - ICOSAF" coordinated by CRF (Centro Ricerche Fiat Scpa - `www.crf.it`) and financially supported by MIUR (Ministero dell'Istruzione, dell'Università e della Ricerca). The authors are extremely grateful to CRF WCM R&I (World Class Manufacturing Research and Innovation) sites of Orbassano and Campus Melfi, for the access to experimental data, and the general support over the course of these activities. In particular, the authors wish to thank Alessandro Zanella, Gianmarco Genchi, and Mariano Quagliano for their technological insights in the interpretation of the results.

Statistical process monitoring of thermal images in additive manufacturing: a nonparametric solution for in-situ monitoring

Monitoraggio statistico di processo di immagini termiche in manifattura additiva: una soluzione non parametrica per il monitoraggio in situ

Panagiotis Tsiamyrtzis[1], Marco Luigi Giuseppe Grasso[2] and Bianca Maria Colosimo[3]

Abstract Statistical Process Control and Monitoring (SPC/M) is a well-defined area of statistics, which aims to provide tools (typically in the form of control charts) that can be used in monitoring the quality in an ongoing process. Specifically, the goal is to determine whether a process works under statistical stability (i.e. with endogenous to the process variation) also called "In Control" (IC) state, or if any assignable (i.e. exogenous to the process) variation exists, named "Out of Control" (OOC) state. A powerful control chart will be able to detect a transition form the IC to the OOC state "soon" after its occurrence, maintaining a "low" false alarm rate. Once the IC state distribution is estimated, then a control chart can be calibrated and used for the process monitoring. The control chart choice will depend on the data dimension (univariate/multivariate), on the type of parameter shift that we aim to detect (transient/persistent) and are built under the Frequentist, Non-parametric or the Bayesian approach.

In this work our focus is in the use of SPC/M to a novel field of engineering called Additive Manufacturing (AM), where a three dimensional object is build, layer by layer, from a Computer Aided Design (CAD), permitting custom made products that would be impossible to construct otherwise. In AM we have a new quality monitoring framework as we move from mass production to a single custom made product. This is the first challenge that we face since we are not able to talk about the quality stability over multiple products, as we do in SPC/M, but we need to guarantee a stable (IC) state over a single product/process (Colosimo et al, 2018).

[2] Marco Luigi Giuseppe Grasso, Dept. of Mechanical Engineering, Politecnico di Milano, marcoluigi.grasso@polimi.it
[3] Bianca Maria Colosimo, Dept. of Mechanical Engineering, Politecnico di Milano, biancamaria.colosimo@polimi.it

As AM processes move from one layer to the next, opportunities arise as quality characteristic measurements are of non-invasive nature and in-situ in-line monitoring represent a significant opportunity for first-time right production (Grasso et al, 2021). The most widely used sensors in such cases are cameras (infrared and/or visual), which can record in near real time the ongoing process, providing time-stamped images that can be used in monitoring the quality, i.e. we have unstructured data. Nowadays, video based data become more and more informative of the process, as the frame rate and the resolution increases, producing orders of magnitude larger volumes of data compared to what we used to have in the past. In the industry 4.0 era, where big data streams are available, the SPC/M (and statistics in general) faces the challenge of handling efficiently all this flow of information. Opportunities and challenges of moving SPC/M to image data has been discussed in the literature (Megahed et al., 2011) and several approaches have been proposed in the framework of image-based SPC/M for AM (Grasso et al., 2018; Colosimo and Grasso, 2018 and Yan et al, 2021).

In a recent work, Tsiamyrtzis et al. (2021) presented two novel non-parametric process monitoring methodologies that utilized the concept of partial first order stochastic dominance (PFOSD) in handling all the above mentioned challenges. In this work they used infrared thermography (i.e. univariate) pixel based data for which spatial information was neglected permitting complex underlying dynamics and tested the performance on simulated and real data from the production of zinc samples, demonstrating efficient performance in the presence of different OOC scenarios of various severity levels.

In this contribution, the PFOSD approach and different extensions are presented and discussed in the framework of in-situ SPC/M for AM. In particular, a multivariate extension of the approach is discussed to improve performance of the proposed method by enhancing the informative content to be monitored layerwise. A self-starting solution is also presented as very appealing to start monitoring layerwise with the beginning of the process, breaking free of the usual off-line calibration phase.

Multiple Arrows in the Bayesian Quiver: Bayesian Learning of Partially Directed Structures from Heterogeneous Data

Frecce Multiple all'Arco Bayesiano: Apprendimento Bayesiano da Dati Eterogenei di Strutture Parzialmente Orientate

L. La Rocca, F. Castelletti, S. Peluso, F.C. Stingo and G. Consonni

Abstract Motivated by the identification of complex dependencies in biological networks, we present a Bayesian method for structural learning of graphical models that exhibits two distinctive features: i) it does not assume a priori an ordering of the variables, but it learns arrows when possible and lines otherwise; ii) it assumes that the observations form subgroups having different but similar structures.
Abstract *Motivati dall'identificazione di dipendenze complesse in reti biologiche, presentiamo un metodo bayesiano per l'apprendimento strutturale di modelli grafici che esibisce due caratteristiche distintive: i) non assume a priori un ordinamento delle variabili, ma apprende frecce quando possibile e linee altrimenti; ii) assume che le osservazioni formino sottogruppi aventi strutture diverse ma simili.*

Key words: Markov equivalence, Markov random field, objective Bayes

1 Introduction

Biological networks, where biomolecules are represented by nodes and molecular influences by edges, are crucial to modern biology [14]. The representation can be made precise as a graphical model for a vector of molecular variables to be measured in biological samples, but it is important to understand that there is no unique way to take this step: Section 2 illustrates this point. A biological network interpreted as a graphical model can be learned from data [8], and this can be useful to identify the complex dependencies represented by its structure.

It is not uncommon for biological samples to form subgroups in such a way that greater similarity is expected within groups than across groups: Kornblau et al. [11], for instance, measured protein levels on leukemia patients classified in 4 subtypes (17 subjects of type M0, 34 subjects of type M1, 68 subjects of type M2, and 59 subjects of type M4) disregarding subtypes with fewer observations. In such a case, if a single structure is learned from all samples, the estimate will be based on 178 observations, but the differences between subtypes will be lost. On the other hand, if individual structures are learned from each group of samples, the estimates will be based on 68 observations at best (and 17 observations at worst) despite the fact that some common structure across subtypes is only to be expected. This tension, which is at the heart of multiple structural learning, was overcome by Peterson et al. [17] using a Bayesian method to borrow strength across subgroups.

It turns out that Bayesian methods are well-suited to graphical models: besides their ability to express uncertainty in natural terms, using simple concepts like the probability of inclusion for a given edge, they can incorporate prior information and encourage sparsity; see Ni et al. [15] for a recent overview geared towards modern biological applications.

Peterson et al. [17] dealt with undirected graphical models. We [6, 12] deal with (acyclic) directed graphical models, which introduce the problem of directing the edges of the graph (without forming cycles). If an ordering of the variables is known a priori, the graphical model reduces to a product of regression models and can be learned very effectively; see Altomare et al. [1] for a treatment of the simpler case without subgroups. If no ordering of the variables is know a priori, one faces Markov equivalence: different graphs may give rise to the same statistical model, so that observational data are unable to distinguish one from another, and not all arrows can be directed; see Section 2 for more information. We work in this second, harder, but more realistic, scenario, as described in Section 3.

2 Graphical Models

Let $Y_1, \ldots, Y_q$ be q molecular variables of interest (random variables representing a population of interest) collected together in a vector $\mathbf{Y} = (Y_j)_{j \in V}$ indexed by the set of biomolecules $V = \{1, \ldots, q\}$. Each variable will be associated to a node in a graph $\mathbb{G}$, like those depicted in Fig. 1, with edges representing molecular influences.

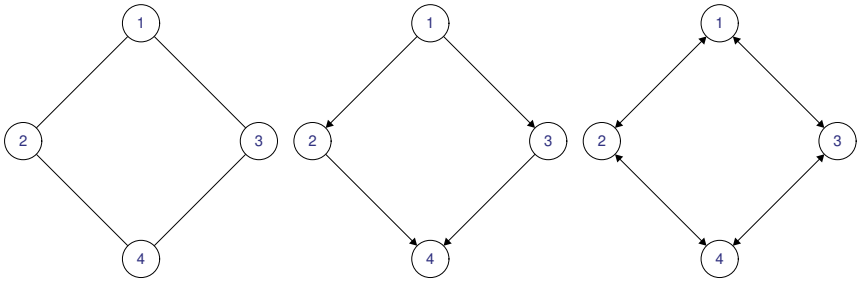

Fig. 1 Three example graphs for four variables: an undirected graph (left), an acyclic directed graph (center), and a bidirected graph (right).

The lacking edges of $\mathbb{G}$ can be read as (conditional) independence statements about subvectors of $\mathbf{Y}$, thus defining a statistical model for $\mathbf{Y}$, by choosing a specific Markov property [9, 13, 19], which is usually suggested by the type of edges that form the graph. For instance, the left graph in Fig. 1 consists of undirected edges (lines) and is usually interpreted as stating

$$Y_1 \perp\!\!\!\perp Y_4 \mid Y_2, Y_3 \quad \text{and} \quad Y_2 \perp\!\!\!\perp Y_3 \mid Y_1, Y_4 \tag{1}$$

where $\perp\!\!\!\perp$ denotes independence and $\mid$ conditioning. On the other hand, the central graph in Fig. 1 consists of directed edges (arrows) and is typically interpreted as stating

$$Y_1 \perp\!\!\!\perp Y_4 \mid Y_2, Y_3 \quad \text{and} \quad Y_2 \perp\!\!\!\perp Y_3 \mid Y_1 \tag{2}$$

where the second independence statement is no longer conditional on Y_4. Finally, the right graph in Fig. 1 consists of bidirected edges (double arrows) and is typically interpreted as stating

$$Y_1 \perp\!\!\!\perp Y_4 \quad \text{and} \quad Y_2 \perp\!\!\!\perp Y_3 \tag{3}$$

where there is no conditioning at all. Clearly, equations (1), (2) and (3) have different implications on the data that can be observed from $\mathbf{Y}$.

We remark that the left and right graphs in Fig. 2 are essentially the same graph, because they only differ in the choice of depicting symmetric influences as lines or double arrows, but the statistical models given by (1) and (3) are radically different, because the pictorial choice leads to using different Markov properties. One should be wary of a potential mismatch between the substantial meaning of a biological network and its implications on data when it is interpreted as a graphical model (statistical model specified by a graph through a Markov property).

In the following, we restrict our attention to acyclic directed graphs (like the central one in Fig. 1). These graphs are especially interesting, because they explicitly provide a data generating mechanism and can be used for causal reasoning [16]. It should be noted, however, that bidirected graphs (like the right one in Fig. 2) can emerge from acyclic directed graphs under marginalization [9]; this implies that we are assuming all relevant variables are observed as components of $\mathbf{Y}$.

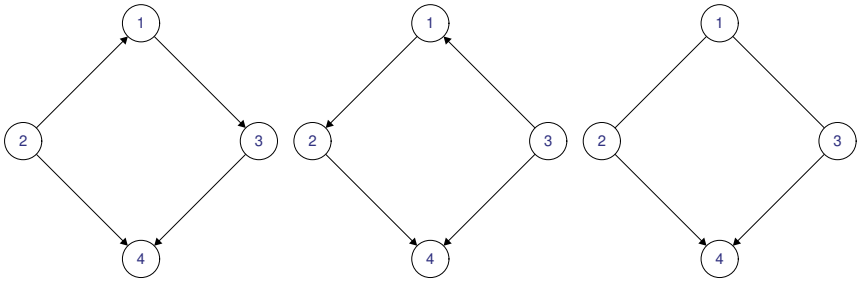

Fig. 2 Two equivalent acyclic directed graphs (left, center) and their essential graph (right); the latter has $\{1,2,3\}$ and $\{4\}$ as chain components.

Two graphs are Markov equivalent (under a given Markov property) if they define the same statistical model: this happens, for acyclic directed graphs, if and only if [20] they have the same skeleton (undirected graph obtained turning all arrows into lines) and the same immoralities (sugbraphs $i \to k \leftarrow j$ with i and j not joined by an edge). For instance, the left and central graphs in Fig. 2 are Markov equivalent: they share the left graph in Fig. 1 as skeleton and have $2 \to 4 \leftarrow 3$ as their unique immorality. They are also equivalent to the central graph in Fig. 1 and it is clear that data observed from $\mathbf{Y}$ will not be able to discriminate between these three graphs. Hence, in effect, we will be learning a Markov equivalence class.

Each Markov equivalence class can be represented by an essential graph [2] like the right graph in Fig. 2. The nodes of an essential graph can be partitioned in blocks, called chain components, such that: i) nodes in the same block are connected by lines; ii) nodes in different blocks can be joined by arrows; iii) there are no cycles containing arrows. This partitioning can be used to factorize the probability density function of $\mathbf{Y}$ (conditional on the essential graph $\mathbb{G}$) as

$$f_{\mathbb{G}}(\mathbf{y}) = \prod_{\tau \in \mathcal{T}} f_{\mathbb{G}}(\mathbf{y}_\tau \mid \mathbf{y}_{\mathrm{pa}(\tau)}), \quad \mathbf{y} \in \mathbb{R}^q \tag{4}$$

where $\mathcal{T}$ is the family of all chain components of $\mathbb{G}$, τ denotes the generic chain component, $\mathrm{pa}(\tau) = \{i \in V \mid \mathbb{G} \text{ contains } i \to j \text{ for some } j \in \tau\}$ is the parent set of τ, and $\mathbf{y}_\tau = (y_j)_{j \in \tau}$ denotes the subvector of $\mathbf{y}$ indexed by τ. Equation (4) defines the same statistical model as the acyclic directed graphs in the class represented by $\mathbb{G}$; see Andersson et al. [3] for a discussion of the underlying Markov property.

Since a characterization of essential graphs is available [2, 18], equation (4) can be used to carry out structural learning in the space of essential graphs [5]. This leads to learning a graph where edges are arrows if data permit and lines if data do not permit, which is a fair graphical summary of the information contained in the data. In case interventional data are also available, that is, data collected after intervening on same variables, it may be possible to learn more arrows [4, 10], but an essential graph is the best possible output, in terms of learning arrows, when the analysis is based on observational data (as opposed to interventional data).

3 Learning Method

Let $\mathbf{Y}_{[k]}$ be the $n_k \times q$ data matrix obtained observing $\mathbf{Y}$ in group k, for $k = 1, \ldots, K$, and obtain the full data matrix $\mathbf{Y}_{[1:K]}$ by stacking $\mathbf{Y}_{[1]}, \ldots, \mathbf{Y}_{[K]}$ on top of one another. Then, conditional on a multiple essential graph $\mathbb{G}_{[1:K]} = (\mathbb{G}_{[1]}, \ldots, \mathbb{G}_{[K]})$, assuming independence across groups (as well as within groups) and Gaussian observations, the likelihood, constrained by (4), can be written as

$$f_{\mathbb{G}_{[1:K]}}(\mathbf{Y}_{[1:K]} \mid \boldsymbol{B}_{[1:K]}, \boldsymbol{\Omega}_{[1:K]}) = \prod_{k=1}^{K} \prod_{i=1}^{n_k} \prod_{\tau \in \mathcal{T}_k} f_{\mathbb{G}_{[k]}}(\mathbf{y}_{[k]i\tau} \mid \mathbf{y}_{[k]i\mathrm{pa}(\tau)}, \boldsymbol{B}_{[k]\tau}, \boldsymbol{\Omega}_{[k]\tau}) \quad (5)$$

where $\mathcal{T}_k$ is the family of all chain components of $\mathbb{G}_{[k]}$, $\mathbf{y}_{[k]i}$ is the i-th row of $\mathbf{Y}_{[k]}$, $\mathbf{B}_{[k]\tau}$ is a $\{|\mathrm{pa}(\tau)| + 1\} \times |\tau|$ matrix of regression coefficients (including intercepts), $\boldsymbol{\Omega}_{[k]\tau}$ is a $|\tau| \times |\tau|$ precision matrix constrained by the lacking lines between nodes in the chain component τ of $\mathbb{G}_{[k]}$, and $f_{\mathbb{G}_{[k]}}(\mathbf{y}_{[k]i\tau} \mid \mathbf{y}_{[k]i\mathrm{pa}(\tau)}, \boldsymbol{B}_{[k]\tau}, \boldsymbol{\Omega}_{[k]\tau})$ denotes the $|\tau|$-dimensional Gaussian density that regresses $\mathbf{y}_{[k]i\tau}$ on $\mathbf{y}_{[k]i\mathrm{pa}(\tau)}$.

We eliminate the nuisance parameters $\boldsymbol{B}_{[k]\tau}$ and $\boldsymbol{\Omega}_{[k]\tau}$ from (5) by assigning their parameter priors $\pi_{\mathbb{G}_{[k]}}(\boldsymbol{B}_{[k]\tau}, \boldsymbol{\Omega}_{[k]\tau})$ independently over k and τ, so that the resulting marginal likelihood also factorizes over k and τ, and the posterior probability for the multiple essential graph (parameter of interest) can be written as

$$\Pr(\mathbb{G}_{[1:K]} \mid \mathbf{Y}_{[1:K]}) \propto \Pr(\mathbb{G}_{[1:K]}) \prod_{k=1}^{K} \prod_{\tau \in \mathcal{T}_k} m_{\mathbb{G}_k}(\mathbf{Y}_{[k]\tau} \mid \mathbf{Y}_{[k]\mathrm{pa}(\tau)}) \quad (6)$$

where $\Pr(\mathbb{G}_{[1:K]})$ is the corresponding prior probability (specified below), $\mathbf{Y}_{[k]\tau}$ is the submatrix of $\mathbf{Y}_{[k]}$ formed by the columns of $\mathbf{Y}_{[k]}$ indexed by τ, and the quantity $m_{\mathbb{G}_k}(\mathbf{Y}_{[k]\tau} \mid \mathbf{Y}_{[k]\mathrm{pa}(\tau)}) = \int \pi_{\mathbb{G}_{[k]}}(\boldsymbol{B}_{[k]\tau}, \boldsymbol{\Omega}_{[k]\tau}) \prod_{i=1}^{n_k} f_{\mathbb{G}_{[k]}}(\mathbf{y}_{[k]i\tau} \mid \mathbf{y}_{[k]i\mathrm{pa}(\tau)}, \boldsymbol{B}_{[k]\tau}, \boldsymbol{\Omega}_{[k]\tau})$ is available in closed form [6] for the objective parameter priors of Consonni et al. [7].

We specify the prior probability of $\mathbb{G}_{[1:K]}$ in two steps: we first use the prior of Peterson et al. [17] for the skeletons of $\mathbb{G}_1, \ldots, \mathbb{G}_K$, so that we encourage similarity among them and control their sparsity; we then assume, for the sake of simplicity, that all multiple essential graphs with given skeletons are equally probable. The prior of Peterson et al. [17] is a Markov random field depending on i) a vector $\boldsymbol{\nu}$ of sparsity parameters (one per each pair of nodes) and ii) a symmetric matrix $\boldsymbol{\Theta}$ of pairwise association parameters (one per each pair of groups). The prior for $\boldsymbol{\nu}$ controls sparsity, while the prior for $\boldsymbol{\Theta}$ encourages similarity, but the data are free to suggest which nodes are joined by an edge and which groups are not similar.

We target the joint posterior distribution of $\mathbb{G}_{[1:K]}$, $\boldsymbol{\Theta}$ and $\boldsymbol{\nu}$ with a Markov chain of Metropolis-Hastings type, which we marginalize to approximate the posterior distribution (6) on the set of all multiple essential graphs. As a point estimate from this distribution, we resort to the *projected median probability graph model* [5]. We refer the reader to Castelletti et al. [6] for details, as well as for simulations validating the method and some promising results on real data (including those of Kornblau et al. [11] presented in the Introduction).

Applications in Machine Learning

A neural network approach to survival analysis with time-dependent covariates for modelling time to cardiovascular diseases in HIV patients

Un approccio basato su reti neurali per l'analisi di sopravvivenza con variabili tempo-dipendenti per predire il tempo all'evento cardiovascolare in pazienti affetti da HIV

Federica Corso, Agostino Lurani Cernuschi, Laura Galli, Chiara Masci, Camilla Muccini, Anna Maria Paganoni and Francesca Ieva

Abstract In this study, we investigate the impact of AntiRetroviral Therapies (ART) and clinical features of HIV patients on the risk of a cardiovascular event, with a survival analysis approach. Clinical and demographic features of 4512 HIV patients are collected during a follow-up time of 15 years. Two different methods for survival analysis are adopted: the classical Cox Proportional Hazard model and a deep-learning approach, DeepHit, based on neural-network. Models are implemented including both time-invariant and time-varying covariates. Results of the two methods are compared in terms of predictive performance and interpretability, with a special focus on the different potentialities of the two approaches.

Abstract *In questo studio, analizziamo l'impatto delle Terapie AntiRetrovirali (ART) e delle caretteristiche cliniche di pazienti affetti da HIV sul rischio di evento cardiovascolare, applicando metodi di analisi di sopravvivenza. Il dataset è composto da 4512 pazienti affetti da HIV di cui sono note le informazioni cliniche e demografiche. Per l'analisi di rischio cardiovascolare adoperiamo due approacci: il classico modello di Cox a rischi proporzionali e il DeepHit basato su reti neurali. I modelli includono sia covariate tempo-invarianti che tempo-dipendenti, monitorate lungo il follow-up. I risultati dei modelli sono confrontati sia in termini di capacità predittiva che di interpretabilità, con una particolare attenzione alle diverse potenzialità dei metodi confrontati.*

1 Introduction

The Antiretroviral Therapy (ART) has allowed people affected by Human Immunodeficiency Virus (HIV) to live longer, especially with the introduction of drugs such as Protease Inhibitors (PIs) combined with Nucleoside Reverse Transcriptase Inhibitors (NRTIs) and Non-Nucleoside Reverse Transcriptase Inhibitors (NNRTIs), with a decrease of 60% in the expected rate of death [8]. Recently, the link between ART and CardioVascular Diseases (CVDs) has been explored [3] and some results have highlighted an association between the exposure to these drugs and the risk of CVD events [1]. In this work, we analyse the occurrence of a CVD event in 4512 patients affected by HIV, with a follow-up of 15 years from the beginning of the ART. Patients data are collected at each medical visit, producing a longitudinal dataset that tracks patients information through time. Given the complexity of the dataset, we adopt two different survival analysis approaches, the Cox Proportional Hazard (PH) model [2, 4] and DeepHit [6, 7], including both variables measured at the baseline, i.e., at the ART start, and during the follow-up, i.e., longitudinal data. The goal of this work is twofold: to investigate the relationship between ART and other patient's characteristics with the risk of a CVD event over time and to compare a classical survival method with an advanced machine learning one in which the assumptions of linear relationships and of proportional hazards are relaxed. To the best of our knowledge, the applications of time-dependent neural networks for survival analysis are still very rare in the literature and part of our work consists in the exploration of the potentialities of these methods in modelling and predicting time-to-event data.

2 HIV patients' data

A cohort of 4512 people living with HIV infection, attending the IRCCS Ospedale San Raffaele for routine care, who started ART since 1998 were included in the present study. For each patient, medical information was registered including demographic variables (e.g., sex, race, age, etc.), laboratory parameters (e.g., viremia, cholesterol, etc.) and time-exposure to ART drugs. 24 variables are selected according to clinician's experience and proportion of missing data. Specifically, our data include five variables describing the ART: four of them regard the cumulative time of exposure to drugs, each classified by the stage of the cycle they inhibit, and the last one regards the year of ART start, treated as categorical variable with 2007 as cut-off. Among the 4512 patients, only 90 (2%) experienced a CVD event within 15 years of follow-up.

3 Methods

Survival analysis is a common method used to predict the time-to-event, e.g., the time until a CVD event happens. The target variable is defined as the couple of the survival time $T_i = min(T_i^*, C_i)$ and the censoring indicator $\delta_i = \mathbb{I}(T_i^* \leq C_i)$, for each observation $i = 1, \ldots, N$, where C_i is the censoring time and T_i^* is the CVD event time, if any.

3.1 The Cox Proportional Hazard model

Cox Proportional Hazard model is a semi-parametric method that models the association between covariates and the event risk, through time. The Cox PH model assumes the hazard function for an individual i to be described as follows:

$$h_i(t|\mathbf{x}_i) = h_0(t)e^{\mathbf{x}_i^T \boldsymbol{\beta}} \tag{1}$$

where $h_0(t)$ is the baseline hazard function, $\mathbf{x}_i^T$ is the covariates vector for the i^{th} individual and $\boldsymbol{\beta}$ is the vector of the regression coefficients. The parameter estimation is obtained by maximizing the *partial likelihood*, that considers only the probabilities for the patients who experience the event. The Cox PH model has two strong assumptions: the hazard ratios are assumed to be constant over time (proportional hazards) and the relationship between the *log* hazard and the covariates is assumed to be linear. Cox PH model can also handle time-dependent covariates. In this case, the hazard function at time t depends on the time-invariant covariates and on the values of the time-dependent covariates only at time t:

$$h_i(t|\mathbf{x}_i(t)) = h_0(t)e^{\left[\sum_{k=1}^{P_{fix}} x_{ik}\beta_k + \sum_{z=1}^{P_{td}} x_{iz}(t)\delta_z\right]} \tag{2}$$

where $\mathbf{x}_i(t)$ is the vector of covariates of the i^{th} patient, including P_{fix} fixed variables with coefficient vector $\boldsymbol{\beta}$ and P_{td} time-dependent variables, assuming different values at each time t, with coefficient vector $\boldsymbol{\delta}$. It is worth to underline that the coefficients are assumed to be time-invariant.

3.2 DeepHit: Neural-network based approach to survival analysis

DeepHit [7] is a Neural-Network (NN) based model that is able to capture complex patterns such as interactions among variables and non-linear relationships between the covariates and the outcome. DeepHit can handle k competing risks and is structured by feed-forward blocks such as a shared sub-network and k cause-specific networks. The shared sub-network captures the patterns of the relationships

between covariates and the time-to-event that are common to all different k events. Each cause-specific network captures the features of a specific event. The cause-specific cumulative incidence function expresses the probability that a particulat event $k^* \in K$ occurs on or before time t^* conditional on the covariates $\mathbb{X}^*$. The parameter estimation is based on the minimization of the weighted sum of two loss functions, *L1* and *L2*. *L1* is the log-likelihood of the joint distribution modified for right censored data, while *L2* is the ranking loss that incorporates the estimated cumulative incidence functions to finetune the network to each cause-specific event. The extension of the DeepHit structure for longitudinal data [6] is a recurrent NN where the shared block is replaced with a shared recurrent NN and the k specific networks. In this case, a loss function, that handles time-dependent variables and right censored data, is introduced in the shared NN. In particular, it is defined as the sum of three sub-loss functions, including *L3* loss function that makes predictions on the one step-ahead covariate x.

4 Results and model evaluation

We apply Cox PH method and Deephit method, both at baseline, i.e. at the ART start, and at the end of the follow-up, by including time-dependent covariates, to model the time to a CVD event in HIV patients, within 15 years from the baseline. For each method, full (24 covariates) and reduced models are implemented. DeepHit results are interpreted by means of the Permutation Feature Importance (PFI) and the Shapley value Additive Explanation [5]. Results are compared in terms of interpretability and predictive power (on training and test sets).

4.1 Cox and DeepHit models at baseline

At baseline, the full Cox PH model enables to understand which are the significant variables and how they contribute in the prediction of the time-to-CVD. The Hazard Ratios of the Cox model allow to deduce that an hypertensive patient has a risk of a CVD event 2.74 times higher than a non-hypertensive patient. Regarding the protective factors, a patient who started the ART before 2007 is less likely to experience a CVD event. Results of DeepHit are less quantitatively interpretable but, by using Shapley values, we can understand how the covariates interact on the risk of having a CVD event. By looking at the Shapely values, we observe that hypertension is again a risk factor and the year of ART start is still a protective factor. The Cox model predicts with a C-index of 0.66 on the test set while the DeepHit reaches 0.74 on the test set. Given the low percentage of observations with CVD event and the high number of covariates, we proceed with models reduction to obtain more robust performances. While the Cox models is reduced with a one-step procedure based on the Hazard Ratios, the feature selection for the DeepHit model is computed by

adopting Shapley values of the variables in Fig.1. Some interesting behaviors are highlighted by the DeepHit model: a short exposure to NRTIs increases the risk of CVD events while a medium-long exposure decreases it. Moreover, Shapley values allow to visualize interactions between couples of covariates: if we look at the interaction between exposure to NRTIs and patient's age (Fig. 2), we observe that the effect of therapies is stronger in old patients both in increasing the risk (for short exposure) and in decreasing it (for long exposure). The reduced Cox model achieves slightly better performance on the test set (C-index 0.69) while the reduced DeepHit model is similar to the complete model.

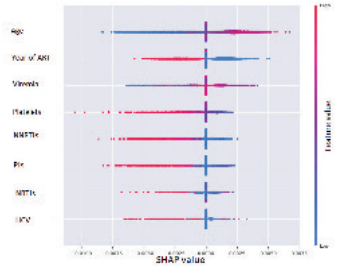

Fig. 1 The Shapley value importance of the reduced DeepHit model at the baseline.

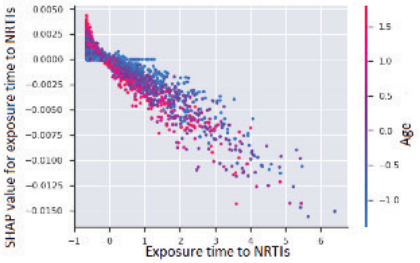

Fig. 2 The Shapley value dependency on the time of exposure to NRTIs as the age of the patients varies for the reduced DeepHit model at the baseline.

4.2 Time-dependent Cox and dynamic DeepHit models

The results of the time-dependent Cox model are interpreted through the Hazard Ratios and, again, the most significant variables are the year of ART start and hypertension. Since the computational cost of Shapaley values for logitudinal data is prohibitive, we measure the contribution of each covariate in the dynamic DeepHit with the PFI using the C-index on the training set. The NNRTIs and PIs drugs are the most important variables differently from the time-dependent Cox model. This is possibly due to DeepHit ability of capturing non-linear relationships. The dynamic DeepHit reaches a C-index of 0.77 while the Cox model achieves a lower C-index on the test set. We identify from the reduced time-dependent Cox model that the time to exposure to NNRTIs is a protective factor and the reduced dynamic DeepHit confirms the importance of the covariates NNRTIs and PIs. These results underline that time to exposure to drugs, which is an information that varies over time, remains the most important features for the prediction in both the full and the reduced models. The time-dependent Cox model with reduced covariates obtains a C-index of 0.70 in the test set while the Dynamic DeepHit reduced model does not perform as well as the complete model.

5 Conclusions

So far, the relationship between ART and CVD events was approached with classical regression and classification methods and only few studies adopted survival analysis tools or machine learning algorithms. In this study, the classic Cox PH model is compared with DeepHit on a real dataset with fixed and time-dependent variables. Specifically, the DeepHit models show that the time of exposure to ART drugs is associated with lower risk of CVD event and only under short exposure the risk might increase. Both the models find that the NNRTI drugs are protective factors even if the correlation among ART drugs might mask the effect of other variables. Moreover, patients who started the ART before 2007 are found to be less exposed to CVD risk. This work point out that in long term analysis the influence of ART drugs decreases the risk of CVD events. Better performances are achieved by including longitudinal data and in particular by the dynamic DeepHit that allows to analyse the relationship between covariates and time to CVD event in a more flexible way.

Analyzing the Correlation Structure of Financial Markets Using a Quantile Graphical Model

Analisi della struttura di correlazione dei mercati finanziari usando un modello grafico quantile

Beatrice Foroni, Luca Merlo and Lea Petrella

Abstract In this paper we develop a quantile graphical model to identify the tail conditional correlation structure in multivariate data across different quantiles of the marginal distributions of the variables of interest. To implement the procedure, we consider the Multivariate Asymmetric Laplace distribution and exploit its location-scale mixture representation to build a penalized EM algorithm for estimating the sparse precision matrix of the distribution by means of an L_1 penalty. The empirical application is performed on a set of market indexes, cryptocurrencies and commodities.

Abstract *In questo articolo sviluppiamo un modello grafico quantile per identificare la struttura di correlazione condizionata di coda attraverso lo studio dei quantili delle distribuzioni marginali delle variabili di interesse. Per implementare la procedura, consideriamo la distribuzione di Laplace asimmetrica multivariata e sfruttiamo la sua rappresentazione a mistura per costruire un algoritmo EM penalizzato per la stima della matrice di precisione sparsa della distribuzione mediante una penalità L_1. La metodologia presentata viene applicata sui rendimenti finanziari dei principali indici di mercato, criptovalute e materie prime.*

1 Introduction

In recent years, the urge to identify how the impact of financial stress events can spread across the whole financial global system has made network science a useful tool for describing the propagation of systemic risk. Within this literature, Gaussian Graphical Models (GGM) have received an enormous attention because they provide a simple method to model the pair-wise conditional dependence structure of a collection of stochastic variables. In a high-dimensional framework, when a large set of random variables is considered, we are interested in identifying only a smaller subset of variables that exhibits the most relevant and strongest dependencies. Among the several methods proposed in literature, there is the *Graphical LASSO* (*glasso*) algorithm of [4], which maximizes the likelihood of the model penalized by the L_1-norm of the elements of the precision matrix. However, several empirical studies show that financial returns exhibit most of the well known stylized facts like fat tails, leptokurtosis and skewness, and deviation from normality makes it harder to characterize conditional dependence structures. The literature regarding non-Gaussian graphical models is fairly limited. In this context, the work of [3] provides a tool for robust model selection using multivariate *t*-distributions to model the data. Moreover, these proposals are not able to recover the dependencies in the tails of the distribution. Be able to understand and focus on specific part of a distribution such as the tails can really improve the knowledge in areas like financial contagion and systemic risk, where the dynamic of extreme events is of utmost importance. In this paper we develop a quantile graphical model to estimate the conditional tail correlation structure in multivariate data at different quantile levels of interest, without relying on the restrictive assumption of normally distributed data. In order to model the conditional correlation structure of multiple random variables at quantile-specific indices, we generalize the work of [7], which consider a reparametrization of the Multivariate Asymmetric Laplace (MAL) distribution of [6] to jointly model conditional quantiles of multiple random variables in a likelihood framework. Following [3], we demonstrate that the precision matrix of the MAL distribution completely characterizes the conditional dependence structure among the random variables at each quantile level, and allows us to construct a graph whose edges correspond to relations of conditional dependency. To induce sparsity in the precision matrix, we exploit the Gaussian location-scale mixture of the MAL and apply the *glasso* algorithm. In particular, following [5], we build a suitable Penalized EM (PEM) algorithm based on the maximization of the likelihood of the model penalized by the L_1-norm of the off-diagonal elements of the

precision matrix. The estimated networks can be analyzed with respect to centrality measures as functions of the quantile level. The relevance of our approach is shown empirically among the cryptocurrency, commodity and stock market sectors from 2017 to 2021, and the modeling approach we propose is able to identify the connectedness as more serious levels of distress are considered, and can describe the topological structure of the underlying graph at different quantile levels of interest.

2 Model Specification

Given p quantile indexes $\tau = [\tau_1, \ldots, \tau_p]'$, with $\tau_j \in (0,1)$, for $j = 1, \ldots, p$, let $\mathbf{Y}_t = [Y_t^{(1)}, \ldots, Y_t^{(p)}]$ denote a continuous p-dimensional random vector for $t = 1, \ldots, T$. Generalizing the approach of [7], our objective is to develop a quantile graphical model for learning the conditional tail dependence structure among the components of $\mathbf{Y}_t$ at different quantile levels of interest τ. Specifically, we employ the MAL distribution, $\mathscr{MAL} \sim (\mu, \mathbf{D}\tilde{\xi}, \mathbf{D}\Sigma\mathbf{D})$, (see [6]) as:

$$f_{\mathbf{Y}}(\mathbf{y}_t) = \frac{2\exp\left\{(\mathbf{y}_t - \mu)'\mathbf{D}^{-1}\Sigma^{-1}\tilde{\xi}\right\}}{(2\pi)^{p/2}|\mathbf{D}\Sigma\mathbf{D}|^{1/2}} \left(\frac{\tilde{m}_t}{2+\tilde{d}}\right)^{\nu/2} K_\nu\left(\sqrt{(2+\tilde{d})\tilde{m}_t}\right), \quad (1)$$

where μ is the location parameter, $\mathbf{D}\xi \in \mathscr{R}^p$ is the scale (or skew) parameter, with $\mathbf{D} = \text{diag}[\delta_1, \delta_2, \ldots, \delta_p]$, $\delta_j > 0$ and $\xi = [\xi_1, \xi_2, \ldots, \xi_p]'$, having generic element $\xi_j = \frac{1-2\tau_j}{\tau_j(1-\tau_j)}$. Σ is a $p \times p$ positive definite matrix such that $\Sigma = \Lambda\Psi\Lambda$, with Ψ being a correlation matrix and $\Lambda = \text{diag}[\sigma_1, \sigma_1, \ldots, \sigma_p]$, with $\sigma_j^2 = \frac{2}{\tau_j(1-\tau_j)}$, $j = 1, \ldots, p$. Finally, $\tilde{m}_t = (\mathbf{y}_t - \mu)'(\mathbf{D}\Sigma\mathbf{D})^{-1}(\mathbf{y}_t - \mu)$, $\tilde{d} = \tilde{\xi}'\Sigma^{-1}\tilde{\xi}$, and $K_\nu(\cdot)$ denotes the modified Bessel function of the third kind with index parameter $\nu = (2-p)/2$. One of the key benefits of the MAL distribution is that, using (1) and following [6], the $\mathscr{MAL} \sim (\mu, \mathbf{D}\tilde{\xi}, \mathbf{D}\Sigma\mathbf{D})$ admits the following location-scale mixture representation:

$$\mathbf{Y} = \mu + \mathbf{D}\tilde{\xi}W + \sqrt{W}\mathbf{D}\Sigma^{1/2}\mathbf{Z} \quad (2)$$

where $\mathbf{Z} \sim \mathscr{N}_p(\mathbf{0}_p, \mathbf{I}_p)$ denotes a p-variate Normal distribution and $W \sim \text{Exp}(1)$ has a standard Exponential distribution, with $\mathbf{Z}$ being independent of W. Hence, the mixture representation in (2) represents the generating process of a MAL random vector $\mathbf{Y}$ from a latent Gaussian random vector $\mathbf{Z}$ with correlation matrix Ψ and a single latent Exponential variable with mean 1. In particular, the constraints imposed on $\tilde{\xi}$ and Λ represent necessary conditions for model identifiability for any fixed quantile level $\tau_1, \ldots, \tau_p$ and guarantee that $\mu^{(j)}$ is the τ_j-th quantile of $Y_t^{(j)}$, for

$j = 1, \ldots, p$.

To build the graphical model, let $G = (V, E)$ be an undirected graph where $V = \{1, \ldots, p\}$ is the set of nodes, such that each component of the random variable $\mathbf{Y}_t$ corresponds to a node in V, and $E \subseteq V \times V$ represents the set of undirected edges. In order to study the conditional dependence structure of $\mathbf{Y}_t$ through the graph G, we exploit the MAL representation in (2). For notational convenience and to illustrate the similarities with the GGM, we define the precision matrix $\mathbf{K} = \Psi^{-1}$. Following the t-distribution graphical model approach in [3], we establish the following proposition.

Proposition 1. *For a fixed p-dimensional vector of quantile levels* $\tau = [\tau_1, \tau_2, \ldots, \tau_p]'$ *such that* $\tau_j \in (0,1)$*, for* $j = 1, \ldots, p$*, let* $\mathbf{Y} \sim \mathscr{MAL}(\mu, \mathbf{D}\tilde{\xi}, \mathbf{D}\Lambda\mathbf{K}^{-1}\Lambda\mathbf{D})$*. If two nodes* j *and* k*, with* $j,k \in V$ *and* $j \neq k$*, of the graph are separated by a set of nodes* $C \in V$*, then* $\mathbf{Y}^{(j)}$ *and* $\mathbf{Y}^{(k)}$ *are conditionally uncorrelated given* $\mathbf{Y}^{(C)}$*.*

The proof of Proposition 1 follows directly from the mixture representation of the MAL in (2) and the closure property of the Normal distribution under conditioning of its components. Most importantly, from Proposition 1 follows that the zero entries in the precision matrix $\mathbf{K}$ imply the conditional uncorrelation between the components of $\mathbf{Y}_t$ at each given quantile level τ. To estimate and make inference on the model parameters we develop a suitable Expectation-Maximization (EM) algorithm, which exploits the mixture representation of the MAL distribution, treating W as missing data. In order to identify only a smaller subset of variables that exhibit the most relevant and strongest dependencies, we construct a PEM algorithm by adding an L_1-norm penalty of the off-diagonal elements of $\mathbf{K}$ to the likelihood of the model. Specifically, for a given vector $\tau = [\tau_1, \tau_2, \ldots, \tau_p]'$, the penalized complete log-likelihood function is proportional to:

$$\ell_c(\Phi_\tau) \propto \frac{T}{2}\log|\mathbf{D}^{-1}\mathbf{K}\mathbf{D}^{-1}| - \frac{T}{2}\mathrm{tr}\{\mathbf{K}\mathbf{S}\} - \rho||\mathbf{K}||_1 \tag{3}$$

with

$$\mathbf{S} = \frac{1}{T}\sum_{t=1}^{T}\frac{1}{W_t}\Lambda^{-1}\mathbf{D}^{-1}(\mathbf{Y}_t - \mu - \mathbf{D}\xi W_t)(\mathbf{Y}_t - \mu - \mathbf{D}\xi W_t)'\mathbf{D}^{-1}\Lambda^{-1} \tag{4}$$

and where W_t is an Exponential random variable with mean 1.

As it can be noticed, the likelihood function in (3) is convex in $\mathbf{K}$. Therefore, at each iteration of the PEM, this feature allows us to adopt the *glasso* algorithm for efficient estimation of the sparse precision matrix $\mathbf{K}$.

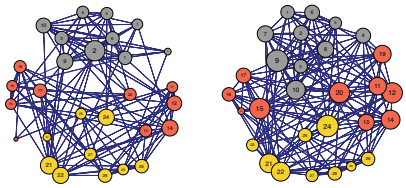

Fig. 1 Graphs for $\tau = 0.50$ (left) and $\tau = 0.95$ (right). Yellow, grey and red nodes represent respectively indexes, cryptocurrencies and commodities while the vertex labels are illustrated in Table 1.

3 Main Results and Conclusions

The empirical analysis is performed using the R software on the log-returns of 29 financial assets comprising stock market indices, commodity futures and digital currencies from September 14, 2017 and to June 21, 2021. We set $\tau = \tau_j$, $j = 1,\dots,29$, and fit the proposed model for a sequence of 99 quantile levels $\tau = [0.01, 0.02, \dots, 0.98, 0.99]'$. Then, for each τ, we construct the corresponding graph G_τ.

Table 1 Financial sectors considered in the analysis. Numbers identify vertex labels in Figure 1.

In Figure 1 we represent the estimated graph at $\tau = 0.50$ and $\tau = 0.95$ to show how the density of the network changes between tranquil ($\widehat{G}_{0.50}$) and bullish periods ($\widehat{G}_{0.95}$), respectively. The size of the node is proportional to the degree centrality and the width of the edges is determined by the magnitude of the estimated correlations in $\widehat{K}$. A deeper analysis to describe how the interconnectedness and contagion risk change as a function of the quantile index τ, is conducted by showing in Figure 2 the edge density (left) and the modularity measure (right) as functions of τ. The edge density shows a highly interconnected system, even for the smallest ratio of value at the center of the distribution. It is evident a strongest dependency during bearish and bullish periods, as the edge density is the largest in the tails.The presence of community structures is summarized in the modularity measure plot of Figure 2.
Consistently with the estimated graph $\widehat{G}_{0.50}$ in Figure 1, during tranquil periods the reduced number of connections brings out heterogeneity in the distribution of

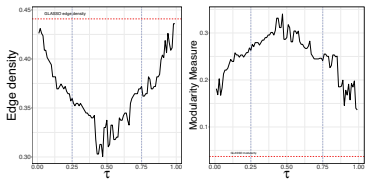

Fig. 2 From left to right, Edge density and Modularity measure as a function of τ. Blue dotted lines identify the 25th and 75th percentiles to mark respectively crisis and bullish markets periods. Red dotted line identify the centrality measure associated with the *glasso*.

edges, i.e., high concentration of edges within groups of nodes and low concentrations between groups. This behavior can be explained by the so-called co-explosion of cryptoassets already discussed by [1],which evidences that price explosivity in one cryptocurrency can lead to explosivity in other cryptocurrencies. In conclusion, with our approach we are able to recover valuable information at each quantile level even without the assumption of normality. The whole analysis conveys a highly connected network which becomes even more dense during bearish and bullish markets periods, and the results are in line with existing studies ([2, 1]). With this model we strengthen the existing literature in this field, implementing a technique to adjust the *glasso* algorithm to a quantile structure of dependence.

Neural Network for statistical process control of a multiple stream binomial process with an application to HVAC systems in passenger rail vehicles

Rete neurale per il controllo statistico di un processo binomiale a flussi multipli con un'applicazione per sistemi HVAC nei veicoli ferroviari a trasporto passeggeri

Gianluca Sposito, Antonio Lepore, Biagio Palumbo, Giuseppe Giannini

Abstract A multiple stream binomial process (MSBP) is a process at a point in time that generates several output streams that can be modelled as binomial processes. A multilayer perceptron is embedded in a control charting scheme and is trained to classify whether each sample is drawn from the in-control process distribution or not. The performance of the proposed scheme is evaluated through a wide Monte Carlo simulation and is compared with the Wludyka and Jacobs's MSBP control charts in terms of out-of-control average run length. Finally, the practical applicability of the proposed approach is illustrated through real operational data from heating, ventilation and air conditioning (HVAC) systems installed on-board modern passenger trains.

Abstract *Un processo binomiale a flussi multipli (MSBP) è un processo descritto nel tempo da flussi concorrenti che possono essere modellati come processi binomiali. Viene presentato uno schema di controllo statistico di un MSBP che integra un percettrone multistrato addestrato a classificare se i dati raccolti siano generati da un processo in controllo o fuori controllo statistico. Le prestazioni dell'approccio proposto sono valutate mediante un'estesa simulazione Monte Carlo e confrontate con le carte di controllo per MSBP di Wludyka e Jacobs, in termini di lunghezza media delle sequenze fuori controllo. Infine, la pratica applicabilità dell'approccio proposto viene illustrata attraverso un caso studio reale su dati operativi provenienti da sistemi di riscaldamento, ventilazione e condizionamento dell'aria, installati a bordo di moderni veicoli ferroviari.*

1 Introduction

In the railway transport sector, it is of paramount importance to ensure high comfort levels of passengers on board through an efficient regulation of the air conditioning. Recent European regulations, such as UNI EN 14750 [1], prescribe operational requirements for passenger rail coaches, in terms of air quality and comfort level, and the continuous monitoring of the heating, ventilation and air conditioning (HVAC) system installed on modern passenger railway vehicles. For this purpose, the high sensorization and digitalization of modern trains make available large amounts of data and create an urgent call for statistical models and methods able to transform this information into value. Typically, each passenger coach is equipped with a dedicated HVAC system, and the simultaneous statistical process control/monitoring (SPC/M) of the sensor signals coming from each HVAC data acquisition system installed on-board each coach can be regarded as a multiple stream process (MSP) [8]. In particular, referring to a MSP [6] control by attributes, a multiple stream binomial process (MSBP) is a process at a point in time that generates several output streams that can be modelled as binomial processes. From the SPC/M point of view, the quality of interest and its specifications are identical in all streams. Motivated by the industrial context and the latest attempts at the integration of NNs into classical control charting procedures [12, 7, 4], this paper aims to develop a new approach based on artificial neural networks (NNs) in the field of SPC/M of MSBPs with the twofold objective of detecting changes both in the individual stream means and the overall process mean.

In what follows, we present (i) the proposed control charting procedure by briefly framing MSBPs and NNs; (ii) the proposed NN training through a wide Monte Carlo simulation and its comparison with traditional Wludyka and Jacobs' Chi-squared [10] and group p [11] MSBP control charts; (iii) an application to the operational data acquired for the monitoring of HVAC systems installed on board of passenger railway vehicles, courtesy the rail transport company Hitachi Rail STS (https://www.hitachirail.com/).

2 Materials and Methods

Let us suppose that over a subgroup of N consecutive points at time t, the quality of interest is a variable counting the number of times a particular event occurs. Let Y_{tj} denote this counting variable for each stream $j = 1,...,s$ and time index $t = 1,...,T$. A MSBP assumes Y_{tj} distributed as independent binomial random variables $Y_{tj} \sim \text{Bin}(N, p_j)$ over time and streams, where p_j denotes the probability that

the event of interest occurs for the jth stream at each subgroup point. For an in-control (IC) homogeneous MSBP p_j is assumed, for each j, equal to the same constant $p \in (0,1)$, which therefore represents the overall process mean. The process is said to be out of control (OC) if an assignable cause affects (i) all of the streams uniformly (the overall p changes) or (ii) one or more streams differently (p_j changes for one or more streams). Inspired by the real-case study, for each stream, we generate pseudorandom observations of Y_{tj} from a binomial random variable with $s = 6$, $N = 30$, and $p = 0.52$. To the best of our knowledge, Wludyka and Jacobs are the only authors to have investigated the SPC/M of a MSBP.

In this paper, a multilayer perceptron (MLP) [3], which is one of the most widely used NN, is designed to be used for the SPC/M of a MSBP, that is, to classify a sample as drawn from an IC or OC process. Specifically, the MLP is trained such that, when a sample (called *negative sample*) is drawn from an IC process, the target value of the output neuron is coded as zero, otherwise, when a sample (called *positive sample*) is drawn from an OC process, it is coded as one. The MLP has s neurons in the input layer to represent the s monitored statistics Y_{tj} at time t, for each stream $j = 1,2,...,s$. In order to train and properly design the MLP, 300 positive samples are generated through a Monte Carlo simulation from all possible $\sum_{l=1}^{s} \binom{s}{l}$ OC scenarios in which $l = 1,\ldots,s$ streams shift off the target p at the same time by as much as $\Delta p = -1.0\sigma, -2.0\sigma, -3.0\sigma, 1.0\sigma, 2.0\sigma, 3.0\sigma$, where $\sigma = \sqrt{p(1-p)/N}$. To get a balanced data set, the total number of negative and positive samples must be equal. The MLP is trained through the back-propagation algorithm [3]. To compare different NN architectures, the area under the receiver operating characteristic (ROC) curve (AUC) [2] is used as a performance measure and is calculated on the validation set, obtained by retaining the 30% of the generated samples. Then, a MLP with one hidden layer with ten neurons, a rectified linear unit (ReLU) and a sigmoid activation function [3] for the hidden and output layer, respectively, is shown to have the best performance in terms of AUC. Furthermore, to allow a fair comparison with the traditional MSBP control charts, the NN must be tuned to a corresponding level of discriminating power [4], that is, the cut-off value (CV) of the output neuron must be properly fixed to set the Type-I and Type-II error rates of the resulting control charting scheme denoted by α and β, respectively. Or, equivalently, one may set the IC or OC average run lengths [6], respectively, defined as $ARL_0 = \frac{1}{\alpha}$ and $ARL_1 = \frac{1}{1-\beta}$. Further 100000 Monte Carlo simulations from an IC process are generated to set the CV to achieve an ARL_0 as close as possible to the desired one. By simulation, α is the proportion of the wrongly classified samples as drawn from an OC process. At a fixed ARL_0, we can evaluate the performance of the proposed approach in terms of ARL_1 by simulating 100000 data sets from each of the OC scenarios in which at least one stream of the MSBP shifts off-target at different mean shift sizes. By simulation, β is the proportion of negative samples that the MLP incorrectly classifies as drawn from an IC. The proposed NN based control charting procedure is compared with the competitor Wludyka and Jacobs' Chi-squared [10] and group p [11] MSBP control charts by means of the ARL_1, at fixed $ARL_0 = 20, 100, 358$, that is $\alpha = 0.05, 0.01, 0.0028$, respectively.

3 Real-case study

In addition, data mentioned in Section 1, courtesy of Hitachi Rail STS, are employed to demonstrate the effectiveness of the proposed method. Operational data from modern railway HVAC systems installed on-board a passenger 6-coach rail vehicle are collected every two minutes in the summer season and the available variables for each coach are summarised in Table 3. A central unit monitors the HVAC system performance through temperature sensors that activate heating or cooling mode based on changes in the readings of the outside (T_{out}) and interior (T_{in}) temperatures to ensure the passenger thermal comfort required by the European regulations [1]. The HVAC system is designed to maintain T_{in} as close as possible to the target (T_{set}) temperature, that is the desired temperature value at which the HVAC sys-

Table 3 Operational variables available for each of the $s = 6$ train coaches

Variable	Description
T_{in}	Interior temperature
T_{out}	Outdoor Temperature
T_{set}	Target temperature
T_{supply}	Air temperature provided by the HVAC
C_{m}	Cooling mode status

tems attempt to maintain the T_{in} value at each time instant. [1] allows the difference $\Delta T = T_{\text{in}} - T_{\text{set}}$ to be no larger than 2°C, otherwise the train cannot operate. For each of the $s = 6$ coach HVAC streams, the quality variable of interest Y_{tj} is the number of times the cooling mode status (C_{m}) is 1 over $N = 30$ samples (i.e., 1 hour). Specifically, C_{m} is coded by 1 if the HVAC system is cooling at a given subgroup point, 0 otherwise. The parameter $p = 0.52$ is estimated from an IC sample. The idea is to monitor whether or not an HVAC system is cooling properly to ensure the passenger thermal comfort. When a stream j returns a p_j estimate that is significantly different from that of the other streams, then an alarm should be provided. Note that the data used in this short paper refer to the same HVAC systems and time window of [8]. However, in [8], the operational variable monitored was instead the difference $T_{\text{set}} - T_{\text{in}}$, with a sampling period of two minutes. Differently from the number of times ($C_{\text{m}} = 1$) over $N = 30$ samples, $T_{\text{set}} - T_{\text{in}}$ is a continuous random variate and there is no known engineering/physical relationship between them.

4 Conclusions

For comparison purposes, Tables 1 and 2 show the ARL_1 performance at fixed $ARL_0 = 358$ of the Wludyka and Jacobs' Chi-squared and group p MSBP control charts, as well as that of the proposed one at different number $l = 1, ..., s$ of streams that shift off-target by as much as $\Delta p = -2.0\sigma, -1.0\sigma, -0.5\sigma, 0.5\sigma, 1.0\sigma, 2.0\sigma$. Numerical investigations at different $ARL_0 = 20, 100$ give similar results and thus, are not reported here for conciseness. In particular, the proposed monitoring strategy outperforms the competitor control charts when at least one stream shifts off-target for all severity levels of mean shift. By means of a real-case study in the transportation sector, the proposed method was also demonstrated to be capable of signalling OC conditions in real time, even when more than one streams (from different coaches) are OC.

The computations are performed by using a single core of an Intel Xeon Platinum 8160 node of the ENEA CRESCO6 system (2.10GHz, 192 GB RAM, no GPU) [5] and are numerically implemented by means of the open source software environment Python [9]. The training time of the NN is about 16 seconds and the computational time required to process a new sample is about 1 millisecond. This facilitates

the repeatability and reproducibility of this research and the attained results as well as the practical application of the proposed approach in similar industrial scenarios.

Sparse Signal Extraction via Variational SVM

Estrazione di Segnali Sparsi via SVM variationali

Cristian Castiglione and Mauro Bernardi

Abstract This paper presents a new semiparametric variational Bayes algorithm for estimating a wide class of regularized support vector machine models. We focus in particular on robust sparse signal extraction via Bayesian support vector regression, taking advantages from a Bayesian formulation for handling both the inclusion of inducing shrinkage priors and automatic learning of the associated penalization parameters. A simulation study is then presented to assess the benefits of the proposed method.

Abstract *In questo articolo viene presentato un nuovo algoritmo variazionale Bayesiano per stimare un gran numero di modelli appartenenti alla classe support vector machine. Un'attenzione particolare viene posta nell'estrazione di segnali sparsi attraverso modelli di regressione robusta, sviluppati all'interno di una cornice inferenziale Bayesiana. Quest'ultima permette di gestire in forma unificata sia l'utilizzo di specifiche informazioni a priori, che una selezione automatica dei parametri di penalizzazione associati alla priori. Infine, viene proposto uno studio di simulazione comparativo per verificare le proprietà del metodo.*

1 Introduction

Support vector machines (SVM) [11] are a family of robust prediction models often used in machine learning applications with high dimensional covariates. They are

Cristian Castiglione
Department of Statistical Sciences, University of Padova, via Cesare Battisti 241, Padova, Italy
e-mail: cristian.castiglione@phd.unipd.it

Mauro Bernardi
Department of Statistical Sciences, University of Padova, via Cesare Battisti 241, Padova, Italy
e-mail: mauro.bernardi@unipd.it

typically regularized with an inducing sparsity penalty to manage the bias-variance trade-off and to perform variable selection.

The historical estimation method for SVM relies on dual constrained optimization, which is extremely efficient, but does not permits to quantify the variability of the point estimates and, more in general, to do inference on the model parameters. Here, instead, we take a variational Bayes perspective [5] in order to perform approximate posterior inference and uncertainty quantification. Variational inference does not require computationally expensive posterior simulation and can be performed via efficient optimization methods, allowing for a fast processing of high dimensional data.

Our aim is then to present a semiparametric variational Bayes (SVB) scheme to perform sparse SVM regression. Differently from [6] and [4], our approach does not need to exploit complicate data augmentation strategies and, instead, approximates directly the original posterior density employing the so-called Knowles-Minka-Wand formula [10, 9] for variational Gaussian approximations.

2 Bayesian model

Regularized SVM regression predict the response variable $y_i \in \mathbb{R}$, $i = 1,\dots,n$, as the linear combination $x_i^\top \beta$, where $x_i \in \mathbb{R}^p$ is a vector of covariates and $\beta \in \mathbb{R}^p$ is a parameter vector. The unknown coefficients are then estimated by minimizing a penalized objective function $L_p(\beta;y) = L(\beta;y) + P_\lambda(\beta)$, balancing a goodness of fit criteria, i.e. the loss function $L(\beta;y)$, with a model complexity criteria, i.e. the penalization function $P_\lambda(\beta)$, which depends on the regularization parameter λ. The loss function characterizing the SVR optimization problem is the so-called ε-insensitive loss [11], being defined as

$$L(\beta;y) = \sum_{i=1}^{n} \max(0, |y_i - x_i^\top \beta| - \varepsilon).$$

This makes the SVR model robust to outlier contamination and insensitive to small prediction errors, since $L(\beta;y)$ assigns no loss to residual values $y_i - x_i^\top \beta$ within the insensitivity band $[-\varepsilon, +\varepsilon]$, for any $\varepsilon > 0$.

Here, we assume for the model a Bayesian formulation where

$$\pi(y|\beta) = \exp\{-L(\beta;y)\}, \quad \pi_\lambda(\beta) = \exp\{-P_\lambda(\beta)\},$$

are, respectively, the pseudo-likelihood function and the prior distribution on β. Thus, our subjective beliefs about β can be updated to the general posterior [2] through the Bayes formula: $\pi_\lambda(\beta|y) \propto \pi(y|\beta)\pi_\lambda(\beta)$.

As pointed out by [6, 4], a Bayesian formulation provides a unified approach to overcome many shortcomings of classical SVR, allowing for the inclusion of random effects, structured prior distributions, spatial and temporal processes and automatic tuning of the penalty parameter λ. Here, we focus on the estimation of

sparse signals assuming for β an inducing shrinkage prior belonging to the class of global-local distributions [1]. In particular, we consider an adaptive Bayesian Lasso penalty [3], that can be expressed via the hierarchical representation

$$\beta_j|\tau^2,\psi_j^2 \sim DE(0,\tau^2\psi_j^2), \quad \tau^2 \sim IG(A_\tau,B_\tau), \quad \psi_j^2 \sim IG(A_\psi,B_\psi).$$

where $\tau^2 > 0$ is the so-called global parameter and $\psi_j^2 > 0$ is the element-specific local parameter; $A_\tau, B_\tau, A_\psi, B_\psi > 0$ are fixed user-specified hyperparameters. We denote with $DE(\mu,\sigma)$ the Double-Exponential, or Laplace, distribution with location $\mu \in \mathbb{R}$ and scale $\sigma > 0$, while $IG(A,B)$ is the Inverse-Gamma distribution with shape $A > 0$ and rate $B > 0$. Within this model specification the regularization term λ corresponds to the vector $(\tau^2,\psi_1^2,\ldots,\psi_p^2)$.

A common feature of all global-local priors is to operate an aggressive shrinkage on the parameters corresponding to non-significant variables, while introducing a negligible amount of bias on the signal components. To this end, more involved prior models can be considered [1], such as the Horseshoe, or the Dirichlet-Laplace, however no relevant differences arise in the derivation of our method, that is agnostic to any prior choice.

3 Variational inference

Let us denote with $\theta = (\beta,\psi^2,\tau^2)$ and $\Theta = \mathbb{R}^p \times \mathbb{R}_+^p \times \mathbb{R}_+$ the set of all parameters in the model and the corresponding parameter space, respectively.

Bayesian inference on the SVR model is then carried out via variational approximation [5]. This proceeds by replacing the true posterior $\pi(\theta|y)$ with a simpler density function $q(\theta)$ belonging to a specific functional space. The optimal approximating density for θ is then estimated maximizing the lower bound on the marginal log-likelihood, also called evidence lower bound: $\log \underline{\pi}(y;q) = \mathbb{E}_q\big[\log\{\pi(y,\theta)/q(\theta)\}\big]$, where $\mathbb{E}_q(\cdot)$, or $\mu_{q(\cdot)}$, is the expectation calculated with respect to $q(\theta)$. Assuming the mean field restriction $q(\theta) = q(\theta_1)\ldots q(\theta_K)$, for any partition of θ, there exists an exact coordinatewise solution for $q(\theta_k)$, being

$$q^*(\theta_k) \propto \exp\{\mathbb{E}_{-k}(\log\pi(\theta_k|\text{rest}))\}, \quad k = 1,\ldots,K, \tag{1}$$

where $\mathbb{E}_{-k}(\cdot)$ is the expectation taken with respect to $\prod_{j\neq k} q(\theta_j)$ and $\pi(\theta_k|\text{rest})$ is the full-conditional distribution of θ_k. Whenever θ_k has a conjugate prior distribution, formula (1) can be derived in closed form, otherwise a parametric restriction can be imposed, in order to project the exact solution (1) into the appropriate functional space.

Here, we both assume the factorization $q(\theta) = q(\beta)q(\psi^2)q(\tau^2)$ and a parametric restriction for $q(\beta)$. In particular, we impose $q(\beta) = q(\beta;\mu,\Sigma)$ to be a multivariate Gaussian density with mean vector $\mu \in \mathbb{R}^p$ and variance-covariance matrix $\Sigma \in \mathbb{R}^{p\times p}$. Defining $f(\mu,\Sigma) = \mathbb{E}_q[\log\pi(\beta|\text{rest})]$, $g(\mu,\Sigma) = \nabla_\mu f(\mu,\Sigma)$ and $H(\mu,\Sigma) =$

$\nabla^2_\mu f(\mu,\Sigma)$ and employing the so-called Knowles-Minka-Wand method [10, 9] for updating $q(\beta)$ and formula (1) for updating $q(\psi^2)$ and $q(\tau^2)$, we obtain an iterative optimization algorithm that cycles over the following steps:

- $q^*(\beta) \sim N_p(\hat{\mu},\hat{\Sigma})$, where $\hat{\mu} \leftarrow \hat{\mu} - H(\hat{\mu},\hat{\Sigma})^{-1} g(\hat{\mu},\hat{\Sigma})$ and $\hat{\Sigma} \leftarrow -H(\hat{\mu},\hat{\Sigma})^{-1}$;
- $q^*(\psi^2) \sim IG(\hat{A}_\psi,\hat{B}_\psi)$, where $\hat{A}_\psi \leftarrow A_\psi + 1$ and $\hat{B}_\psi \leftarrow B_\psi + \mu_{q(1/\tau^2)}\mu_{q(|\beta|)}$;
- $q^*(\tau^2) \sim IG(\hat{A}_\tau,\hat{B}_\tau)$, where $\hat{A}_\tau \leftarrow A_\tau + p$ and $\hat{B}_\tau \leftarrow B_\tau + \mu^\top_{q(1/\psi^2_j)}\mu_{q(|\beta|)}$.

Here all the involved expectations can be calculated analytically. In particular, the gradient vector and Hessian matrix needed for the Newton update of $\hat{\mu}$ and $\hat{\Sigma}$ are

$$
\begin{aligned}
g(\mu,\Sigma) &= -Dv^{(1)} - X^\top w^{(1)} \\
H(\mu,\Sigma) &= -DV^{(2)} - X^\top W^{(2)} X
\end{aligned}
$$

where $D = \mathrm{diag}[\mu_{q(1/\tau^2)}\mu_{q(1/\psi^2)}]$, $V^{(2)} = \mathrm{diag}[v^{(2)}]$, $W^{(2)} = \mathrm{diag}[w^{(2)}]$, and

$$
\begin{aligned}
v^{(1)}_j &= 2\Phi(0;-\mu_j,\Sigma_{jj}) - 1, \\
v^{(2)}_j &= 2\phi(0;-\mu_j,\Sigma_{jj}), \\
w^{(1)}_i &= 2\big[\phi(+\varepsilon;y_i - x_i^\top\mu, x_i^\top\Sigma x_i) - \phi(-\varepsilon;y_i - x_i^\top\mu, x_i^\top\Sigma x_i) - 1\big], \\
w^{(2)}_i &= 2\big[\phi(+\varepsilon;y_i - x_i^\top\mu, x_i^\top\Sigma x_i) + \phi(-\varepsilon;y_i - x_i^\top\mu, x_i^\top\Sigma x_i)\big],
\end{aligned}
$$

for $j = 1,\ldots,p$ and $i = 1,\ldots,n$. The symbols $\phi(\cdot;\mu,\sigma^2)$ and $\Phi(\cdot;\mu,\sigma^2)$ denote the probability density function and the cumulative density function of a $N(\mu,\sigma^2)$ distribution.

4 Simulation study

The performances of the proposed approximation are then assessed by means of a simulation study, where the responses $y_1,\ldots,y_n$ are independently generated according with the location-scale model

$$
y_i \sim t(f(z_i),\sigma,\nu), \quad z_i \sim U(0,1), \quad i = 1,\ldots,n, \quad n = 300,
$$

with $t(\mu,\sigma,\nu)$ denoting a t-distribution with location $\mu \in \mathbb{R}$, scale $\sigma > 0$ and degrees of freedom $\nu > 0$ and $U(0,1)$ being the uniform distribution over the interval $[0,1]$. Further, $f(z) = -1.02z + 0.018z^2 + 0.4\phi(z;0.38,0.08) + 0.08\phi(z;0.75,0.03)$ is a non-linear function defined over $z \in [0,1]$, $\sigma = 0.31$ and $\nu = 3$.

In this context, we try to reconstruct the true signal, i.e. the function $f(x)$, via semiparametric regression. A set of 40 orthogonal O'Sullivan spline basis [8] $B_1(\cdot),\ldots,B_{40}(\cdot)$ are displaced over the interval $[0,1]$; the i-th row of our design matrix is then equal to $x_i^\top = [1, z_i, B_1(z_1),\ldots,B_{40}(z_i)]$. The rest of the model is specified as discussed is section 2. The parameters are hence estimated using the Gibbs

sampler (MCMC) of [6], the mean field variational Bayes (MFVB) of [4] and the proposed semiparametric variational Bayes (SVB) algorithm.

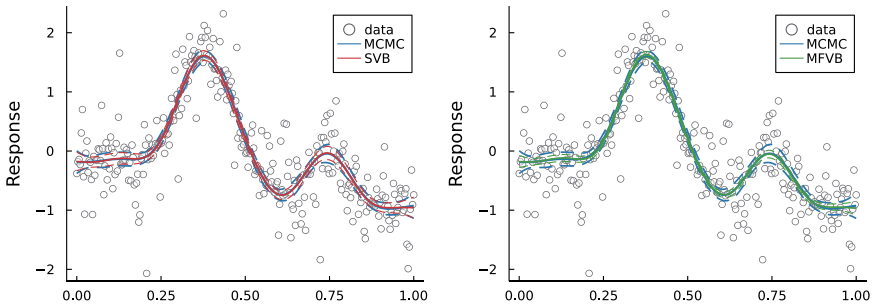

Fig. 1 Fitted values for the MCMC, MFVB and SVB methods. The solid lines are the pointwise predictions, while the dashed lines correspond to the 95% HPD posterior credibility bands.

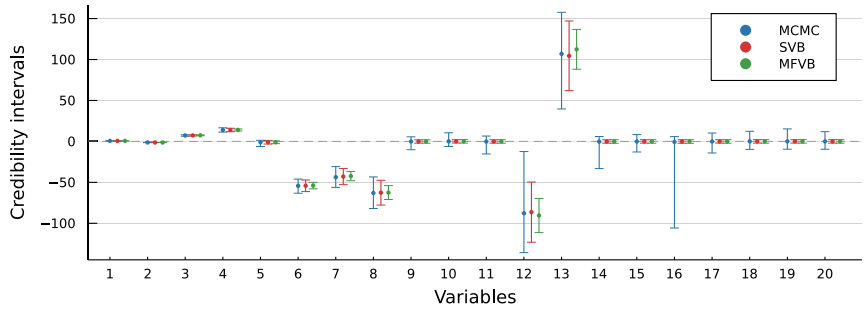

Fig. 2 Point estimates and 95% HPD posterior credibility intervals for the first 20 parameters estimated using the MCMC, MFVB and SVB methods.

Figure 1 shows the predicted values obtained with the methods mentioned so far. MFVB and SVB are comparable in terms of point prediction, but not in terms of variability quantification. Indeed, the prediction bands corresponding to SVB are far closer to MCMC than MFVB, which instead tends to produce narrower bands. The same phenomenon is highlighted by figure 2, which shows the posterior point estimates (posterior mean) and 95% HPD credibility intervals for the first 20 regression parameters.

On the other side, all the three approaches encourage the non-relevant parameters to be overshrunk toward 0, but the deterministic approximation methods, i.e. MFVB and SVB, collapse in a far more aggressive way the irrelevant signals, shrinking not only the posterior mean, but also the posterior variability. Here we use the signal adaptive variable selection (SAVS) method proposed by [7] to distinguish between signal and noise. With all the three approaches we found 32 non-relevant variables and 10 signals, which approximately correspond to the parameters with a posterior HPD interval not including 0.

	RMSE	Accuracy				
		10%	25%	50%	75%	90%
MCMC	0.0897					
MFVB	0.0875	0.6621	0.7205	0.7523	0.7683	0.7761
SVB	0.0848	0.7291	0.7430	0.7592	0.7734	0.9511

Table 1 Posterior goodness of fit measures for MCMC, MFVB and SVB. RMSE denotes the root mean squared error calculated between the estimated curve and the true function $f(\cdot)$. Accuracy refers to the score defined as $\text{Acc}_j(q)$, for $j = 1,\ldots,42$. The percentages correspond to 5 quantiles of the marginal empirical distribution of the accuracy scores, calculated for the 42 parameters in the model.

The ability of a deterministic variational density to approximate the true posterior, i.e. the MCMC one, can be estimated by calculating the marginal accuracy index $\text{Acc}_j(q) = 1 - 0.5 \int_{\mathbb{R}} |q(\beta_j) - \pi(\beta_j|y)|\, d\beta_j$, $j = 1,\ldots,p$, that is a real quantity defined over $[0,1]$. An optimal approximation is reached for values close to 1, whereas values close to 0 suggest a poor approximation. The accuracy scores are then calculated for all the parameters estimated with MFVB and SVB and the results are shown in table 1. For all the 5 considered quantiles, SVB presents a higher level of precision in estimating the true posterior than MFVB, confirming the evidences obtained looking at figure 1 and 2.

Bayesian modelling and inference 1

Bayesian Inference for the Multinomial Probit Model under Gaussian Prior Distribution

Inferenza Bayesiana per il Modello Probit Multinomiale con Distribuzione a Priori Normale

Augusto Fasano, Giovanni Rebaudo and Niccoló Anceschi

Abstract Multinomial probit (MNP) models are fundamental and widely-applied regression models for categorical data. [1] proved that the class of unified skew-normal distributions is conjugate to several MNP sampling models. This allows to develop Monte Carlo samplers and accurate variational methods to perform Bayesian inference. In this paper, we adapt the above-mentioned results for a popular special case: the discrete-choice MNP model under zero-mean and independent Gaussian priors. This allows to obtain simplified expressions for the parameters of the posterior distribution and an alternative derivation for the variational algorithm that gives a novel understanding of the fundamental results in [1] as well as computational advantages in our special settings.

Abstract *I modelli probit multinomiali (*MNP*) sono una classe popolare di modelli di regressione per dati categoriali. [1] hanno dimostrato che la classe delle distribuzioni normali asimmetriche è coniugata rispetto a modelli* MNP*. Questo ha permesso di sviluppare schemi di campionamento ed accurati metodi variazionali per l'inferenza Bayesiana. Nel presente articolo, adattiamo tali risultati ad un caso particolarmente rilevante: il* MNP *a scelta discreta con distribuzioni a priori normali a media zero. Questo permette di otterenere espressioni semplificate per i parametri della distribuzione a posteriori ed una derivazione alternativa dell'approccio variazionale che fornisce una nuova compresione del risultato fondamentale in [1] oltre a vantaggi computazionali nel nostro caso particolare.*

1 Introduction

Multinomial probit (MNP) models constitute a fundamental tool for categorical data regression, thanks to their interpretability and flexibility [2]. Originally introduced by [3] to avoid the restrictive assumption of the *independence of irrelevant alternatives* typical of multinomial logit models, such models have faced the growth of many different specifications. Among them, we consider the Bayesian formulation of the discrete choice MNP model with class-specific effects [4], under a zero-mean and independent Gaussian prior for the parameters, adapting the results of [1] obtained under more general prior specifications and for a wider range of models. In such a construction, originally developed in the econometrics literature, to each possible choice (or class) $\ell = 1, \dots, L$ that individual $i = 1, \dots, n$ faces, a corresponding random latent utility $z_{i\ell} = \mathbf{x}_i^\intercal \boldsymbol{\beta}_\ell + \varepsilon_{i\ell}$ is associated, where $\mathbf{x}_i \in \mathbb{R}^p$ is the covariate vector for observation i, $\boldsymbol{\beta}_\ell \in \mathbb{R}^p$ is the class-specific vector of the covariate effects and $\boldsymbol{\varepsilon}_i = (\varepsilon_{i1}, \dots, \varepsilon_{iL})^\intercal \sim \mathrm{N}_L(\mathbf{0}, \boldsymbol{\Sigma})$, independently across units $i = 1, \dots, n$. Note that the error terms for different alternatives can be correlated, since $\boldsymbol{\Sigma}$, which is assumed to be known, is not necessarily diagonal. Among all the possible choices $1, \dots, L$, individual i chooses the one giving her the maximal utility, meaning that $y_i = \ell$ if and only if $z_\ell = \max\{z_1, \dots, z_L\}$. Thus, for each $i = 1, \dots, n$, independently

$$\begin{aligned} \Pr(y_i = \ell \mid \boldsymbol{\beta}_1, \dots, \boldsymbol{\beta}_L, \mathbf{x}_i) &= \Pr(z_{i\ell} > z_{ik}, \forall k \neq \ell) \\ &= \Pr(\mathbf{x}_i^\intercal \boldsymbol{\beta}_\ell + \varepsilon_{i\ell} > \mathbf{x}_i^\intercal \boldsymbol{\beta}_k + \varepsilon_{ik}, \forall k \neq \ell). \end{aligned} \tag{1}$$

Since in (1) only pairwise differences between the parameters matter, we set $\boldsymbol{\beta}_L = \mathbf{0}$ for identifiability purposes. In order to perform Bayesian inference, we complete the model by specifying a multivariate Gaussian prior distribution for the vector of parameters $\boldsymbol{\beta} = \left(\boldsymbol{\beta}_1^\intercal, \dots, \boldsymbol{\beta}_{L-1}^\intercal\right)^\intercal$ centered in zero, with independent and homoscedastic components. Thus,

$$\boldsymbol{\beta} \sim \mathrm{N}_{p(L-1)}\left(\mathbf{0}, \nu^2 \mathbf{I}_{p(L-1)}\right). \tag{2}$$

The more general results under a unified skew-normal (SUN) prior have been developed in [1] for a broader class of MNP models. In fact, it is shown that in that case the posterior belongs again to the class of SUN distributions, with updated dimensionalities and parameters. This allows to perform posterior inference via i.i.d. samples in small-to-moderate n settings, while a blocked variational procedure is developed to avoid the computational bottlenecks that one may encounter in large n scenarios. The prior specification (2), however, constitutes a popular choice in case there are no reasons to *a priori* assume any dependence between the parameters or asymmetry in their distribution, and it is worth a separate treatment as it allows the simplification of the expression of some important parameters in the posterior distribution and the derivation of an alternative proof for the variational algorithm that can have computational advantages. These two important aspects represent the main focus of the present article and will be the focus of Sections 2 and 3 below, while Section 4 is dedicated to the discussion of possible future research directions.

2 Posterior inference via Monte Carlo samples

Recently, [1] showed that for a broad class of MNP models, a SUN prior distribution leads to a SUN posterior distribution, extending the previous conjugacy results derived by [5] for the classical binary probit model. We specify here results in Section 2.2 in [1] under the particular Gaussian prior distribution (2), for the peculiar advantages explained in Section 1. Before doing that, we briefly recap the definition and the main properties of the SUN distribution. Further details can be found, for instance, in [6]. A random vector $\boldsymbol{\beta} \in \mathbb{R}^q$ has SUN distribution, $\boldsymbol{\beta} \sim \text{SUN}_{q,h}(\boldsymbol{\xi}, \boldsymbol{\Omega}, \boldsymbol{\Delta}, \boldsymbol{\gamma}, \boldsymbol{\Gamma})$, if its density function $p(\boldsymbol{\beta})$ can be expressed as

$$p(\boldsymbol{\beta}) = \phi_q(\boldsymbol{\beta} - \boldsymbol{\xi}; \boldsymbol{\Omega}) \frac{\Phi_h[\boldsymbol{\gamma} + \boldsymbol{\Delta}^\top \bar{\boldsymbol{\Omega}}^{-1} \boldsymbol{\omega}^{-1}(\boldsymbol{\beta} - \boldsymbol{\xi}); \boldsymbol{\Gamma} - \boldsymbol{\Delta}^\top \bar{\boldsymbol{\Omega}}^{-1} \boldsymbol{\Delta}]}{\Phi_h(\boldsymbol{\gamma}; \boldsymbol{\Gamma})},$$

where the covariance matrix $\boldsymbol{\Omega}$ of the Gaussian density $\phi_q(\boldsymbol{\beta} - \boldsymbol{\xi}; \boldsymbol{\Omega})$ can be decomposed as $\boldsymbol{\Omega} = \boldsymbol{\omega} \bar{\boldsymbol{\Omega}} \boldsymbol{\omega}$, i.e. by rescaling the correlation matrix $\bar{\boldsymbol{\Omega}}$ via the diagonal scale matrix $\boldsymbol{\omega} = (\boldsymbol{\Omega} \odot \mathbf{I}_q)^{1/2}$, with $\odot$ denoting the element-wise Hadamard product. Moreover, $\Phi_h(\mathbf{u}; \mathbf{W})$ denotes the cumulative distribution function of a $\text{N}_h(\mathbf{0}, \mathbf{W})$ evaluated at $\mathbf{u}$. The following additive characterization constitutes a fundamental property to further understand the role of the parameters and to develop an i.i.d. sampler. If $\boldsymbol{\beta} \sim \text{SUN}_{q,h}(\boldsymbol{\xi}, \boldsymbol{\Omega}, \boldsymbol{\Delta}, \boldsymbol{\gamma}, \boldsymbol{\Gamma})$, then $\boldsymbol{\beta} \overset{\text{d}}{=} \boldsymbol{\xi} + \boldsymbol{\omega}(\mathbf{V}_0 + \boldsymbol{\Delta}\boldsymbol{\Gamma}^{-1}\mathbf{V}_1)$, with

$$\mathbf{V}_0 \sim \text{N}_q(\mathbf{0}, \bar{\boldsymbol{\Omega}} - \boldsymbol{\Delta}\boldsymbol{\Gamma}^{-1}\boldsymbol{\Delta}^\top), \ \mathbf{V}_1 \sim \text{TN}_h(\mathbf{0}, \boldsymbol{\Gamma}; A_{-\boldsymbol{\gamma}}),$$

where $A_{-\boldsymbol{\gamma}} = \left\{\mathbf{a} \in \mathbb{R}^h \colon a_i \geq -\gamma_i \ \forall i\right\}$ and $\text{TN}_h(\mathbf{m}, \mathbf{W}; A)$ denotes the h-variate normal distribution with mean $\mathbf{m}$ and covariance matrix $\mathbf{W}$, truncated in the region A.

In order to derive the SUN posterior distribution of $\boldsymbol{\beta}$ for model (1)-(2), we explicitly write the likelihood expression for the observed responses $\mathbf{y} = (y_1, \ldots, y_n)^\top$.

Proposition 1 (Proposition 2 in [1]). *For each $\ell = 1, \ldots, L$, denote with $\mathbf{v}_\ell$ the $L \times 1$ vector with value 1 in position l and 0 elsewhere, and with $\mathbf{V}_{[-\ell]}$ the $(L-1) \times L$ matrix whose rows are obtained by stacking vectors $(\mathbf{v}_k - \mathbf{v}_\ell)^\top$, for $k \neq \ell$. Finally, define $\mathbf{X}_{i[-\ell]} = -\bar{\mathbf{V}}_{[-\ell]} \otimes \mathbf{x}_i^\top$, where $\bar{\mathbf{V}}_{[-\ell]}$ is the $(L-1) \times (L-1)$ matrix obtained by removing the L-th column from $\mathbf{V}_{[-\ell]}$ and $\otimes$ denotes the Kronecker product.*

$$p(\mathbf{y} \mid \boldsymbol{\beta}, \mathbf{X}) = \prod_{i=1}^{n} \Phi_{L-1}(\mathbf{X}_{i[-y_i]}\boldsymbol{\beta}; \mathbf{V}_{[-y_i]}\boldsymbol{\Sigma}\mathbf{V}_{[-y_i]}^\top) = \Phi_{n(L-1)}(\bar{\mathbf{X}}\boldsymbol{\beta}; \boldsymbol{\Lambda}),$$

where $\bar{\mathbf{X}}$ is an $n(L-1) \times p(L-1)$ block matrix with $(L-1) \times p(L-1)$ row blocks $\bar{\mathbf{X}}_{[i]} = \mathbf{X}_{i[-y_i]}$, whereas $\boldsymbol{\Lambda}$ denotes an $n(L-1) \times n(L-1)$ block-diagonal covariance matrix with $(L-1) \times (L-1)$ diagonal blocks $\boldsymbol{\Lambda}_{[ii]} = \mathbf{V}_{[-y_i]}\boldsymbol{\Sigma}\mathbf{V}_{[-y_i]}^\top$, for $i = 1, \ldots, n$.

By combining the prior specification (2) with the likelihood (1), the following closed-form expression for the posterior distribution of $\boldsymbol{\beta}$ is obtained as a direct consequence of Theorem 1 in [1] adapted to the special case described in Section 1.

Algorithm 1: Strategy to sample from the SUN posterior in Theorem 1

for *i=1,...,N* **do**

- **[1]** Sample $\mathbf{V}_0^{(i)} \sim \mathrm{N}_{p(L-1)}(\mathbf{0}, \mathbf{I}_{p(L-1)} - \boldsymbol{\Delta}_{\text{pst}}\boldsymbol{\Gamma}_{\text{pst}}^{-1}\boldsymbol{\Delta}_{\text{pst}}^{\intercal})$ [in R use the function `rmvnorm`]
- **[2]** Sample $\mathbf{V}_1^{(i)} \sim \mathrm{TN}_{n(L-1)}(\mathbf{0}, \boldsymbol{\Gamma}_{\text{pst}}; [0,\infty)^{n(L-1)})$ [in R use the function `rtmvnorm`]
- **[3]** Compute $\boldsymbol{\beta}^{(i)} = \nu(\mathbf{V}_0^{(i)} + \boldsymbol{\Delta}_{\text{pst}}\boldsymbol{\Gamma}_{\text{pst}}^{-1}\mathbf{V}_1^{(i)})$

Output: i.i.d. samples $\boldsymbol{\beta}^{(1)}, \ldots, \boldsymbol{\beta}^{(N)}$ from the posterior distribution in Theorem 1.

Theorem 1 (from Theorem 1 in [1]). *Under model* (1)-(2)*, the posterior density is*

$$(\boldsymbol{\beta} \mid \mathbf{y}, \mathbf{X}) \sim \mathrm{SUN}_{p(L-1),n(L-1)}(\mathbf{0}, \boldsymbol{\Omega}_{\text{pst}}, \boldsymbol{\Delta}_{\text{pst}}, \mathbf{0}, \boldsymbol{\Gamma}_{\text{pst}}) \tag{3}$$

with $\boldsymbol{\Omega}_{\text{pst}} = \nu^2\mathbf{I}_{p(L-1)}$*,* $\boldsymbol{\Delta}_{\text{pst}} = \nu\bar{\mathbf{X}}^{\intercal}\mathbf{s}^{-1}$ *and* $\boldsymbol{\Gamma}_{\text{pst}}$ *is an* $n(L-1) \times n(L-1)$ *correlation matrix* $\boldsymbol{\Gamma}_{\text{pst}} = \mathbf{s}^{-1}(\nu^2\bar{\mathbf{X}}\bar{\mathbf{X}}^{\intercal} + \boldsymbol{\Lambda})\mathbf{s}^{-1}$*, where* $\mathbf{s} = [(\nu^2\bar{\mathbf{X}}\bar{\mathbf{X}}^{\intercal} + \boldsymbol{\Lambda}) \odot \mathbf{I}_{n(L-1)}]^{1/2}$.

Theorem 1 and the additive representation of the SUN (2) allow to develop an i.i.d. sampler of the posterior of $\boldsymbol{\beta}$ as described in Algorithm 1.

3 Partially-factorized blocked mean field approximation (PFM-B)

Basic manipulations of the posterior (3) show that $p(\boldsymbol{\beta} \mid \mathbf{y}, \mathbf{X}) \propto p(\boldsymbol{\beta}) \cdot \Pr[\bar{\mathbf{z}} > \mathbf{0} \mid \boldsymbol{\beta}, \bar{\mathbf{X}}]$, where $\bar{\mathbf{z}} = (\bar{\mathbf{z}}_1, \ldots, \bar{\mathbf{z}}_n)^{\intercal} \in \mathbb{R}^{n(L-1)}$ and $\bar{\mathbf{z}} \mid \boldsymbol{\beta}, \bar{\mathbf{X}} \sim \mathrm{N}_{n(L-1)}\left(\bar{\mathbf{X}}\boldsymbol{\beta}, \boldsymbol{\Lambda}\right)$. Thus, $p(\boldsymbol{\beta} \mid \mathbf{y}, \mathbf{X})$ can be seen as the marginal posterior distribution of the dual model

$$\boldsymbol{\beta} \sim \mathrm{N}_{p(L-1)}\left(\mathbf{0}, \nu^2\mathbf{I}_{p(L-1)}\right) \tag{4a}$$

$$\bar{\mathbf{z}}_i \mid \boldsymbol{\beta}, \bar{\mathbf{X}} \overset{ind}{\sim} \mathrm{N}_{L-1}\left(\bar{\mathbf{X}}_{[i]}\boldsymbol{\beta}, \boldsymbol{\Lambda}_{[ii]}\right), \quad i = 1, \ldots, n, \tag{4b}$$

$$\bar{\mathbf{y}}_i = \mathbb{1}\left[\bar{\mathbf{z}}_i > \mathbf{0}\right], \qquad i = 1, \ldots, n, \tag{4c}$$

in which one observes $\bar{\mathbf{y}}_i = (1, \ldots, 1)^{\intercal} \in \mathbb{R}^{L-1}$ for $i = 1, \ldots, n$ and $\mathbb{1}[\cdot]$ in (4c) is intended component-wise. Thus, it holds $p(\boldsymbol{\beta} \mid \mathbf{y}, \mathbf{X}) = \int_{\mathbb{R}^{n(L-1)}} p(\boldsymbol{\beta}, \bar{\mathbf{z}} \mid \bar{\mathbf{y}}, \bar{\mathbf{X}}) d\bar{\mathbf{z}}$, with $\bar{\mathbf{y}} = (\bar{\mathbf{y}}_1, \ldots, \bar{\mathbf{y}}_n)^{\intercal}$ an $n(L-1)$ vector of ones. Since direct sampling from $p(\boldsymbol{\beta} \mid \mathbf{y}, \mathbf{X})$ can run into computational issues when $n(L-1)$ is large due to step 2 in Algorithm 1, one can resort to variational methods, see, e.g., [7], to compute the 'best' possible approximating joint density $q^*(\boldsymbol{\beta}, \bar{\mathbf{z}})$ in a given class of tractable density functions $\mathscr{Q}$. This optimal solution is the minimizer of the Kullback-Leibler divergence [8] $\mathrm{KL}\left[q(\boldsymbol{\beta}, \bar{\mathbf{z}}) \,||\, p(\boldsymbol{\beta}, \bar{\mathbf{z}} \mid \bar{\mathbf{y}}, \bar{\mathbf{X}})\right] = \mathbb{E}_{q(\boldsymbol{\beta}, \bar{\mathbf{z}})}\left[\log\left(q(\boldsymbol{\beta}, \bar{\mathbf{z}}) / p(\boldsymbol{\beta}, \bar{\mathbf{z}} \mid \bar{\mathbf{y}}, \bar{\mathbf{X}})\right)\right]$.

In order to get a tractable approximation, but retain as much structure of the posterior distribution as possible, following [1], we take $\mathscr{Q} = \mathscr{Q}_{\text{PFM-B}} = \{q(\boldsymbol{\beta}, \bar{\mathbf{z}}) : q(\boldsymbol{\beta}, \bar{\mathbf{z}}) = q(\boldsymbol{\beta} \mid \bar{\mathbf{z}}) \prod_{i=1}^{N} q(\bar{\mathbf{z}}_i)\}$. This class of densities leverages on the partially-factorized mean field approximation developed for the classical probit model in [9], but allows to maintain the intra-correlations between the components of the $\bar{\mathbf{z}}_i$'s, $i = 1, \ldots, n$, while enforcing the inter-correlations between them to be zero. A first result about the optimal approximating density is obtained by the chain rule for the KL divergence: $\mathrm{KL}[q(\boldsymbol{\beta}, \bar{\mathbf{z}}) || p(\boldsymbol{\beta}, \bar{\mathbf{z}} \mid \bar{\mathbf{y}}, \bar{\mathbf{X}})] = \mathrm{KL}[q(\bar{\mathbf{z}}) || p(\bar{\mathbf{z}} \mid \bar{\mathbf{y}}, \bar{\mathbf{X}})] + \mathbb{E}_{q(\bar{\mathbf{z}})}\{\mathrm{KL}[q(\boldsymbol{\beta} \mid \bar{\mathbf{z}}) || p(\boldsymbol{\beta} \mid \bar{\mathbf{z}}, \bar{\mathbf{y}}, \bar{\mathbf{X}})]\}$. Thus, whatever is the value for $q(\bar{\mathbf{z}})$, the second summand is

Algorithm 2: CAVI algorithm for $q^*(\boldsymbol{\beta},\bar{\mathbf{z}}) = q^*(\boldsymbol{\beta} \mid \bar{\mathbf{z}}) \prod_{i=1}^n q^*(\bar{\mathbf{z}}_i)$

[1] For each $i = 1,\dots,n$, set $\boldsymbol{\Sigma}_i^* = \left(\boldsymbol{\Lambda}_{[i,i]}^{-1} - \mathbf{H}_{[i,i]}\right)^{-1}$ and initialize $\mathbb{E}_{q^0(\bar{\mathbf{z}}_i)}[\bar{\mathbf{z}}_i] \in \mathbb{R}^{(L-1)}$

[2] **for** *t from* 1 *until convergence* **do**

  for *i from* 1 *to n* **do**

    [2.1] Set $\boldsymbol{\mu}_i^{(t)} = \boldsymbol{\Sigma}_i^* \mathbf{H}_{[i,-i]} (\mathbb{E}_{q^{(t)}}[\bar{\mathbf{z}}_1]^\intercal, \dots, \mathbb{E}_{q^{(t)}}[\bar{\mathbf{z}}_{i-1}]^\intercal, \mathbb{E}_{q^{(t-1)}}[\bar{\mathbf{z}}_{i+1}]^\intercal, \dots, \mathbb{E}_{q^{(t-1)}}[\bar{\mathbf{z}}_n]^\intercal)^\intercal$

    [2.2] Compute $\mathbb{E}_{q^{(t)}}[\bar{\mathbf{z}}_i]$ with $\bar{\mathbf{z}}_i \sim \text{TN}_{L-1}\left(\boldsymbol{\mu}_i^{(t)}, \boldsymbol{\Sigma}_i^*; [0,\infty)^{L-1}\right)$ [in R use `MomTrunc()`]

[3] Set $q^*(\bar{\mathbf{z}}_i) = q^{(t)}(\bar{\mathbf{z}}_i)$ for $i = 1,\dots,n$

[4] Set $q^*(\boldsymbol{\beta} \mid \bar{\mathbf{z}}) = \phi_{p(L-1)}(\boldsymbol{\beta} - \mathbf{V}\bar{\mathbf{X}}^\intercal \boldsymbol{\Lambda}^{-1}\bar{\mathbf{z}}; \mathbf{V})$

Output: $q^*(\boldsymbol{\beta},\bar{\mathbf{z}}) = q^*(\boldsymbol{\beta} \mid \bar{\mathbf{z}}) \prod_{i=1}^N q^*(\bar{\mathbf{z}}_i)$

zero, and hence minimal, if and only if, calling $\mathbf{V} = (\nu^{-2}\mathbf{I}_{p(L-1)} + \bar{\mathbf{X}}^\intercal \boldsymbol{\Lambda}^{-1}\bar{\mathbf{X}})^{-1}$,

$$q(\boldsymbol{\beta} \mid \bar{\mathbf{z}}) = q^*(\boldsymbol{\beta} \mid \bar{\mathbf{z}}) = p(\boldsymbol{\beta} \mid \bar{\mathbf{z}}, \bar{\mathbf{y}}, \bar{\mathbf{X}}) = \phi_{p(L-1)}(\boldsymbol{\beta} - \mathbf{V}\bar{\mathbf{X}}^\intercal \boldsymbol{\Lambda}^{-1}\bar{\mathbf{z}}; \mathbf{V}),$$

which follows by standard properties of multivariate normals applied to model (4). This means that in order to find the KL minimizer $q^*(\boldsymbol{\beta},\bar{\mathbf{z}}) = q^*(\boldsymbol{\beta} \mid \bar{\mathbf{z}}) \prod_{i=1}^N q^*(\bar{\mathbf{z}}_i)$ in $\mathscr{Q}_{\text{PFM-B}}$, we just have to find $q^*(\bar{\mathbf{z}}) = \prod_{i=1}^N q^*(\bar{\mathbf{z}}_i)$ minimizing $\text{KL}[q(\bar{\mathbf{z}}) || p(\bar{\mathbf{z}} \mid \bar{\mathbf{y}}, \bar{\mathbf{X}})]$. See [1] for further details. Due to the imposed factorization for $q^*(\bar{\mathbf{z}})$, which takes the name of 'mean-field approximation', the desired solution is known to satisfy the following mean field equations (see [7] for additional details):

$$\log q^*(\bar{\mathbf{z}}_i) \propto \mathbb{E}_{q^*(\bar{\mathbf{z}}_{-i})}[\log p(\bar{\mathbf{z}}_i \mid \bar{\mathbf{z}}_{-i}, \bar{\mathbf{y}}, \bar{\mathbf{X}})], \quad i = 1,\dots,n,$$

where the expectation is taken with respect to the distribution of all the $\bar{\mathbf{z}}_j$ other than $\bar{\mathbf{z}}_i$. Here, we show how this solution can be obtained by exploiting the dual hierarchical model (4). This gives further intuition and a broader understanding of the procedure. Moreover, besides specifying to the current setting the results derived in [1] under more general constructions, it allows computational gains due to the simplification of certain parameters, above all the covariance matrices in $q^*(\bar{\mathbf{z}}_i)$.

First, by marginalizing out $\boldsymbol{\beta}$ in (4b), we get $\bar{\mathbf{z}} \mid \bar{\mathbf{X}} \sim \text{N}_{n(L-1)}\left(\mathbf{0}, \boldsymbol{\Lambda} + \nu^2 \bar{\mathbf{X}}\bar{\mathbf{X}}^\intercal\right)$, thus $\bar{\mathbf{z}} \mid \bar{\mathbf{y}}, \bar{\mathbf{X}} \sim \text{TN}_{n(L-1)}\left(\mathbf{0}, \boldsymbol{\Lambda} + \nu^2 \bar{\mathbf{X}}\bar{\mathbf{X}}^\intercal; [0,\infty)^{n(L-1)}\right)$. Taking $\mathbf{V}$ as above and $\mathbf{H} = \boldsymbol{\Lambda}^{-1}\bar{\mathbf{X}}\mathbf{V}\bar{\mathbf{X}}^\intercal\boldsymbol{\Lambda}^{-1}$, by Woodbury's identity it holds $(\boldsymbol{\Lambda} + \nu^2\bar{\mathbf{X}}\bar{\mathbf{X}}^\intercal)^{-1} = \boldsymbol{\Lambda}^{-1} - \mathbf{H}$ and so

$$\begin{aligned} p(\bar{\mathbf{z}}_i \mid \bar{\mathbf{z}}_{-i}, \bar{\mathbf{y}}) &\propto \exp\left\{-0.5\,\bar{\mathbf{z}}^\intercal(\boldsymbol{\Lambda} + \nu^2\bar{\mathbf{X}}\bar{\mathbf{X}}^\intercal)^{-1}\bar{\mathbf{z}}\right\} \mathbb{1}[\bar{\mathbf{z}}_i > \mathbf{0}] \\ &\propto \exp\left\{-0.5\,\bar{\mathbf{z}}^\intercal(\boldsymbol{\Lambda}^{-1} - \mathbf{H})\bar{\mathbf{z}}\right\} \mathbb{1}[\bar{\mathbf{z}}_i > \mathbf{0}] \\ &\propto \exp\left\{-0.5\,\bar{\mathbf{z}}^\intercal(\boldsymbol{\Lambda}_{[i,i]}^{-1} - \mathbf{H}_{[i,i]})\bar{\mathbf{z}} + \bar{\mathbf{z}}_i^\intercal \mathbf{H}_{[i,-i]}\bar{\mathbf{z}}_{-i}\right\} \mathbb{1}[\bar{\mathbf{z}}_i > \mathbf{0}], \end{aligned}$$

from which we get

$$q^*(\bar{\mathbf{z}}_i) \propto \exp\left\{-\frac{1}{2}\bar{\mathbf{z}}^\intercal\left(\boldsymbol{\Lambda}_{[i,i]}^{-1} - \mathbf{H}_{[i,i]}\right)\bar{\mathbf{z}} + \bar{\mathbf{z}}_i^\intercal \mathbf{H}_{[i,-i]}\mathbb{E}_{q^*(\bar{\mathbf{z}}_{-i})}[\bar{\mathbf{z}}_{-i}]\right\} \mathbb{1}[\bar{\mathbf{z}}_i > \mathbf{0}],$$

which shows that $q^*(\bar{\mathbf{z}}_i)$ is the density of a normal random variable with parameters $\boldsymbol{\mu}_i^* = \boldsymbol{\Sigma}_i^* \mathbf{H}_{[i,-i]}\mathbb{E}_{q^*(\bar{\mathbf{z}}_{-i})}[\bar{\mathbf{z}}_{-i}]$ and $\boldsymbol{\Sigma}_i^* = \left(\boldsymbol{\Lambda}_{[i,i]}^{-1} - \mathbf{H}_{[i,i]}\right)^{-1}$, truncated above zero. In

order to obtain in practice the optimal PFM-B variational solution, one can resort to standard CAVI algorithms (see, e.g., [7]), as shown in detail in Algorithm 2. It is worth noting that, differently from Algorithm 1, in Algorithm 2 we only have to deal with expectations of $(L-1)$-variate truncated normals, significantly reducing the computational burden. After $q^*(\boldsymbol{\beta}, \bar{\mathbf{z}})$ has been computed, approximate posterior moments for $\boldsymbol{\beta}$ can be easily obtained leveraging on the law of total expectation as

$$\mathbb{E}_{q^*(\boldsymbol{\beta})}(\boldsymbol{\beta}) = \mathbf{V}\bar{\mathbf{X}}^\intercal \boldsymbol{\Lambda}^{-1}\mathbb{E}_{q^*(\bar{\mathbf{z}})}[\bar{\mathbf{z}}], \quad \text{var}_{q^*(\boldsymbol{\beta})}(\boldsymbol{\beta}) = \mathbf{V} + \mathbf{V}\bar{\mathbf{X}}^\intercal \boldsymbol{\Lambda}^{-1}\text{var}_{q^*(\bar{\mathbf{z}})}(\bar{\mathbf{z}})\boldsymbol{\Lambda}^{-1}\bar{\mathbf{X}}\mathbf{V},$$

while more complicated functionals can be computed with i.i.d. sampling, which, due to the particular block-diagonal structure of the resulting covariance matrix of the multivariate truncated normal distribution $q^*(\bar{\mathbf{z}})$, would require sampling only from multivariate truncated normals of dimension $L-1$.

4 Discussion

This article provides a novel derivation for the PFM-B variational method for a relevant class of MNP models with independent Gaussian priors. As shown in Section 3, this provides a novel understanding of the results in [1] as well as computational advantages in our special settings. Future works include deriving results for the posterior also for the dynamic MNP, which allows to model sequential decisions in the time series framework. In such a way, we plan to extend closed-form expressions, and the related samplers, for the filtering, predictive and smoothing distributions of multivariate dynamic probit models for binary time series in [10]. Finally, the variational Bayes approach in Section 3 can be generalized to perform inference for the smoothing distribution of the dynamic MNP extending the results in [11].

Mapping Indicators on the Unit Interval: the tipsae Shiny App

Mappare Indicatori sull'Intervallo Unitario: la tipsae Shiny App

Silvia De Nicolò and Aldo Gardini

Abstract The tipsae shiny app is a dedicated R-based tool for mapping proportions and indicators defined on the unit interval, working in the framework of small area estimation. It implements Beta-based Bayesian Hierarchical models defined at area level through Stan. A set of diagnostics, exploratory analysis and complementary tools complement the application.

Abstract *La shiny app tipsae si presenta come uno strumento, costruito in R, utile a mappare proporzioni o, più in generale, indicatori definiti nell'intervallo unitario nel contesto della stima per piccole aree. Permette di stimare, attraverso Stan, modelli gerarchici Bayesiani basati sulla distribuzione Beta a livello di area. L'applicazione fornisce diagnostiche specifiche, analisi esplorative ed altri strumenti complementari all'analisi.*

1 Introduction

Timely and reliable statistical estimates at a great level of disaggregation are increasingly in demand and require an extensive exploitation of survey data. Nonetheless, domains or areas of study are often different from the ones for which the survey was originally planned, leading to unreliable survey estimates due to observations-poor and possibly non-representative samples.

Small Area Estimation (SAE) techniques exploit auxiliary information to borrow strength across areas and produce estimates of interest with an acceptable level of uncertainty. Specifically, the area-level class of SAE models maps survey estimators of target quantities to areas-specific covariates, generally measured without error (e.g. census data), via an explicit regression model.

We focus on unit interval responses, common in SAE modelling because of the high presence of rates and proportions releases in official statistics. Two different bodies of literature relate with this field, revolving around linear mixed models with suitable transformations [11] and Beta regression models [8]. Although several routines for SAE have been released by developer teams in `R`, only the `emdi` package [9] directly accounts for unit interval responses at area-level via Gaussian models with proper transformations. Furthermore, Beta-based small area models lack of a proper implementation and the `tipsae` package, available on CRAN [4], aims at filling this gap.

We implement area-level models based on the Beta likelihood comprising the standard Beta regression model, Zero and/or One Inflated Beta [14] and Flexible Beta [3] models. Moreover, particular dependence structures can be modelled, including spatial and/or temporal random effects. We decided to operate in a Bayesian fashion via `Stan` routine [2] to easily manage non-Gaussian assumptions, ease the out-of-sample areas treatment, and capture the uncertainty about target parameters through posterior inference. Within this framework, we developed a Shiny application to further facilitate the workflow for non-expert users.

Our application assists the user in carrying out a complete SAE analysis, starting from data loading step, tracking the entire process of data exploration, model estimation and validation, presentation and exportation of results. This allows to straightforwardly use Bayesian models and complex SAE methods.

2 Beta-Based Small Area Models

A classical Beta small area model for $y_d \in (0,1)$, denoting the direct estimator of a generic target quantity and $\boldsymbol{x}_d$ being a set of P covariates for domain d, constitutes as a hierarchical model with two levels. The sampling level models the conditional distribution of the direct estimator as

$$y_d|\theta_d, \phi_d \overset{ind}{\sim} Beta(\theta_d\phi_d, (1-\theta_d)\phi_d), \quad \forall d.$$

where $\mathbb{E}[y_d|\theta_d, \phi_d] = \theta_d$ is the target parameter and is estimated via a logit regression at the linking level, i.e. $\text{logit}(\theta_d)|\boldsymbol{\beta}, v_d = \boldsymbol{x}_d^T\boldsymbol{\beta} + v_d$, with $v_d|\sigma_v^2 \overset{ind}{\sim} \mathcal{N}(0, \sigma_v^2)$ an area specific random effect. Generally, a small area Beta model assumes the dispersion parameter ϕ_d as known in order to allow identifiability. In our package, we contemplate alternative likelihood assumptions at the

sampling level. The Zero/One Inflated Beta model extends the support of y_d to zero/one values, by assuming a mixture of a Beta and Dirac Delta components. Moreover, the Flexible Beta distribution, defined as a mixture of two Beta components, allow to improve the modelling of target quantities with skewed and heavy tailed distributions [10].

3 Workflow

The application can be launched without any preliminary action by running the following commands.

```
R> library(tipsae)
R> runShiny_tipsae()
```

A browser window pops-up, allowing users to navigate on the application. The interface is organized into 5 main sections briefly described in what follows.

The **Home** page comprises a schematic description of the application with some relevant references.

The **Data** page is divided into 4 subsections: the first 3 tabs concern data entry steps and data pre-treatment, while the latter provides graphical exploratory tools. In the *Loading Data* tab, a CSV file can be loaded and the data input may be visualized through the button "View loaded dataset". Additional information about data must be filled, such as the nature of the inserted variables, labeling the response, the covariates and the dispersion values, specifying also if it is the variance or the effective sample size. Here, it is also possible to set up the smoothing procedure, if needed. Other information can be specified, such as a possible time variable, domain ids and sample sizes, useful for following visual diagnostics. When a smoothing procedure is set up, the *Smoothing* subsection enables to change settings and graphically visualize its output. The procedure is a Generalized Variance Function smoothing technique [6]; for a methodological explanation, refer to the package vignette. Note that only a simplified smoothing procedure is provided in the Shiny app, if compared to the package function: it automatically assumes the response variable as a proportion, employing the related variance function. The user can choose between `"ols"` and `"gls"` regression type for smoothing. In subsection *Load Shapefile*, a spatial structure can be incorporated, loading either a SHP file either an RDS file containing a `SpatialPolygonsDataFrame` object. Such object would enable to account for spatial dependencies in the model and/or plot maps with relevant quantities. The last subsection, called *Data Summary*, provides an accurate data exploration before moving to the modelling step, depicting the distribution of the response variable and its relationship with the covariates and the dispersion measure.

The **Model Fitting** section implements the estimation of mentioned Bayesian models, via Stan routine [2]. It provides an efficient Hamiltonian Monte Carlo (HMC) fitting algorithm and customized parallel computing.

The *Model Specification* tab enables to set the model likelihood: our application automatically constrains the model choice among those allowed by the input data. When any response observation $y_i \in (0, 1)$, $\forall i$ the allowed options are Beta and Flexible Beta models. If some observations are recorded as zeros and/or ones, the application automatically restricts the choice to the Zero and/or One Inflated Beta models. Secondly, the prior for the random effect can be chosen among the standard Gaussian one, a robust alternative following a Student's t distribution [5] and a shrinkage distribution, the variance gamma [7], for a more flexible handling. When the data incorporates a time variable, therefore having a panel nature, the model automatically incorporates a temporal dependency structure, adding to the linear predictor an additional random effect with a random walk prior. Moreover, if a `SpatialPolygonsDataFrame` object related the to areas of interest has been loaded, the application asks whether to include a spatial dependency structure into the model or not. The dependecy is incorporated via an additional random effect in the linear predictor with a intrinsic conditional autoregressive (ICAR) prior.

Some algorithm settings can also be modified in the *Settings about the MCMC Algorithm* tab, such as the number of iterations per chain, including warm-up (half of total iterations), the parallel computation to switch on with a proper tick, the number of chains, and the number of cores. Additional HMC options are the maximum allowed tree depth (Maximum treedepth) and the target average proposal acceptance probability (adapt_delta): refer to the Stan documentation for further details. The "Fit Model" button allows the user to start the estimation, whose progress is depicted by an iterative printed output.

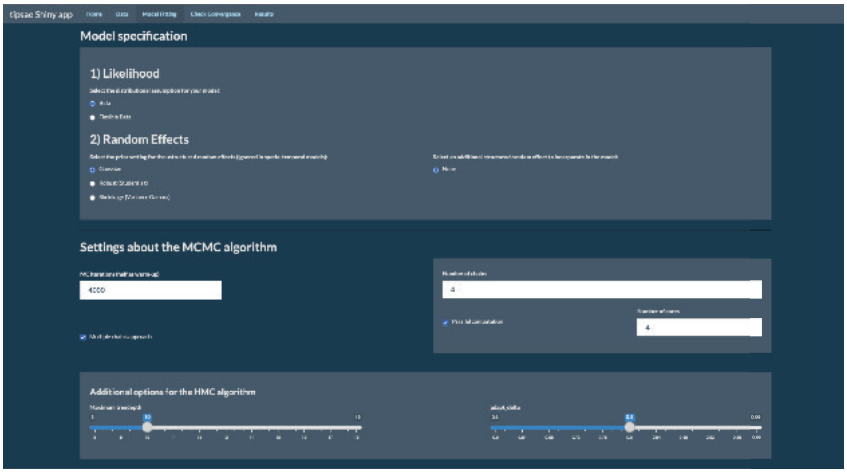

Fig. 1 Model Fitting Section of tipsae Shiny App

Once computations are completed, the mixing of the MCMC algorithm can be checked through graphical tools within the **Check Convergence** section. The posterior densities, chains trace-plots, autocorrelation functions and rank plots can be visualized for any linking level parameter.

Eventually, the model results can be accessed in the **Results** section. The *Model Summaries* subsection provides posterior syntheses of regression coefficients and random effects. Furthermore, a summary of residuals is also reported, including an histogram, and the LOO Information Criterion can be computed through the button "Click to compute LOOIC", enabling for model selection. This criterion is based on approximate leave-one-out cross-validation computed using Pareto-smoothed importance sampling [13]. The *Posterior Predictive Check* subsection displays the sample data kernel density versus those of the datasets generated from the posterior predictive distribution, denoted with $Y_d^\bullet|\boldsymbol{y},\ d = 1, \ldots, D$, in order to assess the goodness of fit. Here, a specific tab focuses on area-specific Bayesian p-values, defined as $BP_d = \mathbb{P}\left[Y_d^\bullet > y_d|\boldsymbol{y}\right]$ [6]. In absence of systematic deviations, the expected Bayesian p-value is 0.5, whereas values near 0 or 1 highlight issues of over-estimation and under-estimation, respectively.

Small area specific diagnostics have a proper subsection (*SAE diagnostics*), visually illustrating the shrinking process induced on model-based estimates and comparing direct and model-based estimates. The standard deviations of both type of estimates are compared and summaries of a measure of standard deviation reduction are provided. The *Random Effect* subsection compares the standardized effects density versus the one of a standard normal and a caterpillar plot, comparing their posterior distributions for each area. Lastly, the *Model Estimates* subsection displays a table with direct and model-based estimates, including relevant posterior summaries of target parameters. Such object can be downloaded in CSV format via a proper button. A caterpillar plot of the target parameter posteriors is also provided.

4 Conclusions

The tipsae shiny app is a dedicated tool for mapping proportions and indicators defined on the unit interval, widely used to measure, for instance, unemployment or disease prevalence. Additional features to be integrated in future releases may be the implementation of shrinking priors for the regression coefficients, allowing for variable selection when several covariates are employed. Other directions may focus on model extensions for variance shrinking [12], able to relax the assumption of known dispersion parameter, and for covariates measured with error [1]. Notice that the `Shiny` app does not include all the package tools. Specifically, the benchmarking procedure has not been implemented and the smoothing procedure does not include as option the `"kish"` method. However, such features may be included in future releases of the package.

A Bayesian spatio–temporal model of PM_{10} pollutant in the Po Valley

Un modello bayesiano spazio–temporale per l'inquinante PM_{10} nella Pianura Padana

Matteo Gianella, Alessandra Guglielmi and Giovanni Lonati

Abstract Po Valley is well known to be one of the most polluted areas in Italy, due to its population density, its shape and climate. Thus, there is obvious interest in monitoring the air quality in several stations scattered in the whole territory. In this work, we develop a Bayesian spatio–temporal model for the analysis of time series of PM_{10} concentration in Po Valley to assess whether the station features have an effect in explaining the spatial time series. In particular, we focus on the Emilia Romagna region and we rely on *Stan* for posterior inference.

Abstract *La Pianura Padana è nota per essere una delle regioni più inquinate d'Italia, a causa della elevata densità abitativa, la sua forma e clima. Vi è quindi un ovvio interesse nel monitorare la qualità dell'aria attraverso numerose stazioni disseminate per tutto il territorio. In questo lavoro proponiamo un modello bayesiano spazio–temporale per l'analisi di serie temporali della concentrazione di PM_{10}. Ci concentriamo, in particolare, sull'Emilia Romagna e ci affidiamo a Stan per il calcolo dell'inferenza a posteriori.*

Key words: Bayesian inference, Gaussian processes, harmonic regression

1 Introduction

Pollution is defined as the introduction of contaminants into the natural environment which cause adverse change. Pollution can take the form of any substance (solid, liquid, or gas) or energy (such as radioactivity, heat, sound, or light). By *air pollution*, in particular, we mean the release by human activities of gases and particulates

Matteo Gianella[1], Alessandra Guglielmi[1] and Giovanni Lonati[2]

[1] Department of Mathematics, Politecnico di Milano, Milano, Italy
e-mail: {matteo.gianella,alessandra.guglielmi}@polimi.it

[2] Department of Civil and Environmental Engineering, Politecnico di Milano, Milano, Italy
e-mail: giovanni.lonati@polimi.it

into the atmosphere. Common gaseous pollutants include carbon monoxide, sulfur dioxide, chlorofluorocarbons (CFCs) and nitrogen oxides produced by industry and motor vehicles. Photo–chemical ozone and smog are created as nitrogen oxides and hydrocarbons react to sunlight. Particulate matter, or fine dust is characterized by their micrometre size PM_{10} to $PM_{2.5}$.

Po Valley is a well-known hotspot for PM pollution in Europe [4]. Many factors might be responsible: an elevated population density, together with a high level of urban and industrial areas, its geographic shape and climate. In particular, the population density and the high number of industries are the main contributors to the high level of emissions in this area, while its shape and climate prevent an adequate dispersion of the emitted pollutants. In this work, we consider air quality data of the Po Valley, which includes hourly and daily averaged concentrations for several pollutants. Such data are collected via fixed monitoring stations at 280 sites distributed over four regions. The management and data collection policies are specific to every region. Data of this type are certainly *spatial*, since they have an intrinsic spatial dependence one may want to investigate, whilst being *multiple time series*, as for each location we have a multi–dimensional time series, one for each pollutant.

Spatial models for point–referenced data are usually modelled via Gaussian Processes (GPs). Since learning a GP is computationally intensive as the number of data points increases, a recent interest to provide alternatives that simplify the computational costs has soared up. Another approach comes from Gaussian Random Markov Fields and its link with Gaussian processes [6]. (Multiple) Time Series analysis in a Bayesian setting (see [5]) is also an interesting research field, for which several different approaches are available: CAR models of various orders, non–parametric dynamic AR models or models built on the frequency domain (spectral models).

In this paper, we propose a Bayesian model for the analysis of spatial time series of air pollutants in the Po Valley. We focus only on PM_{10} pollutant to understand if particular features of the monitoring site affect the estimation of the time series and spatial association of the daily averaged concentrations. The latent spatial and temporal processes are modelled separately via Gaussian Processes with Matérn covariance functions and harmonic regression models, respectively. The paper is organized as follows: Section 2 provides a short description of the dataset; then, in Section 3 we describe the Bayesian model we assume for our data and in Section 4 we give initial findings based on posterior inference along with possible future research directions and developments.

2 The dataset

The dataset we consider for the analysis comes from the air quality monitoring network of the Po Valley, the area of interest. This network is managed autonomously by the Regional Agencies of Environmental Protection (ARPA) of Emilia Romagna, Lombardy, Piedmont and Veneto. Data about concentrations of pollutants are col-

lected through fixed monitoring stations, distributed one the whole valley. Each station collects, through time, the concentration of many pollutants, in particular: nitrogen dioxide (NO_2), benzene (C_6H_6), ammonia (NH_3) and particulate matter (PM_{10}, $PM_{2.5}$).

Since each regional agency is independent, we may observe the same data collected in different time scales. For instance, data about NO_2 are available as hourly averages, except for Piedmont, where we have daily averaged concentrations. Particulate matter is collected as daily averages in all regions. The dataset also provides some details on the station recording the concentration time series. For each station, we have information about its location (lat–long coordinates), the main emission source to which the given station is exposed to (e.g., emissions from traffic, industry, etc.) and the level of urbanization of the surroundings (e.g., urban, suburban, rural areas). Data also take into account specific features of the territory of interest, thus distinguishing different zones, specific for each region, due to the intrinsic diversity among the Po Valley. Exploratory data analysis of the whole dataset is in [3], where the authors investigate the effects of COVID–19 lockdown policies in the first semester of 2020.

3 The Bayesian model

Monitoring processes in natural and environmental sciences often results in the collection of spatial or spatio–temporal data [1]. In this context, the objectives of the analysis include the estimation over spatial locations and over time. As mentioned before, we consider time series for a single concentration of pollutant (PM_{10}) in all stations in Emilia Romagna. We denote by $y(\boldsymbol{s}, t)$ the measurement of a given quantity collected at location $\boldsymbol{s}$ at time t, for $\boldsymbol{s} \in \mathcal{D} \subset \mathbb{R}^d$, with $d = 2$ and for $t \in [0, T] \subset \mathbb{R}^+$. A spatio–temporal regression model for point–referenced data on a spatial domain $\mathcal{D}$ and temporal domain $[0, T]$ can be assigned, in the most general case, as follows:

$$y(\boldsymbol{s}, t) = \boldsymbol{x}(\boldsymbol{s}, t)^T \boldsymbol{\beta}(\boldsymbol{s}, t) + w(\boldsymbol{s}, t) + \epsilon(s, t),$$

where $\boldsymbol{x}(\boldsymbol{s}, t)$ is a $p \times 1$ vector of predictors, $\boldsymbol{\beta}(\boldsymbol{s}, t)$ is the $p \times 1$ vector of regression coefficients, $w(\boldsymbol{s}, t)$ is a spatio–temporal process and $\epsilon(\boldsymbol{s}, t) \overset{\text{iid}}{\sim} \mathcal{N}(0, \tau^2)$ is the random effect, usually in charge of capturing local variability, which can not be detected by the process w neither in space nor in time. As a result, we also need a model for $w(\boldsymbol{s}, t)$. For this purpose, we denote by α the denote temporal effects and w the spatial effect. We consider the following separable model (see [1]) for $w(\boldsymbol{s}, t)$:

$$w(\boldsymbol{s}, t) = \alpha(t) + w(\boldsymbol{s}). \tag{1}$$

Both $\alpha(t)$ and $w(\boldsymbol{s})$ are assumed to be independent from $\epsilon(\boldsymbol{s}, t)$. Equation (1) provides a separable (additive) assumption in the spatio–temporal effect. Non–separable spatio–temporal modeling requires the choice of a specific relationship to connect

space and time scales, which is non trivial and beyond the scopes of this work. Hence, providing a model for our spatio–temporal dataset boils down to the model specification for the temporal process $\alpha(t)$ and the spatial process $w(\boldsymbol{s})$.

Model for the temporal process The concentration of air pollutants often exhibit some periodicity, at least seasonal, mainly due to the different dispersion features of the atmosphere, but also to the sources' activity (e.g., domestic heating). It is then straightforward, at least for an initial modelling, characterize the process using harmonic regression. *Harmonic regression* refers to (usually linear) models describing periodicities in data by means of sinusoidal functions. Standard Fourier representation of periodic functions, in fact, proves useful in modeling series with persistent periodic patterns, especially in dealing with seasonal phenomena. Given an integer period p, a general time series has an exact representation, obtained as super–position of $m = \lfloor p/2 \rfloor$ Fourier harmonics. Thus, for a zero–mean time series as $\alpha(t)$, an appropriate model is given by

$$\alpha(t) = \sum_{k=1}^{m} a_k \cos\left(\frac{2\pi k}{T} t\right) + b_k \sin\left(\frac{2\pi k}{T} t\right).$$

In a Bayesian setting, we need to specify the marginal prior for $\{(a_k, b_k)\}_k$ parameters to assess the contribution of each harmonic in the regression.

Model for the spatial process The most common choice for the spatial process $\{w(\boldsymbol{s}),\ \boldsymbol{s} \in \mathcal{D}\}$ in (1) is the Gaussian Process. Gaussian Processes are specified with a covariance function $Cov[w(\boldsymbol{s}), w(\boldsymbol{s}')] = \Sigma_\theta(\boldsymbol{s}, \boldsymbol{s}')$ for any two points $\boldsymbol{s}$ and $\boldsymbol{s}'$ in $\mathcal{D}$. If $\mathcal{U} = \{u_i\}_{i \in 1,\dots,n}$ and $\mathcal{V} = \{v_j\}_{j \in 1,\dots,m}$ are two finite sets, we define $\Sigma_\theta(\mathcal{U}, \mathcal{V})$ the $n \times m$ matrix such that $[\Sigma_\theta(\mathcal{U}, \mathcal{V})]_{ij} = \Sigma_\theta(u_i, v_j)$. For our spatial process $w(\boldsymbol{s})$ we assume a centered Gaussian Process of variance Σ_θ, i.e.

$$w(\boldsymbol{s}_i) \overset{\text{iid}}{\sim} GP(\mathbf{0}, \Sigma_\theta) \quad \Longleftrightarrow \quad (w(\boldsymbol{s}_1), \dots, w(\boldsymbol{s}_n)) \sim \mathcal{N}_n(\mathbf{0}, \Sigma_\theta) \quad \text{for all } n.$$

In this definition, we require Σ_θ to be a valid spatial covariance function for the process. Validity is attained ensuring that $\Sigma_\theta(\mathcal{U}, \mathcal{U})$ is positive definite for any finite set $\mathcal{U}$. As a consequence, it is not straightforward to define a valid covariance function, so we rely on standard choices. Further details can be found, for instance, in [1] and references therein. In particular, for our process, we choose the *exponentiated quadratic kernel* (i.e., the limit of a Matérn kernel $C_\nu(\boldsymbol{s}_i, \boldsymbol{s}_j)$ when ν tends to $+\infty$), defined as

$$\Sigma_{(\sigma^2,\, \rho)}(\boldsymbol{s}_i, \boldsymbol{s}_j) = \sigma^2 \exp\left\{-\frac{1}{2\rho^2} \|\boldsymbol{s}_i - \boldsymbol{s}_j\|^2\right\}$$

In this case, random parameters are σ^2 and ρ^2, both required to be greater than 0.

Prior The model just described is then completed with suitable marginal prior distributions for each parameter involved in the spatial and temporal process just described. We assume independence between blocks of parameters. We use a rather vague prior for each component of the regression coefficients' vector $\boldsymbol{\beta}$ and for

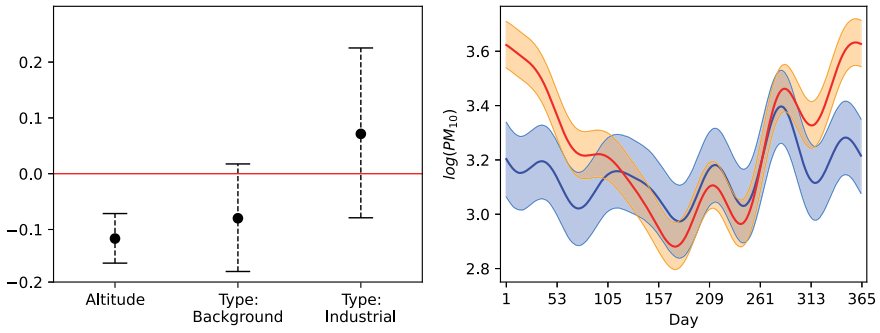

Fig. 1 95% credible intervals for regression coefficients $\boldsymbol{\beta}$ (left); 95% credible bands for the estimate of the temporal process via harmonic regression for rural (blue) and non–rural (red) stations (right)

the harmonic regression pairs $\{(a_k, b_k)\}_k$, assuming a $\mathcal{N}(0, 10^2)$ distribution; the variance of the random effect τ^2 is set in order to avoid infinite variances, thus setting $InvGamma(3, 2)$ as its marginal prior distribution; finally, for the parameters involved in the spatial process, i.e., σ^2 and ρ^2, we set a vague prior on σ^2 and a more informative one to ρ^2. This choice is made to avoid well–known model issues that prevent spatial models to be completely identifiable (see [1]). In particular, since we are more interested in the spatial range associated with the covariance kernel, we keep more care in defining a prior distribution for this parameter. We then set an $\mathcal{U}(0, 1)$ distribution for σ and a $Beta(2, 5)$ for ρ. The supports of those marginal priors matches empirical estimates based on likelihood maximization whilst ensuring enough flexibility.

4 Posterior Inference

At this stage of research, we focus only on the Emilia Romagna region during 2018. This reduced dataset contains daily averaged PM_{10} concentrations in 49 stations for every day of the year (thus $T = 365$). As regressors of interest, we consider the *Altitude* of the station and the most probable source of pollution (*Traffic*, *Industrial* or *Background* in case the source of pollution can not be easily detected).

As mentioned before, we rely on *Stan* probabilistic programming language [2] for posterior simulation. This language, in fact, is flexible enough to quickly set up the model here discussed and carry out posterior inference in reasonable time. As future development, we will consider *ad–hoc* sampling strategies to speed up computation even with more complex models. We run four MCMC chains in parallel in *Stan*, each of them for a total of $10,000$ iterations, discarding the first $6,000$ as burn–in and thinning the chain every two iterations. Hence, the final sample size is $2,000$.

Figure 1, left panel, displays the credible intervals at 95% for the regression coefficients. We find that all regressors are quite significant at this level, especially the *Altitude* seems to play a relevant role in the linear predictor, as expected: air

quality improves with altitude. Note that the *Type: Industrial* regressor exhibit a wider variance than *Type: Background* since the number of stations marked as *Background* is small. Moreover, since the base category is *Type: Traffic*, posterior inference highlights that air quality worsen in presence of Industrial areas. Figure 1, right panel, shows the posterior estimate of the harmonic regression for the temporal process in case the station is located in a rural area (blue band) and non–rural area (red band). In non–rural areas, usually cities or industrial sites, the curve exhibit an interesting U–shape that highlights higher PM_{10} concentration levels in cold seasons. In rural stations, on the other hand, we observe a flatter curve and those areas are generally characterized by a better air quality. As long as the spatial process $w(\boldsymbol{s})$ is concerned, we report the 95% marginal posterior credible interval for ρ, which is a indicative of the level of spatial correlation estimated by our model, that is $[0.001, 0.011]$ with posterior median 0.005. This means that the spatial correlation is weak. This can be motivated by the relatively high regional background of PM_{10} over the whole Po valley and even in rural areas, with lower concentration levels only observed at mountain sites.

Future work includes the assumption of a Bayesian non–parametric model which aims at clustering stations according to the functional shape of the temporal process. Moreover, we plan to further investigate the spatial effect in the model.

Aknowledgements

We would like to thank Camilla Battistini, Michela Frigeri, Francesca Pessina, Michael Ronzulli, Claudia Speranza and Luigi Umana, M.Sc. students in Mathematical Engineering at Politecnico di Milano, for *Stan* code implementation and summary plots in Section 4.

Construction of a proper prior for a Bayesian Envelope Model

Costruzione di una prior propria per un modello Envelope bayesiano

Andrea Mascaretti

Abstract Envelope models are multivariate linear regression techniques that aim at reducing the variance of the estimator. Bayesian envelopes allow to quantify the uncertainty of inference by means of the posterior distribution. In this work, we construct a proper prior distribution and compare it to the existing literature. A prior sensitivity analysis is conducted, yielding similar results.

Abstract *I modelli envelope sono una particolare tipologia di regressione lineare multivariata finalizzata a ridurre la varianze degli stimatori. La formulazione bayesiana di questi modelli consente di quantificare direttamente l'incertezza degli stimatori mediante l'analisi della posterior. In questo lavoro, proponiamo una prior propria per il modello e valutiamo l'impatto della prior sull'inferenza, ottenendo risultati comparabili alle proposte presenti in letteratura.*

Key words: envelope models, bayesian statistics

1 Response Envelopes

Envelopes [2, 1] are a class of models aimed at increasing the efficiency of multivariate regression by exploiting the relations between response and predictors that affect the accuracy of the results and are not taken into account by standard methods. Within the usual multivariate regression setting, the expected value of a random variable $Y \in R^r$ is given a functional form such that we get

$$Y_i = \mu + \beta X_i + \varepsilon_i, \;\; i = 1, \ldots, n, \tag{1}$$

Andrea Mascaretti
University of Padova, Via Cesare Battisti, 241, 35121, Padova (PD), Italy, e-mail: mascaretti@stat.unipd.it

where $\{X_i\}_{i=1}^n$ is a sequence of non-stochastic vectors, with $X_i \in R^p$ for $i = 1,\dots,n$, the errors are independent and identically distributed multivariate normal vectors with zero mean and covariance Σ, $\mu \in R^r$ is an unknown vector of intercepts and $\beta \in M_{(r,p)}$ (where $M_{(a,b)}$ denotes the space of real matrices of dimensions (a,b)) is the unknown matrix of regression coefficients. For simplicity (and without loss of generality), we assume that the predictors are centred, $\sum_{i=1}^n X_i = 0$. Moreover, let Y be the $(n \times r)$ matrix of rows $(Y_i - \bar{Y})^T$, where $\bar{Y}$ is the sample mean, and Y_0 be the non-centred matrix. In a similar fashion, let $X = \left\{X_i^T\right\}$ be the matrix of the predictors, $S_{Y,X} = n^{-1}Y^T X$ and $S_X = n^{-1}X^T X$. The maximum likelihood estimator,

$$\hat{\beta} = S_{Y,X} S_X^{-1}, \tag{2}$$

is incidentally equal to the ordinary least squares estimator. From Eq. 2, we notice that this is akin to performing r separate univariate regressions: one for every element of Y on X. Inference on $\beta_{j,k}$, the (j,k)th element of β is the same we would obtain by constructing a univariate model. The model in Eq. 1 becomes operational when inference is conducted simultaneously on different rows of β or various elements of Y jointly.

The intuition behind envelope models is that there might be linear combinations of the response vectors whose distribution is invariant with respect to the non-stochastic predictors. Explicitly modelling for this property allows to obtain estimator whose variance is reduced. We call such linear combinations of Y X-invariant. Notice that for a linear transformation $G \in M_{(r,q)}$, with $q \leq r$, if $G^T Y$ is invariant, then also $A^T G^T Y$ has the same property for any non-stochastic matrix $A \in M_{(q,q)}$. In other words, only span (G) is identifiable.

From a mathematical point of view, this is equivalent to assuming the existence of two matrices Γ and Γ_0 such that $O = [\Gamma\ \Gamma_0]$ is orthogonal. We obtain

1. $\Gamma_0^T Y | X \sim \Gamma_0^T Y$
2. $\Gamma^T Y \perp \Gamma_0^T Y | X$

The conditions above entail that span $(\beta) \subseteq$ span (Γ) and $\Sigma = \Sigma_1 + \Sigma_2 = P_\Gamma \Sigma P_\Gamma + Q_\Gamma \Sigma Q_\Gamma$, where $P_{(\cdot)}$ is the orthogonal projector operation on a space and $Q_{(\cdot)} = I - P_{(\cdot)}$ is the projection on the orthogonal space. In this scenario, span (Γ) is a reducing subspace of Σ ([2]). The Σ-envelope of $\mathscr{B} =$ span (β), $\mathscr{E}_\Sigma(\mathscr{B})$, is the smallest reducing subspace of Σ that contains $\mathscr{B}$.

Model in Eq. 1 can be rewritten as

$$Y_i = \mu + \Gamma \eta X_i + \varepsilon, \tag{3}$$

where $\beta = \Gamma\eta$, $\Gamma \in M_{(r,u)}$ is an orthogonal basis of $\mathscr{E}_\Sigma(\mathscr{B})$ and u is the dimension of the envelope $\mathscr{E}_\Sigma(\mathscr{B})$. Moreover, the variance is $\Sigma = \Sigma_1 + \Sigma_2 = \Gamma\Omega\Gamma^T + \Gamma_0\Omega_0\Gamma_0^T$, where $\Omega \in M_{(u,u)}$ and $\Omega_0 \in M_{(r-u,r-u)}$ are two diagonal matrices carrying the coordinate information with respect to the basis Γ and Γ_0.

1.1 Bayesian Envelopes

The only contribution, to the best of our knowledge, on Bayesian envelopes models is [3]. The rationale behind Bayesian envelopes is that it allows to quantify the uncertainty of the predictions by computing the posterior distribution (as opposed to bootstrap or asymptotic considerations), as well as extending the model to the cases where $n < r$. Moreover, prior information can be incorporated into the learning process, be it on the values of the parameters or to induce sparsity or other desirable properties. As for the selection of u, the dimension of the envelope, [3] adopt a Deviance Information Criterion to obtain the best value, in lieu of the Likelihood Ratio Tests used within the frequentist framework. The interest in obtaining a proper prior distribution for a Bayesian envelope stems from the fact that this is a prerequisite to extend it to more complex scenarios, such as mixtures or nonparametric formulations. In our work, we build on [3] and change the prior on the mean μ. Notice that we require that the mean component be separated from the regression coefficients because we model our data up to a translation: assuming that a subset of Y is X-invariant does not imply that it has zero mean. We also assume a priori independence, which seems logical for the mean value of Y should not be influenced by the values of X a priori. Whereas [3] employ an improper prior for the data, *i.e.* they set $\pi(\mu) \propto 1$ on the support of μ, our proposal relies on a proper prior distribution.

The prior distribution is defined on the parameters $(\mu, \eta, (\Gamma, \Gamma_0), \Omega, \Omega_0)$. Notice that, for identifiability, we constrain Ω and Ω_0 to be diagonal matrices with entries disposed in decreasing order. This is equivalent to post-multiplying Γ and Γ_0 by the matrices of eigenvectors of the original Ω and Ω_0. From a mathematical point of view, this is equivalent to fix Γ and Γ_0 to be bases of the envelope and, thus, as elements of a subset of a Stiefel manifold restricted to have that the maximum element for each column as positive sign, denoted by $S^+_{(\cdot,\cdot)}$. In this respect, we notice that the Stiefel manifold of arbitrary finite dimensions (a,a) is a compact unimodular group with a unique Haar measure, which induces a measure on $S_{(a,b)}$ and $S^+_{(a,b)}$.

The parameter space is then given by $M_{(r,1)} \times M_{(u,p)} \times S^+_{(r,r)} \times O_u \times O_{r-u}$, where O_a is the set of diagonal matrices of dimension a with entries disposed in decreasing order.

We define the prior on the parameters as follows:

1. μ is set to be independent from the other parameters. We endow it with a multivariate normal distribution, so that $\pi(\mu) = \mathscr{N}_r(\mu_0, \Sigma_0)$,
2. The conditional prior on η is a matrix normal:

$$\pi(\eta | (\Gamma, \Gamma_0, \Omega, \Omega_0)) = \mathscr{N}_{(u,p)}\left(\Gamma^T, \Omega, C^{-1}\right),$$

   where C^{-1} is a positive definite matrix in $M_{(p,p)}$.
3. The prior on $O = (\Gamma, \Gamma_0)$ is a matrix Bingham distribution with parameters G and D, where G is a positive semi-definite matrix in $M_{(r,r)}$ and D is in O_r with positive entries. Thus, $\pi(O) = \mathscr{B}_{(r,r)}\left(G, D^{-1}\right)$. The density is proportional to $\exp\left\{(-1/2)\operatorname{tr}\left(D^{-1}O^T GO\right)\right\}$

4. Denoting by ω and ω_0 the diagonal vectors of, respectively, Ω and Ω_0, we assume that, a priori, they are distributed as order statistics of u and $r-u$ independent and identically distributed observations from Inverse-Gamma distributions of shape and rate parameters α, ψ and α_0, ψ_0.

Notice that the main difference between our work and [3] is the prior on μ. From a computational point of view, this means that the structure of the Gibbs sampler is similar, the only difference being the structure of the full-conditional for μ, which can be easily computed to be of the form

$$\pi\left(\mu|\eta,\left(\Gamma,\Gamma_0\right),\omega,\omega_0,Y\right)=\mathscr{N}_r\left(\mu_c,\Sigma_c\right), \tag{4}$$

where

$$\Sigma_c=\left(\Sigma_0^{-1}+\left(\frac{\Sigma}{n}\right)^{-1}\right)^{-1},$$

and

$$\mu_c=\Sigma_c\left(\Sigma_0^{-1}\mu_0+\left(\frac{\Sigma}{n}\right)^{-1}\bar{Y}\right).$$

Notice that the Harris ergodicity of the chain is also a straightforward extension of [3].

2 Simulation and Data Analysis

We now perform a test for different values of the prior distribution on a synthetic dataset. The aim is to assess the sensitivity with respect to the choice of the hyperparameters. We generated $n=100$ data points from a normal distribution with zero mean and identity matrix as covariance. We set $u=1$, $p=2$, $r=3$. The parameters are defined as follows:

1. $\mu=(12,12,12)$
2. $\omega=6.2$
3. $\omega_0=(3.2,1.4)$
4. $O=I_r$

and Y_i are randomly drawn from a multivariate normal with mean $\mu+\Gamma\eta X_i$ and covariance $\Gamma\Omega\Gamma^T+\Gamma_0\Omega_0\Gamma_0^T$. As for the hyperparamaters, we distinguish between three cases. We focus on μ as it is the most relevant change we make. In the first case, we use a weakly informative proper prior with $\mu_0=(0,0,0)$ and $\Sigma_0=\kappa I_r$, with $\kappa=10$. In the second test case, we set $\mu_0=\bar{Y}$ and $\Sigma=I_r$. Finally, we consider the improper prior as in [3]. The other parameters are set as follows: $C=I_p$, $D=I_r$, $G=I_r$, $\alpha=3$, $\psi=3$, $\alpha_0=3$ and $\psi_0=3$.

For each case study, we run a Gibbs sampler for 1000 iterations, with a burn in of 300. The initialisation for each chain was from the same random point in the parameter space. This was mainly for convenience, as we did not want to find a suitable

initial point (as it is customary for applied Bayesian analysis, *f.i.* by starting from the approximate mode of the posterior), given that we wanted to assess convergence starting from a somewhat arbitrary place.

Results for the three components of μ are reported, respectively in Tables 1, 2, and 3.

We see that even though the empirical and the noninformative priors lead to somewhat closer posterior estimates, the effect of placing a weakly informative prior also yields posterior higher density intervals that are in line with the other two classes of prior distributions. However, the true advantage of a proper prior is that it allows for extending the model to more complex settings. The fact that it yields similar results notwithstanding different hyperparameters is certainly encouraging, although, as always, some care should be put in their refinement.

Table 1 Posterior inference for $\mu = (\mu_1, \mu_2, \mu_3)$ with a weakly informative prior: posterior higher density interval (HDI) are reported.

Parameter	Mean	3% HDI	97% HDI
μ_1	12.67	12.005	13.359
μ_2	12.043	11.715	12.324
μ_3	12.097	11.882	12.313

Table 2 Posterior inference for $\mu = (\mu_1, \mu_2, \mu_3)$ with an empirical prior: posterior higher density interval (HDI) are reported.

Parameter	Mean	3% HDI	97% HDI
μ_1	12.832	12.1	13.49
μ_2	12.071	11.746	12.361
μ_3	12.117	11.903	12.307

Table 3 Posterior inference for $\mu = (\mu_1, \mu_2, \mu_3)$ with a noninformative prior: posterior higher density interval (HDI) are reported.

Parameter	Mean	3% HDI	97% HDI
μ_1	12.85	12.246	13.425
μ_2	12.07	11.74	12.364
μ_3	12.121	11.916	12.286

3 Conclusions

In this work, we have constructed a proper prior distribution for a Bayesian envelope model. We carried out an assessment of the prior sensitivity on a simple test case, obtaining that the choice of the hyperparameters for the parameter μ yields similar results in the three cases studied: a weakly informative, an empirical one and a non-informative prior. The importance of allowing more options stem from different lines of reasoning. First of all, it might be required when prior knowledge is to be incorporated into the model. Moreover, even though the actual impact of any of these prior distributions is somewhat limited whenever the likelihood is dominant, this might not necessarily be the case. In such scenarios, a weakly informative or empirical prior might be preferable. Another advantage of a proper prior is that it allows for an extension of the model to more complex scenarios. For instance, finite mixture models and nonparametric extensions require prior distributions to be proper. This is due to the latent cluster structure they posit on the data: the more the clusters, the more likely they are empty. An improper prior is then ill-suited in this context, as it is not an actual distribution and does not respect the probabilistic properties required by Bayesian inference.

Hilbert principal component regression for bimodal bounded responses

Regressione con componenti principali in Hilbert per risposte limitate bimodali

Enea G. Bongiorno, Agnese M. Di Brisco, Aldo Goia, and Sonia Migliorati

Abstract The flexible beta regression model is an effective approach to deal with bounded and bimodal responses. The aim of this work is to generalized this regression model to cope with a generic Hilbert covariate, either high-dimensional or functional. The dimensionality reduction procedure is based on principal components and the selection of the significant ones in the regression framework is carried out within a Bayesian rationale. The effectiveness of the proposal is illustrated both on simulated and real data.

Abstract *Il modello di regressione flexible beta è un approccio efficace per gestire risposte limitate e bimodali. Lo scopo di questo lavoro consiste nel generalizzare il suddetto modello di regressione per far fronte a una generica covariata Hilbert, sia ad alta dimensionalità che funzionale. La procedura di riduzione della dimensionalità è basata sulle componenti principali e la selezione di quelle significative nel quadro di regressione è effettuata seguendo una logica bayesiana. L'efficacia della proposta è illustrata sia su dati simulati che reali.*

1 Introduction

The issue of modeling a bounded response, further complicated by possibly latent mixture structure inducing a bimodal shape, is common in many applications such as in Kalivas (1997); Reiss et al. (2017); Di Brisco et al. (2022). Standard regression techniques are not feasible in this context, and among many reasons the most evident is the risk of predicting values outside the support. A promising approach, though not the only one possible, relies on modeling the response variable directly on its bounded support by making use of proper distributions. The additional bimodal nature of the response requires even more ad hoc modeling. In particular, here the flexible beta model is considered for which the response is a suitable mixture of two betas (Migliorati et al., 2018). The aim of the work is to describe a Hilbert flexible beta (HFB) regression model, that is when the covariate of interest belongs to a Hilbert space. In the light of the type of covariate, either high-dimentional or functional, a dimensionality reduction procedure based on the principal components (PCs) is considered and a selection of how many and which ones components is carried out with a Bayesian variable selection approach. The outline of this work is as follows. Section 2 illustrates the flexible beta regression model with Hilbert covariate and describes the Bayesian estimation method. Section 3 applies the presented technique to the spectometric example.

2 Hilbert flexible beta regression

Let Y be a real random variable in $(0,1)$, and X a random element, with either high-dimensional or functional nature, in $\mathscr{H}$, a Hilbert space equipped with an inner product $\langle\cdot,\cdot\rangle$. Assume that the conditional pdf of Y given $X=x$ is a flexible beta (FB) (Migliorati et al., 2018), that is

$$f_{FB}(y|\lambda_1,\lambda_2,\phi,p) = pf_B(y|\lambda_1,\phi)+(1-p)f_B(y|\lambda_2,\phi), \qquad 0<y<1, \quad (1)$$

where $f_B(y|\lambda_j,\phi)$ denotes the pdf of a beta random variable with a mean ($0<\lambda_j<1$) and precision ($\phi>0$) parameterization. It is worth noting that λ_1 and λ_2 represent the conditional means given x of the first and second mixture components with the constraint $0<\lambda_2<\lambda_1<1$ to ensure identifiability, $\phi>0$ is the precision parameter, and finally $0<p<1$ is the mixing proportion parameter,

Let $g(\cdot)$ be a monotone and twice differentiable link function and $\mu=\mathbb{E}[Y|x]=p\lambda_1+(1-p)\lambda_2$ be the overall conditional mean of the mixture defined in (1). Assume $g(\mu)=\alpha+\langle\beta,x\rangle$, where $\alpha\in\mathbb{R}$, $\beta\in\mathscr{H}$ is the regression coefficient, either functional or high-dimensional depending on the nature of the covariate. Note that the proposed model does not belong to the GLM family since the related distribution is not in the exponential family. Morever, to explicitly include μ and to obtain a variation independent parameter space as well, the FB distribution can be reparametrized by means of $0<\mu<1$, $0<w<1$, $0<p<1$, and $\phi>0$ where

$w = (\lambda_1 - \lambda_2)/\min\{\mu/p, (1-\mu)/(1-p)\}$ quantifies the distance between the two mixture components.

Let $\{(X_i, Y_i), i = 1, \ldots, n\}$, $n \geq 1$, be a sample of iid copies of (X, Y). To deal with the regression coefficient that belongs to either a high-dimensional or infinite dimensional space, a principal component regression (PCR) strategy is performed leading to

$$\tilde{g}(\mu_i) = \alpha + \sum_{k=1}^{K} b_k \chi_{ik}, \qquad i = 1, \ldots, n, \qquad K \geq 1 \tag{2}$$

where $(\psi_k)_{k=1}^{\infty}$ is the orthonormal basis of principal component analysis, $b_k = \langle \beta, \psi_k \rangle$ are unknown real parameters, and $\chi_{ik} = \langle X_i, \psi_k \rangle$ are real random variables called PCs. To select how many PCs and which ones better explain the response, one takes advantages of Bayesian techniques of variable selection (O'Hara and Sillanp, 2009).

The problem of computing the posterior distribution from which to sample has no analytical solution, and thus one can resort to MCMC techniques which require the definition of the likelihood function and the a priori distributions of the unknown parameters. The complete-data likelihood, computed according to a data augmentation strategy, is given by

$$L(\mathbf{y}, \mathbf{v}|\eta) = \prod_{i=1}^{n} [p f_B(y_i|\lambda_{1i}, \phi)]^{v_i} [(1-p) f_B(y_i|\lambda_{2i}, \phi)]^{1-v_i},$$

where $\mathbf{y} = (y_1, \ldots, y_n)$ is the vector of responses, $\eta = (\alpha, \mathbf{b}, \phi, p, w) \in \mathbb{R}^{K+4}$ is the vector of unknown parameters, and $\mathbf{v}$ is a latent variable with $v_i \sim Bernoulli(p)$, for $i = 1, \ldots, n$.

For what concerns the a priori information, non-informative prior distributions are selected with the scope of inducing the least impact on the posterior distributions.

$$\begin{cases} b_j|I_j, \tau_{b_j} \sim I_j \mathcal{N}(0, \tau_{b_j}^{-1}) + (1-I_j)\delta(0) \\ I_j|\pi_j \sim Bernoulli(\pi_j) \\ \pi_j \sim Unif(0,1) \\ \tau_{b_j} \sim Gamma(\gamma, \gamma) \end{cases} \qquad \begin{cases} \alpha \sim \mathcal{N}(0, \sigma) \\ \phi \sim Gamma(\gamma, \gamma) \\ p \sim Unif(0,1) \\ w \sim Unif(0,1) \end{cases}$$

It is worth noting that the coefficients b_j are associated with spike-and-slab priors showing a mixture structure with Bernoulli weights of a diffuse normal (the slab) and a $\delta(0)$ indicating a discrete measure concentrated at zero (the spike). The hyperparameters γ and σ have been suitably selected to induce non-informativeness.

The joint prior distribution results from the product of the marginal prior distributions since the parametric space is variation-independent. To simulate from the posterior distribution, that is proportional to the joint prior multiplied by the likelihood function, a Gibbs sampling procedure is adopted. In particular, a metropolis-Hasting algorithm within Gibbs is performed for sampling from the full conditionals that have not closed form. The implementation of the estimation algorithm is done

through the software OpenBUGS and R. Numerical and graphical inspections of the simulated chains are performed to assess the stationarity, the absence of autocorrelation, and overall the convergence to the posterior distributions.

3 Numerical example: high-dimensional setting

A first illustration of the proposed method concerns a toy example with a high-dimensional covariate X_i, for $i = 1,\dots,n = 100$, generated from a $D = 200$ dimensional multivariate centered normal with a covariance matrix $\Sigma = \left[0.9^{|i-j|}\right]_{1\leq i,j\leq D}$. As a result, the first 30 PCs explain more than 80% of the total variability and are thus included in the regression model. The response variable is simulated from a flexible beta distribution with $\phi = 100$, $p = 0.8$, and $w = 0.7$, thus being characterized by both boundedness and bimodality. Its conditional mean is as in (2) with $\tilde{g}(\cdot) = logit(\cdot)$, $\alpha = 0.5$, $b_1 = 3$, $b_3 = -3$, $b_6 = 1.5$, and all remaining b_k equal to zero. Estimation is performed by adopting the Bayesian approach described in Section 2. The main results, based on 100 Monte Carlo replications, are reported in Table 1. In all Monte Carlo replications the coefficients b_k different from zero are identified as significant, meaning that the posterior probability of inclusion are (by far) greater than 0.5. The remaining coefficients are therefore shrunk to 0 in almost all replications. Overall, the HFB provides very precise estimates with low associated MSEs for both the regression coefficients and the additional parameters of the FB.

Table 1 Monte Carlo posterior means and MSEs

	$\alpha = 0.5$	$\beta_1 = 3$	$\beta_3 = -3$	$\beta_6 = 1.5$	$log(\phi) = 4.6$	$p = 0.8$	$w = 0.7$
Post. Mean	0.491	3.008	-2.973	1.522	4.603	0.796	0.698
MSE	0.01	0.098	0.098	0.082	0.026	0.002	0.001

4 Application: infinite dimensional setting

The proposed application is based on a spectroscopic dataset described in Kalivas (1997). The functional data refers to the observed spectra measuring the intensity of reflection over the near infra-red wavelength of the radiation and collected on 100 wheat samples. Instead, the bounded response variable is the moisture content measured in percentage. Left-hand panel of Figure 1 shows the estimated density curve of the moisture content, which is characterized by an evident bimodality in addition to the bounded support. Right-hand panel of Figure 1 shows the once-differenced spectra of the wheat samples collected on a regular grid of 701 points ranging be-

tween 1100nm and 2500 nm. The HFB regression model has been estimated either

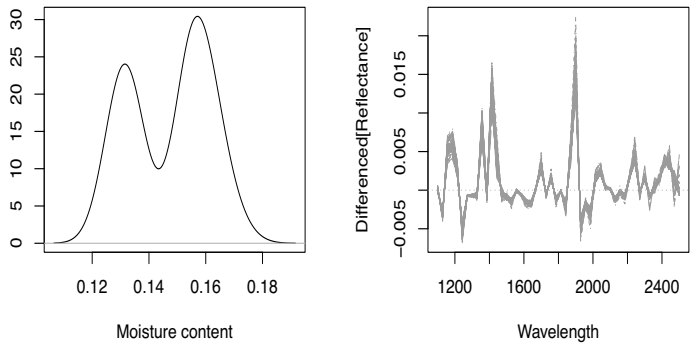

Fig. 1 Left-hand panel: estimated density curve of the moisture content in percentage. Right-hand panel: once-differenced wheat spectra.

by including the observed spectra or the once-differenced spectra as functional covariate with $g(\cdot) = logit(\cdot)$, according to Reiss et al. (2017). In what follows only results concerning the model with the once-differenced spectra are included, since the direct use of the observed spectra leads to consistent results. The posterior means and standard deviations (SD) of the coefficients are provided in Table 2. In particular, only the posterior estimates of the significant coefficient b_k are reported, i.e. those for which the posterior probability of inclusion of that coefficient is greater than 0.5. It is worth noting that only the first six (except for the fourth) components were significant, despite from the third component onwards the percentage of explained variability of the covariate is negligible. Moreover, it is of interest to observe that the model recognises two almost equally weighted groups (posterior mean of p around 0.57) whose component means are well-separated (posterior mean of w around 0.7). For comparative purpose, a beta-type regression model has been implemented too. The estimated functional parameter β is quite similar to that of the proposed model, but the overall fit to data ($WAIC = -915.509$) is worse than that provided by the HFB model ($WAIC$=-923.479).

Finally, a 5-fold cross-validation analysis was performed. The predictive accuracy of the model is measured by computing the RMSE and is compared to the one obtained from a standard generalized linear model (GLM) (Ramsay and Silverman, 2005) and a non parametric (NP) scalar-on-function regression model (Ferraty and Vieu, 2006) evaluated with respect to the $logit$ transformation of the response. As it emerges from Table 3, the proposed model is the best choice both in terms of overall fit on the whole sample and in terms of predictive accuracy in cross-validation.

Table 2 Posterior means and SD of the parameters

	α	β_1	β_2	β_3	β_5	β_6	$log(\phi)$	p	w
Post. Mean	-0.626	-0.038	-0.029	-0.069	-0.010	0.009	9.785	0.567	0.702

Methods of causal inference

Bayesian causal mediation analysis through linear mixed-effect models

Analisi di mediazione causale Bayesiana mediante modelli lineari a effetti misti

Chiara Di Maria, Antonino Abbruzzo and Gianfranco Lovison

Abstract In mediational settings, the main focus is on the estimation of the indirect effect of an exposure on an outcome through a third variable called mediator. The traditional maximum likelihood estimation method presents several problems in the estimation of the standard error and the confidence interval of the indirect effect. In this paper, we propose a Bayesian approach to obtain the posterior distribution of the indirect effect through MCMC, in the context of mediational mixed models for longitudinal data. A simulation study shows that our method outperforms the traditional maximum likelihood approach in terms of bias and coverage rates.
Abstract *In contesti in cui è presente una mediazione, ci si concentra sulla stima dell'effetto indiretto di un'esposizione su una risposta tramite una terza variabile detta mediatore. Il tradizionale metodo di stima basato sulla massima verosimiglianza presenta diversi problemi nella stima dell'errore standard e dell'intervallo di confidenza dell'effetto indiretto. In questo articolo, proponiamo un approccio bayesiano per ottenere la distribuzione a posteriori dell'effetto indiretto tramite MCMC, applicato a modelli di mediazione a effetti misti per dati longitudinali. Uno studio di simulazione mostra che il nostro metodo è superiore alla stima con massima verosimiglianza in termini di distorsione e copertura.*

those related to the insurgence of psychological issues like depression or violent behaviours. Causal mediation analysis is a statistical technique widely used for this scope, since it allows researchers to understand how an exposure X exerts its effect on a response Y, if only directly, or also indirectly though intermediate variables called *mediators*. Longitudinal data are particularly suited for mediation analysis, since they ensure the correct time ordering of the variables (exposure has to precede the mediator, which in turn has to precede the outcome) and the necessary time span for the causal mediational effects to unfold [1, 6]. Both in single-time and longitudinal frameworks, if mediation models are linear, the indirect effect is generally obtained as a product of regression coefficients. Even if the estimators of such regression coefficients are assumed to be normally distributed, their product may not [2, 4]; hence, the estimation of the standard error and the confidence intervals of indirect effects is not straightforward using maximum likelihood (ML).

In this paper, we address the problem of estimating the indirect effect in a longitudinal setting, modelling data through linear mixed models (LMM) within a Bayesian framework, adopting a Markov Chain Monte Carlo (MCMC) approach. This allows us to draw values from the posterior distribution of the indirect effect, and derive point estimates and highest credibility intervals (HDI).

We will first introduce the modeling framework, then we move to the description of a simulation study comparing the performance of ML and the Bayesian approach in terms of standard errors, bias and coverage rates, the latter using bootstrap confidence intervals and HDIs, respectively. Some conclusions will follow.

2 The counterfactual mediation framework

Defining mediation in a causal framework requires specific notation and assumptions. Causality is indeed a concept difficult to address, especially in observational studies, where the randomisation of the exposure is not guaranteed and there is plenty of potential unobserved confounders.

One of the most widely accepted (although not free from controversies) framework to deal with causality is the counterfactual one [7, 8]. Imagine to observe a patient dying of stroke after taking a drug. Has it caused the stroke and led the patient to death or would he/she have died in any case because of other reasons? To answer this question one should observe the same patient not taking the medication and see if he/she dies anyway or not. This is clearly impossible, but it is the kind of reasoning at the very basis of the counterfactual framework. The definition of *causal effect* of X on Y relies on the comparison of the two counterfactual values $Y(x)$ and $Y(x')$ which the outcome would assume if X were set to x and x', respectively. In the very common case of binary exposure, the *total causal effect* is defined as the expected difference $\mathbb{E}[Y(1) - Y(0)]$.

In the mediational framework the total effect of the exposure on the response can be decomposed into two effects, the *direct effect*, i.e. the effect not passing through the mediator, and the *indirect effect*, i.e. the effect conveyed through the

mediator. There exist several definitions of mediational effects, and the most popular is that of natural direct and indirect effects [9]. The former is defined as $NDE = \mathbb{E}[Y(x, M(x)) - Y(x', M(x))]$, that is, the expected difference between the values of the response if X were set to x and x', respectively, keeping the mediator fixed at the natural value it would assume if X were x. The latter is defined as $NIE = \mathbb{E}[Y(x, M(x)) - Y(x, M(x'))]$, that is, the expected difference in the outcome if X were fixed at x and the mediator at the value it would naturally assume if X were set to x and x', respectively (see [9] for an exhaustive introduction on the topic).

Making inference on the direct and indirect effects is quite hard, especially in complex settings like the longitudinal one, since, in order to make mediational effects identifiable from observed data, strict assumptions on unmeasured confounders have to be made. In particular, it is assumed the absence of unmeasured exposure-mediator confounders, exposure-outcome confounders and mediator-outcome confounders (in the last case, either affected and unaffected by the exposure). See [9] for a discussion on these assumptions in the general setting and [3] for those in the longitudinal one.

3 Model specification and Bayesian approach to longitudinal mediation

In this paper, we focus on a longitudinal mediation setting, where the exposure, the mediator and the outcome are measured repeatedly over a certain time interval. One of the modeling framework proposed to address such a setting is that of mixed-effect models [3].

Let X_{it}, M_{it} and Y_{it} denote the exposure, the mediator and the outcome, respectively, for the i-th subject at the t-th measurement occasion, for $i = 1, \ldots, n$ and $t = 1, \ldots, T_i$. Although the framework proposed by [3] is that of generalised mixed models, here we focus only on the case of normal mediator and outcome with identity link functions, i.e. on LMMs. The expected values of the mediator and the outcome can then be written as

$$\mathbb{E}[M_{it}|X_{it} = x, \mathbf{b}_i] = (\beta_0 + b_{0i}) + (\beta_1 + b_{1i})x \tag{1}$$

$$\mathbb{E}[Y_{it}|X_{it} = x, M_{it} = m, \mathbf{g}_i] = (\gamma_0 + g_{0i}) + (\gamma_1 + g_{1i})x + (\gamma_2 + g_{2i})m \tag{2}$$

where $\mathbf{b}_i = (b_{0i}, b_{1i})^T$ and $\mathbf{g}_i = (g_{0i}, g_{1i}, g_{2i})^T$ are vectors of subject-specific random effects. It is assumed that $(\mathbf{b}_i, \mathbf{g}_i)^T$ follows a multivariate normal distribution with null mean vector and variance-covariance matrix allowed to be non-diagonal.

[3] prove that, under the aforementioned traditional assumptions concerning the absence of unobserved confounders, and assuming the absence of time-varying confounders, the natural mediational effects, defined as

$$NDE = \mathbb{E}[Y_{it}(x, M_{it}(x)) - Y_{it}(x', M_{it}(x))|\,\mathbf{b}_i, \mathbf{g}_i] \tag{3}$$
$$NIE = \mathbb{E}[Y_{it}(x, M_{it}(x)) - Y_{it}(x, M_{it}(x'))|\,\mathbf{b}_i, \mathbf{g}_i], \tag{4}$$

are identifiable from observed data. In particular, they derive closed forms of these effects for some combinations of distributions of the mediator and the outcome, and link functions of the corresponding models. For example, in the normal-normal/identity-identity link case the mediational effects, marginalising over the random effects are:

$$NDE = \gamma_1(x - x') \tag{5}$$
$$NIE = (\beta_1\gamma_2 + \sigma_{b_1 g_2})(x - x'), \tag{6}$$

where $\beta_1, \gamma_1, \gamma_2$ are as in Eq. (1)-(2) and $\sigma_{b_1 g_2}$ is the covariance between b_1 and g_2.

It can be noticed that the expression for the NIE includes a product of coefficients. As already mentioned, this makes inference on the indirect effect not straightforward, since, even assuming that the two regression coefficients estimators are normally distributed random variables, generally their product is not. In fact, the distribution of the product may be highly skewed and, most importantly, unknown and this complicates the estimation of confidence intervals for the mediated effect [5]. [3] use non parametric bootstrap to obtain standard errors and confidence intervals, but it is well know that this technique is computationally intensive.

Bayesian MCMC methods allow to obtain the posterior distribution of the indirect effect and a highest density credibility interval, which, broadly speaking, is more interpretable and accurate than its frequentist version, since it takes into account the asymmetry of the distribution and the information deriving from the data.

4 Simulation study

We carried out a simulation study in order to compare the performance of the Bayesian approach to the traditional ML estimation method. The simulations were conducted making use of R and JAGS, by considering six scenarios obtained by varying the number of subjects $n = 100, 1000$ and the number of measurement occasions $T_i = T = 5, 7, 10$. Abiding by the setting described by [3], the exposure at time 1 was randomly drawn from a Bernoulli and its subsequent measurements were obtained by fitting an autoregressive model so that $\mathbb{E}[X_{it}] = \text{logit}^{-1}(\alpha_0 + \alpha_1 X_{it-1})$, where α_0 and α_1 were drawn independently from a Uniform(-2,2).

The mediator and the outcome were generated from a normal distribution with expectations as in Eq. (1) and (2), respectively, and standard deviations are set to 1. As regards the random factors, we drew $(\mathbf{b}_i, \mathbf{g}_i)^T \sim MVN(\mathbf{0}, \Theta)$, where Θ is drawn from a Wishart with five degrees of freedom and scale matrix given by a Toeplitz matrix. Fixed coefficients do not vary over iterations, while $\sigma_{b_1 g_2}$ changes at each, as well as the true value of the indirect effect.

Table 1 Results of the simulation study showing the bias of indirect effect, the percent relative bias, standard errors and the coverage rate of bootstrap confidence intervals and HDI.

		ML				Bayes			
	T	S.E.	Cov. Rate	Bias	% Bias	S.E.	Cov. Rate	Bias	% Bias
n = 100	5	0.289	75%	-0.13	18.75	0.419	95.5%	0.05	1.44
	7	0.289	75%	-0.11	18.36	0.410	98%	0.051	0.048
	10	0.283	76.5%	-0.13	13.90	0.394	96%	0.006	0.678
n = 1000	5	0.090	19%	-0.28	27.71	0.145	94%	-0.013	0.284
	7	0.090	36.5%	-0.17	17.7	0.133	94%	-0.004	0.009
	10	0.089	44%	-0.11	14.09	0.126	94.5%	0.001	1.11

In the Bayesian estimation, we used non-informative priors. We modeled the mediator and the outcome as $M_{it} \sim N(\mu_{it}, \tau_m)$, $Y_{it} \sim N(\nu_{it}, \tau_y)$, where μ_{it} and ν_{it} are as in Eq. (1) and (2), respectively, while τ_m and τ_y are precision parameters[1] following a Gamma$(0.01, 0.01)$. All regression coefficients were assumed to be drawn from a normal distribution with null mean and precision 0.01. Finally, the random effects were modeled as draws from a multivariate normal with zero mean and precision matrix from an Inverse Wishart. The Bayesian estimation procedure relied on three chains of length 10,000 and adaptation 5,000.

We compared the performance of the ML estimation method, combined with non-parametric bootstrap for estimating the standard error and the confidence interval of the indirect effect, and the Bayesian approach using 95% highest density credibility intervals. We ran 200 iterations, and for each one we computed the bias, the relative bias and the standard error of the estimated indirect effect and the coverage rates of its bootstrap-based confidence intervals and HDIs. In the Bayesian case, the standard error was obtained by averaging standard errors of the NIE mean estimated in the 200 iterations.

Table 1 shows the results of the simulation study. It is evident that the Bayesian approach performs better than ML in terms of bias and coverage rate, while standard errors are smaller in the ML approach. It is also worth remarking that the Bayesian approach is advantageous even from a computational perspective, since estimates are obtained much faster than those obtained from bootstrap. Figure 1 shows twenty randomly selected indirect effects and corresponding ML/Bayesian estimates in the scenario with $n = 100$ and $T = 10$. It is easy to see that Bayesian posterior means are generally closer to the true effect and HDIs generally include it, although they are often wider than bootstrap CI. These differences attenuate in the scenario with 1000 observations.

5 Conclusions

This work addresses the issue of making inference on the indirect effect in a longitudinal mediational setting through the Bayesian approach, whose main strength is the

[1] JAGS requires precision instead of variance.

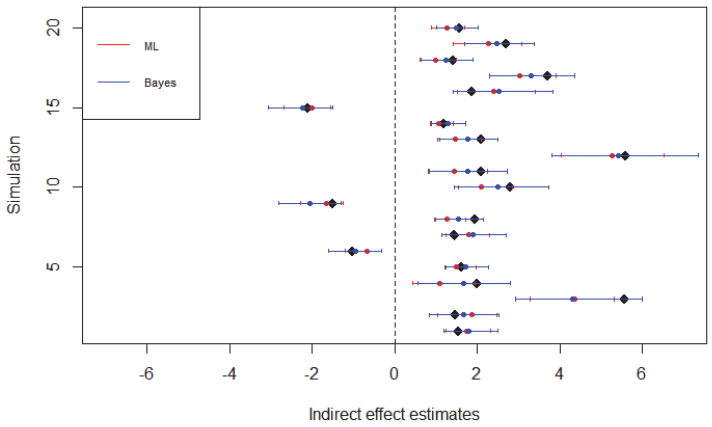

Fig. 1 Simulation results in the scenario $n = 100, T = 10$ for 20 randomly selected iterations. Black diamonds is the true indirect effect, blue and red dots/lines correspond to posterior means/HDI and ML point estimates/bootstrap confidence intervals, respectively.

possibility of obtaining the whole distribution for the indirect effect and, as a consequence, more reliable credibility intervals. The simulation study shows excellent results in the case of normal mediator and outcome modeled through linear mixed models. Further research is required to evaluate the performance of this approach when the mediator and/or the outcome are not normally distributed and the link functions differ from the identity, and in the presence of covariates, either baseline and time-varying.

Bootstrap-aggregated Adjustment Set Selection

Selezione di un Adjustment Set tramite Bootstrap-aggregating

Lorenzo Giammei

Abstract Causal effects can be estimated from observational data within the Causal Graph framework. When the true causal graph is unknown, data can be used to learn the graph and then select a sufficient set of covariates for adjustment according to its structure. Graph learning is a crucial step of the process since misspecifications of the graph can result in biased causal estimates. We propose a procedure that resorts to bootstrap-aggregating to select the adjustment set based on its stability across bootstrap resamples. The performance of the novel method is tested on graphs of different complexity and compared to three alternative procedures. The results show that the relative accuracy of the proposed methodology improves as the complexity of the graph increases.

Abstract *Gli effetti causali possono essere stimati tramite dati non sperimentali nel framework dei Grafi Causali. Quando il grafo causale non è noto, i dati posso essere impiegati per apprendere il grafo e selezionare un adjustment set di variabili che consenta di ottenere stimatori non distorti degli effetti causali. Proponiamo una procedura che seleziona un adjustment set sulla base della sua stabilità nelle repliche bootstrap. La performance del nuovo metodo è testata su grafi di diversa complessità e confrontata con tre procedure alternative. I risultati mostrano che l'accuratezza relativa della procedura proposta migliora all'aumentare della complessità del grafo.*

1 Introduction

Causal inference investigates causal relations between variables. One of the possible frameworks to investigate causal claims, when dealing with observational data, are Causal Graphs [7], also called Causal Diagrams or Causal Bayesian Networks. Causal diagrams represent variable interactions clearly through a graph, and, if identifiable, estimate the treatment's causal effect on an outcome variable.

When treatment assignment is not randomized, the main concern is confounding: the situation where there is at least one variable that has a direct causal effect on both the treatment and the outcome. This kind of configuration can generate biased estimates unless adequately accounted for. However, if the causal relations between variables are known a priori, it is possible to select a sufficient set of covariates for confounding adjustment, if such a set exists. In the Causal Graphs framework, sufficient adjustment sets can be derived from the structure of the graph, following the back-door criterion [7]. Once the set is selected, adjustment can be performed through various methods, including matching, weighting, regression adjustment or doubly robust methods.

Unfortunately, in real settings the true graph is often unknown or just partially known. In this case the graph can be learnt from data through causal discovery methods [7]. Once the graph is learnt, it is usually taken as a good approximation of the true graph and then a sufficient adjustment set can be selected to estimate a chosen treatment effect. However, if the structure of the graph is misspecified, the selected adjustment set could be not sufficient for confounding adjustment. Here a procedure to select the adjustment set from multiple graphs, employing bootstrap is proposed. This procedure is tested on three graphs of increasing complexity and then compared to other adjustment set selection techniques.

The paper is organized as follows. Section 2 introduces some basic causal graph terminology and notation. The proposed method is described in detail in Section 3, while Section 4 contains simulations and results. The findings are discussed in Section 5.

2 Causal Graphs

A graph $G = (V, E)$ is a collection of nodes or vertices V and edges E. A *causal graph* is a graph where nodes represent random variables and edges describe the causal relations between these nodes. If two nodes X_i and X_j are connected by an edge the nodes are *adjacent*. A *path* between two nodes X_i and X_j is a sequence of nodes beginning with X_i and ending with X_j where all the nodes are connected to the next. Edges can be *directed* or *undirected*. An edge is directed if it goes out from one node into another and undirected without such orientation. A graph where all the edges are directed is a *directed graph*. If a directed edge goes from X_i to X_j then X_i is a *parent* node of X_j, and X_j is a *child* of X_i. We will denote parents of node X_j with the notation pa_{X_j}. A *directed path* between two nodes is a path where no node

has two edges on the path directed into it, or two edges directed out of it. Given a directed path, the first node is an *ancestor* of every node of the path, and every node of the path is a *descendant* of the first node. A directed path that begins and ends with the same node is a *cycle*. A directed graph containing no cycles is called a *directed acyclic graph* (DAG). If the underlying dependence model of a problem is unknown, the graph can be estimated from a dataset containing the variables of interest through a *structural learning algorithm*.

The transition from an observational context to an interventional one requires some further discussion. Pearl in [7] introduces the notation $do(X_i = x_i)$ to indicate that the variable X_i is set to the value x_i by intervention. Hence $P(X_j|do(X_i = x_i))$ denotes the distribution of X_j given that X_i is forced to take value x_i. In an observational context the quantity $P(X_j|do(X_i = x_i))$ is not measured but it can be derived employing the back-door criterion [7]. Given a graph G with set of nodes $\mathbf{X}$, a treatment variable $T \in \mathbf{X}$ and an outcome variable $Y \in \mathbf{X}$, the back-door criterion is a graphical test that allows the selection of a set of covariates $\mathbf{S} \subseteq \mathbf{X}$, ensuring unbiased causal estimates for the effect of T on Y. A set that satisfies the back-door criterion is called a *sufficient* adjustment set. If a sufficient adjustment set exists, then interventional distribution can be expressed in observational terms:

$$P(X_j|do(X_i = x_i)) = \sum_{\boldsymbol{S}} P(X_j|\mathbf{S} = \mathbf{s}; X_i = x_i)P(\mathbf{S} = \mathbf{s}) \tag{1}$$

3 Bootstrap-aggregated Adjustment Set

Bootstrap [8] is a resampling technique that creates replicates of the original dataset by sampling from it with replacement. The procedure is repeated M times to produce M bootstrap replicates of the same size as the original dataset. This work builds on a particular implementation of bootstrap called bootstrap-aggregating or bagging [3]. Bagging is a machine learning method that generates multiple versions of a predictor through bootstrap and uses these to get an aggregated predictor. A plurality vote is performed if the predicted element is a class. Here, the logic of bagging is applied to graph structural learning and adjustment set selection. The pseudocode of the procedure is contained in Algorithm 1.

Consider a dataset $D = (\mathbf{X}; T; Y)$ of size N sampled from an unknown graph G containing a set of covariates $\mathbf{X}$, an outcome Y and a treatment T. In the first step, D is used to produce M bootstrap replicates of the same size. In step 2, the multiset Θ is initialized as an empty set, which will be populated in the following iterations. A graph $\hat{G}_i$ is learnt with an algorithm $\mathscr{L}$ on each generated bootstrap sample B_i, given the constraint that the treatment T is a parent of the outcome Y. This assumption encodes in the graph the a priori knowledge that T directly causes Y. Then an adjustment set selection method $\mathscr{A}$ for estimating the effect of T on Y is applied to each graph $\hat{G}_i$. The selected sets are then added to Θ until steps 4 and 5 have been iterated over all the bootstrap resamples. The last step of the algorithm

Algorithm 1: Bootstrap-aggregated adjustment set

Input: A sample $D = (\mathbf{X}, T, Y)$ from an unknown graphical model G, a number of bootstrap samples M, a structural learning algorithm $\mathscr{L}$, an adjustment set selection procedure $\mathscr{A}$.

Output: A bootstrapped adjustment set $\theta^\star$

Generate M bootstrap samples $B_1, ..., B_M$ from D;
$\Theta = \emptyset$;
for $i = 1$ *to* M **do**
    $\hat{G}_i = \mathscr{L}(B_i | T \in pa_Y)$;
    add $\mathscr{A}(\hat{G}_i, T, Y)$ to Θ;
end
$\theta^\star = \max_{\theta_j \in \Theta} \{v(\theta_j)\}$

defines the bagged adjustment set $\theta^\star$ as the set which maximizes $v(\theta_j)$ among all sets $\theta_j \in \Theta$, where $v(\cdot)$ denotes the multiplicity of a given element of a multiset. The bagged adjustment set $\theta^\star$ is thus the set, among all $\theta \in \Theta$, which satisfies the back-door criterion in the highest number of learnt graphs.

4 Simulation

In this section, we assess the performance of the proposed method by comparing it to three alternative approaches. The first benchmark procedure consists in a straightforward implementation of structural learning and adjustment set selection; the second resorts to bootstrap to build an average graph[4] and then selects an adjustment set according to its structure; the third employs bootstrap and selects the adjustment set on the graph with the best score across the replicated samples. The main difference between the benchmark methods and the proposed technique is that the latter aims at selecting a stable adjustment set, whereas the other methods focus on retrieving the best graph and in a separate phase select a sufficient adjustment set. The techniques will be tested on graphs of increasing complexity, and the accuracy of the obtained results will be compared.

Given a known graph $G(\mathbf{X}, T, Y)$, where $T \in pa_Y$, we sample K datasets $D_1, ..., D_K$ of size N from it. Then we apply the methods on each sample D to obtain K adjustment sets $\theta_i^\star$ for the estimation of the causal effect of T on Y. Finally, we check if $\theta^\star$ is a sufficient adjustment set for calculating the effect of T on Y in the true graph G. The results are summarized by the quantity

$$R = \frac{\sum_{i=1}^{K} I_G(\theta_i^\star)}{K}, \tag{2}$$

where $I_G(\theta_i^\star)$ is an indicator function taking value 1 if $\theta_i^\star$ is a sufficient adjustment set for (T, Y) in G and 0 otherwise.

R is calculated for each pair (T,Y), such that $T \in pa_Y$ according to the structure of G. The total number of pairs (T,Y) is equal to $\sum_{v \in \mathscr{V}} \#pa_v$ where $\mathscr{V}$ is the ensemble of vertices of graph G and $\#pa_v$ is the number of parents of vertex $v \in \mathscr{V}$. Once R has been calculated for every possible pair (T,Y), an average of the results is computed to obtain a summary of the accuracy measure for the whole graph. If we denote $M = \sum_{v \in \mathscr{V}} \#pa_v$, we can write the average of the accuracy measures for a given graph as

$$\overline{R} = \frac{\sum_{m \in M} R_m}{M}. \tag{3}$$

Equation 3 thus gives an account of the performance of an adjustment set selection procedure over the set of nodes of a causal graph.

The simulations are performed on three discrete networks of increasing dimension and complexity that have been frequently used in the literature: Asia [6], Alarm [1] and Insurance [2]. We set the number of samples $K = 10$, and the number of bootstrap replicates $B = 200$. The same number of replicates is used in the bootstrap-aggregated procedure and in the benchmark methods that implement bootstrap. Different sample sizes are used in the simulations, according to the complexity of the network. The structural learning algorithm $\mathscr{L}$ used to learn the graphs $\hat{G}$ is the *Tabu Search* algorithm [5] with a BIC score. Tabu Search belongs to the family of score-based algorithms, and it has been chosen because it is more accurate and faster than most other learning algorithms, for both small and large sample sizes. The chosen adjustment set selection procedure $\mathscr{A}$ is the *minimal adjustment set*. The method selects the adjustment set with the smallest cardinality between all possible adjustment sets. The results are summarized in Figure 1, where the bootstrap-aggregated procedure is represented by a dotted line. The x-axis represents sample size n, while the y-axis describes the average accuracy measure $\overline{R}$.

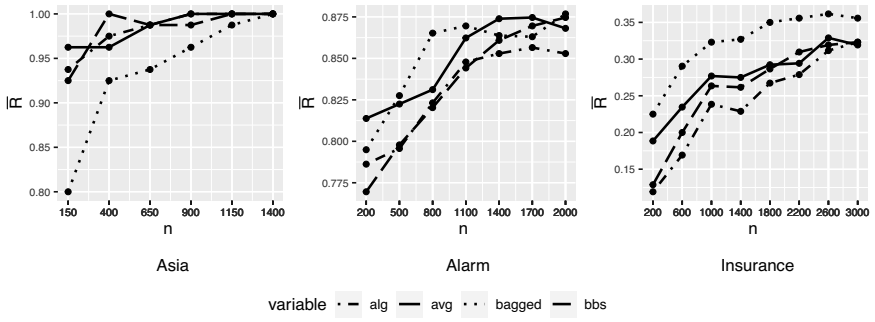

Fig. 1: Accuracy of the methods resulting from simulations (alg: adjustment set selection on a graph learnt through a single algorithm; avg: adjustment set selection on an average graph; bagged: bootstrap-aggregated adjustment set selection; bbs: adjustment set selection on the best-scoring graph among bootstrap replicates).

5 Discussion

This work proposed a novel procedure to select an adjustment set for causal effect estimation when the true causal graph is unknown. The paper contributes to the literature by proposing a procedure that directly aims at selecting a sufficient adjustment set with the use of bootstrap. Bootstrapping has already been used in the graph learning phase to measure confidence toward the presence of an edge between two nodes. However, this implementation is still oriented on recovering the most reliable graph structure and then selecting the adjustment set in a different step. Instead, the proposed procedure uses bootstrap to obtain a multiset of adjustment sets from multiple estimated graphs. This way of proceeding detaches the adjustment set selection from a single learnt graph's structure, thus aiming to achieve higher accuracy.

The technique is tested on different networks, and its results are compared to those obtained with three alternative methods. All the chosen procedures show similar levels of accuracy, which generally decrease as the complexity of the considered structure increases. On the simplest graph, at small sample sizes, the bagged adjustment has a lower accuracy than other benchmark methods. However, as the sample size increases, the performance of bagging improves. When considering more complex graphs, the relative performance of the novel procedure stands out. In particular, the results on the most complex diagram show that even if all the methods achieve low accuracy levels, bagging produces the most accurate results at both low and high sample sizes. Note that these findings remain tied to the tested causal graphs and the assumptions made in the simulations. Further analysis is required to assess how the procedure behaves with different graph configurations and assumptions.

Exploiting partial knowledge to evaluate the average causal effect via an ABC perspective

L'introduzione di conoscenze parziali per valutare l'effetto medio causale tramite una prospettiva ABC

Giulia Cereda, Fabio Corradi, Cecilia Viscardi

Abstract To evaluate the average causal effect, we propose a method to be used when the variables required to remove confounding are not observed. We consider the case in which the causal structure is known, and there is also some additional partial knowledge. The evaluation is probabilistic, and the partial knowledge may consist of an ordering of some relevant conditional probabilities and/or of the marginal distributions of some variables. A simple way to integrate such additional information is to adopt an approximate Bayesian computation perspective to derive an approximate posterior distribution for the average causal effect. We experimentally evaluate our methodology through an example from the literature, and we compare the results with the exact evaluation of the average causal effect.
Abstract *Al fine di valutare l'effetto causale medio, proponiamo un metodo che possa essere usato quando le variabili richieste per eliminare il confondimento non sono osservabili. Consideriamo il caso in cui la struttura causale del modello è nota e sono disponibili alcune informazioni aggiuntive. La valutazione fornita è probabilistica e la conoscenza aggiuntiva può consistere in un ordinamento di alcune rilevanti probabilità condizionate e/o nella conoscenza di distribuzioni marginali. Un modo semplice per incorporare tali informazioni è quello di adottare una prospettiva di calcolo Bayesiano approssimato per derivare una distribuzione a posteriori approssimata dell'effetto causale medio. La metodologia proposta è stata valutata su un esempio noto in letteratura e i risultati sono stati confrontati con una valutazione esatta.*

1 Introduction and preliminaries

In causal inference, the evaluation of the Average Causal Effect (ACE) [5], measuring the difference between the expected values of the outcome under different scenarios, has significant relevance. A starting point to determine ACE is to assume the knowledge of a causal mechanism represented by a graph, more specifically a causal direct acyclic graph

(DAG), defined by two sets $\{V,E\}$. V is the set of nodes representing the model variables, and E is the set of direct edges connecting nodes. Two connected nodes are linked by a direct causal relation, according to the orientation of the edge.

In a simple setting, two nodes of the causal graph are mainly of interest: X, the cause (often a treatment), and Y, the outcome. ACE is evaluated by measuring the difference in the expectation of Y for different interventions on X. An intervention on X, expressed by the so-called $do(\cdot)$ operator, consists of assigning the same x values to quantify changes in the system. This action is purely fictitious (observed x values correspond to past events that cannot be modified), but it has been proved that $do(X = x)$ corresponds to conditioning to $X = x$ in the model obtained as a surgery modified graph removing all the edges incident on X [4].

In the case of boolean Y and dichotomous X, the $do(\cdot)$ operator can be used to calculate the (adjusted) ACE according to:

$$ACE(X \to Y) = p(Y|do(X = x)) - p(Y|do(X = x')) \tag{1}$$

The discrepancy between the estimation of the causal effect obtained by (1) and

$$p(Y|X = x) - p(Y|X = x') \tag{2}$$

is due to confounding. Its detection may be obtained by using some topological properties of the causal graph, such as the well-known Back-door or Front-door criteria [4].

In a simple causal model with only one identified but unobserved confounder, we propose to incorporate some additional knowledge for the probabilistic evaluation of ACE via an algorithm based on the ABC type of reasoning. We experimentally evaluate our methodology through a running example, and we compare our results with a situation where the confounder is observed and the intervention can be evaluated correctly.

2 The running example

As a simple running example, we refer to a well-known causal mechanism with treatment and an outcome both influenced by a third variable, as represented in the causal graph in Fig. 2 (left). This graph represents the causal mechanism behind Simpson's paradox which occurs in many applications.

Fig. 1 (Left) Direct acyclic graph representing the causal mechanism assumed in the running example. (Right) Surgery modified causal graph.

To be concrete, we refer to an example provided by a real-life medical study concerning kidney stone treatments [3]. Let $Y \in \{0,1\}$ represent the no-recovery/recovery of a patient; $X \in \{A,B\}$ stand for two possible treatments; $Z \in \{S,L\}$ represent the size (Small or Large) of the stones of the treated individuals. The study gathers data from 700 patients with kidney stones undergoing the two treatments. Data are summarised in Table 1.

The causal story behind the graph tells us that both treatment and recovery are influenced by the size of the kidney stones of the exposed individual. Actually, doctors prefer

			Treatment (X)	
		Outcome (Y)	$X = A$	$X = B$
Size (Z)	Small	$Y = 1$	81	234
		$Y = 0$	6	36
	Large	$Y = 1$	192	55
		$Y = 0$	71	25
	Total	$Y = 1$	273	289
		$Y = 0$	77	61

Table 1 Complete data for the kidney stones example.

to assign the most effective and expensive treatment (A) to patients with the most severe kidney large stones pathology which experienced a lower rate of recovery. The opposite happens for patients affected by small kidney stones, which are more likely to receive treatment B and are more prone to recover.

If the leftmost graph in Fig. 2 correctly represents the causal mechanism, Z acts as a confounder, and the average causal effect can be evaluated as the difference in the probability of recovery under the two treatment regimes evaluated by using propagation of evidence in the surgery modified causal graph in Fig. 2 (right) or, directly and equivalently, by the so-called Adjustment formula [2]:

$$p(Y = 1|do(X = i)) = \sum_{j\in\{S,L\}} p(Y = 1|X = i, Z = j)p(Z = j) \qquad i \in \{A,B\}. \tag{3}$$

This can be used to calculate ACE according to (1):

$$ACE = \sum_{j\in\{S,L\}} \big(p(Y = 1|X = A, Z = j) - p(Y = 1|X = B, Z = j)\big)p(Z = j). \tag{4}$$

To estimate the components of (3) we need to observe the triplet (x, y, z) over a set of n observations; for the case at hand, the availability of the triplets, including observations on Z, is also the condition established by the Back-door criterion to remove confounding.

3 Dealing with unobserved confounders

Consider the causal graph in Fig. 2 again and assume that we are convinced of the validity of the depicted causal relations, but observations on Z are not accessible to us so that only the totals of Table 1 are available. The empirical joint distribution of X and Y leads to the conclusion that recovery is more likely undergoing treatment B (0.82) than undergoing treatment A (0.78), and the difference in predictions (2) amounts to -0.04.

Actually, the correct evaluation of ACE according to (4) amounts at 0.05, showing that treatment A is better than treatment B. This means that evaluating the causal effect relying on the probability of Y conditionally to X would be misleading.

A way to mitigate the effect of our lack of knowledge on Z is to exploit some additional pieces of information we are willing to assume. The main issue is finding a way to incorporate the available information in estimating the adjustment formula. In our running example we considered a set of three available pieces of information, $\mathscr{I} = \{\mathscr{I}_1, \mathscr{I}_2, \mathscr{I}_3\}$, defined as follows:

- $\mathscr{I}_1$ is the marginal distribution of Z, corresponding to assume that the distribution of small and large kidney stones among people affected by the disease is known in the population of interest;
- $\mathscr{I}_2$ is an ordering of $p(X|Z)$, in particular $p(X=A|Z=L) > p(X=B|Z=L)$ and $p(X=B|Z=S) > p(X=A|Z=S)$, corresponding to assume that Treatment A is more likely assigned to people with large kidney stones, while treatment B is assigned preferentially to people with small kidney stones;
- $\mathscr{I}_3$ is an ordering of $p(Y|X,Z)$, in particular

$$p(Y=1|Z=S,X=A) > p(Y=1|Z=S,X=B) > p(Y=1|Z=L,X=A) > p(Y=1|Z=L,X=B), \tag{5}$$

corresponding to assume that Treatment A is better than treatment B in both small and large kidney stones groups, and that the recovery with small stones is more probable than the recovery with large stones. Notice that this assumption implies a positive ACE.

In principle, a possible solution to estimate (4) is to build a complete database which require to impute Z values by sampling from the predictive

$$p(Z|X,Y) \propto p(Z)p(X,Y|Z) \tag{6}$$

which is based on the unavailable $p(X,Y|Z)$ in (3).

To deal with this issue and to incorporate $\mathscr{I}$ in the estimation, we adopt the same type of reasoning as ABC methods [6]. In particular, we consider the following distribution defined on an augmented space where X' and Y' are two auxiliary random variables:

$$p(Z,X',Y'|X,Y) \propto p(Z)p(X',Y'|Z)p(X,Y|X',Y',Z). \tag{7}$$

Generally speaking, samples from the above distribution can be obtained by implementing an ABC sampling scheme: 1) sample Z from its marginal $p(Z)$; 2) sample pairs (X',Y') from $p(X',Y'|Z)$; 3) approximate $p(X,Y|X',Y',Z) \approx \mathbb{1}\{(X,Y)=(X',Y')\}$. In practice, a two-fold approximation is usually introduced relying on $p(X,Y|X',Y',Z) \approx \mathbb{1}\{d\big(s(X,Y),s(X',Y')\big) \leq \varepsilon\}$, where $d(\cdot,\cdot)$ is a proper distance function, $s(\cdot)$ are summary statistics reducing the size of the data, and ε is a positive tolerance threshold.

Note that in the case at hand, the tuple (X',Y') represents pseudo-data to be generated from a *simulator*. The simulator would be a computer program producing samples from $p(X',Y'|Z)$ in the ABC framework. Here, due to the unavailability of such a generative mechanism, we consider an approximation $\hat{p}_{\mathscr{I}}(X',Y'|Z)$ that complies with $\mathscr{I}_2$ and $\mathscr{I}_3$. Such a mechanism may be based on the decomposition $\hat{p}_{\mathscr{I}}(X',Y'|Z) = \hat{p}_{\mathscr{I}_2}(X'|Z)\hat{p}_{\mathscr{I}_3}(Y'|X',Z)$ and the fact that $X'|Z$ and $Y'|X',Z$ are Bernoulli random variables whose parameters, denoted as $\theta_{X=A|Z}$ and $\theta_{Y=1|X,Z}$ for $X \in \{A,B\}$ and $Z \in \{S,L\}$, satisfy constraints implied by $\mathscr{I}_2$ and $\mathscr{I}_3$. More precisely, we get samples from $\hat{p}_{\mathscr{I}}(X',Y'|Z)$ as detailed in Algorithm 1.

Algorithm 1 SIMULATOR

Draw $\theta_{X=A|L} \sim Uniform(0.5,1)$; $\theta_{X=A|S} \sim Uniform(0,0.5)$ and $\theta_{Y=1|B,L} \sim Uniform(0,1)$
Draw $\theta_{Y=1|A,L} \sim Uniform(\theta_{Y=1|B,L},1)$
Draw $\theta_{Y=1|B,S} \sim Uniform(\theta_{Y=1|A,L},1)$
Draw $\theta_{Y=1|A,S} \sim Uniform(\theta_{Y=1|B,S},1)$

Once defined a simulator, we can exploit the knowledge deriving from observed data and get samples from an approximate distribution $\hat{p}_{\mathscr{I}}(Z,X',Y'|X,Y)$ following the ABC scheme in Algorithm 2.

Algorithm 2 ABC SCHEME

Draw $Z^{(t)} \sim p(Z)$ according to $\mathscr{I}_1 \quad \forall t \in \{1,...,T\}$
Generate $(X',Y')^{(t)} \sim \hat{p}^{(t)}_{\mathscr{I}}(X',Y'|Z)$ simulated according to Alg.1 $\quad \forall t \in \{1,...,T\}$
Accept $((X',Y')^{(t)},Z^{(t)})$ if $d(\widehat{p}^{(t)}_{X',Y'},\widehat{p}_{X,Y}) \leq \varepsilon \quad \forall t \in \{1,...,T\}$

Note that here observed and simulated data are compared by means of sufficient summary statistics, the empirical distributions $\hat{p}_{X,Y}$ and $\hat{p}_{X',Y'}$.

Looking at Alg. 2, it is apparent that the outlined sampling scheme can incorporate whatever state of knowledge simply by replacing Alg. 1 with a proper simulator based on different information $\mathscr{I}$. In any case, the output of the algorithm is a sample from an approximate posterior distribution $\hat{p}_{\mathscr{I}}(X',Y',Z|X,Y)$ which can be used to evaluate $p(Y=1|do(X=i))$ as

$$\sum_{j\in\{S,L\}} \hat{p}_{\mathscr{I}}(Y'^{(t)}=1|X'^{(t)}=i,Z^{(t)}=j)p(Z^{(t)}=j) = \sum_{j\in\{S,L\}} \theta^{(t)}_{Y=1|i,j}\cdot p(Z^{(t)}=j) \qquad i\in\{A,B\}$$

for each retained sample t. It follows that we came up with a posterior distribution of ACE based on the accepted triplets $((X',Y')^{(t)},Z^{(t)})$.

4 Experiments

We consider the example described in the previous section. Using the frequencies of Tab. 1, and formula (4) we obtain an ACE equal to 0.05.

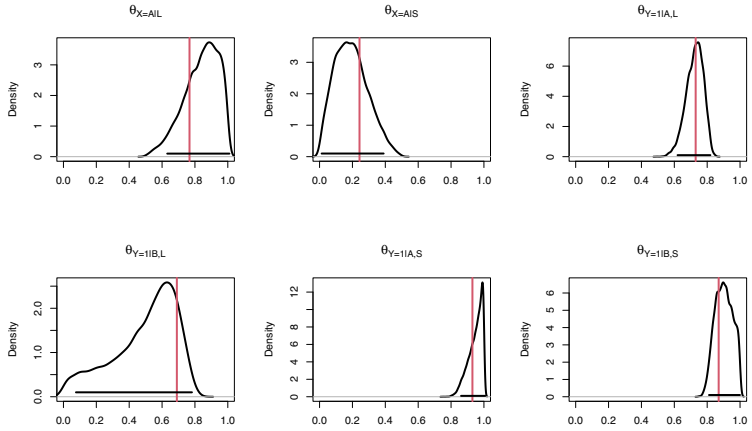

Fig. 2 Posterior distribution of the six θ parameters corresponding to the conditional probabilities of Algorithm 1.

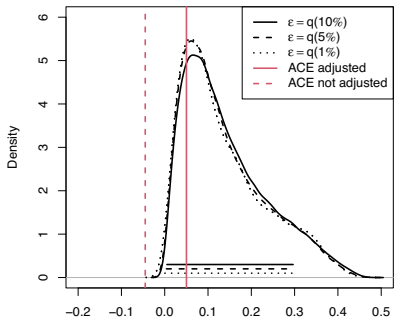
To evaluate the performance of our method, we pretend that the values of Z are not observable and compute a posterior distribution for ACE by using $800,000$ samples from $\hat{p}_{\mathscr{I}}(Z,X',Y'|X,Y)$, obtained with the procedure described in Alg. 1 and Alg. 2.

Figure 2 shows the posterior distributions for $\theta_{X=A|S}$, $\theta_{X=A|L}$, $\theta_{Y=1|A,S}$, $\theta_{Y=1|B,S}$, $\theta_{Y=1|A,L}$ and $\theta_{Y=1|B,L}$, $\varepsilon = 0.076$, corresponding to the 1% quantile of the distance empirical dis-

tribution. Considering that before the analysis we had a uniform prior belief about their values, we can conclude that the procedure allows to learn appreciably about the six parameters. Figure 3 shows the ACE posterior distributions obtained using three different values of the ABC threshold, ε, selected through the quantile method [1].

Note that the three posterior modes are almost coincident with the true ACE, and they get closer and closer as the threshold ε decreases.



quantile	epsilon	HPD	MAP
1%	0.076	(0.000, 0.299)	0.057
5%	0.128	(0.004, 0.293)	0.059
10%	0.164	(0.005, 0.297)	0.062

Fig. 3 Posterior distributions for the adjusted ACE obtained using three different values of ε, along with the corresponding 90% HPD intervals. Table contains the specification of the ε values along with corresponding 90% HPD intervals and MAP.

5 Conclusions

In causal inference, this work provides a flexible method to evaluate ACE when observations of the variable(s) required to remove confounding are not available. The research stage is at its infancy, and we plan to consider more complex causal stories to verify the ability of the method to exploit qualitative information about the conditional probabilities beyond the causal DAG to provide useful probabilistic information about the required ACE. As a final remark, we want to stress that the method measures the confounding only under the assumption of its existence.

Intertemporal propensity score matching for casual inference: an application to covid-19 lockdowns and air pollution in Northern Italy

Propensity score matching intertemporale per inferenza causale: un'applicazione su covid-19 lockdown e inquinamento atmosferico nel Nord Italia

Daniele Bondonio and Paolo Chirico

Abstract This paper develops an intertemporal propensity score matching (PSM) approach for estimating the impact of covid-19 lockdowns on air pollution. While PSM has been exclusively applied in the context of matching cross-sectional units, this paper shows that, under specific circumstances, PSM can be also applied for estimating causal inference by means of matching across different temporal units in the context of multivariate time series data. We apply our intertemporal PSM model to the data collected from a large number of air-pollution-measurement stations in Northern Italy, estimating the casual effect of the March-May-2020 lockdown on air-pollution without resorting to the more stringent functional form assumptions of the existing literature.

Abstract *Questo paper sviluppa una procedura intertemporale di propensity score matching (PSM) per stimare l'impatto dei lockdown covid-19 sull'inquinamento atmosferico. Sebbene il PSM sia stato applicato esclusivamente nel contesto dell'abbinamento di unità cross-sezionali, questo paper mostra che, in circostanze specifiche, il PSM può essere applicato anche per stimare l'inferenza causale mediante l'abbinamento tra diverse unità temporali nel contesto di serie temporali multivariate. Applichiamo il nostro modello di PSM intertemporale ai dati raccolti da un ampio numero di stazioni di rilevamento dell'inquinamento atmosferico nel Nord Italia, stimando l'effetto casuale del lockdown di marzo-maggio-2020 senza ricorrere alle più stringenti ipotesi di forma funzionale dei modelli regressivi utilizzati nella letteratura esistente.*

1 Introduction

Statistical matching is widely used as tool for estimating casual inference in the context of quasi-experimental designs in which cross-sectional units are sorted into treated and untreated units based on the exposure of the program intervention of interest. For all known statistical matching estimations, including propensity score matching (PSM), the temporal periods in which the outcome variables are measured have to remain equal across all treated and untreated units. This is a strict requirement for all quasi-experimental designs, in which the existence of the comparison group of untreated units is aimed at controlling for the secular trends that may affect Y independently from the treatment. For this reason, intertemporal PSM matching (i.e. matching across units with Y measured at different times) is not usually considered a viable impact identification strategy. The stringent covid-19 lockdowns of the first half of 2020 provide an exceptional source of an abrupt exogenous decrease on human activities (transportations and productions) that offers a unique opportunity to quantify the effect of human activities on air pollution in urbanized areas. What is unique about the impact identification conditions related to the covid-19 lockdowns, however, is also the fact that the available data are in terms of a number of multivariate time-series, one for each air-pollution measurement station, with units of observations represented by the days in which air pollution and weather characteristic are measured. These features of the data represent a scenario in which the abrupt change in the secular trend (i.e. the lockdown-induced sharp decrease in traffic and production activities) is the treatment of interest, while all the major confounding factors to be controlled for (i.e. the weather characteristics) are observable in the data and they can be safely assumed of not being subject to unobserved secular trend (within the short pre- post-treatment periods of times considered in the analysis). This paper aims at showing that in such a data scenario, an intertemporal statistical matching in which, separately for each air-pollution measurement station, the treated days (corresponding to the lockdown periods) are matched to previous non-lockdown days (untreated units) that share the same weather features, is a viable empirical option that overcomes the limitations of the recently-emerging literature on the air-quality impact of the covid-19 lockdowns.

2 Existing Literature and Impact Identification Properties of Intertemporal PSM

Since spring 2020, an increasingly large number of studies have been using covid-19 lockdowns data on a variety of locations around the world in order to estimate the reduction of air pollution caused by an abrupt decrease of traffic and human activities. A number of these papers fail to properly address the challenges of a reliable causal inference that requires, above all, a suitable controlling of the possible differences in the distribution of the weather characteristics of the pre-lockdown days

(untreated units) and the lockdown days (treated units) [1, 3, 4, 14]. These papers identify the causal effect of the lockdowns only under the very stringent assumption of a perfectly equal distribution of the weather characteristics between the lockdown and the pre-lockdown periods. Other studies make use of panel-data regression approaches that have to face the issue of error autocorrelation, and that require strong functional form assumptions with respect to the way in which the observable cofounding factors affect air-pollution [7, 5, 15, 16].

The intertemporal PSM matching approach developed in this paper can be described as follows. Let $\{Y_t\}$ be a stochastic process on which an intervention lasting for a time interval L_1 produces an effect. The causal effect of the intervention should be determined as the difference:

$$\mathrm{E}[Y_t^{(1)}|t \in L_1] - \mathrm{E}[Y_t^{(0)}|t \in L_1] \tag{1}$$

where $Y_t^{(1)}$ is the observable outcome at time t if time t were affected by the intervention, and $Y_t^{(0)}$ if not affected. In the case of the lockdown studies, the temporal units t are represented by the days in which air-pollution and weather characteristics are measured. The difference (1) can be considered as an intertemporal version of the standard *Average Treatment effects on the Treated* (ATT). As $\mathrm{E}[Y_t^{(0)}|t \in L_1]$ is not observable, the intertemporal ATT (1) can be identified in terms of

$$E_{X_1}\left[\mathrm{E}[Y_t|t \in L_1, X_1] - \mathrm{E}[Y_t|t \in L_0, X_1]\right] \quad X_1 = X_t|t \in L_1 \tag{2}$$

when two conditions apply: i) the period of observation $L = L_0 \cup L_1$, that includes also a previous time-interval L_0, is short enough so that the process Y_t can be assumed to have no underlying trend (besides the break in the observed outcome caused by lockdown period that represents the treatment under consideration); ii) the existing multivariate process $\{X_t\}$ of observable covariates (i.e. the weather controls) makes the expected value of $Y_t^{(0)}$ independent of $t \in L$, i.e.:

$$\mathrm{E}[Y_t^{(0)}|t \in L_1, X_t] = \mathrm{E}[Y_t^{(0)}|t \in L_0, X_t] \tag{3}$$

Similarly to cross-sectional PSM, if assumption (3) is satisfied, the intertemporal ATT can be also identified when conditioning on propensity score such as $\varphi_t = P[t \in L_1|X_t]$:

$$E_{\varphi_1}\left[\mathrm{E}[Y_t|t \in L_1, \varphi_1] - \mathrm{E}[Y_t|t \in L_0, \varphi_1]\right] \quad \varphi_1 = \varphi_t|t \in L_1 \tag{4}$$

This leads to the following intertemporal PSM estimation procedure: (i) treated times are matched with the untreated ones that have an equal (similar) propensity score; (ii) the sample mean of Y_t for the matched treated and control times ($M_t = 1$) is computed; (iii) the ATT is estimated as the difference of the sample means ii):

$$(\bar{y}_t|t \in L_1, M_i = 1) - (\bar{y}_t|t \in L_0, M_i = 1) \tag{5}$$

iv) the estimated ATT is validated if the balancing property of PSM is checked [13]; v) in the case of data containing multiple multivariate time-series, the procedure (i)-

(iv) is repeated separately for each time-series, yielding a series of local ATTs that are then averaged-out to a global impact estimate.

Compared to the panel-data regression approaches adopted elsewhere in the literature, this intertemporal PSM approach share the same well-known advantage [2, 8] of the standard cross-sectional PSM in strongly diminishing the sensibility of the estimated impacts to the choice of functional form that links the effects of the controls on the outcome variable.

3 The impact of covid-19 lockdowns on air pollution in northern Italy

We apply the intertemporal PSM model described in the previous section to the air-pollution data from five regions in Northern Italy located along the Po-river Valley, i.e. Piedmont, Lombardy, Emilia-Romagna, Veneto, Friuli Venezia Giulia. These regions represent the most industrialized and densely-populated area of Italy (with an average density of 252 inhab. per km2). Due to these characteristics and the specific orographic features of the Po Valley (that determine a systemic lack of sustained ventilation), this area has some of the highest levels of air-pollution in Europe. For the analysis we collected data on the average daily levels of nitrogen dioxide (NO2) and particulate matter (PM10) detected at 83 ARPA air-pollution measurement stations, located in the main urban areas of the five regions. The observation period covers both the entire length of the nationwide covid-19 lockdown period of March 10 - May 17, 2020 (that posed a very strict stay-at-home mandate and closure of all schools, universities and non-essential services) and the corresponding (untreated) period of the previous year (March 10 – May 17, 2020). The assembled database also includes as controls (X_t) the main weather characteristics that are known in the literature to influence air pollution: average daily temperature (TEMP), rainfall (RAIN), maximum daily wind speed (WIND) [7, 5, 15, 16].

Table 1 shows the average values of the air-pollutants and weather variables during the 2020 lockdown days (treatment) and the corresponding (untreated) period of 2019. These descriptive statistics do not provide a reliable indication of causal effect of the lockdown on air-pollution because the comparison between the treated and non-treated days does not control for the possible differences in the distribution of the weather variables in the two periods. Indeed, the data from Table 1 show, for example, that the lockdown (L_1) period of 2020 experienced less than half of the rain than the corresponding non-treated period of 2019 (L_0). For this reason, any casual inference drawn from a descriptive-statistics comparison between the two periods would be highly biased, particularly for the PM10 outcomes that has a high potential of being influenced by rain and wind conditions.

In order to grant a perfect balancing also of the locational characteristic of the ARPA measuring station (i.e. distance from major roads, highways, airports, surrounding production activities, etc.), we apply to the analysis our intertemporal PSM approach in terms of comparisons between the 2020 lockdown and the 2019

(untreated) period holding constant the same ARPA station. This empirical strategy entails estimating 83 different local impact parameters obtained by applying the intertemporal PSM model (implemented in terms of caliper radius matching) separately to the single multivariate time-series data from each the ARPA stations. The final (global) estimated impact is then obtained as the average of the different local impacts for which the balancing property was successfully tested by means of the Rubin's R and B indices [13].

Table 1 Descriptive statistics of air-pollution and weather characteristics in the 2020 lockdown and corresponding untreated period of 2019

period	N 83x69	NO2 (μg/m^3)	PM10 (μg/m^3)	WIND (m/s)	RAIN (mm)	TEMP (C^o)
10/3 - 17/5, 2019	5727	25.45 (16.08)[a]	20.27 (12.05)	2.28 (1.47)	2.85 (7.73)	12.55 (2.80)
10/3 - 17/5, 2020	5727	15.26 (11.12)	23.90 (17.41)	2.20 (1.49)	1.35 (5.11)	13.74 (4.15)

[a] Std.dev. in parentheses

The main results from the intertemporal PSM analysis are summarized in Table 2. Restricting the focus on the working days only, the covid-19 lockdown is shown to cause a reduction of about 13.1 ($\mu g/m^3$) in the daily average level of NO2 and a reduction of about 3.3 ($\mu g/m^3$) in the level of PM10, compared a counterfactual scenario of no-lockdown (estimated from a comparison group composed by the corresponding calendar days of 2019 with similar weather characteristics). These estimates correspond to 51.3% and a 16.2% decrease in the daily average level of NO2 and PM10, respectively. Taking into account also the week-ends and the festivities ("All days" column), the estimated impacts, albeit slightly smaller, remain of a quite large magnitude: about -12.1 ($\mu g/m^3$), corresponding to -47.7%, and -2.9 ($\mu g/m^3$), corresponding to -14.1%, for the NO2 and the PM10, respectively.

Table 2 Locdown effect on NO2 and PM10 estimated by means of intertemporal PSM

polluttant	Aggregate ATT estimates working days	all week days	Descriptive-statistics Difference $L_1 - L_0$
NO2	-13.07 *** (.221)[a]	-12.12 *** (.206)	-10.27 *** (.745)
PM10	-3.29 *** (.378)	-2.86 *** (.364)	3.60 *** (.220)

Statistical significance: *=at 10% level; **= at 5% level; ***= at 1% level
[a] Std.dev. in parentheses

Due to a higher incidence of unfavourable weather conditions in the lockdown days, compared to previous-year period, the results from a mere descriptive-

statistics comparison ($L_1 - L_0$, last column in Table 2) are indeed of a lower magnitude than the intertemporal PSM estimates. This is particularly relevant for the case of PM10, for which the descriptive-statistics analysis is suggestive of a worsening impact of the lockdown ($+3.6\mu g/m^3$), a result that highlights how misleading could be the evidence produced in the absence of adequate statistical tools for a reliable causal inference.

Methods for Spatio-temporal data

Local Spatio-Temporal Log-Gaussian Cox Processes for seismic data analysis

Processi Log-Gaussiani di Cox locali e spazio-temporali per l'analisi di dati sismici

Nicoletta D'Angelo, Giada Adelfio, and Jorge Mateu

Abstract We propose a local version of the spatio-temporal log-Gaussian Cox processes (LGCPs) employing the Local Indicators of Spatio-Temporal Association (LISTA) functions into the minimum contrast procedure to obtain space as well as time-varying parameters. We resort to the joint minimum contrast method fitting method to estimate the set of second-order parameters for the class of Spatio-Temporal LGCPs. We employ the proposed methodology to analyse real seismic data occurred Greece between 2004 and 2015.

Abstract *Proponiamo una versione locale dei processi spazio-temporali Log-Gaussiani di Cox (LGCP) che impiegano le funzioni LISTA (Indicatori spazio-temporali locali di associazione) nella procedura di minimo contrasto per ottenere parametri variabili sia nello spazio che nel tempo. Si ricorre al metodo di adattamento del metodo del minimo contrasto congiunto per stimare l'insieme dei parametri del secondo ordine per la classe degli LGCP spazio-temporali. Vi presentiamo un'analisi dei dati reali dei dati sismici in Grecia.*

1 Introduction

Local extensions of spatio-temporal point process models are very welcome in many fields of study, such as epidemiology and seismology. Indeed, one could be interested in identifying the most inhomogeneous locations, both in space and time, to

Nicoletta D'Angelo and Giada Adelfio
Dipartimento di Scienze Economiche, Aziendali e Statistiche, Università degli Studi di Palermo, Italy e-mail: nicoletta.dangelo@unipa.it; giada.adelfio@unipa.it

Jorge Mateu

be further examined separately. For spatial point process, Baddeley (2017) presents a general framework based on the local composite likelihood to detect and model gradual spatial variation in any parameter of a spatial stochastic model (such as Poisson, Gibbs and Cox processes). In particular, the parameters in the model that govern the intensity, the dependence of the intensity on the covariates and the spatial interaction between points, are estimated locally. D'Angelo et al. (2022) show that these spatial local models provide good inferential results, if applied to seismic data.

Motivated by this, we propose a local version of the spatio-temporal log-Gaussian Cox processes (LGCPs) employing the Local Indicators of Spatio-Temporal Association (LISTA) functions in the minimum contrast procedure to obtain space as well as time-varying parameters. The underlying hypothesis is that also temporal characteristics vary within the point process, in addition to the spatial ones, as proved in D'Angelo et al. (2022). From a methodological point of view, we extend the joint minimum contrast method (Siino et al., 2018) to the local context, managing to estimate a set of second-order parameters of the spatio-temporal LGCPs for each point.

The structure of the paper is the following. In Section 2 the spatio-temporal log-Gaussian Cox Processes are recalled, as well as the joint minimum contrast procedure. Section 3 contains the proposed method to estimate local parameters, and it is applied in Section 4 to earthquakes occurred in Greece between 2005 and 2014. Conclusions are drawn in Section 5.

2 Spatio-temporal log-Gaussian Cox processes

In the point process theory, log-Gaussian Cox processes are the most prominent clustering models. By specifying the intensity of the process and the moments of the underlying Gaussian Random Field (GRF), it is possible to estimate both the first and second-order characteristics of the process. Following the inhomogeneous specification in Diggle (2013), a log-Gaussian Cox process for a generic point with $\mathbf{u}$ and t coordinates in space and time, has the intensity

$$\Lambda(\mathbf{u},t) = \lambda(\mathbf{u},t)\exp(S(\mathbf{u},t))$$

where S is a Gaussian process with $\mathbb{E}(S(\mathbf{u},t)) = \mu = -0.5\sigma^2$ and so $\mathbb{E}(\exp S(\mathbf{u},t)) = 1$ and with variance and covariance matrix $\mathbb{C}(S(\mathbf{u}_i,t_i),S(\mathbf{u}_j,t_j)) = \sigma^2\gamma(r,h)$, with $\gamma(\cdot)$ the correlation function of the GRF, and r and h some spatial and temporal distances. Following Møller et al. (1998), the first-order product density and the pair correlation function of a log-Gaussian Cox process are $\mathbb{E}(\Lambda(\mathbf{u},t)) = \lambda(\mathbf{u},t)$ and $g(r,h) = \exp(\sigma^2\gamma(r,h))$, respectively.

We consider a separable structure for the covariance function of the GRF that has exponential form for both the spatial and the temporal components,

$$\mathbb{C}(r,h) = \sigma^2 \exp\left(\frac{-r}{\alpha}\right)\exp\left(\frac{-h}{\beta}\right), \tag{1}$$

where σ^2 is the variance, α is the scale parameter for the spatial distance and β is the scale parameter for the temporal one. The exponential form is widely used in this context and nicely reflects the decaying correlation structure with distance or time. Moreover, we can consider a non-separable covariance of the GRF useful to describe more general situations.

In general, the Cox model is estimated by a two-step procedure, involving first the intensity and then the cluster or correlation parameters. First, a Poisson model with the same model formula is fitted to the point pattern data, providing the estimates of the coefficients of all the terms in the model formula that characterize the intensity. Second, the estimated intensity is taken as the true one and the cluster or correlation parameters are estimated by one among the method of minimum contrast, Palm likelihood, or composite likelihood.

The most common technique is the *minimum contrast*. Let the function J represent either the pair correlation function g of the K-function, and $\hat{J}$ stands for the corresponding non-parametric estimate. Siino et al. (2018) propose a new fitting method to estimate the set of second-order parameters for the class of spatio-temporal log-Gaussian Cox point processes with constant first-order intensity function. We denote by θ the vector of (first-order) intensity parameters, and by ψ the cluster parameters, also denoted as correlation or interaction parameters. In the case of a spatio-temporal log-Gaussian Cox process with exponential covariance as the one in Equation (1), the cluster parameters correspond to $\psi = \{\sigma, \alpha, \beta\}$.

The vector of estimates $\hat{\psi}$ is found by minimizing

$$M_{J,i}\{\psi_i\} = \int_{h_0}^{h_{max}} \int_{r_0}^{r_{max}} \phi(r,h)\{\nu[\bar{J}_i(r,h)] - \nu[J(r,h;\psi)]\}^2 \mathrm{d}r\mathrm{d}h,$$

where $\phi(r,h)$ is a weight that depends on the space-time distance and ν is a transformation function. Its main advantage is that it can be used in the case of both separable and non-separable parametric specifications of the correlation function of the underlying GRF, representing a more flexible method with respect to other available methods.

3 Locally weighted spatio-temporal minimum contrast

In the purely spatial context, a localised version of minimum contrast is developed using the local K-functions or local pair correlation functions by Baddeley (2017), bearing a very close resemblance to the local Palm likelihood approach.

Combining the *joint minimum contrast* (Siino et al., 2018) and the *local minimum contrast* (Baddeley, 2017) procedures, we can obtain a vector of parameters $\hat{\psi}_i$ for each point i, by minimizing

$$M_{J,i}\{\psi_i\} = \int_{h_0}^{h_{max}} \int_{r_0}^{r_{max}} \{\bar{J}_i(r,h) - J(r,h;\psi)\}^2 \mathrm{d}r\mathrm{d}h, \tag{2}$$

where $\bar{J}_i(r,h)$ is the average of the local functions $\hat{J}_i(r,h)$, weighted by some pointwise kernel estimates. This procedure not only provides individual estimates, but it does also account for the vicinity of the observed points, and therefore the contribution of their displacement on the estimation procedure. Thus, consider the weights $w_i = w_{i,\sigma_s} w_{i,\sigma_t}$ given by some kernel estimates, where w_{i,σ_s} and w_{i,σ_t} are weight functions and $\sigma_s, \sigma_t > 0$ are the smoothing bandwidths. It is not necessary to assume that w_{σ_s} and w_{σ_t} are probability densities. For simplicity, we shall consider only kernels of fixed bandwidth, even though spatially adaptive kernels could also be used. Then, the averaged weighted local statistics $\bar{J}_i(r,h)$ in Equation (2) are

$$\bar{J}_i(r,h) = \frac{\sum_{i=1}^{n} \hat{J}_i(r,h) w_i}{\sum_{i=1}^{n} w_i},$$

one for each point i. In particular, we consider $\hat{J}_i(\cdot)$ as the local spatio-temporal pair correlation function (in short, pcf-function)

$$\hat{J}_i(r,h) = \hat{g}_i(r,h) = \frac{1}{4\pi r |W \times T| \hat{\lambda}^2} \sum_{j \neq i} \frac{\kappa_{\varepsilon,\delta}(||\mathbf{u}_i - \mathbf{u}_j|| - r, |t_i - t_j| - h)}{\omega(\mathbf{u}_i, \mathbf{u}_j)\omega(t_i, t_j)} \tag{3}$$

where ω is the edge correction factor. The kernel function κ has a multiplicative form $\kappa_{\varepsilon,\delta}(||\mathbf{u}_i - \mathbf{u}_j|| - r, |t_i - t_j| - h) = \kappa_\varepsilon(||\mathbf{u}_i - \mathbf{u}_j|| - r)\kappa_\delta(|t_i - t_j| - h)$ where κ_ε and κ_δ are kernel functions with bandwidths ε and δ, respectively. Both of them are computed using the Epanechnikov kernel and the bandwidths are estimated with a direct plug-in method.

After having properly chosen the bandwidth of the weight in both the minimum contrast procedure and in the pair correlation function, the result of the maximization of Equation (2) provides a set of covariance parameters $\hat{\psi}_i = \{\hat{\sigma}_i^2, \hat{\alpha}_i, \hat{\beta}_i\}$ for each point i, which can be also interpolated along the whole spatio-temporal area under study.

4 Seismic data analysis

The analysed data concern 1111 earthquakes occurred in Greece between 2005 and 2014, and come from the Hellenic Unified Seismic Network (H.U.S.N.). Only seismic events with a magnitude larger than 4 are considered in this study.

In Figure 1 (a) earthquakes are reported, while in Figure 1 (b) the observed pcf-function is represented. The theoretical value indicating Complete Randomness is $pcf = 1$. The pcf statistic of the observed point pattern, with larger values than the theoretical one of a Poisson process especially for shortest distances, suggests that distances among the point of the observed pattern are shorter than the Poisson ones. In other words, events are more clustered than an homogeneous Poisson pattern, as it is also evident in Figure 1 (a).

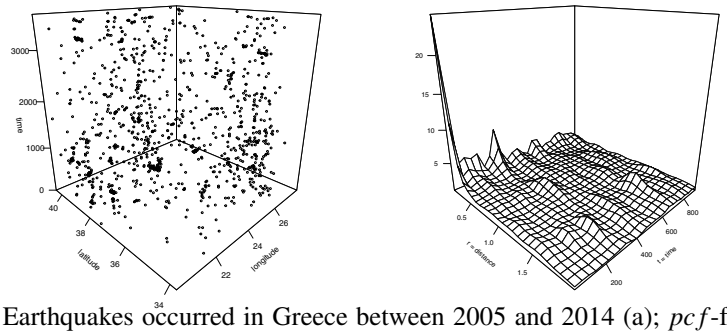

Fig. 1: Earthquakes occurred in Greece between 2005 and 2014 (a); pcf-function of the observed point pattern of the Greek data (b).

A spatio-temporal log-Gaussian Cox process is fitted, following the locally weighted minimun contrast proposed in Section 3 with exponential covariance function as in Equation (1). The bandwidths ε and δ, for the kernel in the pair correlation function are equal to 0.15 and 28.49, for space and time respectively, while the bandwidths $\{\sigma_x, \sigma_y, \sigma_t\}$ are chosen to be $2.58, 1.79, 1140.31$, for x, y, and t coordinates respectively.

The results of the fitting come in Table (1) and in Figure (2). As shown in Table (1), the proposed procedure provides a whole distribution for each parameter. Then, as evident from Figure (2), the estimated parameters allow to clearly distinguish different sub-areas where point behave differently from each other. Indeed, by the inspection of the top panels of Figure (2), we can clearly spot two main spatial regions: the one on the top and on the left with higher $\hat{\sigma}_i^2$ values but lower estimates for $\hat{\alpha}_i$ and $\hat{\beta}_i$, and the area on the bottom-right which displays the opposite situation (low variance but large scale parameters).

This result is particularly appealing because it gives us more insight in the local behaviour of the seismic phenomenon. Indeed, from the global estimates (see Table (1)) we could draw the conclusion that the analysed process is overall clustered (given the high estimated variance, and the relatively small scale parameters). Conversely, our application, shows that earthquakes occurred on the top-left of the analysed area are grouped in smaller clusters, while the ones on the bottom-left have a way more diffuse clustering behaviour.

Furthermore, by the inspection of the bottom panels of Figure (2), we can assess also the time-varying behaviour of the estimates and therefore on the underlying process: the most relevant result concerns the variability of the covariance parameters $\hat{\sigma}_i$ in time, indicating that the number of earthquakes tends to increase in time, and in particular, in the top-left spatial region.

Table 1: Estimates of both the local and global LGCPs fitted to the data

	Min.	1st Qu.	Median	Mean	3rd Qu.	Max.	Global
σ^2	1.28	5.19	6.03	5.77	6.60	12.47	6.14
α	0.13	0.25	0.28	0.39	0.35	1.94	0.27
β	42.34	366.43	534.86	535.52	597.59	1411.45	449.55

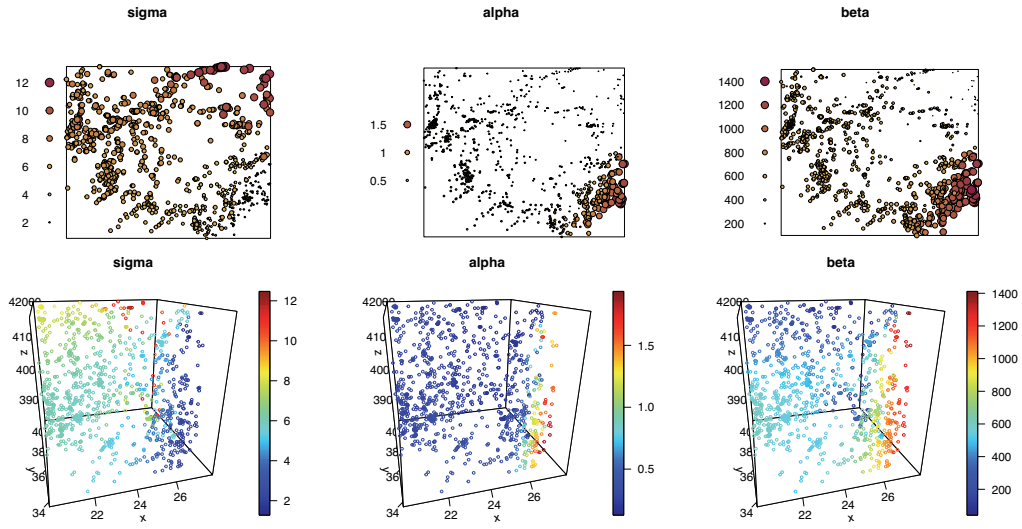

Fig. 2: Local estimates in space (*top panels*) and space-time (*bottom panels*).

5 Conclusions

In this paper, we have introduced a novel local fitting procedure for obtaining space-time varying estimated for a log-Gaussian Cox process fitted to the data. From a methodological point of view, we have resorted to the joint minimum contrast procedure (which is appealing for its flexibility in dealing also with non-separable covariances), extending it to the local context, and therefore allowing to obtain a whole set of covariance parameters for each point of the analysed process.

The motivating problem came from the seismic application, where of course it is of interest studying the characteristics of the process in relation to both the spatial and the temporal occurrence of points. Our proposal could pose the basis for many further investigations and applications, such as in the epidemiological context.

Spatial explorative analysis of thyroid cancer in Sicilian volcanic areas

Analisi spaziale esplorativa del tumore tiroideo nelle zone vulcaniche della Sicilia

Francesca Bitonti, Angelo Mazza

Abstract In the most advanced countries the epidemiological transition has led non-communicable diseases to dominate the causes of death (ruling out the recent Covid-19 pandemic). Therefore, the spatial methodologies traditionally implemented to study the infectious diseases have been also exploited to analyse those non-communicable diseases whose causes include environmental risk factors. In this work, we explore the spatial distribution of thyroid cancer (TC) near Mt Etna (Sicily). It is well-known in literature that active volcanoes emit carcinogens substances. Here, we apply the standardised incidence ratio (SIR) and the local Moran I to verify the presence of high-risk pockets, considering both the proximity to the volcano and the demographic heterogeneity in the at-risk population.

Abstract *Nei Paesi avanzati, in seguito alla transizione epidemiologica, le malattie non trasmissibili sono diventate la prima causa di mortalità (escludendo la recente pandemia da Covid-19). Pertanto, le metodologie spaziali tradizionalmente implementate per lo studio delle malattie infettive sono state applicate anche alle malattie non trasmissibili le cui cause includono fattori di rischio ambientale. In questo lavoro, esploriamo la distribuzione spaziale del tumore tiroideo (TT) vicino all'Etna (Sicilia). È noto in letteratura che i vulcani attivi emettono sostanze cancerogene. Qui, applichiamo il rapporto standardizzato di incidenza (RSI) e il Moran I locale per verificare la presenza di aree ad alto rischio, considerando sia la vicinanza al vulcano che l'eterogeneità demografica nella popolazione a rischio.*

1 Introduction

In the most advanced countries experiencing the third phase of the epidemiologic transition, infectious disease pandemics (ruling out the recent Covid-19 pandemic) are replaced by degenerative diseases as major causes of death [24]. Specific patterns of human behaviour (e.g., violence, accidents, or substance abuse) overtake infectious agents as the major contributor to morbidity and mortality. In these contexts, the use of the spatial analysis methodologies, typical approaches to the analysis of infectious diseases, has also spread within the study of non-communicable diseases, in which environmental risk factors are often included among the possible contributing causes [1,7,12,13,23,25].

Thyroid cancer (TC), the object of this study, is the most widespread endocrine neoplasm, whose incidence has steadily increased worldwide in recent decades [9,11,19]. Epidemiological studies suggest that the aetiology of TC includes iodine consumption, familiarity, and exposure to ionising radiation [16,28]. Kung et al. [18] identified the elements present in volcanic gases as possible further TC etiological agents. Other studies have confirmed a higher TC incidence than national averages in the Hawaiian Islands [14,17], Iceland [3,15], the Philippines [8,10], New Caledonia [29] and French Polynesia [6,9], all regions whose common denominator is the presence of active volcanoes. Goodman et al. [14] compared the standardised TC incidence rates of different ethnic groups residing in Hawaii with those of the same groups residing in other geographic areas. Also in Sicily, a region located in South Italy, higher TC incidence rates than the regional and national averages were detected in the vicinity of an active volcanic areas, [21,22,30,31]. In particular, a double incidence compared to that of the region was observed near Mt Etna [27].

This work is organized as follows: the next section describes the applied methodology and the exploited data sources; the third section discusses the main findings.

2 Methodology and analyzed data

The spatial distribution of TC cases can be described through the inhomogeneous Poisson point process. In this model, the expected number of events $N(u)$ in a generic sub-area U of the region under study R follows a Poisson distribution whose intensity λ varies over space. For a generic point u we will have $\lambda=\lambda(u)$ and the expected number of events $E[N(u)]$ is

$$E[N(U)] = \int_U \lambda(u)du\,. \tag{1}$$

The Standardised Incidence Ratio (SIR) is computed at census tract level and is exploited to produce maps of TC risk. The SIRs were calculated by indirect standardization [32]. The SIR is the ratio between observed O_i and expected TC cases E_i in each census tract i

$$RSI = \frac{O_i}{E_i} \tag{2}$$

The expected number of cases is computed as the product of the population at risk P_i (and therefore the entire resident population) in the given census tract i and the general incidence rate r_+ for the entire investigated area

$$E_i = P_i r_+ \quad . \tag{3}$$

Hence it follows that the SIR of a single census tract is thus computed as

$$RSI = \frac{O_i}{P_i \frac{O_+}{P_+}} \quad . \tag{4}$$

where O_+ corresponds to the total number of observed TC cases and P_+ is the total resident population of eastern Sicily. When the characteristics of the population determine a subdivision into strata with different risk levels (for instance, by sex and age group), a proper weight is associated with each stratum based on the risk of the specific stratum. In this case, the general incidence rate r_+ is replaced by a different rate computed for each stratum j as $r_j = \frac{\sum_i O_{ij}}{\sum_i P_{ij}}$. Hence, the expected number of cases in census tract i is given by $E_i = \sum_j P_{ij} r_j$. Any deviation of the observed SIR distribution from the theoretical one, obtained if the allocation of TC cases over the territory were random, would depend on other variables than the demographic structure of the resident population. Comparing the two distributions enables to verify, for each sub-area, whether potential environmental risk variables determine significant departures in TC risk from the expected one. The inferential test is based on the Poisson distribution and admits that under the null hypothesis, the SIR is equal to 1 and that an observed value of SIR significantly greater than 1 implies an increase in risk [4].

The local Moran's I was proposed by Anselin [2] and it is defined by the following formula

$$I_i = \frac{(y_i - \bar{y})}{S_i^2} \sum_{j=1, j \neq i}^{n} \left(w_{ij} \left(y_j - \bar{y} \right) \right) \tag{5}$$

where n is the number of geographical units, y_i is the value of the variable y in region i, $\bar{y}$ is the sample mean of the variable, y_j is the value of the variable y in unit j, S_i^2 is the sample variance of the variable y, and w_{ij} is a weight that can be defined as the inverse of the distance between the various geographical units. There are several alternatives to define w_{ij} , some contemplate the choice of a limit distance to define the neighbourhood of a given geographical unit: the units falling within the limit distance take on a positive weight, while the external ones take on a weight equal to zero. Positive values of local Moran's I for a given region indicate that the region is surrounded by regions that have mostly similar values of the variable under study. The emerging spatial groups are defined as "high-high" (region with a high value surrounded by regions with high values) or "low-low" (region with low value surrounded by regions with low values). Spatial outliers result in the composition of two cluster types: "high-low", in the presence of a high value surrounded by neighbours with low values, or "low-high", viceversa. To test the statistical significance of the local Moran's statistic we performed conditional permutation proposed by Anselin (1995).

The data available come from the Cancer Registry of Eastern Sicily and refer to TC cases diagnosed in the period 2003-2016 to residents in the four provinces of interest with age between 5-95 years. Overall, 7,085 cases are included. The data

concerning the resident population in the census tracts of the four provinces of interest come from the 15th General Population Census carried out by Istat in 2011 (https://www.istat.it/it/archivio/104317). Google Maps API was exploited to geocode the residential addresses of TC cases (https://cloud.google.com/maps-platform/).

3 Results and discussion

The TC cases distribution is influenced by the spatial arrangement and the age and sex structure of the resident population. It's well-known that adult females are the most affected by TC [26]; furthermore, the population ageing in inner areas, where depopulation dynamics are in place, tends to accentuate the imbalance between sexes, given the higher life expectancy of women compared to men [33]. In an attempt to distinguish the effects of the demographical and environmental components on the TC cases spatial distribution, we propose SIR maps at the census tract level and together with the geographical representation of the statistical significance. Figures 1.a-1.b respectively report the SIR and the results of the one-tailed test with significance level α=0.05 highlighting the census tracts with SIR significantly greater than 1. From the mere SIR calculation (fig. 1.a) different areas of risk emerge. These areas are located in the area nearby Mt Etna, but also in the non-volcanic provinces, especially in those of Enna and Messina. The area south-east of Mt Etna and different sections located mainly in the Messina province prove to be statistically significant from the one-tailed test (fig. 1.b). Finally, whether in the non-volcanic provinces the census

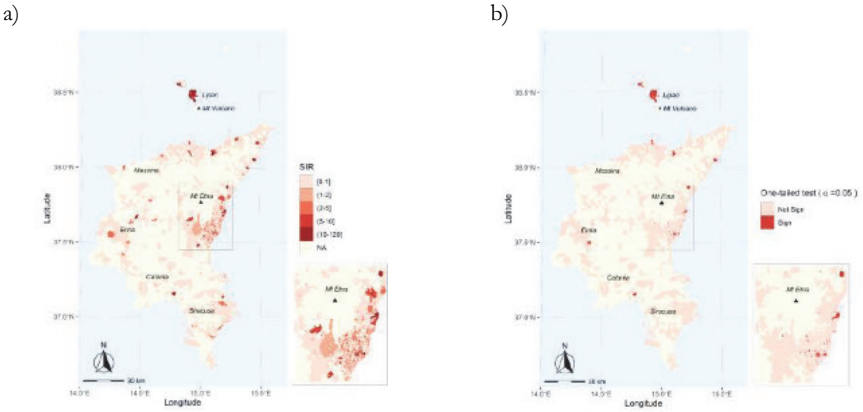

Figure 1: SIR distribution by census tracts (a) and representation of their statistical significance (b). Source: authors' original elaboration.

sections with SIR greater than 1 are randomly arranged, in the province of Catania the high-risk sections mainly concentrate in an area close to Mt Etna, leaving the rest of the province almost empty. To detect the location of the TC cases clusters

over the area and to visually assess their arrangement in relation to the proximity of Mt Etna, the local Moran's I on the SIR was computed. Figures 2.a-b show the local statistic for all TC cases with a bandwidth of 10 km and the pseudo p-values obtained from the conditioned permutation procedure, respectively. Two high-risk areas appear: the first in the south-eastern side of Mt Etna and the other to the north, between the Aeolian Islands and near Barcellona Pozzo di Gotto. The location of the high-risk areas along the NW-SE axis could suggest that the presence of persistent winds toward the SE direction, documented by Boffetta et al. [5], can carry the toxic volcanic substances and therefore pollute the atmosphere of the territories positioned along the axis itself. A similar consideration could be applied to the Aeolian Islands and the sections near Barcellona Pozzo di Gotto which are in proximity of Mt Vulcano, an active volcano presenting limited activity compared to that of Mt Etna.

Using geo-spatial topic modelling to understand the public view of Italian Twitter users: a climate change application

Utilizzo della modellazione geospaziale degli argomenti per comprendere la visione pubblica degli utenti italiani su Twitter: un'applicazione sul cambiamento climatico

Yuri Calleo[a] and Francesco Pilla[a]

Abstract The spread of climate change uncertainty among citizens requires the adoption of different methods to understand the public view and to take efficient actions. In the Big Data framework, a large amount of data from location-aware devices are available, which can constitute a valuable information resource. However, in social networks, the lack of geo-spatial data still remains a challenge and for this reason, we implemented a new approach to extract a larger sample, using spatial data mining techniques. Finally, to detect the Italian Twitter users' discussion and the geographical areas of origin, we applied probabilistic topic models, to a dataset of tweets in the climate change context.

Abstract *La diffusione di incertezza sui cambiamenti climatici tra i cittadini richiede l'adozione di diversi metodi per comprendere l'opinione pubblica e per intraprendere azioni efficienti. Nel framework dei Big Data una grande quantità di dati provenienti da dispositivi location-aware è disponibile, i quali possono costituire un'utile risorsa informativa. Tuttavia, nei social network, la mancanza di dati geospaziali rimane*

ancora una sfida e per questo motivo implementiamo un nuovo approccio per estrarre maggiori dati, utilizzando tecniche di data mining spaziale. Per rilevare le discussioni degli utenti Twitter italiani e le aree geografiche di provenienza, applichiamo topic models su un dataset di tweet sul cambiamento climatico.

Key words: geo-spatial data, topic modeling, climate change

1. Introduction

In the current climate change context, our planet is facing numerous environmental challenges that are threatening the future of public health and the well-being of citizens. Studies demonstrate [1] how citizens' health is compromised by different climate impacts, including environmental degradation, urban pollution, rising temperatures, heatwaves, and storms. In this context, climate complications [2] could not only lead to possible environmental disasters but they are spreading anxiety and fear among citizens, unaware of the future perspectives [3]. From what was previously described, we need valid solutions to reduce concern among citizens, starting from the study of their perceptions and visions.

With the exponential increase of data available from the use of social networks, it is possible to extract valuable resources to understand the public view of users. The availability of textual data is increasing in social network platforms, and with the use of location-aware devices (LAS), more geo-spatial data are proliferating (we refer here in a broad meaning, as information useful to link textual data to a geographic object), making possible different methodological implementations. However, due to their sensibility and low presence, the extraction and analysis of geospatial data still remains a challenge.

Normally, on Twitter, the percentage of users attaching their location to textual information (tweets) is low (as we will see below, less than 10% of the total corpus). For these reasons this study developed here a different method to extract and manage geo-spatial data, combining users' profile location to each tweet to then apply the Latent Dirichlet Allocation (LDA), extracting the major topics in the Italian climate change context. This contribution provides an answer to the following research questions (RQ): RQ1: does this approach improve the number of geospatial data obtained? RQ2: what benefit can the combination of spatial and textual techniques provide for understanding the public debate on climate change? And finally: what are the most discussed topics and in which geographical areas? (RQ3).

2. Materials and Methods

In order to understand the public view of the Italian Twitter users, we use unsupervised learning models extracting major topics within a dataset of tweets, in a

time span of 15 years. A dataset of 120.222 tweets was extracted using a Python Scraper script, which allows us to obtain tweets by generating an extraction-loop. We perform it through a cleaning process that provides the tokenization (we use the NLTK Python package and the nltk.word_tokenize function) [4], the conversion in lowercase, and finally the special characters (e.g., "#", "@", "*") and stop words removal. For this preliminary analysis, we use here: "cambiamento climatico" as a principal keyword, obtaining tweets starting from the newest to the oldest (November 19, 2021, to June 26, 2007). Once we obtain the data, two datasets are available: 1) containing users' information (e.g., name, username, location, URL, etc.) and 2) containing textual data. Our approach, in order to obtain only the tweets written by Italian users, consider the user location present in the personal profile excluding the location attached in the singular tweet. At this point, from 31.776 users, only 25.315 profiles contained the geographical position within their Twitter account, and after the removal of non-significant and non-existent locations a total of 18.540 profiles have significant data. After this first analysis, the resulting tweets with geodata number 37.430. Once we obtain a dataset composed by tweet and geographical area of reference, we use the Latent Dirichlet allocation (LDA), analysing the whole corpus of tweets in order to obtain a frequency distribution useful to calculate the discussion rate for each topic and for each Italian region. We can define Latent Dirichlet allocation [5] as a generative Bayesian model of a corpus, composed of three different hierarchical levels [6]. In this case, LDA is based on a Dirichlet distribution definable as the probability density with vector value having the same principle as the multinomial parameter θ with non-zero values, in particular in LDA terms are associated or related with a latent (or hidden) topic, resulting from the following joint probability:

$$p(\beta_{1:K}, \theta_{1:D}, z_{1:D}, w_{1:D}) = \prod_{i=1}^{K} p(\beta_i) \prod_{d=1}^{D} p(\theta_d) \left(\prod_{n=1}^{N} p(z_{d,n} \mid \theta_d)\, p(w_{d,n} \mid \beta_{1:K}, z_{d,n})\right)$$

where $z_{d,n}$, is the equivalent of the topic assignment, related on the per-document topic distribution θ_d; and the term $w_{d.n}$ is dependent on all of the topics $\beta_{1:K}$ and the topic assignment $z_{d,n}$ [7].

Once we obtained the results of the LDA, we extracted the relative frequencies in order to create different cartograms of the specific topics, highlighting the spatial distributions using GIS Software (Q-GIS Development Team, Open Source Geospatial Foundation Project. http://qgis.osgeo.org.).

3. Results and discussion

The results fully answered the research questions, it was possible, with the adoption of this process, to obtain an increased amount of geo-spatial data, useful to better understand the public view on climate change in Italian areas. With this process, we obtained 37.430 pure tweets, by extracting the users' profile location and linking

to the corresponding tweet, otherwise, considering only the position attached in each single tweet, we would have obtained only 1827 pure tweets (6% of the total corpus).

From the LDA, in Table 1 we represented the document-topic probabilities highlighting 10 topics with 5 keywords obtained with two validation sets of a topic coherence metric, where $\alpha = 0.1$ and $\beta = 0.1$. Overall, in the 10 topics we can find three principal themes of discussion: a) climate change effects; b) perception and uncertainty; c) government policies. In the first theme, some topics (e.g., topic 1, topic 4, topic 8, and topic 9) focus on the climate change effects on the society, reporting problems related to the weather, environmental sustainability, and animal extinction. In the second theme, it is possible to analyse the fear, concern, and anxiety that climate change is creating in society (e.g., topic 2), while also a conspiracy "cluster" emerges in topic 7.

Table 1: *Topic modelling results ordered by the keywords weight*

Topic	***Keywords***
Topic1	inadeguatezza (0.049), vedere (0.025), estate (0.025), caldissime (0.025), boschi (0.025)
Topic2	preoccupata (0.037), clima (0.037), urgente (0.025), stop (0.025), ansia (0.015)
Topic3	sviluppo (0.018), popolare (0.018), futuro (0.018), crisi (0.014), rapido (0.010)
Topic4	mitigazione (0.039), glasgow (0.033), gradi (0.025), caldo (0.015), torrido (0.010)
Topic5	convincere (0.032), gradi (0.032), pensiamo (0.020), estinzione (0.011), negano (0.009)
Topic6	marina (0.030), animali, (0.030), emmanuelmacron (0.025), eu (0.017), commissione (0.010)
Topic7	tv (0.039), mente (0.020), terrorismo (0.17), allarme (0.015), record (0.010)
Topic8	sostenibilità (0.081), ristorazione (0.042), ambiente (0.032), collasso (0.015), svizzero (0.007)
Topic9	morte (0.049), specie (0.037), panda (0.020), koala (0.012), nonostante (0.002)
Topic10	incapacità (0.032), fare (0.0015), possibilità (0.010), governo (0.003), america (0.001)

In the third theme, the public view addresses the climate change crisis from a future perspective (topic 3), discussing action and policies in Europe and the United States (e.g., topics 6 and 10). Once we obtained the relevant topics and the keywords, we constructed a cartogram for each of them (as represented in figure 1.) reported below as relative frequencies. In topic 1, two Italian regions, Lombardia (0.39) and Lazio (0.37) particularly emerged, discussing the effects of global warming on planet earth. In topic 2, the anxiety and uncertainty about climate change effects are discussed more in Lazio (0.27) and Lombardia (0.19) region, followed by Emilia Romagna (0.12) and Molise (0.11). The third topic, Lazio (0.15), Emilia-Romagna (0.12), Veneto (0.12), and Toscana (0.11) regions, focused more on the crisis and the future development of climate change, citing the rapid growth of the world population. In topic 4, Abruzzo (0.15), Sicilia (0.15), Puglia (0.12), and Umbria (0.12) users,

talked more about the high temperature and the possible mitigation of it, also citing the United Nations Climate Change Conference (COP26) held in Glasgow in 2021. In topic 5, emerges issues relating to the human extinction due to the global warming problem in Liguria (0.015), Sicilia (0.13), Puglia (0.12), and Toscana (0.12) regions.

The sixth topic focuses on the government policies, Lazio (0.15), Trentino-Alto Adige (0.15), and Piemonte (0.12) users discussed it, citing, for example, the EU commission. In topic 7, a conspiracy topic emerged, discussed more by Lazio (0.27) and Puglia (0.14) region, highlighting the unjustified alarmism by the media about climate change. In topic 8, Emilia Romagna (0.17), Friuli Venezia Giulia (0.12), and Liguria (0.15) discussed the sustainability of cuisine in an environmentally sustainable food system.

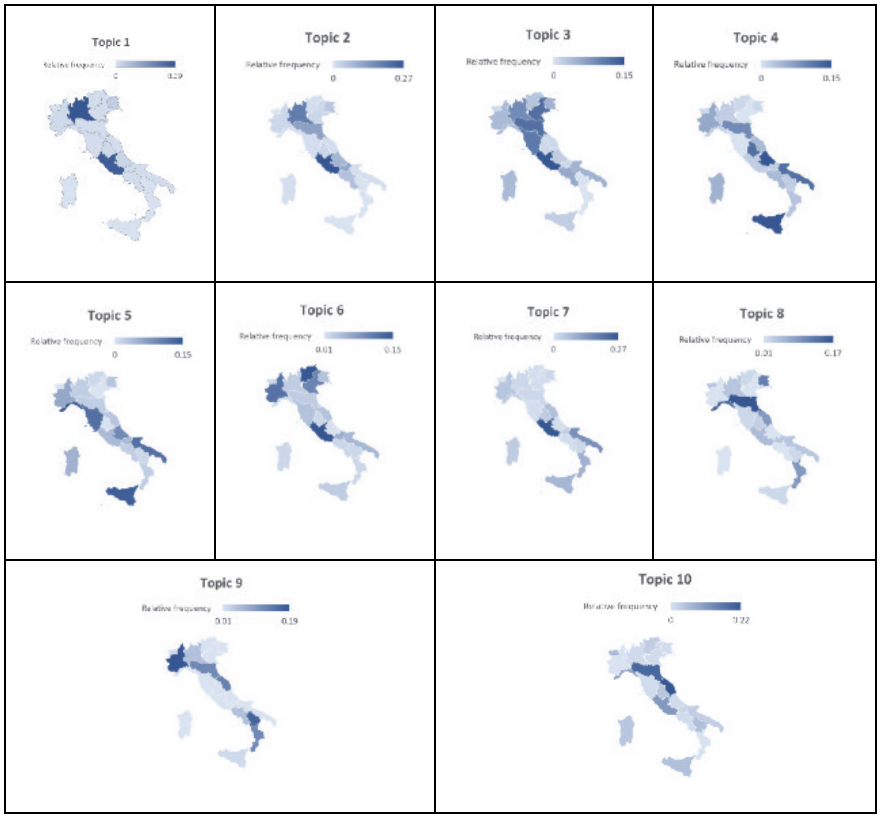

Figure 1: *Geo-spatial topic analysis outputs*

In topic 9, particular attention to the animal extinction (see the keyword "koala" and "panda") emerged, specifically in Piemonte (0.19), Basilicata (0.17), Marche (0.13), Emilia (0.12), and Calabria (0.12) regions. Finally, in the last topic (Topic 10),

users from Marche (0.22), Emilia-Romagna (0.19), and Lazio (0.11) discussed more the action and the policies of the American government.

4. Conclusions and future works

In conclusion, the approach provided a new implementation for improving geo-spatial topic modeling, increasing the availability of geodata compared to the standard approach. However, this study proposed a preliminary approach that in future works could be improved. The correlation between the Italian language and tweets that were written by an Italian user, does not allow us to say a priori that they are always related, in fact, sometimes users may enter a misleading (or old) location in their profile.

In these terms, this contribution is the first step and future works could be implemented using more keywords with larger datasets of Twitter data. Furthermore, it will be possible to implement different text-mining techniques to understand the sentiment of the discussions and analyse the dataset periodically (e.g., what were the most discussed topics from 2007 to 2011? Or, in which areas was a particular topic most discussed in 2020?).

To have a more complete vision of the object of study, different spatial analyses (e.g., spatial autocorrelation analysis) can be taken into consideration, we did not apply them to this study due to low contiguity of the regions.

Acknowledgment The work carried out in this paper was supported by the project SCORE which has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement No 101003534.

Comparing local structures of spatio-temporal point processes on linear networks

Confronto fra strutture locali di processi di punto spazio-temporali su reti lineari

Nicoletta D'Angelo, Giada Adelfio, and Jorge Mateu

Abstract We employ the Local Indicators of Spatio-Temporal Association (LISTA) functions on linear networks to build a statistical test for local second-order structure. This allows to identify differences in the spatio-temporal clustering behaviour of two point patterns, a point pattern of interest and a background one, both occurring on the same linear network. We illustrate the proposed methodology analysing a traffic-related problem.

Abstract *Utilizziamo le funzioni LISTA su reti lineari per costruire un test statistico per la struttura locale del secondo ordine. Ciò consente di identificare le differenze nel comportamento di clustering spazio-temporale di due pattern di punti, uno di interesse e uno di background, entrambi sulla stessa rete lineare. Illustriamo la metodologia proposta analizzando un problema relativo al traffico.*

1 Introduction

Point processes on linear networks are recently considered to analyse events occurring on particular network structures, as it is the case, for example, with traffic accidents. They were firstly introduced in the spatial context (see Baddeley et al. (2020) for a review) and then extended to the spatio-temporal case (Moradi and Mateu (2020); Cronie et al. (2020), to cite a few).

While most of the literature about point processes on networks is concerned with non-parametric estimation of the spatio-temporal intensity and second-order analysis of point patterns occurring on linear networks, none of these approaches has considered local properties of the introduced second-order statistics to measure local first- or second-order structure.

In the Euclidean point process theory context, while the use of global spatio-temporal second-order summary statistics is a well-established practice to describe global interaction structures between points in a point pattern, the use of local tools was firstly advocated by Siino et al. (2018).

As local second-order characteristics provide information on how events relate to nearby events, in this paper, we aim at employing the LISTA functions on linear networks to build a local test to identify differences between the local spatio-temporal second-order structure of two patterns occurring on the same linear network.

The above-mentioned test is proposed in D'Angelo et al. (2021), where the authors provide simulation studies to assess the performance of the testing procedure of local second-order structures, considering in particular homogeneous, inhomogeneous, clustered spatio-temporal point processes to study how the test behaves under these different settings, as well as more complex spatio-temporal point processes, such as self-exiting processes, where each point of the pattern can potentially produce offspring. They found, as expected, that the power of the test increases as the number of points and the clustered structure of the point pattern of interest increase too. The test for local spatio-temporal second-order structure is implemented in the package `LISTAnet`[1] available on `GitHub`.

In this paper, we provide an application of the proposed methodology to a traffic-related dataset that is of particular importance.

Section 2 presents the definition of LISTA functions on linear networks. In Section 3 we recall the permutation test for assessing local differences between the spatio-temporal second-order structure of two point patterns occurring on the same linear network. Section 4 contains the application to a traffic dataset. Conclusions come in Section 5.

2 LISTA functions on linear networks

Definition 1. Local Indicators of Spatio-Temporal Association
The Local Indicators of Spatio-Temporal Association (LISTA) functions are a set of functions that are individually associated with each of the points of the point pattern and can provide information about the local behaviour of the pattern (Siino et al., 2018).

In the Euclidean context, several second-order characteristics of point processes are considered for building LISTA functions, such as the K-function, the pair correlation function, and the product density function.

[1] https://github.com/nicolettadangelo/LISTAnet; R package version 0.1.0

D'Angelo et al. (2021) provide the operational definition based on the local second-order spatio-temporal summary statistics on a linear network.

Definition 2. LISTA functions on linear networks
Any local second-order spatio-temporal summary statistic $\lambda^i_{2,L}((\mathbf{u},t),(\mathbf{v},s))$ computed on an observed point pattern $\mathbf{x}$ on a linear network L, that satisfies the following operational definition: $\hat{\lambda}_{2,L}((\mathbf{u},t),(\mathbf{v},s)) = \frac{1}{n-1}\sum_{(\mathbf{u}_i,t_i)\in\mathbf{x}} \hat{\lambda}^i_{2,L}((\mathbf{u}_i,t_i),(\mathbf{v},s))$, where $\hat{\lambda}_{2,L}$ is an estimator of the global second-order intensity function, can be called a LISTA function on a linear network.

In this paper, we consider the local spatio-temporal K-function on networks, defined for each point $(\mathbf{u}_i,t_i)$ as

$$\hat{K}^i_L(r,h) = \frac{1}{\hat{\lambda}^2|L||T|}\sum_{(\mathbf{u}_i,t_i)\neq(\mathbf{v},s)} \frac{I\{d_L(\mathbf{u}_i,\mathbf{v})<r, |t_i-s|<h\}}{M((\mathbf{u}_i,t),d_L(\mathbf{u}_i,\mathbf{v}),|t_i-s|)}, \qquad r\geq 0, h\geq 0$$

obtained weighting for a constant intensity $\hat{\lambda} = n/(|L||T|)$, since our aim is to find out differences in the local structure of two point processes by comparing their second-order characteristics, whichever is the first-order intensity. Here $|L|>0$ and $|T|>0$ are the total length of the network L and of the time interval T, respectively, $M((\mathbf{u}_i,t_i),r,h)$ is the number of points lying exactly at the shortest-path distance $r\geq 0$ and the time distance $h\geq 0$ away from the point $(\mathbf{u}_i,t_i)$.

In this particular context, ignoring the network would result in bias when computing the K-functions, as without the network correction $M((\mathbf{u},t),r,h)$ (introduced by Moradi and Mateu (2020) for the spatio-temporal context) we would overestimate the number of points in any spatio-temporal lag considered.

3 Testing for local second-order structure on a network

We test the null hypothesis of no differences in the spatio-temporal second-order structure of the two observed point patterns $\mathbf{x}$ and $\mathbf{z}$ with respect to the i^{th} point $\mathbf{x}_i = (\mathbf{u}_i,t_i)\in\mathbf{x}$, with $i=1,\ldots,n$. Formally, for each point $(\mathbf{u},t)\in\mathbf{x}$, the hypothesis test reads as

$$\begin{cases} \mathscr{H}_0: & \text{no difference in the second-order local structure of } (\mathbf{u},t) \quad \text{w.r.t} \quad \{\{\mathbf{x}\setminus(\mathbf{u},t)\}\cup\mathbf{z}\} \\ \mathscr{H}_1: & \text{significant difference in the second-order local structure of } (\mathbf{u},t) \quad \text{w.r.t} \quad \{\{\mathbf{x}\setminus(\mathbf{u},t)\}\cup\mathbf{z}\} \end{cases}.$$

Rejecting $\mathscr{H}_0$ for most of the points in the point pattern $\mathbf{x}$ means that the local second-order structures of $\mathbf{x}$ and $\mathbf{z}$ around those arbitrary points $(\mathbf{u},t)$ are different, and therefore the second-order global structure of $\mathbf{x}$ and $\mathbf{z}$ is different, meaning that they are most likely coming from different underlying point processes.
Nevertheless, in addition to this global conclusion, the most interesting results concern the rejection of $\mathscr{H}_0$ for specific points, allowing for the identification of points for which the spatio-temporal local behaviour varies with the spatio-temporal loca-

tion. This could also result in the identification of areas where the spatio-temporal local second-order structure of the points in the pattern of interest **x** differs the most and needs to be further analysed. If, for instance, the significant points tend to cluster in time and space, this could indicate multiple underlying generating processes, in contrast to a unique one. Furthermore, the identification of a significant point may already be an indication of outlying behaviour for the remaining points.

3.1 The permutation test

To take into account the geometry of the underlying network, we develop a testing procedure based on the homogeneous LISTA functions reviewed in Section 2. A permutation test approach is considered, where the null distribution of a given statistical test is estimated by randomly permuting the labels attached to the two point patterns. The steps of the testing procedure are as follows

1. Define the point pattern of interest **x** and the background pattern **z**, assumed to be realisations of the point processes X and Z, with $N(X) = n$ and $N(Z) = m$. Typically, **x** is the point pattern with the most clustered structure;
2. Set k as the number of permutations;
3. For each point $(\mathbf{u}_i, t_i) \in \mathbf{x}$
   a. Estimate the LISTA function $\hat{K}^i_L(r,h)$;
   b. Compute the local deviation test $T^i = \int_0^{t_0}\int_0^{r_0}\left(\hat{K}^i_L(r,h) - \hat{K}^{-i}_{L,H_0}(r,h)\right)^2 \mathrm{d}r\mathrm{d}h$ where $\hat{K}^{-i}_{L,H_0}(r,h)$ is the LISTA function for the i^{th} point, averaged over the $j = 1,\ldots,k$ permutations, and where r_0 and t_0 are the maximum spatial and temporal ranges considered in the K-functions;
   c. A p-value is computed for each point of the pattern **x** as $p^i = \sum_{j=1}^{k} \frac{\mathbf{I}(T^{i,j}_{H_0} \geq T^i)}{k}$, where $T^{i,j}_{H_0} = \int_0^{t_0}\int_0^{r_0}\left(\hat{K}^{i,j}_L(r,h) - \hat{K}^{-i,j}_{L,H_0}(r,h)\right)^2 \mathrm{d}r\mathrm{d}h$, with $\hat{K}^{i,j}_L(r,h)$ being the LISTA functions on the k patterns generated from the null hypothesis, and $\hat{K}^{-i,j}_{L,H_0}(r,h)$ being the LISTA function averaged over the points of the k^{th} permutation.

The testing procedure ends with providing a vector p^i of $N(X) = n$ p-values. The null hypothesis is rejected if $p^i \leq \alpha$, where α is the fixed nominal value of the type I error.

We note that using a Bonferroni correction, too conservative results under the null hypothesis where obtained. So we are in such a case that the non-corrected test provides good significance levels while the corrected one is too conservative (see existing literature Siino et al. (2018); Tamayo-Uria et al. (2014) where no such correction was considered).

4 Medellin traffic data

We analyse traffic accidents in the city of Medellin (Colombia), a dataset containing the locations of traffic accidents consisting of 1215 traffic accidents in 2019 in downtown of Medellin. The entire data were published in the OpenData portal of Medellin Town Hall at https://www.medellin.gov.co/geomedellin/index.hyg. The dataset actually consists of a multitype point pattern, categorised based on the damages caused by the accident. In particular, 675 "damages only" events are recorded, and 536 "injuries to people".

In our analysis, we do not consider the four events representing car accidents that lead to deaths, and we define the accidents leading to damages as the point pattern of interest $\mathbf{x}$, and the accidents causing injuries to people as the alternative (background) pattern $\mathbf{z}$.

We thus test the hypothesis of difference in the spatio-temporal local second-order structure between the two point patterns considered, setting the number of permutations to $k = 99$. The application of the test provides a p-value for each point in $\mathbf{x}$, and by comparing those to the confidence level $\alpha = 0.05$ we can identify *significant* events, i.e. those points for which $\mathscr{H}_0$ is rejected and therefore the local second-order structure is significantly different from the background process, and *non-significant* events. The significant events are 100 out of the 675 events, and they are shown in Figure 1.

Fig. 1: *Left panel*: Significant events. *Right panel*: Non-significant events.

The application results of the local test support the hypothesis that the two point patterns behave differently in terms of spatio-temporal local second-order structure.

Furthermore, displaying the significant events and the non-significant events allows identifying the areas containing those events whose spatio-temporal local second-order structure is different from the background pattern.

For instance, the results of the proposed application suggest that damages tend to cluster more near road intersections.

5 Conclusions

In this work, we have presented a test to assess local differences between the spatio-temporal second-order structure of two point patterns occurring on the same linear network, based on the Local Indicators of Spatio-Temporal Association on linear networks, and we have applied it to a case study, analysing traffic data represented by a marked point process occurring on the streets of Medellin, where the marks represent the type of car accident. We have been able to explore how individual points are related to their neighbouring events and classify points with similar spatio-temporal local structures, identifying the areas that differ in terms of clustering behaviour. Furthermore, displaying the significant events has allowed to identify the areas containing those events whose spatio-temporal local second-order structure is different from the background pattern.

The analysed point patterns are basically identified by characteristics of the events, i.e. the marks, recorded together with their spatial and temporal location. Future analyses could regard the application of the local test to patterns whose splitting is due to a statistical procedure, such as the stochastic declustering of the self-exciting point processes. Indeed, the topic of fitting parametric point process model, accounting also for the underlying network structure, is still quite unexplored, and only a recent attempt has been carried out to fit self-exciting models to processes occurring on a network (D'Angelo et al., 2022).

DISTATIS-based spatio-temporal clustering approach: an application to business cycles' time series

Un approccio di clustering spazio-temporale basato sull'algoritmo DISTATIS: un'applicazione alle serie storiche relative ai cicli economici

Raffaele Mattera and Germana Scepi

Abstract In this paper we propose a clustering approach based on the DISTATIS algorithm for the study of time series showing spatial spillover effects. This clustering approach involves the use of a spatio-temporal distance, obtained from the combination of temporal and spatial distances. An application to real time series, related to Euro Area business cycles, enriches this paper.

Abstract *In questo articolo proponiamo un approccio di clustering basato sull'algoritmo DISTATIS per lo studio di serie temporali che mostrano effetti di spillover spaziale. Questo approccio di clustering prevede l'uso di una distanza spazio-temporale, ottenuta dalla combinazione di distanze temporali e spaziali. Un'applicazione alle serie storiche reali, relative ai cicli economici dell'Area Euro, arricchisce questo lavoro.*

1 Introduction

The presence of spatial spillover effects is well acknowledged when we deal with macroeconomic time series. An interesting example is given by the interaction among business cycles, since macroeconomic fluctuations are affected by spillover effects generated by neighbouring countries (e.g. see Hájek and Horváth, 2016).

Germana Entropy
Department of Economics and Statistics, University of Naples "Federico II" e-mail: Entropy@unina.it

With the introduction of the Euro, different countries are now characterized by the same monetary policies. However, the effect of monetary policies can be asymmetric if there is not a business cycles' syncronization. Economists argue that, in theory, the monetary union enhances the business cycle' syncronization of the countries involved (Artis and Zhang, 2002). However, there are a lot of studies documenting the absence of a common business cycle in the Euro Area (e.g. Ahlborn and Wortmann, 2018; Artis and Zhang, 2002). Most of these studies use cluster analysis to group countries together on the basis of different business cycles. They find evidence of the so-called core–periphery division, where a "core" group (typically identified with the founding EU Member countries) is opposed to another group, called "peripherical" that typically contains all the other countries.
The definition of real clusters based on business cycles is a very relevant problem for public policy. Previous studies provide very different clusters' composition because they use different businsess cycles' estimating methods, clustering algorithms and dissimilarities measures (Artis and Zhang, 2002; Ahlborn and Wortmann, 2018; Aguiar-Conraria and Soares, 2011).
Surprisingly, the relevant spatial nature of the phenomenon has not been considered by previous studies yet. We fill this gap by introducing spatial dimension in the clustering procedure. In particular, we propose a clustering approach based on the use of a spatio-temporal distance, obtained from the combination of temporal and spatial distances. Optimal weights are computed by the DISTATIS algorithm (Abdi et al., 2005).
The rest of the paper is structured as follows. Section 2 discusses the proposed spatio-temporal clustering algorithm, while section 3 provides an application to Euro Area business cycles' time series. Some final remarks can be found at the end.

2 Methodology

Assuming we observe the values of a variable $C_{i,t}$ for a set of $N(i = 1,\ldots,N)$ spatial units over $T(t = 1,\ldots,T)$ time. In the business cycle case, $C_{i,t}$ represents the cyclical fluctuation of an i-th nation over the time T. When we deal with spatial units, it is common to study the presence of a spatial association that indicates if there is a similarity in the values among contiguous units. The existence of a spatial association among neighbouring locations can be assessed either globally or locally. While global measures define the overall presence of spatial correlation in a dataset, local measures can be used to identify the degree of similarity of each i-th unit to its neighbours. Local Indicators of Spatial Association (LISA) can be used to study the spillover effects (e.g. see Ying, 2000). Note that classical LISA are defined as static measures, so that they show a unique value for each time t.
Clustering of spatial data can be developed by considering both models based on spatial dissimilarity measures (e.g. based on LISA as in Scrucca, 2005) or spatially constrained models (Romary et al., 2015). When the variables are observed at the

same time on space and time, it is possible to use both non spatial models with spatio-temporal distance (Izakian et al., 2012) or spatially constrained models with temporal distance (D'Urso et al., 2021).
We follow a not spatial clustering approach (Parition Around Medoids, see Kaufman and Rousseeuw, 1990) with the following spatio-temporal distance between two units i and j:

$$D_{i,j}(s,t) = \lambda_s D_{i,j}(s) + \lambda_t D_{i,j}(t) \tag{1}$$

where $D_{i,j}(s,t)$ is the distance over space s and time t, $D_{i,j}(s)$ and $D_{i,j}(t)$ are, respectively, the spatial and temporal distances with λ_s and λ_t the spatial and temporal weights, such that $\lambda_s + \lambda_t = 1$. The spatial distance measures the similarity between two units in terms of spillover effects. It is an Euclidean distance computed on the standardized Getis and Ord (1992) index. $D_{i,j}(s)$ is an *instantaneous* spatial distance calculated on the last observation $t = T$. $D_{i,j}(t) = \sqrt{2(1-\rho_{i,j})}$, is a correlation-based distance, where $\rho_{i,j}$ is the correlation coefficient between two business cycles' time series $C_{i,t}$ and $C_{j,t}$.
A crucial step involves the computation of the weights λ_s and λ_t. For this purpose, we propose to adopt the DISTATIS algorithm of Abdi et al. (2005). The DISTATIS algorithm aims to analyze and synthetize a set of distance matrices. It is a generalization of the classical multidimensional scaling (MDS). The DISTATIS algorithm computes the weights as the eigenvalues of the following data matrix cross-product:

$$\mathbf{X}^T\mathbf{X} = \left[vec\left\{\mathbf{S}(s)\right\}, vec\left\{\mathbf{S}(t)\right\}\right]^T \left[vec\left\{\mathbf{S}(s)\right\}, vec\left\{\mathbf{S}(t)\right\}\right] \tag{2}$$

where $vec(\cdot)$ is the vectorization operator, $\mathbf{S}(s) = \Xi D_{i,j}(s)\Xi^T$ and $\mathbf{S}(t) = \Xi D_{i,j}(t)\Xi^T$, given $\Xi = I_N - 1_N m^T$ with I_N the Identity matrix, m a vector of length N containing equal elements $m_i = 1/N$ and 1_N a vector of length N containing values equal to 1.
We adopt a Partition Around Medoids (PAM) clustering algorithm. Therefore, the final clustering problem takes the following form:

$$\min: \quad \sum_{i=1}^{N}\sum_{k=1}^{K} D_{i,k}(s,t)^2 \tag{3}$$

where $D_{i,k}(s,t)$ is equal to (1) for the k-th centroid. Therefore, the PAM clustering algorithm finds the optimal partition of the dataset into C clusters with the aim of minimizing the distances of the units from their centroid.

3 Application to Euro Area business cycles' time series

We consider the quarterly GDP data of the Euro Area countries from the Eurostat website[1], observed from 1995 to 2021. We estimate the business cycle for each country by means of the Hodrick-Prescott (HP) filter (see Fig. 1).

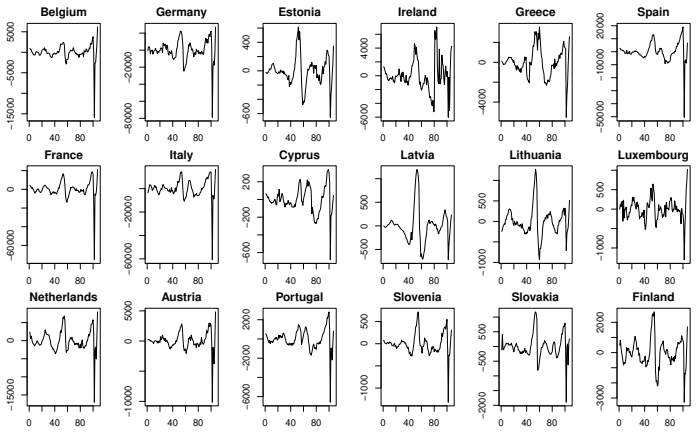

Fig. 1 Business cycles estimates obtained with the Hodrick-Prescott (HP) filter

The standardized Getis and Ord (1992) indices are reported in Tab. 1.

Table 1 Standardized Getis and Ord (1992) index by countries

Belgium	Germany	Estonia	Ireland	Greece	Spain	France	Italy	Cyprus
2.4741	3.283	-1.1964	0.4221	-1.2099	-0.5814	1.6503	0.8014	-0.0734
Latvia	Lithuania	Luxembourg	Netherlands	Austria	Portugal	Slovenia	Slovakia	Finland
-0.4225	-1.216	1.8447	1.4647	-0.4771	-1.0429	1.1013	1.3716	-0.0735

Positive values in Tab. 1 indicate that around the i-th location there is positive spillover, while negative values indicate negative spillover. From Tab. 1 we can notice that most of "economic virtous" countries are associated with positive values (e.g. Belgium, Germany, France), while most of PIIGS economies (e.g. Greece, Spain) show negative values. The clustering results, obtained with the proposed spatio-temporal approach, are shown in Fig. 2. The optimal number of clusters is selected by maximizing the Average Silhouette Width (ASW). Firstly, we note that, although the temporal dimension has a higher weight than the spatial one ($\lambda_t = 0.7329, \lambda_s = 0.2670$) in the definition of the distance, the spatial component is quite relevant in the clusters' composition: Portugal and Spain are clustered together, as well as Finalnd and Baltic countries (yellow cluster), while the Benelux

[1] Data can be retrieved at the following link https://ec.europa.eu/eurostat/web/main/data/database

countries (Netherlands, Belgium and Luxemburg) are clustered with their neighbours France, Germany and Italy. Overall, we find evidence favoring the "core-periphery" patterns in the business cycle synchronization, but the final clusters' composition differs from that showed by previous studies. For example, Ahlborn and Wortmann (2018) showed three gropus, whereas we find only two. Moreover, we find that Spain and Portugal belong to "periphery" cluster rather than the "core" one. Moreover, Ahlborn and Wortmann (2018) considers Ireland as a fuzzy unit, while our clustering group Ireland in the "periphery" cluster with a low degree of fuzziness. Such differences can be explained by the relevance of spatial spillovers.

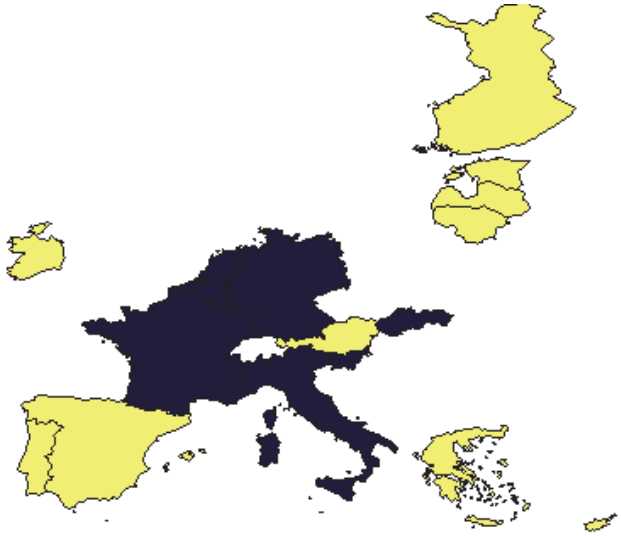

Fig. 2 Clustering results: cluster 1 is with blue color, cluster 2 with yellow one.

4 Final remarks

In this paper we propose a novel approach for clustering spatio-temporal data based on the use of a novel spatio-temporal distance. The spatial component of this distance is defined by means of Local Indicators of Spatial Association (LISA), while temporal one by the correlation among the time series. The two components of the distance are weighted by the DISTATIS algorithm's estimated weights. We notice that DISTATIS is applied, for the first time, in the definition of a spatio-temporal distance.
We apply the proposed clustering approach in the relevant problem of business cycles' syncronization of Euro Area countries.
A future study will be devoted to the comparison of the proposed clustering ap-

proach with other established techniques for spatio-temporal data. Moreover, we aim to evaluate the robustness of the results employing both alternative filters for business cycle estimation and different approaches for measuring spatial and temporal distances.

Developments in composite indicators

Bayesian networks for monitoring the gender gap

Le reti bayesiane come proposta per monitorare il gender gap

Flaminia Musella and Lorenzo Giammei and Silvana Romio and Fulvia Mecatti and Paola Vicard

Abstract Composite indicators are a common choice for synthesizing complex phenomena. Over the years, they have grown in popularity and are now applied in many social and environmental sciences. Among others, a subject of increasing interest is gender equality analysis. Gender composite indicators, even if easy to read, may provide a limited picture of the problem. Here we discuss the potentiality to integrate the use of composite indicators for gender gaps with Bayesian networks, powerful tools for explaining the complex association structure in the dataset and developing scenarios to orient policy-making. An example is carried out on Italian province-level data.

Abstract *Gli indicatori compositi rappresentano una scelta comune per sintetizzare fenomeni complessi; la loro popolarità e la vastità di ambiti in cui sono applicati ha raggiunto anche l'analisi della parità di genere. Seppur gli indicatori compositi di genere siano di facile lettura, essi rischiano di fornire un quadro limitato al problema. Nel presente paper discutiamo la possibilità di integrare l'uso di indicatori compositi per il gender gap con un modello statistico-probabilistico basato sulle reti bayesiane e sviluppato a partire da un set di dati raccolto a livello provinciale.*

1 Introduction

As revealed by United Nations Statistics Division – UNSD Global Gender Statistics Programme, gender statistics stands upon data collection disaggregated by sex with the aim of detecting and untangling gender bias in the analysis of real phenomena. A critical examination of the potential effect of unbalanced opportunities and denied rights can greatly benefit from being done according to statistical reasoning to point out the tangled relations among predictors of the gender gaps. Furthermore, gender statistic is motivated by the growing demand for gender-sensitive statistical information, coming from society and made even more urgent by the Covid-19 planetary crisis and its consequences that go well beyond public health. Finally, the increasing interest in gender equality is justified by the Goal 5 of UN Agenda 2030, which aims to achieve a sustainable gender balance for the benefit of society as a whole, both men and women.

The most popular strategy for gender data analysis is based on building composite indicators. They are easy to implement and interpret but unable to fully catch the multivariate and inter-sectional nature of gender inequalities. In this paper the potentiality of complementing composite indicators with an approach based on Bayesian networks (BNs) is discussed. BNs are multivariate statistical models for managing the intricate net of dependencies among variables. Applied to gender statistic, BNs can help describing the dependence of men-women distance from a set of observed variables, among which those used for the composite indicators. Hence BNs become a powerful tool for developing scenarios of gender balance and, together with composite indicators, could support decision-makers in orienting policies activated in different fields (*i.e.* economic, social and health) and simultaneously impacting the gender gap.

In this paper we firstly introduce composite indicators (Section 2) by focusing on the European Gender Index (GEI henceforth); in Section 3 we both review Bayesian Networks and present an illustrative example based on real Italian data collected at province-level of disaggregation; conclusions are addressed in Section 4.

2 Composite Indicators and Gender Equality Index

Composite indicators have grown in popularity due to their ease of reading and effectiveness in comparative analyses [6]. Their implementation is common in many disciplines, ranging from social to environmental and governance applications [1, 2]. Global institutions, among which the OECD, World Bank and EU, are also increasingly adopting synthetic indices for supporting policy makers around the globe [7]. Nevertheless, scientific debate about composite indexes is divided between supporters that highlight their effectiveness in describing an overall complex phenomenon and opponents that instead claim that results may be statistically limited and sometimes misleading [8]. Here we focus on composite indicators for monitoring the gender gap. These have been developed since 1995, trying to catch

different aspects of the gender gap. Some of them aim at measuring gender equality (positive gap) and some others gender inequalities (negative gap). Table 1 summarizes the evolution of the main gender indexes as they have appeared over time.

Table 1 Gender indexes

INDEX	Name	Institute	B-Year
GDI	Gender Development Index	UN Development Programme	1995
GEM	Gender Empowerment Index	UN Development Programme	1995
GEI	Gender Equality Index	EIGE	2000
GGGI	Global Gender Gap Index	World Economic Forum	2006
SIGI	Social Institutions and Gender Index	OECD	2009
GII	Gender Inequality Index	UN Development Programme	2010
WEOI	Women's Economic Opportunity Index	Economist Intelligence Unit	2010
MGII	Multidimensional Gender Inequality Index	University	2014
BIGI	Basic Indicator of Gender Inequaltiy	University	2019

Composite gender indexes are built accounting for several aspects, called domains, related to different areas of life and sometimes sliced into sub-domains. Within these areas, each index catches a specific set of variables that are meant to indirectly measure gap/equality between genders. These variables stand for ingredients of the obtained synthetic indicator. There is a large debate on how to combine the contribution of each variable to the domain since the weighting strategies may be seen simultaneously as opportunities and limitations [5]. Consistently with the most popular choice in Europe, we refer to GEI as a gold standard composite index to be taken in account within our proposal. One of the main objectives of the European Institute for Gender Equality (EIGE) is promoting equality between women and men in European Union. To this aim, since 2010, the institution annually constructs and publishes the GEI index to monitor and compare countries with respect to their level of gender equality/inequality and efforts to reduce gaps. The composite indicator ranges between 0, standing for total inequality, and 100, meaning perfect equality; it is based on six core domains, in some sub-domains, and 27 (univariate marginal) indicators. The index construction consists of the following steps: (i) firstly, indicators are measured by gender and the differences between women and men are computed, (ii) variables are aggregated in sub-domains by an unweighted arithmetic mean; (iii) sub-domains are combined in domains by a geometric mean, still unweighted; (iv) finally, domains are aggregated by means of a weighted geometric mean with weights established by experts. GEI domains are related to the following areas: Work, Money, Knowledge, Time, Power and Health. These domains remain the driver dimensions in our proposal based on Bayesian networks as well.

3 The Bayesian Network version of GEI

In this section we introduce Bayesian Networks [9] and show their use when investigating the gender gap. We begin by briefly describing the basic terminology of graphs and the main elements of a BN. Then we propose an implementation of the method on real province-level gender data.

A graph $G(V,E)$ consists of a set of nodes (or vertices) V and a set of edges E. Two nodes connected by an edge are said to be adjacent. Edges can be directed (arrows) if they are oriented from a node X_i to another node X_j, or undirected (lines) if such orientation is not made explicit with arrow direction. If a graph only contains directed edges, it is called a directed graph. When a directed edge goes from a node X_i to a node X_j, X_i is called a parent of X_j. We will denote with pa_i the set of the parents of node X_i. A path is a sequence of edges traced along pairs of adjacent nodes, such that each edge starts with the vertex ending the preceding edge. A path from X_i to X_j, where all the edges are oriented along the direction of the path, is a directed path. If a directed path begins and ends with the same node, it is called a cycle. A directed acyclic graph (DAG) is a directed graph where cycles are forbidden.

Bayesian Networks are composed by a DAG and a joint probability distribution over its nodes. The vertices of the DAG represent random variables and the edges describe the relations between them. Given a DAG G with node set $\mathbf{V} = \{X_1, ..., X_n\}$, the joint probability distribution $P(V)$ over its nodes can be factorized according to the structure of the graph as follows

$$P(x_1, ..., x_n) = \prod_i P(X_i | pa_i). \tag{1}$$

A BN is here proposed to show how this methodology could contribute to the study of the gender gap and support the analysis conducted with composite indicators. A province-level dataset is used to estimate the graph through a process called structural learning [3]. When the relationships within variables, i.e. associations and dependencies are unknown, structural learning allows to discover the relations from data and encode them into a DAG. The BN is learnt through the PC algorithm [4], a procedure that performs multiple conditional independence tests on data and then translates the obtained independence statements into a DAG. The variables contained in the dataset are listed in Table 2 and cover GEI ingredients, as well as additional structural and socioeconomic features. The logical groups in Table 2 also serve as a guide to learn the BN. It is assumed that structural and socioeconomic features are not affected by GEI ingredients and that structural features are not affected by socioeconomic features. These constraints are translated into graphical form by the algorithm by forcing the corresponding edge directions to be absent.

The obtained DAG is shown in Figure 1. Province-level GEI has been inserted in the network as an additional node, with incoming arcs from each ingredient variable. The presence of a GEI node allows ranking provinces in terms of gender equality. The colour of the vertices denotes the variables group (blue= structural features, orange= socioeconomic features, green= GEI ingredients, white= GEI at province-

Table 2 Variables logical groups

Structural features	Socioeconomic features	GEI Ingredients
Internet access	Province added value	Employment rate gender gap
Firm size	Total employment rate	Female work segregation
Population density	Education rate	Income gender gap
Geographical area		Female education segregation
		Female education rate
		Life expectancy gender gap
		Female entrepreneurs ratio
		Average n. of children

level). The graph provides a clear picture of how all the variables interact. The structure shows those variables affecting the GEI ingredients and those on which a policy maker could intervene to increase gender parity. The relations encoded in the graph structure are consistent with subject matter knowledge emerging from the literature.

4 Discussion and Research Perspectives

Gender parity has become a central objective in policy-making processes and allocation of resources. However, reducing inbalances between genders requires a deep understanding of the the risk factors and the interactions therein, which cannot be achieved without mainstreaming of gender research to improve quality of data and

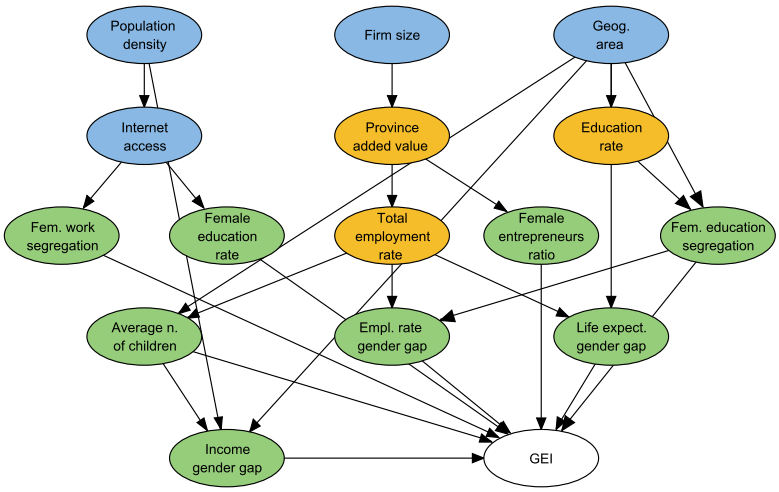

Fig. 1 Bayesian network model including GEI

statistical tools. Constructing composite indicators is the most common statistical approach to investigate inequalities in opportunities and rights based on gender. This methodology is usually straightforward to implement and provides a concise measure of the gender gap, but also presents some limits. Here we proposed a statistical approach based on Bayesian Networks which could be used together with composite indices. This advanced statistical model, based on structural learning, translates the information contained in the data into an effective easy-to-read graphical form, thus revealing how variables interact in a fully multivariate environment. This allows direct identification of the determinants of the gender gap, thus providing a solid data-driven base to support and motivate policies. Implementing BNs together with composite indicators would thus mean complementing the compact descriptive information provided by the latter with a more prediction-oriented multivariate model.

The proposed implementation of BNs on province-level data constitutes an illustrative application of the methodology. The obtained DAG reveals meaningful relations between variables that are consistent with the subject matter knowledge described in the related literature. The network could be thus interrogated to simulate predictive scenarios and explore how the DAG can be used as a decision support system. Further analysis will be carried out to investigate the full potential of this approach.

An Alternative Aggregation Function for the UNDP Human Development Index

Un metodo alternativo per aggregare le dimensioni dell'Indice di Sviluppo Umano

Manuela Scioni[1] and Paola Annoni[2]

Abstract Several composite indices have been proposed in literature to measure well-being or quality of life. A fundamental point in the construction of composite indices in this context is the degree of compensability among the different components of the index. We propose an alternative aggregation function in these cases and apply it to the UNDP Human Development Index (HDI). The method we propose adopts the generalized mean of order 0.5 for the HDI dimensions and adds a penalty to countries with an unbalanced dimension profile, to mitigate the level of compensability. The proposed method allows for adjusting the level of compensability between composite index components, providing a useful instrument when constructing an aggregate metric in general, with particular relevance in the social field.

Abstract *Numerosi indici compositi sono stati proposti in letteratura per misurare il benessere o la qualità della vita. In questo contesto un aspetto fondamentale è il grado di compensabilità ammesso tra le diverse componenti dell'indice. Obiettivo di questo lavoro è proporre un metodo di aggregazione da utilizzare in queste situazioni e analizzarne l'applicazione all'Indice di Sviluppo Umano dell'UNDP (HDI). Il metodo proposto utilizza la media generalizzata di ordine 0.5 a cui viene aggiunta una penalità per i paesi le cui dimensioni presentano un profilo non bilanciato, in modo da mitigare l'effetto compensabilità. Tale metodo permette di controllare il livello di compensabilità tra le componenti, aspetto utile nel costruire una metrica aggregata in generale, e in modo particolare in ambito sociale.*

1. Introduction

Based on the need to go beyond conventional economic measures, and in particular beyond the Gross Domestic Product (GDP), several composite indices have been proposed in the last decades to measure well-being or quality of life. The issue of aggregation in the search for a scalar measure of quality of life is "often perceived as the single most important challenge faced by quality-of-life research" (Stiglitz, Sen and Fitoussi, 2009, pg 56). A fundamental point in the construction of composite indices in this context is the degree of compensability allowed among individual indicators because the deficiency on one aspect shall not be offset by the surplus on another. For this reason, for summarizing the indicators into a single number "partially compensatory" or "non-compensatory" approaches shall be preferred. A well-known composite index that serves as a representative example of this "dilemma" is the Human Development Index (HDI) by the United Nations Development Programme (UNDP, 2010; 2019). Having received quite few criticisms (Desai, 1991; Sagar and Najam, 1998), the HDI developers moved away from the arithmetic mean in 2010. Since then the index is obtained as geometric mean of three dimensions: D1) Life expectancy at birth, D2) Schooling (arithmetic mean of expected years of schooling and mean years of schooling) and D3) Gross National Income (GNI) per capita (natural logarithm). This paper employs the "generalized mean-min" method (Annoni and Scioni, 2022) as an alternative method for the HDI dimensions and investigates the effects on country scores. The "generalized mean-min" method introduces an additive penalisation to country's unbalanced profiles, thus mitigating the compensability among the HDI dimensions. The paper unfolds as follows: Section 2 provides an overview of some aggregation procedure that concerns this application. Section 3 describes results. Concluding remarks are in Section 4.

2. Controlling the level of compensability

The family of the generalised means of order β allows for controlling the level of compensability between the indicators/dimensions in a composite index (Annoni and Weziak-Bialowolska, 2016; Casadio Tarabusi and Guarini 2013; Decancq and Lugo 2013). Let x_{ji} denote the score of indicator (or dimensions) j $(j = 1, \dots, q)$for unit i $(i = 1, \dots, n)$, the generalized mean of order β can be expressed as follows:

$$I_i^{(\beta)} = \left(\frac{1}{q} \sum_{j=1}^{q} w_j x_{ji}^{\beta} \right)^{1/\beta} \qquad \beta \neq 0 \tag{1}$$

where $\{w_1, \dots, w_q\}$ are non-negative weights normalised to have unitary sum and β is

a constant, possibly negative. The indicators (dimensions) are all assumed to be in $\Re+$ and positively oriented with the phenomenon to be measured, for example in the case of the HDI, the higher the dimension's value, the higher the level of human development. Functions $I_i^{(\beta)}$ depend on the value of β. Special cases include the arithmetic mean for $\beta = 1$ and the minimum function (MIN) for the limit value $\beta \to -\infty$ (Decancq and Lugo, 2013; Casadio Tarabusi and Guarini, 2013). The former is a fully compensatory aggregation function whilst the latter is a fully non-compensatory aggregation function. If $\beta = 0$ the generalised mean is defined as the geometric mean, a partially compensatory function. While linear aggregation assumes constant trade-offs among the indicators, geometric aggregation offers inferior compensability for indices with lower values (diminishing returns) (Greco et al., 2019; Munda and Nardo, 2005). In terms of compensability, the family of generalised means of order $\beta \in (0,1)$ occupy an intermediate position, between the arithmetic and the geometric mean.

We apply here the "generalized mean – min" *GMM* function as an alternative aggregation method of the HDI dimensions that introduces a penalty proportional to the unbalance of each country score across the index dimensions (Annoni and Scioni, 2022). The *GMM* function, that is an adaptation of the "mean - min" method originally proposed by Casadio Tarabusi and Guarini (2013), is a two parameters function and uses the generalized mean of order $\beta = 0.5$ plus a penalty applied for the countries with very different values across the three HDI dimensions. For each country i, the penalised HDI score - HDI_{GMM}- is computed as follows:

$$HDI_{GMM}(x_1, x_2, x_3) = \bar{x}_{GM} - \alpha\left(\sqrt{(\bar{x}_{GM} - \min_x)^2 + \gamma^2} - \gamma\right) \quad (2)$$

where (x_1, x_2, x_3) are the HDI dimension scores for country i, $\bar{x}_{GM}$is the generalised mean of order $\beta = 0.5$, $\min_x$= min (x_1, x_2, x_3), the parameter α is the intensity of penalisation for unbalance $(0 \leq \alpha \leq 1)$ and $\gamma \geq 0$ is the level of substitutability between the dimensions. Parameters α and γ are key elements for the choice of the penalisation. Casadio Tarabusi and Guarini (2013) propose $\alpha = \gamma = 1$ as "reasonable values" corresponding "to an intermediate easy case of adjustment with incomplete and progressive compensability" (pg. 31), but guidelines for the selection of these parameter values is not provided in their original proposal. Annoni and Scioni (2022) proposed an empirical, data-driven method to choose the value of the parameters.

Between the two parameters, α is the one with the most limited variability and with the mildest impact on the compensability effects. We set $\alpha = 0.75$. The values $\alpha = 0.5$ and $\alpha = 1$ were also tested but discarded because they led to iso-curves either too linear ($\alpha = 0.5$) or too sharp-cornered ($\alpha = 1$)[1].

The range of variation of γ depends on the order of magnitude of the unbalance term $(\bar{x}_{GM} - \min_x)$. The maximum value of $\Delta = \sqrt{(\bar{x}_{GM} - \min_x)^2 + \gamma^2} - \gamma$ is equal to $(\bar{x}_{GM} - \min_x)$ if $\gamma = 0$ and monotonically decreases as γ increases. If $\gamma \gg (\bar{x}_{GM} - \min_x)$, then γ prevails over the unbalance making it irrelevant in the penalisation term. To select the value of γ we examine two types of graphs:

[1] Results are not shown for sake of brevity.

1) The iso-curves of the penalisation component $\Delta = \sqrt{(\bar{x}_{GM} - \min_x)^2 + \gamma^2} - \gamma$, expressed as a function of γ and of the unbalance $(\bar{x}_{GM} - \min_x)$, moving γ between 0 and the maximum value of the unbalance;

2) The histograms showing the distribution of the unbalance

Figure 1 shows these two graphs for the 2019 HDI (https://hdr.undp.org/en/composite/HDI). The histograms, that depend on the HDI data and not on parameters α and γ, help us assessing the entity and distribution of the unbalance in the case study. Penalisation iso-curves inform us on the choice of γ. For a given a value of γ (here possible values of γ are chosen in between 0 and 0.22), the iso-curves allow us to assess how the penalisation component Δ changes for different values of the unbalance. The two graphs shall be jointly read. For example, for a positively skewed distribution of the unbalance, we would choose a γ value close to 0, in order to differentiate as much as possible the penalization value. In the case of the HDI, the unbalance distribution is quite symmetrical, so we select the value of γ so as to reach a compromise between two extreme situations: the case with minimum or null penalty, Δ close to 0, and the case with maximum penalty. The former case corresponds to the darker area in Figure 1 (left-had side), whilst the latter to the lighter area. This analysis led us to choose $\gamma = 0.1$.

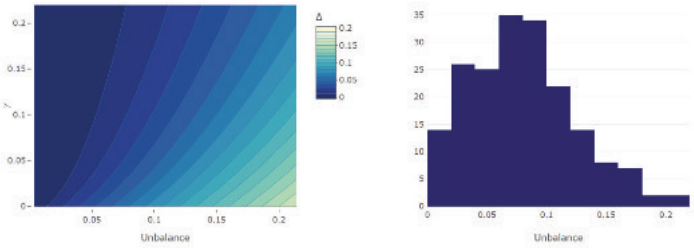

Figure 1 Iso-curves of the penalization components and histograms of the unbalance distribution across the countries

To validate this empirical way of proceeding, a second step is needed. If the aim is to get a level of compensability that is in between maximum penalisation and no penalisation, the shape of the observed iso-curves shall be in between the L-pipe shape and the straight line. To this purpose we aggregate pairwise each HDI dimensions using the *generalised mean-min* aggregation function (2) with $\alpha = 0.75$ and $\gamma = 0.1$ and analyse their corresponding iso-curves. The value of γ is confirmed since the iso-curves have a shape in between the straight line (fully compensatory) and the L-pipe (fully non compensatory)[1].

4. Results

The map in Figure 2 shows the percentage difference between the benchmark (HDI) and the penalised scores (HDI_{GMM}) across the 189 countries assessed by the UNDP.

[1] Figure not shown

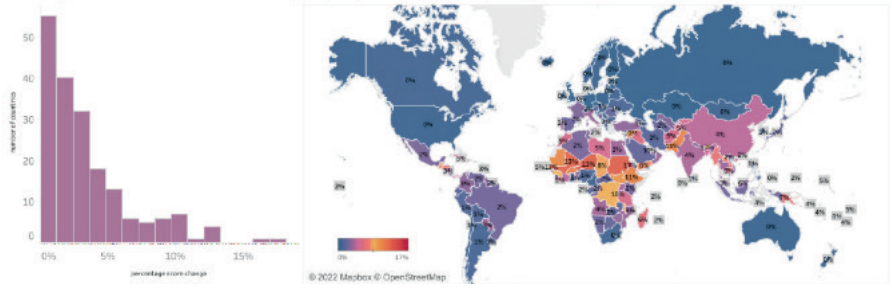

Figure 2 Percentage difference between the HDI and the penalised HDI_{GMM} country scores. Positive changes correspond to a deterioration of the score (the change is defined as: $(HDI - HDI_{GMM})/HDI$.

As expected, the proposed method has the effect of an overall penalisation: all the countries get a score lower than or equal to the HDI one, here considered as the benchmark. The 2019 HDI average is 0.72, while the average HDI_{GMM} is 0.70 (on a 0-1 scale). The level of penalisation goes from a minimum of 0 to a maximum of 0.10, with an interquartile range between 0.008 and 0.035. The percentage difference between the 2019 HDI and the HDI_{GMM} ranges in between 0 and 17.4%.

The penalisation method does not completely disrupt the HDI picture, though, as the correlation between the HDI and HDI_{GMM} scores remains high (0.995 with a p-value<0.001).

The penalisation is less pronounced for countries characterised by a balanced profiles. Amongst the most stable ones, we find Australia and Cameroon. They score very differently on the 2019 HDI, 0.94 for Australia and 0.56 for Cameroon, but their scores do not change with the *GMM* method because their performance is balanced across the three dimensions (Figure 3, top). Among the countries that deteriorate the most, we find Qatar (HDI=0.85, percentage difference=10%) and Senegal (HDI=0.51, percentage difference=17%) (Figure 3, bottom), both penalised by a relatively poorer performance on the Education dimension.

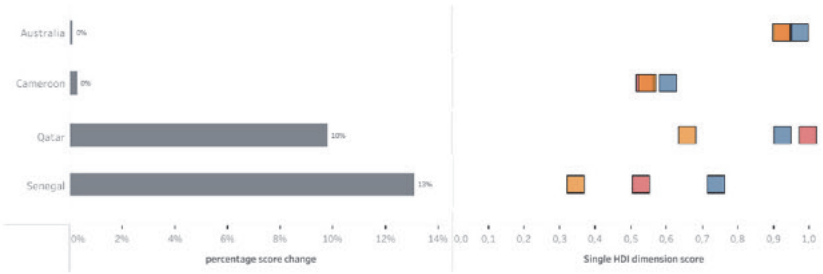

Figure 3 Percentage difference between the HDI and HDI_{GMM} for some countries and corresponding dimensions' scores.

4. Concluding Remarks

Building metrics of well-being or quality of life poses various methodological challenges. The paper addresses the issue of the type of aggregation and uses the Human Development Index (HDI) developed by the UNDP as case study. We apply an alternative aggregation function, the "generalized mean-min" method, to the 2019 HDI that first aggregate the three dimensions through the generalised mean of order 0.5 and apply an additive penalty term (Annoni and Scioni, 2022). The aim is to control the level of compensability between the HDI dimensions. The penalty element is proportional to the unbalance of the country scores across the dimensions and depends on two parameters, α and γ, representing respectively the intensity of the penalisation and the level of compensability (Casadio Tarabusi and Guarini, 2013). The values of the two parameters are chosen following a data-driven approach. In the 2019 HDI case, the values $\alpha = 0.75$ and $\gamma = 0.1$ are found to be the ones ensuring the desired level of compensability, intermediate between full and null compensability. The comparison between the 2019 HDI scores and the penalised ones shows that all countries see their performance either staying the same or deteriorating. As expected, the penalisation effect is particularly evident for countries with an unbalanced profile across the index dimension scores. The proposed aggregation function further reduces the level of compensability among the HDI dimensions with respect to the geometric mean, currently adopted for the index. This is exactly the effect we want for a metric of this type where all the aspects are equally important and a good aspect shall not compensate for a poor one in another.

An ultrametric model for building a composite indicator system to study climate change in European countries

Un modello ultrametrico per la costruzione di un sistema di indicatori compositi per lo studio del cambiamento climatico nei paesi europei

Giorgia Zaccaria and Pasquale Sarnacchiaro

Abstract Nowadays climate change is one of the most urgent topics in public debate, also included into the 2030 Agenda for Sustainable Development adopted by the United Nations, because of its risks for human life. It represents a multidimensional phenomenon defined by different dimensions that pertain to greenhouse gas emissions, human causes of climate change, impacts on humans and natural systems, and efforts of human to avoid and adapt to the consequences, each of which is described by a set of variables directly observed. In this paper, we introduce a new model-based approach to study this phenomenon and its different characterization in European countries. The proposal aims at building a system of composite indicators in order to understand the main determinants of this phenomenon, and to provide guidelines for policy decisions to combat climate change in the European Union framework.

Abstract *Il cambiamento climatico è uno dei temi più urgenti nel dibattito pubblico, incluso nell'Agenda 2030 per lo sviluppo sostenibile adottata dalle Nazioni Unite, a causa dei rischi che può comportare per la vita umana. Esso rappresenta un fenomeno multidimensionale definito da diverse dimensioni, ognuna delle quali misurata da un insieme di variabili direttamente osservabili, che riguardano le emissioni di gas serra, le cause del cambiamento climatico, le sue conseguenze per gli umani e la natura e gli sforzi messi in campo dal genere umano per evitare e adattarsi a tali conseguenze. In questo lavoro, introduciamo un nuovo approccio basato su modello per studiare questo fenomeno e le sue diverse caratterizzazioni nei paesi europei. La proposta metodologica ha l'obiettivo di costruire un sistema di indicatori compositi per identificare i principali fattori che determinano il cam-*

biamento climatico e fornire di conseguenza indicazioni per attuare politiche nel contesto europeo volte a combattere il cambiamento climatico.

Key words: Ultrametric models, hierarchical structures, model-based clustering, composite indicators, climate change, sustainable development goals

1 Introduction

Climate change is a compelling topic in public debate because of its risks for human life. One of the main causes of this phenomenon pertain human activities, e.g., industrial processes, energy consumption by fossil fuels, agricultural exploitation of lands. An urgent action to combat these changes is needed. For these reasons, the United Nations included "climate action" within the goals of the 2030 Agenda for Sustainable Development, adopted in 2015 [6], that are monitored at European level by Eurostat throughout indicators and statistics.

In order to study and evaluate multidimensional phenomena as climate change, composite indicators are often used since they are able to summarize a big amount of information via a synthetic measure. Their construction is characterized by different choices that are usually normative, i.e., based upon experts' opinions or a theory known a priori [8]. For these reasons, methods for composite indicator construction are often criticized and considered to be not statistically rigorous [7]. In this paper, we discuss a new model-based approach to build a system of composite indicators for evaluating climate change at European level. In order to study this phenomenon and its different characterization in Europe, we consider the model introduced by Cavicchia, Vichi and Zaccaria [3]. The latter is an ultrametric Gaussian Mixture Model (GMM), where each component of the mixture has an ultrametric structure which is one-to-one associated with a hierarchy of latent dimensions. The idea herein is to extend the ultrametric GMM proposed by [3] to build a system of composite indicators, i.e., including the quantification of latent concepts for each level of the hierarchy, in order to study on which dimensions and in which countries policies to address climate change should be focused.

The paper is organized as follows. In Section 2 the essential background to introduce the methodology used in the paper is provided. Section 3 illustrates the ultrametric Gaussian Mixture Model, which is then applied to study climate change in European countries (Section 4). A final discussion completes the paper in Section 5.

2 Background

In order to define the parsimonious parameterization of the covariance matrix in Section 3, let us introduce the definition of a strict extended ultrametric covariance matrix [3].

Definition 1 (Strict Extended Ultrametric Covariance Matrix). A matrix $\boldsymbol{\Sigma}$ is said to be a *strict extended ultrametric covariance matrix* if all its elements $\sigma_{jl} \in \mathbb{R}$, for $j,l = 1,\ldots,p$, and the following conditions hold:

(i) *symmetry*: $\sigma_{jl} = \sigma_{lj}$ for $j,l = 1,\ldots,p$;
(ii) *positivity of the diagonal*: $\sigma_{jj} > 0$ for all $j = 1,\ldots,p$;
(iii) *ultrametric inequality*: $\sigma_{jl} \geq \min\{\sigma_{jh},\sigma_{lh}\}$, for $j,l,h = 1,\ldots,p$;
(iv) *strictly diagonal dominance*: $\sigma_{jj} > \sum_{\substack{l=1 \\ l\neq j}}^{p} |\sigma_{jl}|$ for $j = 1,\ldots,p$.

Condition (iv), together with conditions (i) and (ii), is sufficient for the positive definiteness of a matrix as shown by Brouwer and Haemers [2]. Definition 1 extends the definition of an ultrametric matrix introduced by Dellacherie et al. [4, pp. 60-61], which is limited to nonnegative matrices.

In the next section, we model the component covariance structure of a Gaussian Mixture Model via a strict extended ultrametric covariance matrix.

3 Methodology

Let $\boldsymbol{x} = (\boldsymbol{x}_1,\boldsymbol{x}_2,\ldots,\boldsymbol{x}_n)$ be a random sample - where $\boldsymbol{x}_i$ is a p-dimensional random vector - which is drawn from a population composed of G subpopulations. Suppose that, conditional on the membership to the subpopulation, the density of $\boldsymbol{x}_i$ is the following

$$f(\boldsymbol{x}_i|\boldsymbol{\Psi}) = \sum_{g=1}^{G} \pi_g \, \phi\big(\boldsymbol{x}|\boldsymbol{\mu}_g, \mathbf{V}_g(\boldsymbol{\Sigma}_{\mathrm{W}g} + \boldsymbol{\Sigma}_{\mathrm{B}g})\mathbf{V}_g' - \mathrm{diag}(\mathbf{V}_g\boldsymbol{\Sigma}_{\mathrm{W}g}\mathbf{V}_g') + \mathrm{diag}(\mathbf{V}_g\boldsymbol{\Sigma}_{\mathrm{V}g}\mathbf{V}_g')\big), \tag{1}$$

where $\pi_g, g = 1,\ldots,G$, are the mixing proportions (prior probabilities), and the component covariance structure is parameterized according to a strict extended ultrametric covariance matrix subject to the following constraints

$$\mathbf{V} = [v_{jq} \in \{0,1\} : j = 1,\ldots,p, q = 1,\ldots,Q]; \tag{2}$$

$$\mathbf{V}\mathbf{1}_Q = \mathbf{1}_p \quad \text{i.e.} \quad \sum_{q=1}^{Q} v_{jq} = 1 \quad j = 1,\ldots,p; \tag{3}$$

$$\boldsymbol{\Sigma}_{\mathrm{B}} = \boldsymbol{\Sigma}_{\mathrm{B}}', \mathrm{diag}(\boldsymbol{\Sigma}_{\mathrm{B}}) = \mathbf{0}, {}_B\sigma_{qh} \geq \min\{{}_B\sigma_{qs}, {}_B\sigma_{hs}\} \; q,h,s = 1,\ldots,Q, \; s \neq h \neq q; \tag{4}$$

$$\min\{{}_W\sigma_{qq} : q = 1,\ldots,Q\} \geq \max\{{}_B\sigma_{qh} : q,h = 1,\ldots,Q, h \neq q\}; \tag{5}$$

$${}_V\sigma_{qq} > |{}_W\sigma_{qq}|\Big(\sum_{l=1}^{p} v_{lq} - 1\Big) + \sum_{\substack{h=1 \\ h\neq q}}^{Q} |{}_B\sigma_{qh}| \sum_{l=1}^{p} v_{lh} \quad q = 1,\ldots,Q. \tag{6}$$

$\boldsymbol{\Psi} = \{\pi_g, \boldsymbol{\mu}_g, \boldsymbol{\Sigma}_{\mathrm{V}g}, \boldsymbol{\Sigma}_{\mathrm{W}g}, \boldsymbol{\Sigma}_{\mathrm{B}g}, \mathbf{V}_g : g = 1, \ldots, G\}$ is the overall parameter vector, where $\mathbf{V}_g$ is a membership matrix which defines a partition of the variable space into a reduced number of groups Q, each one associated with a latent dimension, $\boldsymbol{\Sigma}_{\mathrm{V}g}$ is a diagonal matrix of order Q whose diagonal entries represent the variance of the variable groups, $\boldsymbol{\Sigma}_{\mathrm{W}g}$ is a diagonal matrix of order Q whose diagonal values identify the covariance within the variable groups, and $\boldsymbol{\Sigma}_{\mathrm{B}g}$ is the matrix of order Q whose off-diagonal elements represent the covariance between the groups. The ultrametric paramaterization of the component covariance structure leads to a hierarchy of latent concepts which can assume different characterizations in the components (subpopulations) of the mixture.

The proposal is estimated via a grouped coordinate ascent algorithm [9, 1] by maximizing the objective function defined by Hathaway [5], which is equivalent to maximize the log-likelihood function of (1).

4 A composite indicator system for evaluating climate change in European countries

Every year, Eurostat collects data for monitoring progress towards the Sustainable Development Goals (SDGs) at European level. In order to study climate change, impacts on humans on it and actions to combat it, indicators related to different goals and measured for the 27 European countries and the United Kingdom can be considered. Indeed, other than the indicators defined to monitor Goal 13 - *Climate Action*, e.g., greenhouse gas emissions, we consider variables for measuring the level of pollution in groundwater and rivers (Goal 6 - *Clean Water and Sanitation*), energy consumption and renewable energy production (Goal 7 - *Affordable and Clean Energy*), exposure to air pollution (Goal 11 - *Sustainable Cities and Communities*) and generation of waste (Goal 12 - *Responsible Consumption and Production*). In detail, we include in our analysis indicators from different goals of the SDGs measured on the 27 European countries and the United Kingdom, and we use their population size (i.e., number of inhabitants) to normalize the variables in order to perform comparison among countries.

The motivation of this study lies on the assumption that it is crucial to combine information from different goals in order to define a general composite indicator for measuring climate change, and a system of specific composite indicators that define it. Indeed, the researcher could be interested in identifying dimensions of the phenomenon under study to which policies should be addressed in order to progress towards climatic goal.

5 Conclusions

In this paper, we provide a new hierarchical model-based approach to build a system of composite indicators, and inspect the nested relationships among specific indicators that define the general latent concept under study. The proposal is based upon the ultrametricity notion, which is related to hierarchical (tree) structures, and its implementation in Gaussian mixture models [3]. In particular, we focus on the analysis of climate change by identifying its dimensions and its different characterizations in European countries. The proposal aims at providing guidelines for policy decisions to combat climate change in the European Union framework.

Functional Weighted Malmquist Productive Index: a proposal for a dynamic composite indicator

L'indice di produttività di Malmquist funzionale pesato: una proposta per un indicatore composito dinamico

Annalina Sarra and Eugenia Nissi and Tonio Di Battista

Abstract Over time, composite indicators have gained extraordinary popularity in a wide variety of areas of research. Undeniably, the many stages in the construction process of a composite index involve compromises and subjective choices. In this work, restricting our attention on the weighting of indicators, we rely on a data-oriented weighted method. A combination of the Beta profile measure and Malmquist Index, is the proposed approach for meeting the challenge of a constructing a dynamic composite indicator. The originality of the study lies in tracking the temporal evolution of the phenomenon of interest by means of functional tools. The appropriateness of our procedure under specific situations, such as presence of outliers, variation of sample size and collinearity between indicators, is validated through a simulation experiment.

Abstract *Nel tempo, gli indicatori compositi hanno guadagnato una popolarità straordinaria in un'ampia varietà di aree di ricerca. Innegabilmente, le molte fasi del processo di costruzione di un indice composito comportano compromessi e scelte soggettive. In questo lavoro, limitando la nostra attenzione alla ponderazione degli indicatori, ci affidiamo a un metodo ponderato orientato ai dati. Una combinazione della misura Beta profile e dell'indice Malmquist è l'approccio proposto per affrontare la sfida di costruire un indicatore composito dinamico. L'originalità dello studio risiede nel tracciare l'evoluzione temporale del fenomeno di interesse attraverso strumenti funzionali. L'adeguatezza della nostra procedura in situazioni specifiche, come la presenza di valori anomali, la variazione della dimensione del campione e la collinearità tra indicatori, viene convalidata attraverso un esperimento di simulazione.*

1 Introduction

In the last years, there is a large agreement in the scientific community regarding the multifaced nature of complex social and natural phenomena, like, for instance, well-being, environment, poverty, human development, innovation. As a result, traditional measurements based on a single variable are now often replace by multidimensional methods (see, among others, [14], [11]). A large number of studies grounded in a multidimensional approach rely on the use of composite indicators (CIs). According to the Organisation for Economic Co-operation and Development (OECD) Glossary of Statistical Terms, "a composite indicator is formed when individual indicators are compiled into a single index on the basis of an underlying model of the multi-dimensional concept that is being measured" [10]. Thanks to their ability to convey large amount of information in a unique measure, CIs are currently employed in various areas of research, for policy analysis, benchmarking comparison, performance monitoring, public communication and decisions. In such way, they enhance the public debate on important issues. Building a composite indicator is far from trivial and there is not a single universal method for achieving taxonomic measures ([1], [9], [12]). Despite their widespread use from governments and international organizations, CIs are not exempt from criticism that surrounds the different steps involved in their construction. Following the recommendations of the document published by the OECD [12], it is well established that the construction decisions range from the selection of a set of sub-indicators, to the standardization method, the weighting and the choice of the aggregation function. In each step, the analyst is tasked with the responsibility of multiple decisions, often compromises and subjective choices, that can have a large impact on the final outcome (e.g.ranking). Our paper contributes to the research on the creation of comparable CIs by presenting a proposal for the construction of a dynamic index, that enables comparative trend analysis. In the proposal, we focus the attention on a fundamental component of index aggregation, namely the weighting of indicators. Specifically, we rely on a data-oriented weighting method, known as Data Envelopment Analysis (DEA). Different works document the application of the DEA in the field of CIs, providing alternative weighting systems (see, among others, [5]). This works takes one step further and addresses the issue of change of performance of units over time, proposing a Functional Weighted Malmquist Productivity Index (hereafter, FWMPI). The rest of the paper is organized as follows. In Section 2, we present the proposed methodological approach and outline the underlying techniques. In Section 3, we give the details of a simulation experiment, while Section 4 concludes the paper.

2 Methodology: the framework

Data Envelopment Analysis (DEA), first introduced by Charnes et al. [3], is a well-known non-parametric method based on linear programming, used for measuring the relative efficiencies of homogenous entities, called Decision Making Units (DMUs), characterised by multiple outputs and inputs. Mathematically, DEA model generates an efficiency score, ranges in an interval from 0 to 1, with efficient DMUs achieving a score of 1 and inefficient DMUs a lower score. The application of DEA to the field of the composite indicators helps to overcome some key limitations. Specifically, the quality of DEA of looking for endogenous weights, for the aggregation of the domains considered into a single composite index, explains a major part of the appeal of DEA-based CIs in real policy-related settings [4]. Within the DEA methodology, the correct way to track the temporal evolution of the phenomenon of interest is by computing the Malmquist Productivity Index (MPI), introduced by Caves et al. [2]. The overall tendency in productivity changes of DMUs over time periods is traditionally obtained through the average of productivity indices of sequential times, implicitly assuming that all sectional indices equally affect the level of productivity. In this work, to eliminate the equal weight effect, we propose a Functional Weighted Malmquist Productive Index (FWMPI). Let us assume to have a set of n DMUs, each having m unitary input denoted by a vector $\mathbf{x}_j$ and s output denoted by a vector $\mathbf{y}_j$, for $(j = 1,\dots n)$, over the periods t and $t+1$. The Malmquist Productivity Index (MPI) allows to calculate the relative performance at different periods of time and is a cross measure, which considers the production of a DMU as the efficient frontier built in the next or previous instant:

$$MPI_0 = \left[\frac{\theta^t x_0^t y_0^t}{\theta^t x_0^{t+1} y_0^{t+1}} \frac{\theta^{t+1} x_0^t y_0^t}{\theta^{t+1} x_0^{t+1} y_0^{t+1}} \right]^{\frac{1}{2}} \tag{1}$$

where $\theta^t x_0^t y_0^t$ and $\theta^t x_0^{t+1} y_0^{t+1}$, $\theta^{t+1} x_0^t y_0^t$ and $\theta^{t+1} x_0^{t+1} y_0^{t+1}$ are respectively the input oriented efficiency measures of DMU_0 at period t and t+1. MPI_0 measures the productivity change between periods t and t+1 [8].

The Malmquist indices computed at two sequential times t and t+1 are denoted by $MPI_{jt}, \quad j = 1\dots n, \quad t = 1,\dots k$. We obtain more objective weights in aggregating the Malmquist indices by averaging the entries of MPI matrix, displayed in Table 1, where the rows represent the MPI measures over times, and the columns represent the DMUs.

Table 1 MPI matrix

	MPI1	MPI2	....	MPIk
DMU_1	MPI_{11}	MPI_{12}	....	MPI_{1k}
DMU_2	MPI_{21}	MPI_{22}	....	MPI_{2k}
DMU_3	MPI_{31}	MPI_{32}	....	MPI_{3k}
....	....	....	....	....
....	....	....	....	....
DMU_n	MPI_{n1}	MPI_{n2}	....	MPI_{nk}

In this work, following the idea of Fallahnejad [7], based on entropy measure and Malmquist method, we propose a functional approach to the problem at hand, adopting the β diversity profile [13]. The overall procedure allows to obtain a functional weighted MPI that facilitates the comparative analysis of the weighted MPI curves. In this regard, it is important to stress that the ranking of DMUs are achieved by means of functional tools, such as analysis of derivatives, radius of curvature and length of a curve, as suggested in [6].
Our proposal can be illustrated via some established steps, as detailed below.
In **Step 1**, the matrix in Table 1 is normalized dividing each element of the column by the sum of column:

$$p_{jt} = \frac{MPI_{jt}}{\sum_{j=1}^{n} MPI_{jt}} \tag{2}$$

The above normalization allows to eliminate anomalies due to different measurement units and scales.
Step 2: find the β diversity profile for all normalized MPI, computed as:

$$\Delta_\beta = \sum_{i=1}^{n} \frac{(1-p_{jt})^\beta}{\beta} p_{jt} \quad \beta \geq -1 \tag{3}$$

In Eq.3, $\sum_{i=1}^{n} \frac{(1-p_{jt})^\beta}{\beta}$ can be interpreted as a measure of relevance of each DMU for the change in productivity over time expressed by each MPI and p_{jt} is defined as above.

Step 3 involves the computation of the degree of diversification, defined as:

$$d_t = 1 - \Delta_\beta \tag{4}$$

In **Step 4** the degree of importance of FMPI at time t is obtained by setting

$$w_t(\beta) = \frac{d_t(\beta)}{\sum_{s=1}^{k} d_s(\beta)} \quad \forall \beta \tag{5}$$

In **step 5**, the functional weighted MPI is calculated as:

$$FWMPI_j(\beta) = \sum_{t=1}^{k} w_t(\beta) MPI_{jt} \quad \forall \beta. \tag{6}$$

3 Simulation design

In this section, we set up a simulation experiment to compare the performance of the Fallahnejad's algorithm and our approach under specific situations, such as presence of outliers, variation of sample size and collinearity between indicators. Specifically, the aim is to document which of the two compared methods leads to a ranking that is substantially closer to outlier-free data. In the simulation setup, we consider

the case of extreme values generated from the Uniform distribution as detailed below, and compare indicators from different sample sizes, over three time periods. The average rank shift (ARS) is used to measure the rank difference between the scalar (Fallahnejad's algorithm) and functional (our proposal) versions of weighted Malmquist index for the DMUs. ARS is defined as:

$$ARS = \frac{1}{n}\sum_{i=1}^{n} |RANK(CIs) - RANK(\tilde{CIs})| \tag{7}$$

In Eq.7, CIs and $\tilde{CIs}$ represent the composite indicator values of a DMU calculated from data contaminated and non-contaminated with extreme values (or Fallahnejad's algorithm *versus* FWMPI). In our simulation experiment, for each period of time, we generate four indicators (I_1,I_2, I_3, I_4) from a Uniform distribution within the interval [5,15] and assume there is no collinearity between them. We successfully vary the collinearity between indicators from no to high correlation. In our setting, we contaminate indicators with extreme values generated from Uniform distribution:

$\tilde{I_1c} \sim \mathrm{U}(k_1 max(I_1); k_2 max(I_1))$,
$\tilde{I_2c} \sim \mathrm{U}(k_1 max(I_2); k_2 max(I_2))$,
$\tilde{I_3c} \sim \mathrm{U}(l_1 min(I_3); l_2 min(I_3))$,
$\tilde{I_4c} \sim \mathrm{U}(l_1 min(I_4); l_2 min(I_4))$,
respectively.

Note that the parameters k_1, k_2 contribute to outlyingness of extreme values on the right tail, while the parameters l_1, l_2 are responsible for the left tail. We set $k_1 = 2$, $k_2 = 3$, $l_1 = 0.2$ and $l_2 = 0.3$. We also enlarge the outlyingness of extreme values over time by increasing k_1, k_2 to 4 and 6 for time period 2 and to 6 and 10 for time period 3, respectively. To randomly select the observations to be contaminated, we define a contamination level ε. Simulation results are obtained under three different scenarios, retained constant over time: no contamination level of contamination ($\varepsilon = 0$) , $\varepsilon = 0.025$ and $\varepsilon = 0.05$. Results of analysis based on simulated data indicate that the FWMPI has the lowest rank shift. Therefore, it follows that our approach enables to weaken the impact of outliers on the ranking of treated DMUs.

4 Conclusions

In recent years CIs have substantially gained in popularity, becoming prevalent as a useful tool for policy evaluations and public communication for understanding multidimensional phenomena. However, it is well acknowledged that if composite indicators are poorly constructed they can affect the overall ranking and send misleading policy messages. It follows that a thorough assessment of assumptions at all stages of construction is required. In this paper, we have contributed, with a dynamic approach, to the research on the creation of comparable composite indicators. Specifically, we have focused on the important issue when constructing composite

indices that comes from the choice of weighting schema of indicators. The existing literature offers a rich menu of alternatives for determining the weights of the components of synthetic measures. As a starting point in our proposal, we have opted for DEA as a data-oriented weighted method. Once we have obtained a measure of the efficiency change over time by means of Malmquist indexes, we proceeded on constructing a functional weighted MPI by integrating the Malmquist DEA scores with the Beta profile. Our methodological approach takes advantages of tools borrowed from Functional Data Analysis, for successfully meeting the challenge of comparative trend examinations. The appropriateness and versatility of the proposal have been validated through a simulation experiment where specific situations, such as presence of outliers, variation of sample size and collinearity between indicators, are taken into account. The sensitivity analysis conducted in this paper, allows us to conclude the robustness of using a functional weighted MPI improves the reliability of CIs ranking over time for policy making.

CFA & PLS-PM for UX-AI product infused
CFA & PLS-PM per l'utilizzo di smart speakers basati su AI

Emma Zavarrone and Rosanna Cataldo[1]

Abstract Since their appearance, artificial intelligence (AI) products have increasingly integrated into our daily life and today they are becoming an ever more pervasive reality. However, our expectations often exceed the current potential performance of AI products, causing disappointment and frustration. Starting from this consideration and taking smart speakers as a reference, the work studies new scale validation oriented to evaluate the user Experience (UX) with AI-infused products. The work compares the results of three-order model under the perspective both in the Partial Least Squares-Path Modeling and in the confirmatory approach.

Abstract *Oggi gli smart speakers basati sull'Intelligenza Artificiale stanno diventando una realtà sempre più pervasiva. Purtroppo, non sempre le aspettative degli utenti sono realmente soddisfatte dalle performance dei prodotti. Il lavoro propone e valida una nuova scala volta a valutare le dimensioni più adatte per valutare le esperienze degli utenti (UX). L'analisi confronta i risultati, considerando l'analisi confermativa e i modelli ad equazioni strutturali.*

Key words: AI-infused products, Confirmatory Factor Analysis, Partial Least Squares- Path Modeling

1 Introduction

Proposing measurement scales to frame the User Experience (UX) of a new generation of products infused with Artificial Intelligence (AI) has been the source of many researches. The literature review (Spallazzo and Sciannammè, 2021) based on 129 papers has highlighted the overlapping of measurement scales able to capture the UX generalist dimensions without covering the aspects linked to Human Computer Interaction (HCI) and AI. These results are consistent with previous studies which had already tackled the issue (Vermeeren *et al.*, 2010; Bargas-Avila and Hornbæk, 2011; Rivero and Conte, 2017; Pettersson *et al.*, 2018). They spotted the main trends and paved the way to new UX research, highlighting, for instance, that it should cope with ever-evolving technologies and non-human intelligence (Pettersson *et al.*, 2018). In general, all these studies focused only on usability, pleasantness of use, emotion/affect, and enjoyment. Furthermore, the literature reveals no agreement on the use of terminology, and sometimes the same words are used without careful attention to the semantic nuances or interchangeably as dimensions and descriptors and items. Our research is placed in this scenario. The purpose of this work is the construction and validation of a scale, defined UX-AI, that takes into consideration, in addition to the aspects already known in the literature, other different aspects. Section 2 is devoted to introducing the model hypothesis characterized by detecting the common core shared between HCI and UX dimensions. Section 3 presents data and compares the results under the perspective both in Partial Least Squares- Path Modeling (PLS-PM) and in the confirmatory approach.

2 Model

The research of a theoretical measurement framework in which the most crucial latent dimensions characterized the UX are clustered, has moved us to choose a reflexive paradigm. Under this perspective we follow the development of UX-AI scale adopting the classical paradigm proposed by Gerbing and Anderson (1988) approach. The paradigm is characterized by four steps: literature review; focus group and item generations, item selection and model validation. The first two steps have been realized conjointly with the Meet AI, a research group of Politecnico of Milan. The hypothetical latent dimensions and their links have been identified by Spallazzo and

Sciannammè (2021), composed by *Pragmatic, Hedonic, Aesthetic,* and *Affective* ones can be considered as second order constructs. Each second order construct can be organized in terms of the first-order constructs as described in Table 1.

Table 1: Latent dimensions and their descriptors

Second Order Constructs	First-Order Constructs
Pragmatic	Helpfulness, Efficiency, and Functionality, easiness, simplicity, clearness, navigation, learnability, reliability, and convenience
Hedonic	Enjoyability, excitement, creativity, inventiveness, innovativity
Aesthetic	Appearance, attractiveness, enjoyability, excitement, creativity, inventiveness, and innovativity
Affective	Valence and arousal

The *Pragmatic* dimension concerns the use of an artifact in terms of *helpfulness, efficiency,* and *functionality*, *easiness, simplicity, clearness, navigation, learnability, reliability, and convenience*. The *Aesthetics* presents multiple facets, can mainly be interpreted in terms of the first order constructs: *appearance* (where *clarity* and *sophistication* are two recurring themes), or *attractiveness* (*good* and *pleasant* qualities being frequently assessed). The *Hedonic* dimension often overlaps with the affective one, as their borders are very subtle. *Enjoyability* and *excitement*, *creativity*, *inventiveness,* and *innovativity* appear to have their weight. Finally, the *Affective* component is largely influenced by basic emotions: *pleasure, fear, sadness, happiness, disgust, anger*, and *surprise* disseminated through referral and appraisal.

The innovative dimensions not explored in the literature but identified following the focus group step are indicated: ***Trustworthiness:*** concerns *accuracy, data management, data protection, reliability,* and *transparency*. ***Conversational dimension:*** is mostly relatable to *accuracy, context awareness, understanding, feedback quality*, *fluidity* and *naturalness*. ***Intelligence:*** presents some traits reminding human capabilities (e.g. *learning, understanding needs, companionship*), and others strictly linked to the machine dimension (e.g. *data elaboration, connectivity*). ***Meaningfulness:*** mostly appeal to the human-computer/product relationship.

The proposed model suggests configuring an endogenous UX third-order dimension linked through the second and first order constructs according to Figure 1 and Table 2.

Table 2: Hierarchical model

Third Order Construct	Second Order Constructs	First-Order Constructs
UX	Intelligence (INT)	Accuracy
		Adaptability
		Context awareness
		Understanding
	Trustworthiness (TRU)	Accuracy
		Data management
		Privacy
		Reliability
		Transparency
		Pragmatic (PRA)
		Hedonic (HED)
		Conversational dimension (CON)
		Meaningfulness (MEAN)

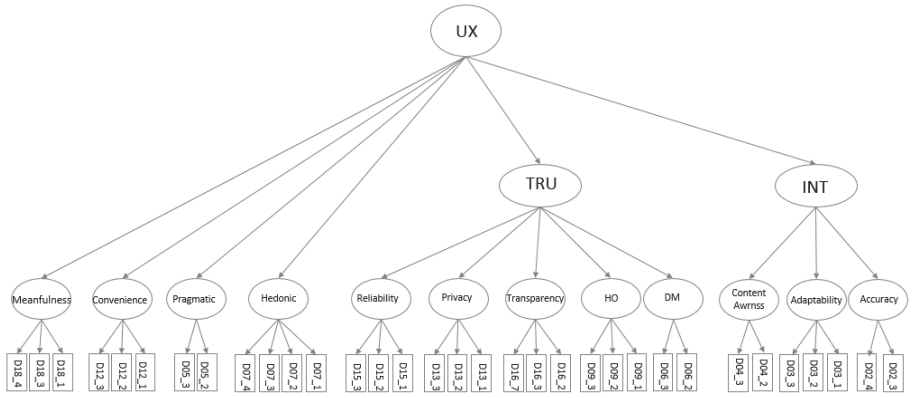

Figure 1: Reflective Hierarchical Model

The item generation step has defined 139 items with an ordinal four-point scale. The choice of even points has been setted for avoiding the uncertainty by forcing the respondent to express an opinion. Recent studies (Rhemtulla et al., 2012) have highlighted that a score with an ordinal nature doesn't represent a limit for the development of a scale in a reflective perspective. The generated pool of items has been evaluated by experts in order to test both the content and face validity and reliability in a pre-test analysis. In this step a considerable reduction of items has been realized obtaining 65 items, on average seven first-order constructs. In a second step a further reduction led to obtaining 33 items, on average three first-order constructs. This structure was validated under both Confirmatory Factor Analysis (CFA) and

PLS-PM approaches. Last step has been devoted to the comparison of the composite reliability

3 Data and Results

A further items reduction has been operated obtaining 36 items through EFA, applied on a polychoric correlation matrix composed of 75 items (collected on 671 Americans and British users) estimated with the WLS method. The validation stage has been characterized by the second survey composed of 735 units. Demo social variables have been measured conjointly with the device type for both the samples. Table 3 shows the structure of the second sample that has been used for applying the Confirmatory Factor Analysis (CFA) using a Diagonally weighted least squares (WLSMV) estimator and PLS-PM Analysis. The CFA excludes three items so the item final number becomes 33. The CFA and PLS-PM goodness of fit index and Cronbach coefficient for each dimension and for overall have been reported in Table 4.

Table 3: Socio-demographic analysis

Gender	58% Male; 42% Female
Country	50% UK; 50% USA
Age	27% 18-30; 23% 31-40; 18% 41-50; 14% 51-60; 18% over 60
Device	64% Amazon Echo; 17% Google Nest; 13% Apple; 6% Other
Use_Device	48% Frequently; 36% Sometimes; 12% Seldom; 4% Never

Table 4: CFA and PLS-PM Goodness of fit and Cronbach coefficients

		N Items	CFA	PLS-PM
Cronbach coefficients	**UX**	33	0.967	0.968
	INT	7	0.873	0.879
	PRA	2	0.800	0.807
	HED	4	0.914	0.914
	TRU	14	0.941	0.944
	CONV	3	0.866	0.872
	MEAN	3	0.873	0.877
Goodness measures			RMSEA= 0.042	GoF= 0.698
			SRMR= 0.033	
			CFI= 0.986	
Composite Reliability			0.99	0.97
AVE			0.89	0.73

About the reliability of the questionnaire, all dimensions present high Cronbach coefficients for both approaches. It is generally held that a Cronbach coefficient of over 0.7 is acceptable (Devellis, 2012; Cataldo et al. 2017).
About goodness of fit measures, for CFA the Root Mean Squared Error of Approximation (RMSEA) and Standardized Root Mean Square Residual (SRMR) are absolute measures of fit and that are used to assess how well the a priori models fits the sample data (a value lower than 0.05 indicates a good model fit), while the Comparative Fit Index (CFI) is a relative measure and assesses the relative improvement in fit of model compared with the baseline model (the conventional threshold for a good fitting model is greater than 0.90). For PLS-PM the Goodness of Fit can be used as a measure of goodness of the model.
As can be seen from Table 4, in our analysis the model presents a good fit as all measures exceed their respective thresholds. Under the two approaches composite reliability (CR), used for measuring internal consistency of items and average validity extracted (AVE), used for measuring on average, how much variations of items scale can be explained by the constructs have been computed. Overall CR and AVE have values greater than 0.75 and 0.5 respectively confirming the validity and reliability of the UX-AI scale.

Fertility, adulthood, and economic uncertainty

Uncertainty and fertility intentions: a comparison between the Great Recession and the Covid-19 crisis

Incertezza e intenzioni di fecondità: la Grande Recessione e la crisi pandemica a confronto

Chiara Ludovica Comolli

Abstract Theories of the fertility response to business cycle fluctuations consider crises exclusively as economic experiences. Yet, economic downturns are also social phenomena, affecting communities and morality. When societal changes are of a sufficient magnitude, they tend to break down the social fabric and represent additional sources of uncertainty which may produce effects on reproductive decisions beyond those of economic unpredictability alone. These aspects have been overlooked by the literature on the determinants of low fertility in western societies in the context of crises. Using the Swiss Household Panel 1999-2020, this study evaluates the effects of forms of uncertainty on childbearing intentions during the two most recent crisis: the Great Recession of 2008 and the Covid-19 pandemics.

Abstract *Le teorie sulla risposta della fecondità alle fluttuazioni del ciclo economico considerano le crisi esclusivamente come esperienze economiche. Tuttavia, le crisi economiche sono anche fenomeni sociali che influenzano le comunità e la moralità. Quando i cambiamenti sono di portata sufficiente, tendono a rompere il tessuto sociale e rappresentano fonti di incertezza che possono produrre effetti sulle decisioni riproduttive oltre a quelli della sola imprevedibilità economica. Questi aspetti sono stati trascurati dalla letteratura sui determinanti della bassa fecondità nelle società occidentali nel contesto delle crisi. Utilizzando i dati del Swiss Household Panel 1999-2020, questo studio valuta gli effetti di queste forme di incertezza sulle intenzioni di fecondità durante le due crisi più recenti: la Grande Recessione del 2008 e le pandemie del Covid-19.*

Key words: fertility, intentions, uncertainty, Covid-19, Great Recession

[1] Chiara Ludovica Comolli, Università di Bologna; email: chiara.comolli@unibo.it

1 Introduction

The 2008 Great Recession triggered negative fertility trends in Europe, but the declines persisted long after the economic recovery [30]. Part of this unaccounted fertility decline can be explained by the rise of economic *uncertainty* – a condition in which the future cannot be deduced by present information [11] – that persisted long after the economic recovery. Economic uncertainty alone, however, does not explain why fertility is still declining more than ten years after the Great Recession, including the United States, or in countries like the Nordic European states which were marginally affected by the crisis and economic insecurity [10].

Against this backdrop, Covid-19 and the measures adopted to contain its diffusion have led to another crisis. The social, financial and labour market losses have been considerable, and the post-pandemic prospects remain highly uncertain. This will possibly produce additional negative effects on childbearing. The Covid-19 crisis is first and foremost a health emergency, but in the longer run individuals may adjust their behaviour to the considerable economic and social costs of the pandemic. As a result, fertility is likely to be affected too [2]. Early evidence hints to a negative effect but the magnitude, contextual heterogeneities, and the mechanisms explaining childbearing delays are unknown [24].

While theories of the fertility response to business cycle fluctuations consider major crises exclusively as economic experiences, their effects are rarely confined to one domain. Economic downturns are also social phenomena. They have an impact on psychological outcomes, communities and morality, and on social interactions and individual's sense of belonging to certain groups. When these societal changes are of a sufficient magnitude, they tend to break down the social fabric and they represent additional sources of uncertainty which may produce effects on reproductive decisions beyond those of economic unpredictability alone. All these features of social change directed towards the fragmentation of societies, greater complexity, and the increase of insecurity about future societies can be subsumed under the notion of *social uncertainty*. These aspects have been largely overlooked by the literature on the determinants of low fertility in contemporary societies and especially in the context of crises [for an exception, see 8]. Using long-term longitudinal Swiss households' data stretching from 1999 to 2020, this study focuses on the last two decades and in particular it compares the effects on childbearing intentions of the Great Recession and the early effects of the Covid-19 pandemics. The study aims at uncovering the link between social and economic uncertainties, and determining the elicited fertility responses.

2 Background

The New Home Economics (NHE) theory sees childbearing as a rational choice based on the costs and benefits of children and posits that a decline in households' income is linked to the postponement of childbearing [5]. When incomes drop and unemployment rates rise, long-term commitments - such as housing purchases or having children - tend to be postponed. The initial declines in Total Fertility Rates (TFR) in the aftermath of the Great Recession, were thus not surprising as births were postponed hoping for a future with better economic prospects. Despite the economic recovery in the second half of the 2010s, however, the US' and European countries' TFRs continued their descent, with countries as diverse as Greece, England, Wales, Finland and Norway reporting all-time-low TFRs in 2019 [13]. Part of this decline has been linked to persistent *economic uncertainty* causing a re-evaluation of future prospects and the postponement of commitments like having children [9].

In fact, objective economic conditions are not the unique rationale of childbearing. First, the subjective perception of those conditions leads to different evaluations of current and future prospects and childbearing opportunities [32]. Second, preferences, attitudes and aspirations together with social norms and values guide individuals' attachment to paid work, reproductive decisions and the link between the two [22]. Third, institutions and structural constraints influence childbearing [13]. Finally, individuals do not live and take decisions in isolation but are embedded in a social context [12].

Individuals use community actions as sources of information to navigate complex situations [28] and to choose their own course of action [26]. Social interaction and the ensuing exchange of information, services and goods between individuals is a powerful determinant of fertility [4]. Yet, social interactions do not only produce *information* but also produce *resources* or *social capital* [27]. Social capital permeates spatial as well as social settings [33]. Social psychologists and political scientists show that social capital tends to be affected by long-lasting periods of lower opportunities. Enduring inequalities elicit lower social cohesion and mounting intra- and inter-generational tensions. Inequality lowers civic spirit, trust, and civic engagement, and correlates with political polarization and the emergence of populist parties [31]. Sociologists add that inequality is socially dysfunctional. It causes marginalization, increasing anxiety over the preservation of social status and reducing social trust. Economic crises threaten individuals' sense of control. To compensate, group-based control increases, fostering in-group limited trust at the expense of generalized trust, hence reducing the *radius of trust* [16].

Generalized trust represents a crucial human strategy to reduce the complexity arising from the burden of the multiplicity of possible events [23], and to mitigate uncertainty [7]. On the contrary, the shredding of good practices induces a sense of insecurity that pervades lives, especially during times of social changes. Lower trust levels have been linked to lower fertility [1] via a lower likelihood to marry [6], a lower quality of institutions (low childcare public provisions) and a lower likelihood of couples to outsource child care [3]. However, while these studies see social capital and morality as invariable traits of groups or societies, the abovementioned literature shows that major crises and the ensuing "miniaturization" of the social fabric [16] do alter these traits, generating further uncertainties related to the future of social support, values and the quality of institutions, which might induce a further childbearing postponement. The hypothesis that economic crises generate not only economic but also social uncertainties and that the latter too drive contemporary fertility declines has never been explored.

3 The current study

The study will expand this literature, first, by integrating theories of *economic* uncertainty with those of *social* uncertainty, as the latter have been overlooked in the literature of low fertility. Second, the study will contextualize post-pandemic fertility trends into a long-term perspective that includes the post-Great Recession developments.

While Covid-19 and confinement measures have possibly led to larger economic losses than the Great Recession, the nature of this latest recession is more exogenous. This could suggest a quicker (V-shaped) recovery leading to smaller effects on fertility than those observed during the 2010s decade. However, the effects of the pandemic might cumulate with those of the Great Recession, exacerbating the existing negative fertility tendency.

3.1 Research questions

On the one hand, the pandemic and lockdowns are redefining the meaning of paid and unpaid work and their boundaries, which represents a discontinuity with the pre-pandemic period and might produce unexpected consequences on childbearing behaviour. While women normally work in less volatile sectors that suffer smaller job losses during recessions, in 2020 jobs' features such as sociality or

teleworkability defined new employment hazards, with women overrepresented in the most hit sectors [29]. The reversal of the gendered employment hazard might weaken the selection of women into certain occupations and change the relationship between female work and childbearing.

Moreover, physical distancing involves limiting access to external care and outsourcing. The relative increase in job insecurity among women coupled with cuts in outsourcing and shrinking boundaries between paid and unpaid work, will likely affect childbearing decisions. *The first research question of the study asks thus whether the relationship between women's employment and childbearing decisions has changed between the Great Recession period and the Covid-19 pandemic years.*

On the other hand, societies and social relationship are likely to be affected by long-lasting periods of lower opportunities. Studies in social psychology and sociology demonstrate that inequality lowers social trust [18]. The spread of Covid-denial, anti-mask, anti-vaccine movements illustrate how divisive for society the experience of the pandemic can be. Isolation may increase stress and conflict between partners, lowering relationship quality and wellbeing, and might induce couples to postpone marriage or anticipate union dissolution [17]. Lockdowns may break kinship and network ties normally sustaining families. Distancing limits socialization, moving physical encounters even more to the digital world. All in all, lower wellbeing, increasing virtual interactions at the expenses of interpersonal contact, and declining social cohesion and trust, might produce childbearing delays through delayed union formation, lower network support, greater uncertainty and lower likelihood of outsourcing [1,3]. *The second research question of the study is thus whether social uncertainties, beyond objective and subjective economic conditions, influence childrearing decisions and, third, whether this relationship has changed from the Great Recession period to the early years of the pandemic crisis.*

3.2 Data and method

To answer the three research questions presented above I use the 22 waves available of the Swiss Household Panel (SHP, 1999-2020), a panel survey of households in which all adult members are interviewed annually.

Two refreshment samples, in 2004 and 2013, were added to the initial sample of 1999 to compensate for attrition. These data are particularly useful for the current study because they cover a very long period of time including the pre and post Great Recession years up to the most recent data collected during the Covid-19 pandemics in 2020, in the early spring during the lockdown in a special Covid-19 module, plus the usual summer-fall wave of the SHP. Longitudinal data are needed to investigate

how changes over time in the explanatory variables of interest affect childbearing decisions.

The analytical sample will consist of women in reproductive age 15-49. Because it is too early now to observe changes in childbearing behavior induced by the pandemics, here I investigate short-time childbearing intentions, considered a good proxy of actual reproductive behavior. The dependent variable is thus the intention to have a first or another child in the next few years. In the SHP the question posed is whether a *child is wanted in the next 24 months* (yes/no).

The first set of independent variables pertaining to the economic realm are women's objective economic conditions (changes in employment status, working hours, sector of occupation or income) and perceived economic uncertainties (job insecurity). A second set of independent variables related to social uncertainty include generalized trust, measured through the question of whether *most people can be trusted or you can't be too careful in dealing with people* (answers in the scale 0-10: from Can't be too careful to Most people can be trusted), and the engagement on *volunteering activities* as a measure of *civic engagement*. In the SHP membership to voluntary associations is measured in term of *active/passive or no membership*[1]. Volunteering is additionally measured with respondents *having honorary or voluntary activities within an association, an organization or an institution*. Another explanatory variable of interest relates to the *sense of control* over life measured in the SHP through the question: "How often have you felt that you were unable to control the important things in your life?" (answers in the scale 1-5: from Never to Very often). Finally, possible mechanisms such as childcare usage and other domestic tasks outsourcing, division of unpaid work in the couple, subjective wellbeing (life and domain specific satisfaction), and relationship quality are also included in the SHP survey. Control variables such as women's age and nationality, marital status, educational level and number of children already had.

In a first set of analyses, I will run several (step-wise) Linear probability Models of the probability of expressing a positive intention to have an (additional) child in the next two years depending on women's objective and subjective economic conditions and, net of those, on the residual effect of social uncertainties on fertility intentions. In the second part of the analysis the main focus will be on the interaction term of economic and social uncertainties with a period categorical variable (1999-2008; 2009-2013; 2014-2019; 2020) to compare their association to fertility intentions in aftermath of the Great Recession with the year of the Covid-19 pandemic.

[1] For instance, local or parents' association, sports or leisure association, organization involved in cultural activities, music, or education, syndicate, employee's association, political party, organization concerned with protection of the environment, charitable organization, women's association, and tenants' rights association.

Interpreting the relationship between life course trajectories and explanatory factors. An example on the transition to adulthood

Due approcci per lo studio delle relazioni tra le sequenze di vita e fattori esplicativi. Un esempio sulla transizione allo stato adulto

Danilo Bolano, Matthias Studer and Reto Buergin

Abstract Using sequence analysis as analytic framework, we discuss two alternative methods to investigate the link between a trajectory (sequence of states) and explanatory factors of interest: implicitative statistics and discrepancy analysis. Data visualisation tools to show the results are discussed as well. An illustrative example on differences in transition to adulthood in Switzerland is shown.
Abstract In questo lavoro si discute due possibili approcci nelle analisi delle sequenze per studiare la relazione tra la sequenza osservata e alcuni fattori esplicativi. Nel primo approccio, basato sulla statistica implicativa, il focus risiede sulle differenze in un dato momento. Il secondo approccio, basato su una analisi di discrepanza, invece prende in considerazione l'intera traiettoria osservata. I due approcci sono illustrati via un esempio sulle differenze di genere e status socio-economico nella transizione allo stato adulto.

Key words: Sequence analysis, Life course research, Sequential data, Discrepancy analysis, Data visualisation tools

1 Introduction

The transition to adulthood is a complex and multifaceted demographic phenomenon that cannot be analysed simply as a "transition" in/out a given condition. It is rather a process that might involve multiple changes in roles and states (e.g changes in living arrangements, moving out parental home, starting a union, becoming parent)

with the time being a crucial determinant. We focus here on sequence analysis. An holistic approach particularly effective in studying periods of life, such as young adulthood, full of events and transitions [2]. In sequence analysis, the variable of interest is not the timing of an event, or the probability of experiencing a given transition, but rather the entire trajectory. The life course of an individual is then seen as an ordered sequences of states.

In a social science perspective, it is crucial not only to describe the different aspects of the sequence, but also to study the association between the sequence and some explanatory variables in order to test specific hypotheses. The most common approach relies on (deterministic) cluster membership. In short, based on a dissimilarity measure, the sequences are clustered in homogeneous groups. Then a regression model is used to study the association between some covariates of interest and cluster membership. The cluster-based strategy, while easy to perform, is based on the relatively strong assumption that the variability of the sequences in each cluster is potentially non-informative and therefore it might be ignored. If this assumption do not hold, as often in applications in social sciences, the deterministic cluster-based procedure may lead to incorrect conclusions.

The present study discusses two alternative approaches to better investigate the effects of explanatory factors on the heterogeneity of the observed sequences: the implicative approach and a discrepancy based one. Moreover, we show data visualisation tools to easily display the results of the two proposed approaches. We illustrate the two approaches investigating the association between family life sequences in early adulthood (age 16 to 30) and potential covariates such as: gender, level of education, cohort and origin. Based on retrospective information (data from the Swiss Household Panel), we constructed yearly trajectories (sequences of states) on more than 40,000 individuals distinguishing between eight types of living arrangement: living alone, with parents, with partner, with others (e.g., flat-sharing), with partner and at least one child, with child(ren) but without partner, with parent and partner, with children and other, other living arrangements. We used such a detailed list of living arrangements to grasp the complexity of potential trajectories in early adulthood.

2 Implicative statistics

Implicative statistic [9] provides an estimation of the relevance of a rule such as "A implies B". This is achieving by measuring the gap between the expected and observed number of counter-examples of the rule. If the observed number of counter-examples is significantly lower than expected in the independence case, then the rule is statistically relevant. Technically, this gap and its statistical significance are computed using the adjusted residuals of a contingency table with a continuity correction [7]. In our context, this is done at each time point.

The implicative statistics can be easily and effectively represented graphically. The plot shown in Figure 1 represents at each time point t and for each state A

considered, the relevance of the rule (i.e. the gap). A higher value means that the rule is more relevant. The dashed horizontal lines represent the confidence thresholds of the rules. We consider that a rule is significant at the 5% level, if it is above the dashed horizontal line 95%. The rule is for instance in top panel of Figure 1: being a man (woman) implies being in state A at time t.

The plot shows that family formation, i.e., any living arrangement that consists of living with the partner and eventually having children, in early adulthood are particularly relevant among women (technically speaking for the rule "being a woman"). On the other hand the significance of the rule "being a man" is particularly strong for the states "living with parents" and only after age of 22 "living alone". The results than confirms the literature with women experiencing a transition our of parental home at earlier age than men. Plots like this allows to have a clear snapshot of differences across levels of the covariates but loses the longitudinal information since we look at sequences of transversal characteristics (e.g., at each time point). Thus, we cannot conclude that patterns like "Living alone - Partner - Partner with children" at early age is typical of women. Nevertheless, these plots are easy to read and may help to uncover important sequences characteristics of a given profile.

The next approach leverages the longitudinal perspective of the sequences using the discrepancy analysis.

3 Discrepancy based approach

The discrepancy analysis allows a direct analysis of the the strength of the sequence-covariate link (i.e., without any prior clustering) [8]. Defining discrepancy of the sequences in terms of their pairwise dissimilarities, the approach is a generalisation of the the principles of analysis of variance—either with a single (ANOVA) or a multifactor framework (MANOVA)—to measure and test the part of the discrepancy among sequences that can be explained by covariates. In practice the response variable is summarized by a dissimilarity matrix. For instance, one can assess what fraction of the differences between early family lives trajectories can be explained by gender and social stratification. It is a proper longitudinal approach as long as the underlying distance measure does (in our case we use the Hamming distance).

Discrepancy-based methods proposed in the literature so far allows only to identify if the associations are statistically significant or not but do not fully provide a way to give a meaning of such relationships. We show here how to use the residuals of discrepancy analysis to leverage the longitudinal nature of the data in interpreting the differences in early adulthood trajectories according to some factors of interest.

Discrepancy analysis with multiple explanatory factors [8] mainly relies on computing the total sum of squares $SS_T = tr\big(\mathbf{G}\big)$ where $\mathbf{G}$ is the Gower matrix [5, 6]. As conventional, we can re-write the total sum of squares as the sum of between sum of squares ($SS_B = tr\big(\mathbf{HG}\big)$) and the residual within sum of squares ($SS_W = tr\big[(\mathbf{I}-\mathbf{H})\mathbf{G}\big]$), where $\mathbf{H}$ is the hat matrix used in traditional linear model.

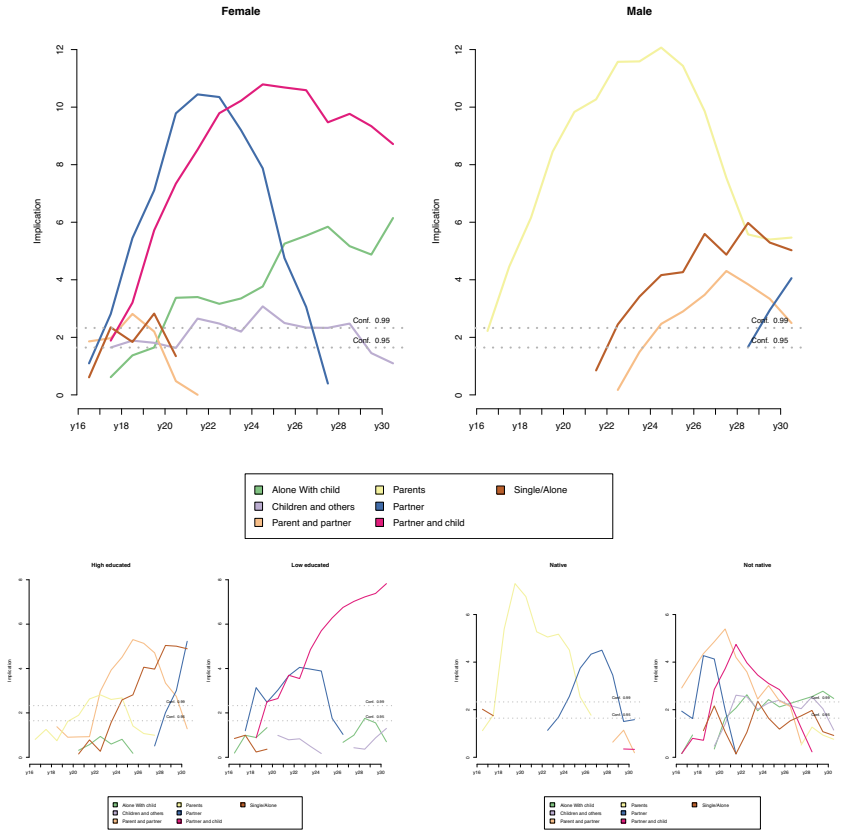

Fig. 1 Evolution of life trajectories in early adulthood according to explanatory factors.

For brevity, we cannot here discuss in details the mathematical formulations used in the general discrepancy analysis but interested readers can refer to [8].

The diagonal elements of the Gower matrix can be interpreted as the contribution of each sequence to the *overall* discrepancy, and also as the distance between a sequence and the gravity center of a set of sequences [8]. We will interpret those values as residuals: a high value means that a sequence is far from its gravity center, and a low value means that the sequence is close to it. Similar to the residual of a null model in a regression setting, these are residuals without accounting for any covariate. In a similar manner, the diagonal elements of the matrix $(\mathbf{I}-\mathbf{H})\mathbf{G}$ can be interpreted as the contribution of each sequence to the *residual* discrepancy. In a linear model, those values could be interpreted as the square of the residual of the fitted model (i.e, including explanatory factors).

By combining these two types of residuals (i.e. contribution to the overall and residual discrepancy), we can identify the sequences that are best represented when

we include a covariate in the model. These are the diagonal elements of the matrix $\mathbf{G} - \left[(\mathbf{I} - \mathbf{H})\mathbf{G}\right] = \mathbf{HG}$. We will call the diagonal elements of this matrix *gain*. A positive value means that the corresponding sequence is better represented if the explanatory factor is taken into account whereas a negative value means that the sequence is less well represented. In practice, we can compute a value for each sequence representing the gain (or loss) of information if we take a covariate into account. Both the "effect" of a single or of multiple factors can be analysed.

Figure 2 presents two index-plots of the sequences separated according to level of education and ordered according to the gain when taking education and the others explanatory factors (gender, cohort, being native) into account. On the right of each index plot, we have plotted the gain associated with each sequence. Sequences at the bottom have the highest gain, whereas sequences at the top have negative gain. The sum of the gains values equals to the explained sum of squares.

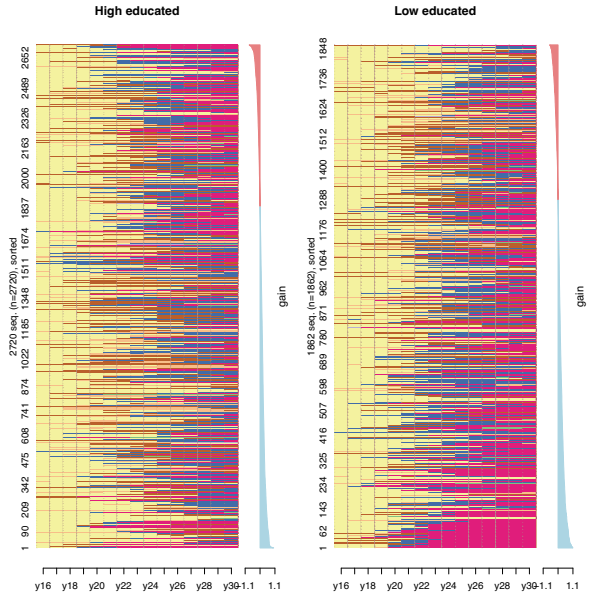

Fig. 2 Sequences ordered according to gain by low and highly educated individuals when taking into account also gender, cohort and being born in the country.

Looking at the sequences at the bottom of the graph, we can notice that after taking into account the effect of gender, cohort and origin, the gravity center of the sequences of those with high level of education has moved in the direction of a predominance of "red" state (having a partner of children) at an early age. This means that we observe a *tendency* of low educated of leaving the parent home and

start their own family at an earlier age than those highly educated. Similarly, it is possible to plot the effect for each single explanatory factor considered.

4 Conclusions

The study discussed two ways to study the relationship between sequence of states and some explanatory factors of interest in a sequence analysis framework. Going beyond the traditional cluster based approach, we have shown how different tools can be used to focus either cross-sectionally on the typical states of a subpopulation (for instance women, as opposed to men) measuring the gap between the expected and observed numbers of counter examples (implicative statistics) or more importantly leveraging the longitudinal nature of trajectories using a discrepancy-based approach. This work focuses on sequences of states taking an holistic approach but it worth mentioning that the study of trajectories can be done using step-by-step probabilistic approaches such as Markov based models [1, 3, 4] where it is straightforward to include both time-varying and time invariant explanatory factors in the model strategy.

The relationship between economic news and fertility: the case of Germany

La relazione tra notizie economiche e fecondità: il caso della Germania

Maria Francesca Morabito, Raffaele Guetto, Matthias Vollbracht, and Daniele Vignoli

Abstract This work contributes to the increasing literature on the relationship between the media coverage of the economy and fertility dynamics. We address this relationship for Germany, a nation with a prosperous economy, by combining individual-level data from the German Socio-Economic Panel (G-SOEP) and Media Tenor data on economic news reported by some German weekly magazines of great circulation. Our analysis scrutinizes the association between economic news items and fertility behaviour. Findings reveal that an increase in negative news on the state of the economy discourages fertility, while positive news items only exert a negligible effect.

Abstract *Il presente studio contribuisce alla crescente letteratura riguardante la relazione tra la copertura mediatica dell'economia e la fecondità. Ci focalizziamo sulla Germania, un paese caratterizzato da un'economia florida, combinando dati individuali derivanti dal German Socio-Economic Panel (G-SOEP) con dati Media Tenor relativi alle notizie economiche riportate da alcuni settimanali tedeschi di grande tiratura. La nostra analisi esplora la correlazione tra notizie economiche e fecondità individuale. I risultati mostrano che un aumento di notizie negative scoraggia la fecondità, mentre le notizie positive esercitato un effetto trascurabile.*

Key words: Fertility; Media; Germany; Economy; Economic News

1 Introduction

A common, albeit heterogenous, decline in fertility levels is investing several countries of Western Europe since 2010. It is involving even countries of North Europe, as well as some countries of the Continental area (e.g., Belgium and France), which did not experience the negative consequences of the Great Recession as harshly as the Southern European countries. In this scenario, the relative growth of the German Total Fertility Rate (TFR) was of 15% during 2010-2019, and represents an exception compared to declines of 8%, 14%, 21%, and 28% in France, Belgium, Norway, and Finland, respectively. As a result of these opposite dynamics, Germany's TFR in 2019 (1.53) reached, or surpassed, that of Norway (1.53) and Finland (1.35), traditionally "high-fertility" countries which are characterized by cultural, institutional, and economic conditions relatively more favourable for childbearing compared to other European areas.

The current puzzled relationships between institutional arrangements, gender ideologies, and economic situations, on one side, and fertility levels, on the other, lead to research into what other (new) forces are involved in shaping fertility choices. A recent line of research suggests the idea that the public discourse around the state of the economy, driven by economic narratives conveyed by the media and fuelled by interactions with parents and peers, is crucial in influencing fertility behaviour in conditions of uncertainty, over and above the (not-negligible) effect of individual and contextual objective economic circumstances [17, 18]. This view is consistent with a new generation of studies emphasizing the importance of subjective perceptions of the economic context as crucial fertility drivers [10, 19].

Media-conveyed narratives consist of news, debates, and all information reported by print news, television, and radio, as well as that available online. Previous studies proved the causal impact of media-conveyed narratives about economic uncertainty and the COVID-19 pandemic on marriage and fertility intentions via laboratory experiments [7, 8, 20]. And lastly, Guetto et al. [6] have documented a robust association between the incidence and tone of economic stories reported by the evening newscast (*TG1*) of Italy's most-viewed TV channel (*Rai 1*) and the probability of conception.

In the present study, we scrutinize the effects of the media coverage of the economy on individuals' fertility behaviour in Germany, net of micro- and macro-level indicators of the objective economic context. This research extends the empirical evidence to the German case, where fertility and economic conditions have had diametrically opposed trends compared to Italy, the only country for which, to the best of our knowledge, micro-level evidence on the relation between the media coverage of the economy and fertility is available [6].

2 Background

According to the agenda-setting theory [13], the media may exert their influence on the individual perception of reality through three main processes: the selection of the contents to report, the salience reserved to them, and, last but not least, the tone and the perspectives through which information is framed [5].

Many studies have addressed the relationship between the media coverage of the economy and economic perceptions of German citizens. Brettschneider [1] found a strong correlation between the proportion of citizens that consider the unemployment as the Germany's most important problem, and the share of news on unemployment. Lamla and colleagues showed that increases in the news coverage about current and future inflation levels improve the accuracy of German consumers' expectations, whereas it worsens when the media overemphasize negative facts [11, 12]. Furthermore, Garz found a correlation between the share of news on labour market policies and perceived job insecurity [3], and between the number of words related to unemployment reported in the news items and households' economic perceptions [4].

Nevertheless, we did not find any study addressing the relationship between the media coverage of the economy and fertility in Germany. At the area-level, Schneider [14] found a significant association between an indicator of the press coverage of the Great Recession and general fertility rates in the US, net of objective economic indicators. At the individual level, the causal effect of media-conveyed narratives of economic uncertainty on fertility intentions has been recently estimated for Italy and Norway [20] through controlled experiments in which participants were exposed to a (mock) news bulletin on the conditions of the national economy in the next three years. More related to this research, Guetto et al. [6] documented that the number of negative economic items reported by the main Italian newscast is negatively associated with fertility, whereas the number of positive news items has an opposite correlation. Furthermore, an increase in the percentage of economic news out of all news has been found to reduce fertility, even if this effect decreases as the tone of media narratives improves.

These findings are limited to a context of low fertility levels and strong economic hardship as that of Italy, but the outlined relationships may potentially vary among countries. Incidentally, the effect of new information on personal perceptions also depends on the standard to which individuals are accustomed [15]. We hypothesize that in countries characterized by prosperous economies, negative economic narratives may have a stronger impact than positive ones, since they are far from the imaginary of citizens, and vice versa. Furthermore, negative news items have proved to be more influential than positive ones on economic perceptions and expectations in wealthy countries, such as Germany [2] and Sweden [11]. Vignoli and colleagues found a stronger impact of negative economic narratives on fertility intentions in Norway, while positive economic narratives have been proved to be more influential in Italy [20]. Consistently, the (positive) effect of an increase in the number of positive news about the economy on fertility behaviour has been found to be stronger than that of an increase in negative news in Italy [6]. Thus, we may

expect that Germans, used to receive reassuring news on the economy, may be more influenced by a worsening of the media coverage of the state of the economy than to improvements.

3 Data and methodology

Media coverage data are provided by *Media Tenor International* and include the monthly number of economic news reported in German weekly magazines of great circulation (*Spiegel*, *Focus*, *Bild am Sonntag*). To each news item is assigned a tone (positive, negative, or no clear) according to explicit language or implicit evaluations reported in the news text. We merged these data with individual information from G-SOEP [9, 16]. We kept observations for female respondents aged 16-40. The monthly panel dataset covers the period Jan 2002 – Apr 2018 and includes 10,788 women (also belonging to the same household). Out of them, we observe 2,932 conceptions.

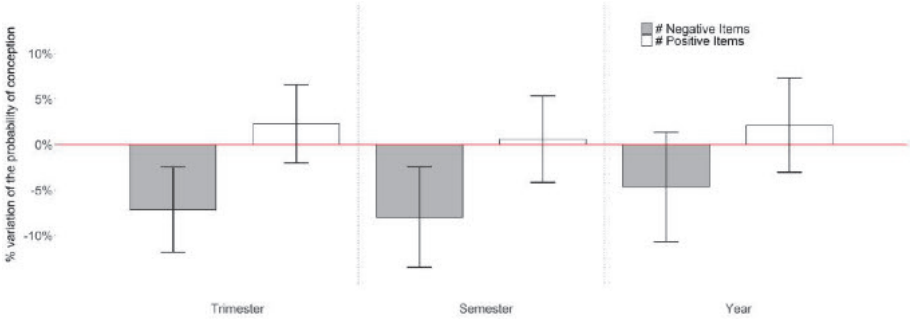
We applied Linear Probability Models with Fixed Effects (at both individual and household levels) to test if and to what extent changes in the media coverage of economic news are correlated to (within-individual) monthly variations of fertility. The dependent variable is a dummy that assumes value 1 in the month of conception of each child, and 0 otherwise. The main independent variables are measures of the coverage of the economy in German weekly magazines. Finally, models control for well-established micro-level fertility predictors (age, level of education, individual labour earnings, participation in education, and type of employment), a linear time trend, and macroeconomic indicators typically employed in fertility studies (such as the growth rate of real GDP, and the female unemployment rate).

4 Findings and discussion

We report the variation in the monthly probability of conception, compared to the mean risk observed in the sample (0.42%), associated to one standard deviation increase in the number of negative and positive news stories (Figure 1). The average numbers of economic news reported over the previous trimester, semester, and year, are included separately in three models, including the same control variables

Results reveal that the average amount of negative news is negatively correlated with the monthly probability of conception. On the other hand, the association between the moving average of the number of positive news and fertility is almost null (and not significant). The impact of negative items is more intense than that of positive ones, and statistically significant (except for the measure calculated on the coverage of the previous year). As shown in Figure 1, these effects are substantially relevant, controlling for micro- and macro-level indicators of objective economic conditions.

Figure 1: Percentage variation of the monthly probability of conception, compared to the mean risk observed in the sample, associated to one standard deviation increase in the media coverage of the economy in the previous trimester, semester and year.



Source: our elaboration on G-SOEP and Media Tenor data.

This is the first study documenting the association between economic news coverage and individual fertility in Germany, and the second addressing this relationship in a European country. This contribution is certainly not exhaustive on the subject, and further studies are needed. Indeed, in our models we do not control for changes in the fruition of magazines over time (nor for variations in the sensitivity of the consumers). However, we consider leading news magazines which also make use of online platforms to convey their contents. Furthermore, the potential influence of economic news coverage in weeklies magazines may result beyond their actual circulation. Items reported by media may also reach those who are not directly exposed to them, by fuelling the wider public discourse about the state of the economy.

Leaving home among Millennials in Italy: does economic uncertainty matter?

L'uscita dalla famiglia di origine fra i Millennials in Italia: il ruolo dell'incertezza economica

Silvia Meggiolaro and Fausta Ongaro

Abstract This paper analyses whether the process of leaving home is changing among recent cohorts of young Italians. We focus on the changes with reference to: a) timing and reasons of exit, and b) role played by (individual) economic uncertainty. We used retrospective data from the pooling of two rounds of a survey conducted by ISTAT in 2009 and 2016 and applied event history models. Results show that, in comparison with previous cohorts, both male and female of younger cohorts have a lower probability of leaving parental home to live with a partner, but, whereas this lower propensity persists for men, whatever the exit, women have a higher likelihood of leaving home for non-union related reasons. Younger cohorts also show a differentiated role of economic uncertainty.

Abstract *Il lavoro esamina le modalità di uscita dalla famiglia di origine dei giovani italiani nell'ipotesi che le coorti più recenti (Millennials) presentino comportamenti diversi da quelle precedenti per modalità di uscita e per ruolo svolto dall'incertezza economica individuale. A tale scopo si utilizzano dati retrospettivi delle due indagini condotte dall'ISTAT nel 2009 e 2016, analizzati con modelli event-history. I risultati mostrano che, tra i Millennials, gli uomini ritardano ulteriormente le uscite sia per unione che per altre ragioni, mentre le donne ritardano solo le uscite per unione e invece tendono ad anticipare quelle per altri motivi. Inoltre, la propensione a uscire dalla famiglia di origine sembra essere influenzata diversamente dall'incertezza economica individuale*

Key words: leaving home, economic uncertainty, event history models.

1 Introduction

Leaving the parental home is a key event to be studied, since it is one of the markers in the process of transition to adulthood and the pathway through which it has been experienced may have important consequences for young adults' life course outcomes. Given the importance of the leaving home process of young adults, a quite rich literature has analysed the determinants of the decision to leave the parental home in Europe (e.g., Iacovou 2010; Schwanitz, Mulder and Toulemon, 2017), showing that – among the numerous (individual, family, contextual) factors influencing the decision of establishing an independent household - the economic ones may play an important role (Blaauboer and Mulder, 2010; Iacovou 2010; Bertolini et al., 2017; Schwanitz, Mulder and Toulemon, 2017).

This paper aims at studying whether and how the process of leaving home is changing among recent cohorts of young Italians (for which data are available, i.e. those born during the '80s and the first '90s), the so-called *Milllennials*, with reference to a) the timing and reasons of exit, and b) the role played by (individual) economic uncertainty on the timing and the reasons of exit.

But why is Italy worthwhile to be considered? Traditionally, Italian young adults tend to leave home at later ages compared to their counterparts in other European countries (Ongaro, 2001) and mainly for union-related reasons (marriage). However, there are not studies focusing on more recent cohorts. As previous cohorts of young Italians, indeed, also recent cohorts live in a context characterized by a persistent familistic welfare, but in comparison with older cohorts, Milllennials are also living in a context of relevant changes: from one hand the economic structural (labour market reforms of 1990) and conjunctural (the 2008-2013 Economic Crisis) changes; from the other hand, cultural changes, such as those determined by the diffusion of the Second Demographic Transition family behaviours, by the globalization, and by decreasing gender inequalities.

Does the leaving home of Italian Millennials differ from that of previous cohorts with respect to timing or reasons for leaving home? Does the individual economic uncertainty of recent cohorts play a role in the possible further postponement? Is there a different role of individual economic uncertainty for leaving home among Millennials in comparison with previous ones? Do young men behaviours differ from those of young women with respect to this points? To answer these questions, we used retrospective data coming from the pooling of two rounds of the survey 'Families and Social Subjects' conducted in Italy by the Italian Statistical Institute (ISTAT) in 2009 and 2016 and applied event history models (in some case in their competing risk version), distinguishing among the gender of the young people.

2 Data and strategy of analysis

The retrospective data on leaving home obtained from the survey 'Families and Social Subjects' allow to consider individuals who at the time of interview (in 2009

and in 2016, respectively, for the two rounds of the survey) were between 20 and 44 (and thus, born between 1965 and 1996). Using this sub-sample of population, we first studied the process of leaving home as a single destination, and then we considered two different pathways out of the parental home: leaving home to live without a partner versus leaving home to live with a partner.

Following previous studies (for example, Blaauboer and Mulder, 2010; Schwanitz, Mulder and Toulemon, 2017), process time starts at age 16 and ends at age 34. Cases were censored at the time of interview or at age 35 when the transition out of the parental home had not been made by that age. In this way, our sample totals 22,218 respondents (50.5% women and 49.5% men).

Since only the year of leaving parental home is recorded, discrete-time event history models were estimated: this required adopting a person-year scheme. Separate analyses were conducted for men and women. In a preliminary analysis, we considered the process of leaving home as a single destination (and thus a logistic regression of person-years is estimated); then, a competing risks approach was used (multinomial logistic regression), where leaving the parental home to live without a partner and leaving home to live with a partner are the outcomes of interest.

As regards the covariates, in this paper, we focused our attention on two core explanatory variables: the cohort of individuals and the "labour market situation", a (time-varying) variable which distinguishes four positions according to the employment status and the type of employment: not employed individuals (including inactive and unemployed individuals), temporary contract employees (those with fixed term or project contract), permanently employees (employed with a permanent contract), and self-employed individuals (including young entrepreneurs and freelancers). In addition, we considered the school enrolment, a time dependent covariate that has to be used in connection with the employment status to properly isolate the cases of unemployed and inactive individuals.

Other individual characteristics controlled for in our analyses were the age of individuals and the level of education. We considered also some family characteristics, namely, parental education, parental separation and maternal employment status during the respondent's adolescence (Schwanitz et al., 2017). Lastly, we considered the area of residence (at the interview) as a contextual characteristic to take into account the geographical heterogeneity and the impact of unobservable context variables (Sironi and Rosina, 2015).

The strategy of analysis started with models 1, which include only the cohort as a covariate (besides the age of individuals included in linear as well as in logistic form); then models 2 add the key covariates (the labour market situation and the student status) and all the control covariates; lastly, models 3 add the interaction term between the key covariates and the cohort.

3 Results

In a preliminary analysis (here not reported) we considered the process of leaving home as a single destination, in which we did not make any distinction of the route

taken out of the parental home. Results show that Millennials have a significant lower likelihood of leaving parental home with respect to previous cohorts for men, but not for women. As regards the role of economic uncertainty, if for young women only a situation of unemployment decreases the likelihood of leaving home, both among older and younger cohorts, for male Millennials some signals of new patterns seem to emerge: for them, unemployment continues to have a negative effect for the risk of departure from home, but with a less strong effect in comparison with previous cohorts. In addition, a condition of economic uncertainty such as defined by having a temporary contract employment increases the probability of leaving home in comparison with that of previous cohorts.

In fact, results of competing risks models describe a quite different situation (Table 1a and 1 b, for men and women, respectively). Results (mod.3), first, suggest that Millennials show a new pattern in the process of leaving parental home in comparison with previous cohorts: both male and female Millennials have a lower likelihood of leaving parental home to live with a partner (the odds of leaving for male Millennials are 22 percent ([1-exp(-0.25)]*100) lower than those of older cohorts; for female Millennials, 15% lower), but, whereas this lower propensity persists considering non-union related exits for men, at the opposite, female Millennials have a higher likelihood of leaving parental home for non-union related reasons in comparison with previous cohorts.

Second, younger cohorts also show a differentiated role of economic uncertainty on the decision about whether to move out parental home. As regards the likelihood of leaving parental home to live with a partner, economic uncertainty plays a similar role among younger and previous cohorts: unemployment lowers the likelihood of leaving parental home with a partner for young men, but not for women, in comparison with that of young adults with a permanent employment (thus confirming Italy as a conservative country with gender differentiated effect of unemployment, Gousia et al., 2021); moreover, experiencing precarious employment conditions - such as those defined by temporary contract - lowers the risk of departure from home with a partner both for men and women (being employed with a temporary contract decreases the odds of leaving by 19 percent = [1-exp(-0.21)]*100 in comparison with being permanently employed for men, and by 11 percent for women).

The situation is completely different considering the exit from parental home for non-union related reasons. In this case, the unemployment, but also an uncertain position such as defined by a self-employment, decreases the probability of leaving parental home both for men and for women, but, these effects are less strong for male Millennials in comparison with previous cohorts. On the opposite, with respect to a permanent contract, a situation of uncertainty as that defined by a temporary contract increases the likelihood of leaving home without a partner both for men and women, and – this effect seems to increase among the male Millennials (the interaction term being positive and significant for women).

Thus, we can therefore argue that in a society where economic uncertainty is becoming a common condition, young adults are finding new strategies to

autonomy. This does not hold for a more traditional way of leaving home, such as that to live with a partner, for which, unemployment or economic uncertainty associated to a temporary job continues to have a detrimental effect: probably young people are less likely to experience a transition, such as in the case of entry into union, where responsibilities are greater than in the case of entry into independence.

4 Discussion and future research

This connection between economic uncertainty and responsibilities should be analysed more in depth with future studies considering more in details the different processes of leaving home, further disentangling the different reasons determining decision about whether to move out: the relatively low sample size of individuals in more recent cohorts does not allow more detailed analyses, but it would be worthwhile to distinguish leaving home to live with a partner in cohabitation from that in marriage, to verify whether the increase in the diffusion of non-marital unions bring also a new pattern of exit from the family of origin, implying less commitment than that implied by marriage and thus more compatible with uncertainty. Similarly, among individuals leaving parental home for non-union related reasons, those leaving to pursue educational opportunities should be distinguished from those leaving to pursue employment opportunities and from those leaving to establish independence, to verify the routes more favoured by economic uncertainty.

Adverse pregnancy outcomes in the United Kingdom following unexpected job loss

Esiti avversi della gravidanza nel Regno Unito a seguito della perdita inaspettata del lavoro

Alessandro Di Nallo and Selin Köksal

Abstract There is no evidence on the effect of a job loss on the extra risk of adverse pregnancy outcomes. We analyse conceptions, partnerships and work histories from the British survey "Understanding Society" to examine whether a woman's and/or her partner's involuntary job loss during a pregnancy increases the risk of a miscarriage and non-live birth. Our findings show that risk of non-live birth increases when the mother or the partner are exposed to an unexpected job loss. Moreover, we find higher risk of adverse outcomes following a job loss during the first trimester of pregnancy.

Abstract *Nella letteratura accademica, non esiste evidenza della relazione tra la perdita del lavoro e l'aumento del rischio di un esito avverso della gravidanza. Questo articolo analizza le gravidanze e le storie lavorative delle donne intervistate dall'inchiesta britannica "Understanding Society", ed esamina se la perdita involontaria del lavoro da parte di una donna e/o del suo partner durante una gravidanza aumenta il rischio di aborto spontaneo e morte alla nascita. I risultati mostrano che i rischi di esito avverso della gravidanza aumentano quando la donna e/o il suo partner sono esposti a una perdita imprevista del lavoro. Inoltre, troviamo un rischio maggiore di esiti avversi come risposta alla perdita di lavoro durante il primo trimestre di gravidanza.*

1 Introduction

An estimated 11%-20% of clinically recognized pregnancies result in miscarriage. The risk of spontaneous termination of pregnancy is even higher for women who experience adverse economic events [3]. Besides somatic costs, spontaneous pregnancy losses (less than 20 weeks' gestation) are associated with an increased risk of long-term depression and anxiety among parents [1, 8]. Studies on stillbirths (above 28 weeks' gestation) signal that the incidence of spontaneous loss has remained relatively stable as compared with steady reductions in mothers' death at delivery, morbidity from childbirth and neonatal mortality [7]. This motivates international institutions' appeal to improve the understanding of preventable causes of pregnancy loss [27].

Many correlates of spontaneous pregnancy loss have been identified: maternal age, behavioural habits and genetic predisposition are among the most cited antecedents [28]. However, these and other known factors fail to explain most events of pregnancy loss [3]. Job market shocks and financial distress have been found to be negatively associated with a wide array of birth-related outcomes [9, 3, 16]. [2], [21] and [3] estimated the effect of economic downturns on perinatal outcomes at the ecological level. One ([18]) examined birth outcomes of couples who self-reported a husband's job loss. The evidence is mixed as some studies show adverse birth outcomes, such as live birth and birthweight [21, 24], and others display no or even better-than-expected results [5]. Some studies found an association between proxies of personal hardship and pregnancy loss in an ecological design [11, 23, 3].

However, it is not clear whether and how an *individual* level job loss plays any role in spontaneous pregnancy loss. To the best of our knowledge, no study has investigated whether a specific life shock at personal or couple-level, such as job loss, is a possible antecedent of miscarriage or non-live birth.

We contribute to existing literature in multiple ways. Firstly, we assess whether and to what extent a job loss of a woman or her partner's increases the risk of spontaneous pregnancy loss, represented by a miscarriage or a non-live birth. Secondly, we clarify whether the timing of a job loss during a pregnancy impacts on pregnancy outcomes, and if any disparities fall along socio-economic status. Thirdly, we use high-quality individual data on the spouses' socio-demographic characteristics and finely grained information on their and their partners' work histories as well as on their reproductive events. Unlike the extant literature, we are able to identify self-reported dates of conception and own or partner's non-voluntary job loss.

2 Data and Methods

We retrieve information on pregnancy outcomes from the UKHLS ('Understanding Society'), a population-representative survey of the United Kingdom spanning from 2009 to 2019. This dataset includes a wide array of information on conception date, duration of pregnancy, cause of pregnancy loss, delivery outcome. Consistent with

the economic literature, we retrieve data on individual employment, job characteristics, tenure and, if any, the voluntary or involuntary causes of a job loss.

We hypothesize that the number of spontaneous abortions would rise above the expected value among the pregnancies of women exposed to involuntary episodes of own or partner's job loss. We analyse associations between job loss and adverse pregnancy outcomes using two model specifications. We estimate a linear probability model of two outcomes: a miscarriage and a non-live birth. In the first model specification, the main explanatory variable is a dichotomous indicator of exposure to (a) woman's or (b) her partner's job loss during pregnancy. If conception and job loss are reported in the same month, we consider the couple to be exposed to the shock. In the second specification, the explanatory variable is distinguished in 6 categories to capture the *timing* of the job loss during over the gestational period. In chronological order, t_0 captures the job loss *preceding* conception by 4 to 1 month(s). The variables t_1, t_2, and t_3 identify, respectively, the job loss occurring during 1st, 2nd or 3rd trimester of gestation. t_4 identifies a job loss occurring between 10 and 24 months post-conception. Therefore, t_0 serves as a placebo test that signals if job displacement and a pregnancy loss are confounded because of pre-conception characteristics of the woman or her partner's.

The confounders include: woman's age (7 categories), ethnicity (8 categories), parents' SES at 16 (5 categories), whether the woman reported any miscarriage in the past, parity (first or second/higher order child), whether in a union (3 categories), time-varying educational attainment (3 categories), religious affiliation (7 categories), woman and her partner's job position (NSSeC-3 categories, lagged by 1 year). These controls are introduced in a step-wise approach. Of the 8,429 women who experience a pregnancy, 7,320 report a valid date of conception.

3 Results

Linear probability models clearly support the increased risk of a miscarriage (Table 1, columns 1-3) and non-live birth (Table 1, columns 4-6) following the exposure to women and partners' unexpected job loss. The statistical significance of the effect of women's job loss remains constant ($p < 0.01$) when accounting for an incremental set of controls. The *in utero* exposure to job loss increases the probability of miscarriage and non-live birth by 8.5 and 11.8 percentage points respectively. The impact of partner's job loss increases in magnitude ($p < 0.05$) when more controls are added. In this case, the probability of miscarriage and non-live birth increase by 8 and 8.3 percentage points respectively.

Linear models addressing the timing of job loss (Table 2) suggest that the influence is stronger in the first trimester both with respect to miscarriage (col. 1-3) and non-live births (col. 4-6). The *in utero* exposure to own and partner's job loss increases the probability of miscarriage and non-live birth by roughly 10 and 12 percentage points, respectively, for all specifications.

4 Discussion

The analysis suggests the existence of link between a couple's exposure to a non-volunary job loss and the risk of miscarriage and non-live birth. This link operates regardless of the partner hit by labour market shock and is highly sensitive to the timing with respect to conception. The first trimester of pregnancy is particularly susceptible to a job loss.

Bayesian modelling and inference 2

A Bayesian beta linear model to analyze fuzzy rating responses

Un modello bayesiano di regressione beta per l'analisi di risposte imprecise

Antonio Calcagnì, Massimiliano Pastore, Gianmarco Altoè, Livio Finos

Abstract In this short paper, we describe a Bayesian beta linear model to analyse imprecise rating responses. The non-random imprecision is extracted from crisp responses via the Item Response Theory tree (IRtree) method and it is represented by means of beta fuzzy numbers. The parameters of the beta linear model are estimated using the adaptive Metropolis-Hastings algorithm, with the fuzzy likelihood function being used as empirical evidence for the imprecise observations. A real case study is used to show the characteristics of the fuzzy beta regression model.

Abstract *Questo contributo descrive l'applicazione del modello di regressione beta nell'analisi di dati imprecisi. In questo contesto, l'imprecisione è riferita ad una fonte non casuale di incertezza ed è calcolata mediante il metodo fuzzy-IRTree. Il risultato di tale pre-trattamento è una collezione di insiemi fuzzy di tipo beta. I parametri del modello di regressione beta sono stimati mediante l'algoritmo Metropolis-Hastings di tipo adattivo mentre l'evidenza empirica dei dati è espressa mediante una funzione di verosmiglianza imprecisa. Il contributo si chiude con l'analisi di un caso studio.*

1 Introduction

Rating data are widespread across disciplines dealing with human-based measurements. In these cases, since the measurement process is based on cognitive actors, the collected data are often affected by non-random imprecision or fuzziness. This type of uncertainty has multiple origins, including the semantic aspects of the items being rated and the individual-level decision uncertainty underlying the response process [1]. To give an example, consider the situation where the item "I am satisfied with my life" is rated through a scale ranging from "strongly disagree" to "strongly agree". A stage-wise response process is usually involved in responding to these types of items. In particular, in a first step cognitive and affective information about the item being rated are retrieved and integrated (opinion formation stage) until the second decision stage is triggered, which includes the selection of the final rating response (e.g., "strongly disagree"). Because of the integration of conflicting cognitive and affective information about the item, fuzziness arises from the conflicting demands of the opinion formation stage [2]. Over the recent years, several fuzzy rating scales have been proposed to quantify fuzziness from rating data, including both direct/indirect fuzzy rating scales and fuzzy conversion scales (for an extensive review, see [1]). While direct fuzzy rating scales quantifies fuzziness by mapping response process to fuzzy numbers directly, fuzzy indirect scales aim at turning standard crisp ratings into fuzzy numbers by means of statistically-based procedures (e.g., see [3]). Unlike for the previous case, here the aim is to represent as much information as possible from the rating process in terms of a more complex number representation. Once fuzzy numbers have been obtained, they can be analysed either by means of standard statistical approaches or by adopting fuzzy statistical methods devoted to this purpose (e.g., see [4]).

In this contribution, we describe an application of a Bayesian beta linear model to the analysis of IRTree-based fuzzy data, a novel type of fuzzy responses which treat fuzziness in terms of decision uncertainty [1]. The remainder of this short paper is as follows. Section 2 describes the fuzzy beta data. Section 3 exposes the Beta linear model along with the parameter estimation procedure. Finally, Section 4 concludes this contribution by illustrating the application of the proposed method to a real dataset.

2 Data

IRTree-based fuzzy data represent a particular type of fuzzy numbers which are the output of a psychometric-based fuzzy conversion method (i.e., the Item Response Theory tree approach). In particular, they are computed in a way that the imprecision encapsulated into the matrix of crisp rating data $\mathbf{Y}_{n\times J}$ is mapped onto beta fuzzy numbers using all the rater's responses $\mathbf{y}_i$ to the J items being rated. The reader can refer to [1] for technical details about the conversion system. In this context, data consist of a collection of n (raters) $\times$ J (items) beta fuzzy numbers:

$$\widetilde{\mathbf{Y}} = (\xi_{\widetilde{y}_{11}}, \ldots, \xi_{\widetilde{y}_{1J}}, \ldots, \xi_{\widetilde{y}_{nj}}, \ldots, \xi_{\widetilde{y}_{nJ}})$$

where

$$\xi_{\widetilde{y}_{ij}}(y) = \frac{1}{C}\, y^{a-1}(1-y)^{b-1} \tag{1}$$
$$a = 1 + ms \quad \text{and} \quad b = 1 + s(1-m)$$

In this representation, $m \in (0,1)$ is the mode of the set, $s \in (0,\infty)$ is the precision of the set, whereas C is a constant ensuring that $\max_{y\in\mathcal{Y}} \xi_{\widetilde{y}}(y) = 1$. Note that $\xi_{\widetilde{y}_{ij}}$ is a normal and convex fuzzy set which lies in the interval $(0,1) \subset \mathbb{R}$. Because of the parametric representation involved by beta fuzzy numbers, the observed fuzzy data can be represented using two matrices, namely the matrix of modes $\mathbf{M}_{n\times J}$ and that of precisions $\mathbf{S}_{n\times J}$. Figure 1 shows an example of beta rating responses. It should be remarked that, in view of the fuzzy-IRTree representation adopted here, m represents the most plausible rating choice, s is the precision of m (i.e., smaller values indicate larger levels of hesitation in the rating choice), and $\xi_{\widetilde{y}_{ij}}$ codifies the decision uncertainty in terms of fuzziness (the larger the fuzziness, the highest the decision uncertainty). Ideally, in the case of no decision uncertainty, the fuzziness would vanish and the true rating realization would be precisely observed.

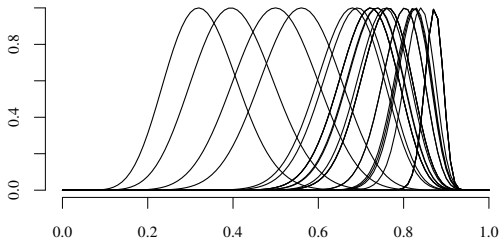

Fig. 1 An example of beta fuzzy responses.

3 Model and parameter estimation

To analyse fuzzy rating data we will adopt the Beta linear model proposed by [4], which is particularly well-suited for bounded rating responses. For a crisp collection of i.i.d. $(0,1)$-realizations $\mathbf{y} = (y_1, \ldots, y_n)$, the Beta density is as follows:

$$f_{\mathbf{Y}}(\mathbf{y};\mu,\phi) = \prod_{i=1}^{n} \frac{\Gamma(\phi_i)}{\Gamma(\phi_i\mu_i)\Gamma(\phi_i-\mu_i\phi_i)}\, y_i^{(\mu_i\phi_i-1)}(1-y_i)^{(\phi_i-\mu_i\phi_i-1)} \tag{2}$$

where

$$\mu = (1+\exp(\mathbf{X}\beta))^{-1} \quad \text{and} \quad \phi = \exp(\mathbf{Z}\gamma) \tag{3}$$

where $\mu \in (0,1)^n$ is the $n \times 1$ vector of location parameters and $\phi \in (0,\infty)^n$ the $n \times 1$ vector of precision parameters, which have been linearly expanded to account for the presence of covariates. To estimate model parameters $\theta = (\beta,\gamma)$, we use an adaptive Metropolis-Hastings algorithm where the transition distribution is approximated by means of a multivariate Normal distribution $q(\theta^{(t)}|\theta^{(t-1)}) = \mathcal{N}(;\theta^{(t-1)},\Sigma^{(t)})$, with the covariance matrix $\Sigma^{(t)}$ being adapted at each step by using a convenient subsample from the previous samples [5]. In this context, the acceptance ratio of the sampler is as follows:

$$\alpha^{(t)} = \frac{\mathcal{L}(\theta^{(t)};\mathbf{m},\mathbf{s})q(\theta^{(t-1)}|\theta^{(t)})f(\theta^{(t)})}{\mathcal{L}(\theta^{(t-1)};\mathbf{m},\mathbf{s})q(\theta^{(t)}|\theta^{(t-1)})f(\theta^{(t-1)})} \tag{4}$$

where $\mathcal{L}(\theta^{(t)};\mathbf{m},\mathbf{s})$ is the likelihood function for the fuzzy sample of data and $f(\theta^{(t)})$ is the prior density ascribed to the model parameters. In the case of i.i.d. and non-interactive fuzzy responses, the imprecise likelihood function is as follows [6, 7]:

$$\mathcal{L}(\theta^{(t)};\mathbf{m},\mathbf{s}) = \prod_{i=1}^{n} \int_0^1 \xi_{\tilde{y}_i}(y;m_i,s_i) \frac{\Gamma(\phi_i)y^{(\mu_i\phi_i-1)}(1-y)^{(\phi_i-\mu_i\phi_i-1)}}{\Gamma(\phi_i\mu_i)\Gamma(\phi_i-\mu_i\phi_i)}\, dy \tag{5}$$

4 Application

In the present application we aimed to investigate the predictors of sexual intimacy in a sample of $n = 450$ participants from Flanders (73% female, mean age 32.9 years, mean relationship length 7.68 years).[1] Because of its characteristics, assessing the determinants of sexual intimacy is a typical situation in which raters show some levels of decision uncertainty in providing their self-reported responses. The survey consisted of four questionnaires used to measure (i) the perceived sexual intimacy with the partner, (ii) the perceived partner responsiveness (i.e., the extent to which one experiences the partner as being responsive to emotional needs), (iii) the sexual desire, (iv) the avoidant attachment score (i.e., how ambivalent early developmental experiences affect the current relationship). The items have been measured on a 7-point Likert-type scale with response categories ranging from 1 ("definitely not") to 7 ("yes, definitely"). The items associated with sexual intimacy have been fuzzified using the fuzzy-IRTree method [1] and the ensuing fuzzy beta responses

[1] The dataset is publicly available at `http://osf.io/adgw2/`. For further details about the survey, see [8].

have been averaged to form the final intimacy indicator (see Figure 1 for a subsample of fuzzy responses). Following the findings by [8], three additive Beta linear models M1-M3 have been defined to predict sexual intimacy (see Table 1). The models have been varied in terms of covariates for the term μ, whereas no covariates have been used to model the precision term (i.e., $\phi = \exp(\mathbf{1}\gamma)$). For all the models, diffuse Normal densities have been used for the priors $f(\beta) = \mathcal{N}(\beta; \mathbf{0}, \mathbf{I}10)$ and $f(\gamma) = \mathcal{N}(\gamma; 0, 3)$ and four parallel MCMC have been run with 20000 samples (5000 samples for the burn-in phase) by means of the R package `MHadaptive`. The final model has been chosen according to the LOO information criterion as implemented by the R package `loo` [9]. According to the Gelman and Rubin's convergence diagnostics, all the chains reached the convergence (i.e., $\hat{R} = 1.00$). Table 2 reports the posterior quantiles along with the 95% HDIs for the six model parameters. Figure 2 shows the marginal posterior densities for the model parameters whereas Figure 3 plots the predicted curves against the observed fuzzy data as a function of both continuous and categorical predictors. The posterior results suggest that sexual intimacy is predicted by the perceived partner responsiveness, with a slight decrease of the outcome for the case in which the partner is male. The other predictors seem to play a marginal role in predicting sexual intimacy, with a negative relationship between avoidant attachment style and sexual intimacy as expected.

Model	Covariates	LOOIC
M1	`partner_respo`, `sex_desire`	873.80
M2	`partner_respo`, `sex_desire`, `attach_avoid`	863.50
M3	`partner_respo`, `sex_desire`, `attach_avoid`, `gender_partner`	**857.00**

Table 1 Application: Models for the sexual intimacy fuzzy rating data. Note that M3 is the best model according to the lowest LOO-IC criterion.

	β_0	$\beta_{\texttt{partner\_respo}}$	$\beta_{\texttt{sex\_desire}}$	$\beta_{\texttt{attach\_avoid}}$	$\beta_{\texttt{gender\_partner:Male}}$	γ
min	-1.01	0.11	-0.01	-0.05	-0.26	3.90
mean	-0.59	0.13	0.02	-0.03	-0.11	4.35
max	-0.12	0.15	0.04	-0.00	0.03	4.90
0.95 HDI_{lb}	-0.83	0.12	0.01	-0.04	-0.20	4.10
0.95 HDI_{ub}	-0.36	0.14	0.03	-0.01	-0.04	4.68

Table 2 Application: Posterior quantiles and 95% HDI for the model parameters. Note that β_0 is the intercept of μ and codifies the level `gender_partner = Female`.

A Mixture Model for Multi-Source Cyber-Vulnerability Assessment

Un modello di mistura per la valutazione delle cyber-vulnerabilitá

Mario Angelelli, Serena Arima and Christian Catalano

Abstract Cyber-risk assessment is gaining increasing attention due to the potential impact of cyber-incidents on digital and physical systems, with consequent effects on individuals and organisations. This work introduces a Bayesian mixture model to relate individual cybervulnerability features and accessible information that could affect attackers' evaluation and cyber-incident occurrence. Individual cybervulnerability features are clustered according to a Dirichlet process. Future research directions aimed at prioritising cyber-vulnerabilities and access to information are discussed too.

Abstract *La valutazione del cyber-rischio è oggi un ambito di interesse crescente a causa del potenziale impatto che gli incidenti informatici possono avere su sistemi digitali e fisici, con conseguenti ricadute sulle persone e sulla collettività. In questo lavoro, si introduce un modello di regressione Bayesiana per collegare le caratteristiche individuali delle cyber-vulnerabilità con le informazioni accessibili che potrebbero influenzare la percezione di tali vulnerabilità e e il verificarsi di incidenti informatici. Il modello prevede un effetto casuale rappresentato da una mistura e volto a evidenziare raggruppamenti di cyber-vulnerabilità senza assunzioni stringenti a priori. Il lavoro si conclude con la discussione di future direzioni di ricerca volte alla prioritizzazione delle cyber-vulnerabilità e all'accesso alle informazioni.*

1 Introduction

Cyber-incidents are of paramount relevance in current technological systems. Issues posed by compromised data Confidentiality, Integrity, and Availability ("CIA" paradigm) may affect the validity of experimental results in the scientific context, as well as the generated value in productive sectors. The plurality of incidents and attack categories (e.g. Denial-of-Service, Malware, but also social engineering) may lead to informative, economic, functional, or reputational impact. These issues are now further amplified by the high level of connectivity among devices and networks entailed by the Digital Transformation.

For these reasons, cyber-risk assessment is gaining increasing attention for an informed use of digital resources. Widely accepted standards for cyber-risk assessment comes from the qualitative evaluation of a set of features associated with each cyber-vulnerability. The National Institute of Standards and Technology (NIST) provides a severity ranking of emerging cyber-vulnerabilities based on their impact (along the "CIA" dimensions) and accessibility assessment [2]. However, the actual risk entailed by a cyber-vulnerability also depends on additional factors that may influence attackers' perception regarding a cyber-vulnerability's exploitability: exposure of vulnerable technologies, their diffusion in critical systems, exploit[1] availability (existence and value).

The present work introduces a statistical model to address the relation between cyber-vulnerability assessment and information on the extent of its exploitability. The multiplicity of information sources, impact dimensions, means of exploitation, and attackers' perception suggests adopting a model without *a priori* assumptions on the cyber-vulnerability classification. Formally, we consider a regression model involving: i. categorical regressors, i.e. cyber-vulnerability features, and ii. a set of response variables that express the priority of the cyber-vulnerability, which can be understood as severity, exposure, or availability of resources for exploitation. Multiple response variables reflect the multiplicity of information sources quantifying these interpretations. Then, we choose a Bayesian mixture model to take into account potential grouping effects.

2 Data description and methodology

2.0.1 Data description

The set of regressors that qualitatively assess the cyber-vulnerability features is based on the *attack vector* in the NIST classification. This is a 6-dimensional vector $\mathbf{X}$ of categorical variables.

[1] An exploit is defined as software that can be directly executed to realise a cyber-attack.

- Variables X_C, X_I, X_A reflect the assessed impact on data in terms of Confidentiality, Integrity, and Availability, respectively; each of these categories contains three levels ("none: 0", partial: 0.275", "complete: 0.660").
- Variables X_{AV}, X_{AC}, X_{Au} describe the accessibility prompted by the cyber-vulnerability: i. x_{AV} describes the Access Vector ("Requires local access: 0.395, "Local Network accessible: 0.646", "Network accessible: 1"); ii. x_{AC} assesses Access Complexity (ranked "high: 0.35, "medium: 0.61", "low: 0.71"); iii. x_{Au} assesses Authentication ("Requires no authentication: 0.704", "Requires single instance of authentication: 0.56", "Requires multiple instances of authentication: 0.45).

CVSS is widely accepted as a relevant measure for cyber-vulnerabilities along different dimensions[2]. *Known* vulnerabilities are ranked in terms of the CVSS, the score representing the severity of such vulnerabilities [2]. Conditioned to the attack vector, the CVSS severity score is deterministic: based on the quantitative assessment of regressors presented in Subsection 2.0.1, the impact I, the exploitability E, and the severity score CVSS, are

$$\begin{aligned} \mathrm{I} &= 10.41 \cdot (1-(1-X_C)\cdot(1-X_I)\cdot(1-X_A)), \\ \mathrm{E} &= 20 \cdot X_{AV} \cdot X_{AC} \cdot X_{Au}, \\ \mathrm{CSVV} &= (0.6\cdot \mathrm{I} + 0.4 \cdot \mathrm{E} - 1.5) \cdot 1.176 \cdot (1-\delta_{\mathrm{I}}) \end{aligned} \tag{1}$$

where δ denotes Kronecker's delta.

Different response variables y can be considered to address multiple information sources: we will focus on exposure of vulnerable technologies, software availability for exploitation, and their value. These views on cyber-vulnerabilities are associated with actual data from multiple sources (databases).

With these premises, the composition of the dataset is described as follows:

- statistical units are associated with a unique ID and are extracted from the Common Vulnerabilities and Exposures (CVE) database, which is the knowledge base regarding exploited vulnerabilities.
- Each CVE is associated with an evaluation of the regressors presented above, which is provided by the NIST.
- the Shodan database[3] reports exposed hosts for known vulnerabilities: this may represent a relevant driver for attackers' intervention. Shodan allows including CVE and Country as keys for queries.
- Reported exploits for CVEs can be extracted from ExploitDB[4].
- The information on exploits can be further refined from VulnDB[5], a database that collects information on the price range for exploits associated with a CVE. Fields extracted from VulnDB include the price range as 0-day (i.e. when the vulnerability was not disclosed and there were no available solutions to patch it),

[2] https://nvd.nist.gov/vuln-metrics/cvss

[3] https://exposure.shodan.io

[4] https://www.exploit-db.com/

[5] https://vuldb.com/

the price rance at the moment of querying, and the exploitability (specified by levels “No defined”, ”Unproven”, ”Proof-of-Concept”, and “Highly functional”).

For all these databases, we prepared scripts using Python in order to automatically extract the required data through APIs. We started from the selection of exposure data in Italy through Shodan to obtain a base set of CVEs. Subsequently, the scripts was adapted to extract Attack Vectors associated with these CVEs from NIST database, and to check the exploits availability from ExploitDB and VulnDB.

The final dataset consists of $n = 593$ records.

2.0.2 Model definition

The regression model is

$$y = \mathbf{X}^{\mathbf{T}} \cdot \beta + \rho + e \tag{2}$$

where

- β_p are the regression parameters, $p \in \mathscr{I} \subseteq \{1,\dots,6\}$. Being associated with categorical data, we adopt an ANOVA representation where each β_p correspond to $\beta_{p,\ell} \sim \mathscr{N}(0,100)$, $\ell \in \{0,\dots,L_p-1\}$, and L_p is the number of levels for the p-th variable.
- ρ is a random effect associated with groups of cyber-vulnerabilities, i.e.

$$\rho \sim \sum_{i=1}^{\infty} w_k \mathscr{N}(\mu_k, 100). \tag{3}$$

- $e \sim \mathscr{N}(0,1)$ is the residual.

In order to implement the Bayesian model, we consider ρ as arising from a Dirichlet process, which is realised using the stick-breaking representation [3]:

$$\begin{aligned}
\alpha &\sim \Gamma(1,1),\\
v_k &\sim \mathrm{B}(1,\alpha), \quad k \in \mathbb{N},\\
w_k &= v_k \cdot \prod_{i=1}^{k-1}(1-v_i), \quad k \in \mathbb{N},\\
\mu_k &\sim \mathscr{N}(0,100), \quad k \in \mathbb{N},\\
\rho|k &\sim \mathscr{N}(\mu_k,100) \quad \text{with } p(k|w) = w_k.
\end{aligned} \tag{4}$$

From this model, y_i, ρ_i, and e_i, $i \in \{1,\dots,n\}$ represent i.i.d. samples.

The evaluation of posterior distributions is based on this model and data X_i describing the attack vector for n cyber-vulnerabilities, and it is carried out through Markov Chain Monte Carlo (MCMC) sampling.

3 Preliminary results

MCMC algorithm allows us to obtain samples from the posterior distribution of all model parameters. The algorithm identified four main components starting from two regressors, namely the categorical variable X_{AV} and the $CVSS$ severity score, and a response variable expressing monitored exposure. The posterior distribution of regressors indicates that they are significant, as shown in Figure 1. The analysis

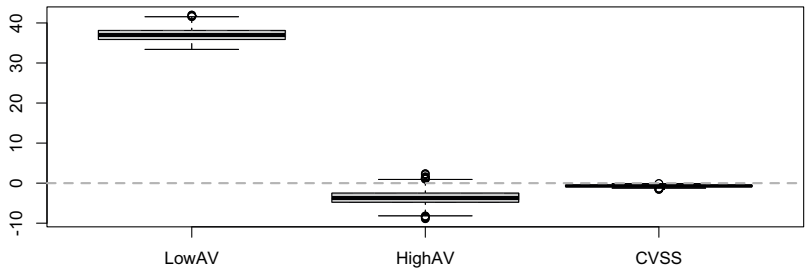

Fig. 1 Box plots for regression parameters associated with the categorical variable X_{AV} (corner: β_{LowAV}; differential: β_{HighAV}) and the severity score $CVSS$.

of the cluster membership for the n units shows that the attack vector does not fully determine the grouping of sampled vulnerabilities. In particular, CVEs associated with the same attack vector do not always lie in the same group k. This suggests that the extent to which vulnerable hosts can be identified, which is quantified by the Shodan response, does not only depend on technical features of the cybervulnerability (expressed by the attack vector), but also on contextual factors that depend on the diffusion and the use of a given technology.

In order to better explore these factors, further analyses involving different combinations of regressors and response variables, with special regard to available resources for exploitation are necessary.

4 Conclusion and Future Work

The present work is a first study aimed at an integrated study of cyber-vulnerabilities through statistical modelling. Other statistical models are being developed for cyber-risk assessment, e.g. [1], and different models can be used to highlight specific aspects that are relevant for cyber-risk assessment.

The actual realisation of cyber-attacks does not only rely on technical features represented by attack vectors, but also on different information sources that can promote or mitigate cyber-attacks. It is plausible that access to information has a relevant role in this regard: as mentioned in [1], data regarding cyber-security are subject to limited disclosure and underestimation, both to adhere to security standards and to prevent reputational loss. On the other hand, open data provided by Organisations may be used not only to prevent cyber-incidents, but also to guide cyber-attackers.

Future work will further explore these issues, addressing the role of ranking of cyber-vulnerabilities dependent on multiple information sources and criteria, as well as relations between these rankings, in order to support decision-makers in both prioritisation and information disclosure.

Hierarchical Bayesian models for analysing fish biomass data.

An application to Parapenaeus longirostris biomass data.

Rita Fici, Antonino Abbruzzo, Luigi Augugliaro and Giacomo Milisenda

Abstract The Mediterranean International Trawl Survey (MEDITS) programme provides spatially referenced ecological data. We adopted a hierarchical Bayesian model to analyse *Parapenaeus longirostris* biomass data. The model comprises three parts, each of which identifies: the variability due to the explanatory variables, the variability due to the spatial domain (seen as a Gaussian Process) and the irregular component modelled as white noise. The estimated parameters show that some seabed characteristics affect biomass quantity and that the estimated behaviour of the Gaussian Process changes over different groups of years.

Abstract *Il programma di ricerca internazionale Mediteranean International Trawl Survey (MEDITS) raccoglie dati ecologici identificati geograficamente. In questo lavoro, per analizzare dati sulla biomassa del Parapenaeus longirostris, è adottato un approccio Bayesiano gerarchico dove il modello di regressione spaziale è formato da tre componenti che dovrebbero racchiudere: la variabilità relativa alle variabili esplicative, quella dovuta alla componente spaziale (modellata attraverso un Processo Gaussiano), e una componente erratica modellata come un white noise. I parametri stimati indicano che alcune caratteristiche del fondale marino influenzano la quantità di biomassa, e che il Processo Gaussiano stimato cambia tra i diversi gruppi di anni analizzati.*

1 Introduction

Several social, political, and economic players show a substantial interest in studying the marine ecosystem. The MEDITS project started in 1994 with the cooperation between several research institutes from the Mediterranean States. The target is to conduct a standard bottom trawl survey in which all the participants use the same sampling protocol and the same methodology [1]. The data concern the biomass quantity of *Parapenaeus longirostris* in the area extending from the southern coasts of Sicily. This fish species is one of the most critical in biological and economic terms. This paper aims to investigate the dependency structures between the biomass and some explanatory variables and study the covariance and autocovariance structures as a function of geographical coordinates. The hierarchical Bayesian model (Equation (1) in Section 2) captures these two aims by equating the response variable with the sum of three components: the effect of explanatory variables, the impact of latent variables, as a function of space, and a white noise.

2 Model specification

Let $\mathbf{Y}(\mathbf{s}) = \{Y(\mathbf{s}_1), Y(\mathbf{s}_2), \cdots, Y(\mathbf{s}_n)\}$ be an n-dimensional random vector of observations of biomass quantity for one species in the spatial points $\mathbf{s}_1, \ldots, \mathbf{s}_n$. We specify a regression equation as follows:

$$Y(\mathbf{s}_i) = \mathbf{x}(\mathbf{s}_i)^\top \boldsymbol{\beta} + W(\mathbf{s}_i) + \varepsilon(\mathbf{s}_i), \qquad \mathbf{s}_i \in \mathbb{R}^2; \tag{1}$$

where $\mathbf{x}(\mathbf{s}_i)$ are the geographically determined covariates, $\boldsymbol{\beta}$ is a vector of regression parameters, $W(\mathbf{s}_i)$ are the latent variable's effects incorporating the variability due to the space domain, and $\varepsilon(\mathbf{s}_i)$ are the independently and identically distributed *white noise*'s manifestations, with variability τ^2, representing the short scale randomness in the regionalized variable, also called *nugget effect* [2].

Assuming that the latent variable's effects follow a Gaussian Process (GP), $\mathbf{W}(\mathbf{s}) \sim GP(\mathbf{0}, \mathbf{C}_\theta)$, and $\boldsymbol{\varepsilon} \overset{\text{i.i.d.}}{\sim} N(\mathbf{0}, \tau^2 \boldsymbol{I})$, the posterior parameter distribution is proportional to:

$$p(\boldsymbol{\beta}, \boldsymbol{\theta}, \tau^2) \times GP(\mathbf{w}|\mathbf{o}, \mathbf{C}_{\boldsymbol{\theta}}) \times N(\mathbf{y}|\mathbf{X}\beta + \mathbf{W}, \tau^2 \mathbf{I}), \tag{2}$$

where the first element is the joint prior distribution of the parameters, which depends on prior's choice. We consider as prior $\boldsymbol{\beta} \sim N_p(\boldsymbol{\mu}_\beta, \boldsymbol{\Sigma}_\beta)$ where p is the number of explanatory variables. The choice of prior distributions for τ^2 and $\boldsymbol{\theta}$ are explained in the next paragraphs. The second element of the posterior in (2) is specified as a GP, with $\mathbf{C}_{\boldsymbol{\theta}}$ as the correlation matrix defined by a parametric covariance function. The last term in (2) represents the probability density distribution attributed to the analysed phenomenon, where the measurement errors or microscale variance depend on the parameter τ^2, while the mean is given by the sum of the process effects and the regression on explanatory variables [3].

Covariance matrix. Using Wackernagel's coregionalization approach [5], a possible specification of the entries in the covariance matrix is $\mathbf{C}_{\boldsymbol{\theta}}(\boldsymbol{s}_i,\boldsymbol{s}_j) = \sigma^2\rho(\boldsymbol{s}_i,\boldsymbol{s}_j;\phi,\nu)$, where $\sigma^2 = var[W(\boldsymbol{s})]$ is the space variance and $\rho(\cdot)$ represents the correlation function between $W(\boldsymbol{s}_i)$ and $W(\boldsymbol{s}_j)$. The specification of the parametric correlation function (which must return a symmetric and positive defined correlation matrix) constitutes an exciting point of reflection regarding the theoretical definition for complex relationships and their practical implementation. We used the correlation function formulated by Matérn [7]:

$$\rho(\boldsymbol{s}_i,\boldsymbol{s}_j;\phi,\nu) = \frac{(||\boldsymbol{s}_i-\boldsymbol{s}_j||\phi)^{\nu}K_{\nu}(||\boldsymbol{s}_i-\boldsymbol{s}_j||;\phi)}{2^{\nu-1}\Gamma(\nu)}, \tag{3}$$

where $||\boldsymbol{s}_i-\boldsymbol{s}_j||$ is the Euclidean distance between observed space coordinates $\boldsymbol{s}_i$ and $\boldsymbol{s}_j$; ϕ tunes the spatial correlation decadence (the bigger ϕ, the faster the spatial correlation comes close to zero when the Euclidean distance increases); $\Gamma(\cdot)$ is the Gamma function and $K_{\nu}(\cdot)$ is the Bessel function of the third kind and order ν. If $\nu = 0.5$, the equation (3) is reduced to the exponential correlation function $\rho(\boldsymbol{s}_i,\boldsymbol{s}_j;\phi) = \exp[-\phi(||\boldsymbol{s}_i-\boldsymbol{s}_j||)]$.

Prior parameters choice. The choice of the Matérn correlation function in equation (3) implies the set of parameters $\theta = \{\sigma^2,\phi,\nu\}$. As recommended by Banerjee *et al.* [6], ϕ is given an informative prior distribution while a relatively vague prior is given to σ^2. The chosen prior for ϕ is a Uniform $(0.003, 0.008)$ and its starting value is 0.005. A decadence parameter of 0.003 or 0.009 means that after two km or after half a km the spatial correlation is close to zero. The parameter ν is chosen to follow a Uniform (0.1 , 0.9) and its starting value is 0.5. The priors for τ^2 and σ^2 follow two Inverse Gamma (IG) distributions. A density-based clustering algorithm [4] is used to choose their hyperparameters. The clusters are composed of at least ten observations less than 2.5 km away from their core point. The prior for τ^2 is an IG(0.07, 24.08) which gives an expected value equal to the median of the biomass's variances within clusters and a τ^2's variance equal to the variance of the clusters variances vector. The starting value of τ^2 is 337.66. The prior for σ^2 is an IG(3.062, 2143.75) which gives an expected value equal to the difference between the total response variance and the expected value of τ^2, and gives a big enough variance of σ^2. Its starting value is 700.
Inference is carried out by MCMC algorithms. The set of parameters $\{\sigma^2,\phi,\nu,\tau^2\}$ is estimated by a Metropolis-Hastings algorithm, where the proposal distributions are Normal with $50, 0.5, 0.2$ and 100 as variance parameters, respectively. A Gibbs-Sampler algorithm is used to estimate $\boldsymbol{\beta}$ and $\boldsymbol{w}$. See [8] for details.

3 Data analysis

We analysed data related to the years in which the sampling was done during the summer (from June to August). Two different subsets of data are analysed, one given by the years from 2002 to 2005 and 2007, and the other given by years from 2011 to 2016 (2014 excluded). In each model comprise 1,005,000 iterations, a burn-in of 25% and a thinning value of 700. The final sample size has 1077 values for each parameter.

We use the Deviance Information Criterion (DIC) as a measure of model choice. The lower the DIC value, the better the model.

Here we show the results related to *Parapenaeus longirostris*'s biomass.

$\rho(\boldsymbol{s}_1;\boldsymbol{s}_j\|\boldsymbol{\theta})$	σ	τ	ϕ	ν	DIC
Esponenziale (2002-07)	(17.231 , 25.179)	(2.978 , 15.291)	(0.003 , 0.008)	0.5	654.0771

Table 1: 95% credible interval of parameters of variability for *Parapenaeus longirostris*'s biomass.

As shown in Table 1, for both groups of years, the value of the DIC is lower when an exponential correlation function is considered. It is possible to note that the estimated values for the parameter σ are bigger than the estimated values for τ: this suggests a bigger impact of the variability due to latent variables related to space than the variability due to the *nugget effect*. In all models, the estimated parameter

$\rho(\boldsymbol{s}_1;\boldsymbol{s}_j\|\boldsymbol{\theta})$	Depth	sq. Depth	Temperature	Seabed
Esponenziale (2002-07)	(-6.66 , 3.34)	(-9.24 , -0.61)	(-6.00 , 1.80)	(1.91 , 10.91)
Esponenziale (2011-16)	(-20.42 , -6.21)	(-10.15 , 1.68)	(-5.39 , 6.37)	(1.68 , 14.94)

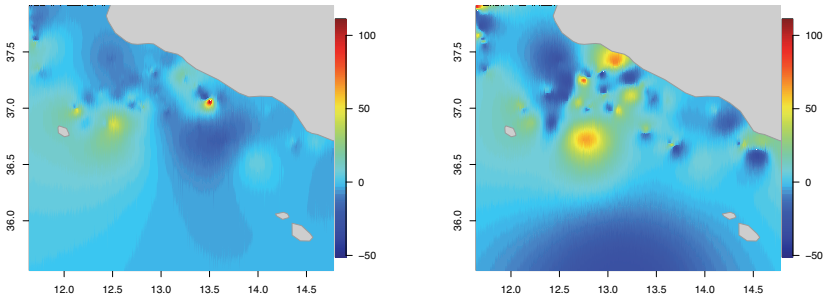
Matérn (2011-16)	(-20.99 , -6.02)	(-9.97 , 1.77)	(-5.40 , 7.00)	(1.37 , 15.00)

Table 2: 95% credible interval of regression coefficients for *Parapenaeus longirostris*'s biomass.

for the slope of the seabed is significant. The depth is significant for the first group of years, while its quadratic component is significant for the second group of years. Temperature is never significant (Table 2).

Figure 1 shows the estimated components of the GP for the two groups of years. Blue and red colours indicate a negative and a positive effect of the GP on the biomass, respectively. W's distribution in the first group of years looks more homogeneous than W's distribution in the second group of years. Indeed, in Figure



(a) First group of years.

(b) Second group of years.

Fig. 1: *Parapenaeus longirostris*'s estimated component of GP.

(1a), excluding the only red-coloured zone, the change from one colour to another is slow. In Figure (1b) the changes from blue to yellow-coloured zones are more sudden than what happens in the first group of years (Figure 1a). Moreover, it is possible to observe darker blue-coloured zones. The difference between the two W's distributions could be due to bigger estimated values of the 95% credible interval for the spatial correlation decadence parameter, ϕ, in the second group of years (0.00314 , 0.00788) than in the first group (0.00305 , 0.00793).

4 Conclusions

Hierarchical Bayesian models have been applied to analyse ecological spatial data. The spatial effect is assumed to follow a Gaussian Process in which a parametric function gives the correlation between points. An informative prior distribution is given to the parameter related to the decadence of spatial correlation to assign a low probability to a correlation close to zero when the distance between the points is too small (less than half a kilometre). Previous sections present the results of applied models to *Parapenaeus longirostris*'s biomass data. Two analyses have been carried out, using a Matérn correlation function and an exponential correlation function. The comparison between them shows a better algorithm performance using the exponential function. The explanatory variables are the linear and the quadratic components of the depth, the temperature and the seabed slope. The seabed is always significant. Depth is significant with its linear component for some models and its quadratic component for others. Comparing the estimated Gaussian processes between the two groups of years is possible to note a stronger space correlation in the earliest years than in the latest years of observation.

We conclude with some final remarks regarding directions for future research. Analysing multivariate response data would increase the knowledge of the interactions between species and understanding the food web structure.

Insights into the derivative-based method for nonlinear mediation models

Considerazioni sul metodo basato sulle derivate per modelli di mediazione non lineari

Claudio Rubino and Chiara Di Maria

Abstract Associational mediation analysis has generally relied on the linearity of models to estimate the indirect effect as a product of regression coefficients. Very few examples of generalisations to nonlinear settings have been proposed, including a derivative-based method that, however, is far from being widely spread among scholars. In this paper, we clarify some aspects of such an approach to nonlinear mediation models, which have not been addressed by the previous literature. In addition, we run a simulation study to compare confidence intervals for the indirect effect obtained through different approaches.

Abstract *L'analisi di mediazione in contesti associativi si è generalmente basata sulla linearità dei modelli per stimare l'effetto indiretto come prodotto di coefficienti di regressione. Tra i pochi esempi di generalizzazione a contesti non lineari proposti si annovera un metodo basato sulle derivate, che tuttavia è ben lontano dall'essere diffuso tra i ricercatori. In questo articolo chiariamo alcuni aspetti di questo approccio che non sono stati ancora affrontati dalla letteratura precedente. Inoltre, si effettua uno studio di simulazione per confrontare gli intervalli di confidenza per l'effetto indiretto ottenuti con diversi approcci.*

Key words: mediation analysis, derivative method, generalised linear models, bootstrap, Monte Carlo method, Bayesian statistics

1 Introduction

Mediation analysis is nowadays a widely spread approach to address settings where the effect of a variable on a response of interest is not entirely direct, but is transmitted by one or more intermediate variables called *mediators*. Mediation analysis was

Claudio Rubino, Chiara Di Maria
Department of Economics, Business and Statistics, University of Palermo, Viale delle Scienze, Building 13, Palermo 90128, Italy. e-mail: claudio.rubino@unipa.it, chiara.dimaria@unipa.it

developed by social scientists [2] who used the path-analytic framework introduced by [12], subsequently further extended to structural equation models (SEM, [3]).

The main features of such an approach are its associational nature, in the sense that the direct and indirect effects do not have a causal interpretation, and its reliance on linear models. Indeed, when the mediator and the outcome models are linear (identity link functions and no interactions) the indirect effect can be estimated as the product of the coefficients lying on the paths connecting X to M and M to Y [2, 3, 8].

However, in real-world applications, it is frequent to deal with non-continuous variables requiring link functions different from the identity; consider, for example, a binary outcome denoting the presence or absence of a certain disease. Despite the widely spread presence of such variables in applied research, mediation analysis with nonlinear models has primarily been addressed in a causal framework [1, 5, 4]. As regards the associational one, very few approaches to deal with this issue have been proposed, based either on approximations [9], or on the less employed difference method [10].

An exception is given by a generalisation of the product method proposed in the '80s [11], and recently revived by [7, 6]. Although quite intuitive, this approach is not widely known and applied by practitioners, and for this reason it is not well developed, presenting theoretical shortcomings yet to be addressed. The aim of the present paper is to discuss some of these gaps and provide more insights into an approach having much potential. We first describe the method, then we move to some of its aspects to be deepened and finally we show the results of a simulation study concerning some of these issues.

2 Mediation analysis in nonlinear models

The basic idea underlying the method proposed by [11] is that the indirect effect can be interpreted as the variation in the outcome Y corresponding to a change in the exposure X through the variation in the mediator M. Such a definition can be formalised in terms of derivatives. Let $\hat{M}$ and $\hat{Y}$ denote the conditional expectations $\mathbb{E}[M \mid X]$ and $\mathbb{E}[Y \mid X, M]$, respectively, and consider the following models

$$g_1(\hat{M}) = \beta_0 + \beta_1 X \quad \rightarrow \quad \hat{M} = h_1(\beta_0 + \beta_1 X) \tag{1}$$

$$g_2(\hat{Y}) = \gamma_0 + \gamma_1 X + \gamma_2 M \quad \rightarrow \quad \hat{Y} = h_2(\gamma_0 + \gamma_1 X + \gamma_2 M), \tag{2}$$

where g_1 and g_2 are possibly non-linear link functions, connecting the conditional expectations of the mediator and the outcome to their linear predictors, and $h_k = g_k^{-1}$, $k \in \{1,2\}$. The indirect effect is then defined as

$$\frac{\partial \hat{Y}}{\partial M} \frac{\partial \hat{M}}{\partial X}, \tag{3}$$

i.e. the product of the derivative of Y on M and that of M on X. Notice that in the simple case of identity link functions, the indirect effect reduces to the traditional expression obtained via the product method $\beta_1\gamma_2$. In contrast, when at least one of the g functions differs from identity, the indirect effect does not assume a single value, since its expression depends on X and/or M. For this reason, [6] suggest to call the effect in Equation (3) *conditional indirect effect* (CIE). Thus, the researcher chooses some values of X of potential interest, say $x_1,\ldots,x_p$ and, if the expression of the indirect effect involves also the mediator, its values should be selected accordingly to those of X, as the predicted values corresponding to $x_1,\ldots,x_p$, obtained from the fitted model.

Although the main focus of this paper is on mediation analysis with generalised linear models (GLMs), it is worth remarking that the derivative-based approach can be used also in situations where the mediator or the outcome depends on nonlinear transformations of their regressors, such as X^2 or $\log(X)$, see [7] for some examples.

3 Potential issues

In this section, we discuss some aspects of the derivative-based method which have not been addressed or satisfactorily deepened in the previous literature on the topic.

Binary mediator

As already mentioned, when the expression of the indirect effect involves both X and M, the values of M should be fixed at the values it assumes in correspondence of the selected values of X, determined by the fitted model. This is quite straightforward, unless the mediator is binary, when some issues arise.

Consider a setting with a binary mediator and an outcome described by Equations (1)-(2), where g_1 is the logit link and g_2 is a generic function different from identity, say the logarithm to fix ideas. Therefore, applying the formula in Equation (3), the CIE is given by

$$\beta_1\gamma_2\frac{\exp(\beta_0+\beta_1X)}{(1+\exp(\beta_0+\beta_1X))^2}\exp(\gamma_0+\gamma_1X+\gamma_2M),$$

which, as can be seen, depends on both X and M. However, when coming to the estimation of such an effect, the problem of which value of the mediator to choose arises. Indeed, the mediator is binary, assuming only two values, while its predicted values from model (1) with a logit link are probabilities, ranging in the continuum from 0 to 1. Which values to select then? This issue is addressed neither by [7] nor by [6]. We believe that the most appropriate solution consistent with a data generating mechanism of this type is to include binary values of the mediator obtained by the corresponding expected probabilities $\hat{\pi}_{M|X}$ by mean of a cutoff c such that

$$\hat{M}|X = \begin{cases} 1 & \text{if } \hat{\pi}_{M|X} \geq c \\ 0 & \text{if } \hat{\pi}_{M|X} < c \end{cases}$$

A possible criterion for the choice of c could be that of selecting the value for which the sensitivity and specificity of the classification are equal.

Covariates

The models in Equations (1)-(2) are intentionally very simple, but real-word data generally require adjustment for covariates. The inclusion of covariates $\boldsymbol{Z}$ in the mediator and the outcome models impacts on the expression of the indirect effect, which can depend on the covariates' values in addition to those of X and M. [7] suggest to estimate the indirect effects conditional on the values of X and M setting the covariates to their mean values.

The authors do not address the scenario where the mediation models include interactions between the exposure or the mediator and the covariates, i.e. when the covariates act as effect modifiers. This simply makes the partial derivatives in (3) more complex, but does not add any conceptual difficulty.

Confidence intervals for the indirect effect

Estimation of confidence intervals (CIs) for the indirect effect is not straightforward even in the linear case, since the distribution of the product $\beta_1\gamma_2$ does not follow a Normal distribution although the two coefficient estimators are assumed to be Normal. This issue is potentially exacerbated in a nonlinear setting. [6] suggest to use non-parametric bootstrap or Monte-Carlo confidence intervals. The former relies on the resampling of statistical units and the estimation of the parameter of interest in each of these samples, in order to obtain the empirical distribution of the conditional indirect effect. The latter does not require resampling, but assumes that the model coefficients in (1)-(2) comes from a multivariate Normal: by generating multiple samples of regression parameters it is possible to obtain a random sample of indirect effects. In both cases, percentiles can be used to derive 95% confidence intervals which respect the potential asymmetry of the indirect effect's distribution.

Supported by a growing body of literature, see for example [13], we claim that another option for the estimation of CIs could be the Bayesian approach. Each parameter is endowed with an *a priori* distribution and an empirical distribution of the indirect effect is obtained via Monte Carlo Markov Chains (MCMC). To the best of our knowledge, no simulation studies have been run so far to compare the performance of these three approaches. This is the primary focus of the next section.

4 Simulation study

We ran a small simulation study to highlight the differences between bootstrap, Monte Carlo and Bayesian CIs in terms of coverage rates and average interval length. We considered six scenarios obtained by varying the sample size ($n =$

30, 100, 200) and the type of distribution/link function for the mediator and the outcome (binary/logit and Poisson/log). X was generated from a Normal with 0 mean and standard deviation 5, and the values selected to compute conditional indirect effects are the mean and $\pm 1sd$. Both the mediator and the outcome are generated from a Bernoulli in a scenario and from a Poisson in the other one, with expectations as in models (1)-(2) and link functions logit and log, respectively. Model coefficients were chosen arbitrarily. Bootstrap estimates are obtained from 1,000 samples, Monte Carlo from 1,000 draws of regression coefficients, assumed to be distributed as a multivariate Normal and Bayesian estimates derive from two chains of length 10,000 with burnin = 5,000, using sparse priors. The number of iterations was set to 500. Results are shown in Figure 1 and in Table 1.

It can be noticed that for both distributions, the coverage rate of Monte Carlo CIs is higher than that of the other types in the scenario with the smallest sample size, while coverage rates are approximately the same in the other cases. As expected, the average CI lengths and the differences between the three methods reduce as the sample size increases. More detailed studies could help to make possible differences among the approaches emerge.

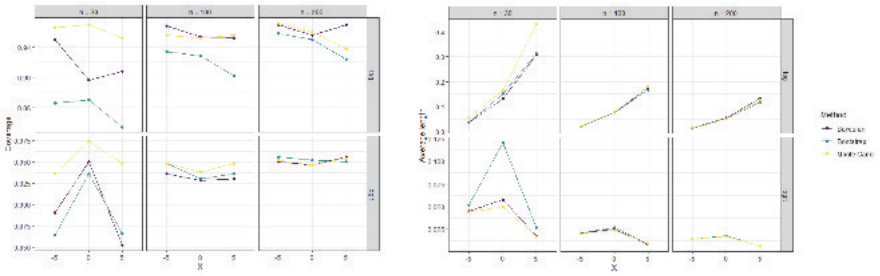

Fig. 1: Results of the simulation study: coverage rates on the left, average CI lengths on the right.

5 Conclusions

In this work, we deepened some aspects of the derivative-based method for mediation analysis in the presence of nonlinear models. A simulation study showed that bootstrap, Monte Carlo and Bayesian confidence intervals are all valid alternatives. The present work can be extended in several ways, for example focusing on the interpretation of conditional indirect effects when the exposure is categorical. In addition, it would be interesting to extend the proposed approach to settings with multiple mediators and to models with random effects.

Table 1: Results of the simulation study. For each method, the average coverage rates and interval lengths are reported.

An exploration of Approximate Bayesian Computation (ABC) and dissimilarities

Un'esplorazione su Approximate Bayesian Computation (ABC) e sulle dissimilarità

Laura Bondi, Marco Bonetti and Raffaella Piccarreta

Abstract In this work we explore the use of dissimilarities among observations to measure the distance between two datasets. This is clearly relevant in the context of ABC, where observed and model-generated data need to be compared. In addition, we propose a new likelihood-free estimation procedure. Results of a simulation study on a simple model are presented.

Abstract *In questo lavoro esploriamo l'uso delle dissimilarità tra le osservazioni per misurare la distanza tra due dataset. Questo è chiaramente rilevante nel contesto di ABC, basato sul confronto tra dati osservati e dati generati da un modello. Proponiamo inoltre una nuova procedura di stima likelihood-free. Sono infine presentati i risultati delle simulazioni per un modello semplice.*

Key words: dissimilarities, ABC, likelihood-free, Wilcoxon-Mosler statistic

1 Introduction

Choosing the summary statistics and the distance function are fundamental issues for inference through Approximate Bayesian Computation (ABC) [10]. Ideally, the summary statistics should be sufficient statistics for the considered model. However, sufficient statistics are often unavailable or unknown, and this makes the choice of the summary statistic at the basis of retention of the generated parameter values one of the most delicate aspect of ABC. The literature on ABC offers several criteria to

select summary statistics or to reduce the dimensionality of the available summaries ([3], [10] and [5]).

Here we suggest a new direction to measure the dissimilarity between two datasets, based on the collection of the pairwise dissimilarities between their cases. Section 2 illustrates some techniques that can be used at this aim, based on a generic measure of dissimilarity and therefore applicable to different types of data. Section 3 describes a new estimation technique - alternative to ABC, but still likelihood-free - built from the same dissimilarity-based metric. The proposed estimator is based on calibration ideas, and is defined as the solution to a minimization problem. In Section 4 we apply the new dissimilarity-based estimation procedure to a simple model: the bivariate normal case. We close with some discussion in Section 5.

2 Dissimilarity-based criteria

Consider an iid sample $y = (y_1, \ldots, y_n)^T$, where each y_i contains information - possibly multivariate - on to the i-th individual. Given the summary statistic $S = S(y)$, in ABC one retains the values of the parameter θ generating a sample with a value of S *close* to the observed data, $S(y_{obs})$. For a fixed value of θ, we focus on the *whole* distribution $f_{S|\theta}(s|\theta)$ of $S(Y)$.

More generally, for a given y_{obs} and for a value y of the random vector $Y \sim f_Y(y|\theta)$, we define a quantity $T(S(y); S(y_{obs}))$ that can be used to measure how far y is from y_{obs}. Note that S can also be the identity transformation, thus $T(y; y_{obs})$. For example, one may set T to be the L^2-distance in Euclidean space. ABC retains the values of θ that generated a sample y such that $T(y, y_{obs}) \approx 0$, i.e. such that $S(y) \approx S(y_{obs})$. The selected parameter values represent a sample from the approximated posterior distribution, and can be *adjusted* to account for the discrepancy between simulated and observed statistics [2, 7].

We aim at introducing alternative possibilities for the definition of $T(y; y_{obs})$. Depending on the kind of data, one can define a one-dimensional dissimilarity measure between two observations y_i and y_j, $d_{ij} = D(y_i, y_j)$. For example, the dissimilarity might be computed as the L^2-distance, or by other distances defined on vector spaces (with the triangle inequality not being strictly necessary). The distribution of the dissimilarity between two randomly selected observations in a population is called the *interpoint distance distribution (IDD)* (see, e.g. [4]).

We propose to use the set of all pairwise dissimilarities $\{d_{ij}\}_{i,j=1,\ldots,n}$ to define a function T measuring the distance between two datasets, to be used in ABC. One can distinguish among three kinds of dissimilarities:

i) within-group dissimilarities within the observed data, i.e. all the pairwise dissimilarities between observed subjects' data;
ii) within-group dissimilarities within the generated data i.e. all the pairwise dissimilarities between generated subjects' data;
iii) between-group dissimilarities, i.e. all the pairwise dissimilarities between an observed and a generated subject's data.

A first approach consists in defining $T(y;y_{obs})$ using the Wilcoxon-Mosler statistic (WM), see [8], that contrasts within-group and between-group dissimilarities through a rank-based test statistic. Specifically, the set including all the dissimilarities (both the within- and the between-group) is sorted in ascending order and ranked, and the test statistic WM is defined as the sum of the ranks of the between-group dissimilarities:

$$\mathrm{WM} = \sum_{i\in\{obs\}} \sum_{j\in\{gen\}} \mathrm{rank}\,(d_{ij})\,, \tag{1}$$

When observed and model-generated data are similar, the ranks of the between-group dissimilarities should be placed at random. In particular, under the null scenario corresponding to the case when the true parameter (and model) generated the data, the pairwise dissimilarities are identically distributed - although not independent. One can show that under permutation of the $m+n$ group labels the statistic WM has expected value

$$E(\mathrm{WM}) = \frac{mn}{2}\left[\binom{m+n}{2}+1\right].$$

For our purposes, no testing of hypotheses, but only quantifying the distance between two datasets is needed. In particular, we define the distance as the squared difference between the observed WM and its expected value under the null hypothesis that observed and simulated data were generated by the same parameter value, i.e. $T(y;y_{\mathrm{obs}}) = [\mathrm{WM} - E(\mathrm{WM})]^2$.

Another approach to quantify the similarity between the observed and simulated data relies on the distance of the estimated cumulative distribution function of the within-group dissimilarities from the cumulative distribution function of the between-group dissimilarities, that can be calculated using one of many available distances, such as the Kolmogorv-Smirnov (KS) statistic. The similarity between model-generated and observed data implies similarity between the distributions of the between-group and of the within-group dissimilarities in the observed data, and a small KS distance.

In the next section we elaborate further on the use of these metrics in ABC, yielding a natural alternative estimator for θ.

3 A new ABC-inspired estimator

For any given θ and y_{obs}, there exists a whole distribution of the random variable $T(Y,y_{obs})$. We now exploit this noting that if T is a *good* measure of the distance of the random vector Y from the sample y_{obs}, its distribution over a range of values of θ can be used to estimate the true value of θ.

Specifically, we may estimate the quantile of order $\tau \in (0,1)$, of the distribution of T conditional to the parameter value θ, $q_\tau(T\,|\,\theta) = \mathrm{argmin}_a E[\rho_\tau(T-a)\,|\,\theta]$. Here,

$\rho_\tau(\cdot)$ is the so-called *check function* and it is given by $\rho_\tau(z) = z(\tau(1 - 1_{\{z<0\}}))$. This is known as quantile regression (see [6] for details). In particular, we perform quantile regression marginally for each parameter component θ (note that one may also apply the multivariate version of quantile regression) and we fit a local linear quantile regression curve $\widehat{q}_\tau(\theta)$, as proposed in [11].

Given the estimated conditional quantile of order τ of the statistic T given θ, we define a new estimator $\widehat{\theta}$ of θ as the solution of the following minimization problem:

$$\widehat{\theta}_\tau(y_{obs}) = \underset{\theta\in\Theta}{\operatorname{argmin}}\, \widehat{q}_\tau(\theta; y_{obs}). \tag{2}$$

This construction is motivated by ABC. Indeed, one would only retain parameter values that produce y's with the *smallest* distance from y_{obs}. One may choose τ to be relatively close to zero (say, $\tau = 0.1$ or 0.05) , and estimate $\widehat{q}_\tau(\theta; y_{obs})$ through quantile regression from the ABC-produced samples (thus exploiting the computational effort already spent to perform ABC), or from samples generated over a grid of values of θ. Observe that as an estimator, $\widehat{\theta}_\tau = \widehat{\theta}_\tau(Y_{obs})$ with $Y_{obs} \sim f_Y(y;\theta^*)$, with θ^* the true value of θ. Also, $\widehat{\theta}_\tau$ clearly depends on the choice of τ.

Note that, if the objective function to be minimized in (2) is regular enough, thus admitting one minimum, it can be obtained by setting the (partial) derivatives of the objective function with respect to θ equal to zero. Clearly, the asymptotic properties, such as consistency and asymptotic normality, of the proposed estimators need to be investigated. Whilst not tackling this issue here, we believe that useful theoretical results can be found in the framework of the theory of estimating equations.

4 The bivariate normal model

We present an example of application of a dissimilarity-based metric in the framework of ABC, and we illustrate how the new estimator introduced in Section 3 can be computed. Let us consider the problem of estimating the centroid $\mu = (\mu_1, \mu_2)^T$ of a bivariate normal distribution with known covariance matrix Σ, $N_2(\mu, \Sigma)$. Let $y_{\text{obs}} = (y_{1i}, y_{2i})_{i=1,\ldots,n}$ be a sample of n observations from the distribution.

To evaluate whether our procedure effectively recovers μ, we set $\mu = (1,2)^T$ and $\Sigma = \text{diag}(2,3)$ and generate a sample of size $n = 100$. We set prior distributions for the unknown parameters $\mu_i \sim N(0,4)$, $i = 1,2$, and generate $K = 10{,}000$ datasets from the model, each one corresponding to a value of μ sampled from the prior distribution (and keeping Σ fixed). We define the pairwise dissimilarity between observations as the L^2-distance, and compute the WM statistic.

We are interested to assess how well the WM distance discriminates among the parameter values proposed by the prior distribution. Figure 1 shows the relationship between the values of the parameters and the distance from the observed data, marginally for the two components of μ.

The blue curves in the figure represent the estimates of the conditional quantiles of order $\tau = 0.1$. The plots in Figure 1 suggest that the metric based on the WM statistic is quite informative about the unknown parameter μ. The minimum dis-

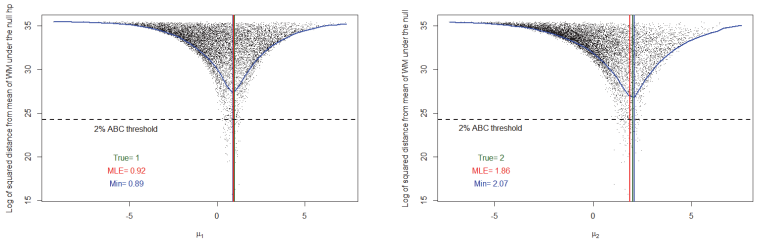

Fig. 1: Samples from the prior distribution of the two mean components, and Wilcoxon-Mosler distance (in log-scale) of each generated dataset from the observed data. The blue curve is the estimated conditional quantile of order $\tau = 0.1$.

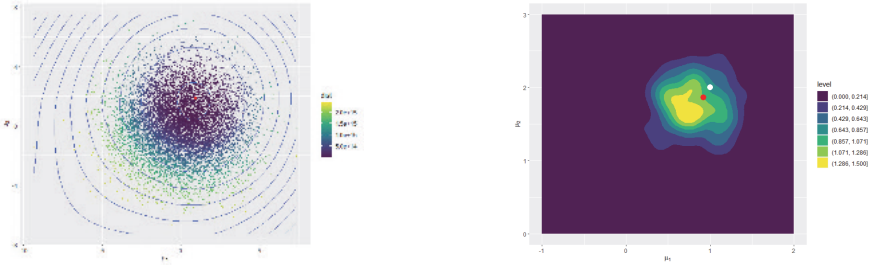
tances are indeed reached for parameter values that are very close to the true ones $(\mu_1 = 1, \mu_2 = 2)$. The figure also shows the suggested estimator for each parameter component (blue vertical lines), i.e. the values for whom the minima of the quantile regression curves are reached (see Section 3), as well as the values of the true parameters (green vertical lines) and of the maximum likelihood estimates (red vertical lines). Note that some of the lines are not visible too clearly because of the overlapping with the others. Figures 2a and 2b report respectively the measure T, together with its level curves, as a function of μ_1 and μ_2 simultaneously, and the level curves of the joint posterior distribution for the parameters obtained through ABC when retaining the best 2% of the values.



(a) Bivariate sample from the prior distribution of μ colored according to the Wilcoxon-Mosler distance, whose level curves are also plotted.

(b) Joint posterior distribution obtained from ABC with retention rate of 0.02. The white dot shows the true data generating parameter and the red one the MLE.

Fig. 2: Posterior distributions for the bivariate normal model with known covariance.

Repeating the experiment with $n = 1000$ suggests that, as expected, the amount of *information* provided by the observed data increases with the sample size, and that the T-based criterion captures that fact.

5 Conclusions

While being only a proof-of-concept, this work suggests that the proposed estimation procedure is promising, and its properties and generalization to more complex models deserve to be investigated.

Importantly, criteria are available to suitably assess the extent of dissimilarity between cases and between two datasets based on the data specific characteristics. An interesting extension of the methods proposed in this article concerns the case of longitudinal data, i.e. when for each subject a sequence of states is observed over discrete time. Several dissimilarity measures among sequences can be defined. Among them, one can test the performance of measures exploiting the continuous nature of the data, such as correlation, as well as measures based on values discretized in bins. In the latter case, a very common choice is the Optimal Matching (OM) algorithm, introduced in molecular biology to study proteins and DNA sequences [9], and then extended to sociology [1]. Such alignment technique, based on the effort needed to transform a discrete sequence into another, can be used to construct a metric for ABC for sequence data.

Advances in Categorical and Preference data

On the predictability of a class of ordinal data models

Sulla capacità previsiva di una classe modelli per dati ordinali

Rosaria Simone and Domenico Piccolo

Abstract The contribution aims at being a pilot study on the prediction performance for the class of mixture models with uncertainty, in order to assess if and to what extent the uncertainty specification provides an added value for model prediction. To this aim, a small simulation study is designed to assess prediction performance of competing models under miss-specification; further, a variable selection procedure based on prediction performance is outlined on a case study.
Abstract *Il contributo propone uno studio preliminare sulla capacità previsiva di una classe di modelli statistici per dati ordinali, usando sia dati simulati che dati reali. In particolare, il valore aggiunto dell'incertezza nella specificazione del modello viene potenziato con l'implementazione di una procedura di selezione delle variabili basata sulle performance predittive.*

Key words: CUB models, Rating Data, Prediction, Variable selection

1 Introduction

The contribution is meant as a pilot study on the added value of uncertainty specification on predictability of the class of mixture models with uncertainty for ratings. The reference modelling framework and the chosen indicators of prediction performance are recalled in Section 2. A pilot simulation experiment is planned in Section 3 to compare the sensitivity, under model mis-specification, of a well-known scoring rule for ordinal responses and of the normalized dissimilarity index used as a measure of prediction error of a given statistical model w.r.t. to a rating distribution. As

a by-product, the effect of covariate specification on prediction performance can be exploited to implement a variable selection procedure (see Section 4): comparisons with cumulative link models is reported for completeness.

2 Methods

The class of CUB mixture models allows to analyse both feeling and uncertainty of the rating process, assuming that the Binomial model is suitable for the latent sentiment as expressed on the discrete support, say with m ordered categories. It can be adjusted for over-dispersion by assuming the Beta-Binomial (CUBE), or mixed with a degenerate distribution to account for inflated frequencies (CUB with shelter): see [8] for an updated overview. Starting from the (shifted) Binomial distribution $b_r(\xi), r = 1,\ldots,m$, with probability parameter ξ, a CUB model for the rating response R is defined by its mixture with a discrete uniform distribution:

$$Pr(R = r|\boldsymbol{\theta}) = \pi_i\, b_r(\xi_i) + (1-\pi_i)\,\frac{1}{m} \tag{1}$$

where parameters π_i, ξ_i can be possibly linked to (row vectors of) subjects' covariates $\boldsymbol{y}_i, \boldsymbol{x}_i$ with a logit link $logit(\pi_i) = \boldsymbol{y}_i\boldsymbol{\beta}$, $logit(\xi_i) = \boldsymbol{x}_i\boldsymbol{\gamma}$. Otherwise, CUB models allow to estimate overall feeling $1-\xi$ and overall uncertainty weight $1-\pi$, meant as importance of the heterogeneity of the distribution not accounted for by the feeling model[1]. For this reason, CUB uncertainty is deemed to play a crucial role in enhancing both fitting and prediction performance of the feeling model. In case covariates are not specified in the model, then the (normalized) dissimilarity index $Diss(\boldsymbol{p},\boldsymbol{f}) = \frac{1}{2}\sum_{r=1}^{m}|f_r - p_r(\boldsymbol{\theta})| \in [0,1]$ allows to assess the extent by which a discrete model $\boldsymbol{p}$ matches category-wise an observed (relative) frequency distribution $\boldsymbol{f}$. For the purpose of the paper, the sensitivity of the Dissimilarity index under miss-specification will be tested when it is used as a measure of prediction accuracy of a model $\boldsymbol{p}$ estimated on a training set w.r.t. the frequency of a validation set.

2.1 The Ranked Probability score for prediction performance

We resort to the Rank Probability Score (RPS, [3, 7, 4]) as a scoring rule specifically designed for ordinal distributions to assess predictive performance of selected models. With the above notation, the RPS for a new observation $R^\star$, based on a fitted probability model $\boldsymbol{p} = (p_1,\ldots,p_m)$ for R, is defined as:

[1] If $p \geq 0$ and $q \geq 0$ covariates are specified for uncertainty and feeling parameters respectively, then we refer to CUB(p,q) model.

$$RPS_{R^\star} = \frac{1}{m-1}\sum_{k=1}^{m}\left(\sum_{s=1}^{k} p_s - \sum_{s=1}^{k} 1_{R^\star=s}\right)^2 \quad (2)$$

The model that has the lowest total RPS score, summed over all observations in the test set, is the one providing the best prediction performance. It is among the most popular prediction indicators for ordinal classifiers, as random forests and trees [5, 6].

3 A simulation study

This section is tailored to assess the sensitivity of prediction performance granted by the RPS score and the dissimilarity index between the model estimated on the training set and the frequency distribution of the test set, showing that the two measures of prediction error behave similarly. In particular, we have planned a simulation experiment to evaluate the effect of uncertainty specification on model-prediction, by sampling $n = 500$ observations from each generating model X for 100 times: Binomial, CUB, CUB with shelter, and CUBE for overdispersion. In the latter two cases, performances of Binomial with shelter and Beta-Binomial are reported for comparative purposes. The sample is then split into training and test set: after candidate models are fitted on the training set, the dissimilarity of each of them with the frequency distribution of both training and test set is computed. Finally, the RPS under each estimated model is computed for each observation in the test set, and then summed. The following list reports the average over simulation runs of both the dissimilarity index and of the RPS for each simulation scenario:

- Starting from a Binomial, with $m = 8$, it can be seen that uncertainty specification adjusts prediction performance of the feeling component, with an improvement that increases with the heterogeneity of the distribution (the relative gain amounts to 1.56% if $\pi = 0.7$ to 5.8% if $\pi = 0.3$ and to 8.32% if $\pi = 0.1$) (see Table 1);

	$X \sim Bin(0.7)$		$X \sim CUB(\pi = 0.7, \xi = 0.6)$		$X \sim CUB(\pi = 0.3, \xi = 0.6)$		$X \sim CUB(\pi = 0.1, \xi = 0.6)$	
Fit:	Binomial	CUB	Binomial	CUB	Binomial	CUB	Binomial	CUB
Average RPS	14.158	14.158	20.348	20.031	26.718	25.160	29.675	27.206
Diss - train set	0.042	0.042	0.131	0.045	0.278	0.047	0.346	0.045

4 On the prediction of subjective probability to survive

It is well-known that people are biased with respect to self-reported life expectancy and this affects financial behavior, pension participation and savings decision. For this reason, the determination of drivers of subjective probability to survive at given age is of strategic importance. To this aim, we consider a survey carried out in 2006 by ISFOL[2], and analyse a sample of $n = 20184$ validated answers to the question: '*In your opinion, what is the probability that you will reach age 90? Please provide a value between 0 (impossible event) and 100 (certain event).*' The continuous measurement was then discretized on a scale with $m = 7$ categories[3]. See [9] for a comparative discussion on fitting and explanatory performance of CUB and cumulative models on this dataset. The average RPS over 10 folds for the Binomial model without covariates amounts to $RPS_{Bin} = 233.545$, whereas $RPS_{CUB} = 229.036$, yielding a relevant decrease in prediction error. On a similar note, the dissimilarity between observed frequency distribution of the validation and model fitted on the training set, averaged over folds, decreases from $Diss(\boldsymbol{f}_{test}, Bin_{train}) = 0.161$ to $Diss(\boldsymbol{f}_{test}, CUB_{train}) = 0.088$. The first step of the proposed variable selection procedure is the identification of the variable that - for a one covariate model - performs the best. Table 4 reports results for competing models: Binomial with covariate, $CUB(0,1)$ with covariate only for feeling, $CUB(1,1)$ with the given covariate specified for both model components, and POM for comparison purposes, highlighting that uncertainty specification, beyond fitting and explanatory performance, improves prediction ability, or at least behaves equivalently to POM.

If we consider all covariates in model specification, we can verify if and to what extent prediction improves when switching from Binomial with covariates to $CUB(0,q)$ with covariates only for feeling and overall uncertainty, and similarly

[2] Institute for training of workers, Ministry of Labour and Welfare, Italy

[3] Class endpoints were set to $0,5,25,45,55,75,95,100$: the resulting relative frequency distribution $(0.095,0.132,0.150,0.166,0.193,0.144,0.120)$ is pretty heterogeneous.

	Gender	Age	No head	Married	Has children	Employed
Binomial	372.709	370.679	372.214	371.096	370.651	372.332
CUB$(0,1)$	351.419	350.436	351.252	350.639	350.334	351.240
CUB$(1,1)$	351.388	348.276	350.750	349.700	349.463	351.051
POM	351.353	349.693	350.944	350.041	349.673	351.059

Table 4 Average over 10-folds of the RPS score for competing models with given covariate

we can assess the gain of switching from CUB$(0,q)$ to CUB(q,q) with the same covariate set for both components: see Table 5.

Binomial	$CUB(0,q)$	$CUB(q,q)$	POM
425.9020	350.1574	348.0456	349.2173

Table 5 Average over 10-folds of the RPS score for competing models with all covariates specified either only for feeling or for both components

Finally, we report in Table 6 the forward selection results obtained by including, at each step, the variable for which the minimum RPS is attained: at each stage, the best performance corresponds to $CUB(p,q)$ with the same set of covariates for both feeling and uncertainty[4]: age, marital status, gender and having children are the most useful factors to predict subjective probability to survive.

	Age	Married	Female	Has children	No head	Work
Average RPS over folds	141.088	141.045	141.017	140.991	140.991	140.991

Table 6 RPS-based variable selection for responses of individuals living in southern Italy: covariates are listed with respect to their entering order in the procedure

For completeness, Table 7 reports the prediction performance for the best fitting model (which foresees an age effect for uncertainty together with differences implied by gender and marital status on feeling) compared to those of POM, Binomial, $CUB(0,q)$, CUB$(p,0)$ (for the latter two, we used only covariates for the corresponding component of the best model) [5].

	Binomial	CUB$(0,q)$	CUB$(p,0)$	CUB(p,q)	POM
Average RPS over folds	150.211	141.777	141.569	140.997	142.994

Table 7 Average RPS over folds for the best fitting CUB(p,q)

[4] For the sake of illustration, we report only results corresponding to respondents that live in Southern Italy ($n = 8107$).

[5] We have resorted to the fast estimation procedure and the corresponding best-subset variable selection available within the `R` library `FastCUB` [11].

5 Further developments

This preliminary research focuses on model-based prediction for rating data to implement a variable selection procedure: on the topics, see [10, 12] on the basis of random forest variable importance for numeric variables and ROC curves for binary outcomes, respectively; see [1] for a Bayesian research on the best predictive normal linear model. Further developments include comparisons between the best model attained with the proposed strategy and prediction achieved via model-based random forests based on CUB model regression trees [2], for instance.

Multivariate analysis of binary ordinal data using graphical models

Analisi multivariata di dati binari ordinali attraverso l'impiego di modelli grafici

Camilla Caroni, Fabio Alberto Comazzi, Andrea Deretti, Federico Castelletti

Abstract In this contribution we address the issue of inferring dependence relations between ordered binary variables. We propose a Bayesian model specification which assumes that ordinal data are generated by discretization of latent Gaussian data and that the joint density of the latent variables satisfies the conditional independencies imposed by a graphical model. We then propose an MCMC strategy for joint structural (graph) learning and parameter estimation.

Abstract *In questo contributo si considera il problema di stima di relazioni di dipendenza tra variabili binarie ordinali. Si propone un modello bayesiano, il quale assume che dati ordinali siano generati attraverso discretizzazione di osservazioni latenti gaussiane e che la distribuzione congiunta delle variabili latenti soddisfi relazioni di dipendenza imposte da un modello grafico. Si propone quindi un algoritmo di tipo MCMC per l'apprendimento della struttura grafica e l'inferenza sui parametri del modello.*

1 Introduction

Modelling dependence relations between variables represents an important issue in many applied domains, and a variety of statistical methods have been proposed for this purpose. Typically the structure of dependencies is unknown and accordingly it must be inferred from the available data. To this end, probabilistic graphical models [6] adopt a graph-based representation of conditional independence relations among variables which are embedded in the joint density through a suitable graph-factorization. Specifically, a graph $\mathscr{G} = (V, E)$ consists of a set of nodes V associated to variables in the system, and a set of edges E, representing dependence relations. The goal is therefore to *learn* the graphical structure $\mathscr{G}$ given the data.

Most of the available methodologies however, both frequentist and Bayesian, deal under the assumption that Gaussian or categorical data are collected; see for instance [4], [5] and [7] for a Bayesian approach. More recently, a few methods for *mixed* (Gaussian and categorical) data have been proposed; see for instance [2] for a frequentist methodology. Still in the categorical framework, the majority of the literature has considered the case of *unordered* data which are represented as contingency tables of counts. In the Bayesian framework, methodologies based on suitable extensions of the Multinomial-Dirichlet model have been proposed for the analysis of unordered categorical data; see for instance [1] and references therein.

This contribution summarizes our first attempt to build a Bayesian framework for the multivariate analysis of categorical *ordinal* variables. For simplicity we assume all variables being *binary*, while in the last section of the work we provide some remarks for possible extensions to a general setting with ordered *polytomous* variables. Ordinal variables, namely variables whose levels are arranged according to a given ordering are quite common in many contexts, specifically in social sciences and psychology. In this framework, the adoption of standard methods for the analysis of categorical unordered data, although possible, is clearly not satisfactory, since the whole information encoded in the ordering of the data is lost.

The key assumption of our method is that the observed categorical variables $X_1, \dots X_q$ are generated by *discretization* of latent Gaussian random variables $Z_1, \dots,$ Z_q, whose joint density satisfies the conditional independence relations imposed by the graph $\mathscr{G}$. The main advantage of the proposed methodology is that we are able to infer both the underlying network structure as well as the *sign* of the dependence relation between pairs of variables. Finally, being fully Bayesian, a coherent quantification of the uncertainty around parameter estimates is provided.

2 Model formulation

In this section we introduce our model specification, which is based on the assumption that ordinal binary data are generated by thresholding of latent Gaussian observations.

Let $(X_1,\ldots,X_q)$ be a collection of ordinal (binary) variables such that $X_j \in \{0,1\}$ for each $j=1,\ldots,q$. Let also $(Z_1,\ldots,Z_q)$ be q continuous variables, each associated with one of the q binary variables. We assume that each binary variable is obtained by *discretization* of its latent counterpart as

$$X_j = \begin{cases} 0 & \text{if } Z_j < \theta_0^{(j)} \\ 1 & \text{if } Z_j \geq \theta_0^{(j)} \end{cases} \tag{1}$$

where Z_j is the (latent) Gaussian random variable associated with X_j and $\theta_0^{(j)} \in (-\infty,\infty)$ represents an unknown cut-off parameter. Observed data then consist of $\mathbf{x}^{(1)},\ldots,\mathbf{x}^{(n)}$ where $\mathbf{x}^{(i)} = \left(x_1^{(i)},\ldots,x_q^{(i)}\right)^\top$ denotes the i-th realization of the random vector $(X_1,\ldots X_q)$, row of the (n,q) data matrix $\mathbb{X}$.

In what follows we assume that the joint distribution of the latent variables is multivariate Gaussian and that the model-parameter (covariance matrix Σ) satisfies the constraints imposed by a graphical model $\mathscr{G}$. Specifically, we rely on decomposable undirected graphical models (UGs) [3] and write

$$\begin{aligned} (Z_1,\ldots,Z_q) \mid \Sigma,\mathscr{G} &\sim \mathscr{N}_q(\mathbf{0},\Sigma) \\ \Sigma \mid \mathscr{G} &\sim \mathrm{HIW}(b,D), \end{aligned} \tag{2}$$

where HIW denotes the *Hyper Inverse Wishart* prior distribution. In addition, under the decomposable UG $\mathscr{G}$, the joint density of $(Z_1,\ldots,Z_q)$ factorizes as

$$p(\mathbf{z} \mid \Sigma,\mathscr{G}) \propto \frac{\prod_{C\in\mathscr{C}} |\Sigma_C|^{-\frac{1}{2}} \exp\left\{-\frac{1}{2}\mathbf{z}_C^T\Sigma_C^{-1}\mathbf{z}_C\right\}}{\prod_{S\in\mathscr{S}} |\Sigma_S|^{-\frac{1}{2}} \exp\left\{-\frac{1}{2}\mathbf{z}_S^T\Sigma_S^{-1}\mathbf{z}_S\right\}}, \tag{3}$$

where $\mathscr{C}$ and $\mathscr{S}$ denotes the sets of cliques and separators respectively of $\mathscr{G}$. We refer the reader to [3] for full details.

Because of (1), the *augmented* density of $(X_1,\ldots,X_q)$ and $(Z_1,\ldots,Z_q)$ can be written as

$$\begin{aligned} p(\mathbf{x},\mathbf{z} \mid \Sigma,\Theta,\mathscr{G}) &= p(\mathbf{z} \mid \Sigma,\mathscr{G})p(\mathbf{x} \mid \mathbf{z},\Theta) \\ &= p(\mathbf{z} \mid \Sigma,\mathscr{G})\mathbf{1}\left\{\mathbf{z} \in C(\mathbf{x},\Theta)\right\}, \end{aligned} \tag{4}$$

where $\mathbf{1}(\cdot)$ is the indicator function, $C(\mathbf{x},\Theta)$ is defined as

$$C(\mathbf{x},\Theta) = \left[\theta_{x_1-1}^{(1)},\theta_{x_1}^{(1)}\right) \times \left[\theta_{x_2-1}^{(2)},\theta_{x_2}^{(2)}\right) \times \cdots \times \left[\theta_{x_q-1}^{(q)},\theta_{x_q}^{(q)}\right),$$

and for each $j=1,\ldots,q$ we adopt the notation $\theta_{-1}^{(j)} = -\infty$, $\theta_1^{(j)} = +\infty$. Given (3) we can write explicitly

$$p(\mathbf{x},\mathbf{z} \mid \Sigma,\Theta,\mathscr{G}) \propto \frac{\prod_{C\in\mathscr{C}} |\Sigma_C|^{-\frac{1}{2}} \exp\left\{-\frac{1}{2}\mathbf{z}_C^T\Sigma_C^{-1}\mathbf{z}_C\right\}}{\prod_{S\in\mathscr{S}} |\Sigma_S|^{-\frac{1}{2}} \exp\left\{-\frac{1}{2}\mathbf{z}_S^T\Sigma_S^{-1}\mathbf{z}_S\right\}} \mathbf{1}\left\{\mathbf{z} \in C(\mathbf{x},\Theta)\right\}. \tag{5}$$

Consider now the (n,q) data matrix $\mathbb{X}$ collecting n i.i.d. (binary) observations $\mathbf{x}^{(1)},\ldots,\mathbf{x}^{(n)}$ from (4) and the corresponding (n,q) latent data matrix $\mathbb{Z}$. Then, we can write the *augmented likelihood* as

$$p(\mathbb{X},\mathbb{Z} \mid \Sigma,\Theta,\mathscr{G}) = p(\mathbb{Z} \mid \Sigma,\mathscr{G}) \prod_{i=1}^{n} \mathbf{1}\left\{\mathbf{z}^{(i)} \in C\big(\mathbf{x}^{(i)},\Theta\big)\right\}$$
$$\propto \frac{\prod_{C\in\mathscr{C}} |\Sigma_C|^{-\frac{n}{2}} \exp\left\{-\frac{1}{2}\mathrm{tr}(\Sigma_C^{-1}S_C)\right\}}{\prod_{S\in\mathscr{S}} |\Sigma_S|^{-\frac{n}{2}} \exp\left\{-\frac{1}{2}\mathrm{tr}(\Sigma_S^{-1}S_S)\right\}} \prod_{i=1}^{n} \mathbf{1}\left\{\mathbf{z}^{(i)} \in C(\mathbf{x}^{(i)},\Theta)\right\},$$

where $S = \mathbb{Z}^T\mathbb{Z}$ and S_C denotes the sub-matrix of S with columns and rows indexed by $C \subseteq \{1,\ldots,q\}$.

Now remember that $\theta_0^{(j)}$, $j = 1,\ldots,q$, are (unknown) random thresholds linking the latent data to the binary observations. As a prior distribution we then assume

$$\theta_0^{(j)} \overset{\text{iid}}{\sim} \mathscr{N}(0,\tau^2), \quad j = 1,\ldots,q. \tag{6}$$

We complete our model specification by assigning a prior to graph $\mathscr{G}$, for any $\mathscr{G} \in \mathbb{S}_q$, the space of decomposable UGs on q nodes. Specifically, let $A_{u,v}$ be the 0-1 (u,v)-element of the lower triangular adjacency matrix of $\mathscr{G}$. We assign hierarchically

$$A_{u,v} \mid \pi \overset{iid}{\sim} \mathrm{Ber}(\pi),$$
$$\pi \sim \mathrm{Beta}(a,b),$$

which corresponds to a multiplicity-correction prior on graph $\mathscr{G}$; see also [8].

3 Posterior inference

Starting from the model formulation introduced in the previous section we can consider the posterior distribution

$$p(\Sigma,\Theta,\mathscr{G},\mathbb{Z} \mid \mathbb{X}) = p(\mathbb{Z} \mid \Sigma,\mathscr{G}) \prod_{i=1}^{n} \mathbf{1}\left\{\mathbf{z}^{(i)} \in C(\mathbf{x}^{(i)},\Theta)\right\} p(\Sigma \mid \mathscr{G}) p(\mathscr{G}) \prod_{j=1}^{q} p(\theta_0^{(j)}),$$

where the latent data $\mathbb{Z}$, since unobserved, are also included among the "parameters" of the model. Because direct sampling from the latter distribution is not possible, we propose to implement a block Gibbs sampler scheme coupled with a Metropolis Hasting step to sample from the full conditional distributions of the model parameters. For convenience, we consider the two sets of parameters $(\Sigma,\mathscr{G})$ and $(\mathbb{Z},\Theta)$.

To start with, the full conditional of $(\Sigma,\mathscr{G})$ can be written as

$$\begin{aligned} p(\Sigma,\mathscr{G} \mid \Theta,\mathbb{Z},\mathbb{X}) &= p(\Sigma,\mathscr{G} \mid \mathbb{Z}) \\ &\propto p(\mathbb{Z} \mid \Sigma,\mathscr{G})p(\Sigma \mid \mathscr{G})p(\mathscr{G}), \end{aligned} \tag{7}$$

where $p(\Sigma,\mathscr{G} \mid \Theta,\mathbb{Z},\mathbb{X})$ reduces to $p(\Sigma,\mathscr{G} \mid \mathbb{Z})$ because Σ and $\mathscr{G}$ are independent of $\mathbb{X}$ and Θ given $\mathbb{Z}$, that is once the latent data are "observed". The latter expression corresponds to a joint posterior of $(\Sigma,\mathscr{G})$ in a Gaussian graphical model with a HIW (conjugate) prior; accordingly, direct sampling from $p(\Sigma,\mathscr{G} \mid \mathbb{Z})$ is possible following the MCMC scheme presented in [9].

The full conditional of $(\mathbb{Z},\Theta)$ can be instead written as

$$p(\mathbb{Z},\Theta \mid \Sigma,\mathscr{G},\mathbb{X}) = p(\mathbb{Z} \mid \Theta,\Sigma,\mathscr{G},\mathbb{X})p(\Theta \mid \Sigma,\mathscr{G},\mathbb{X}). \tag{8}$$

Specifically, we can write the first term as

$$p(\mathbb{Z} \mid \Theta,\Sigma,\mathscr{G},\mathbb{X}) \propto \prod_{i=1}^{n} d\mathscr{N}_q(\mathbf{z}^{(i)} \mid \mathbf{0},\Sigma)\mathbf{1}\left\{\mathbf{z}^{(i)} \in C(\mathbf{x}^{(i)},\Theta)\right\},$$

where $d\mathscr{N}_q(\cdot)$ denotes the density function of the multivariate Normal distribution $\mathscr{N}_q(\mathbf{0},\Sigma)$. Accordingly, we can sample each latent observation $\mathbf{z}^{(i)}$, $i = 1,\dots n$, independently from a suitable multivariate Normal distribution truncated at the region $C(\mathbf{x}^{(i)},\Theta)$. The second term can be written as

$$p(\Theta \mid \Sigma,\mathscr{G},\mathbb{X}) \propto \prod_{i=1}^{n} \left\{ \Phi_q(\theta^{(1)}_{x_{ij}},\dots,\theta^{(q)}_{x_{ij}} \mid \Sigma) - \Phi_q(\theta^{(1)}_{x_{ij}-1},\dots,\theta^{(q)}_{x_{ij}-1} \mid \Sigma) \right\} \cdot \prod_{j=1}^{q} p(\theta_0^{(j)}),$$

where $\Phi_q(\cdot)$ is the c.d.f. of $\mathscr{N}_q(\mathbf{0},\Sigma)$. For $j = 1,\dots,q$, we can update $\theta_0^{(j)}$ sequentially using a Metropolis-Hastings scheme based on the following steps:

- draw $\left(\theta_0^{(j)}\right)^*$ from a suitable proposal distribution $q\left(\left(\theta_0^{(j)}\right)^* \mid \theta_0^{(j)}\right)$, for instance $\mathscr{N}\left(\theta_0^{(j)},\sigma_0^2\right)$;
- given the current value of $\theta_0^{(j)}$ accept $(\theta_0^{(j)})^*$ with probability

$$\alpha_j = \min\left\{ 1\,;\ \frac{p\left(\left(\theta_0^{(j)}\right)^*,\ \theta_0^{-j} \mid \Sigma,\mathscr{G},\mathbb{X}\right)}{p\left(\theta_0^{(j)},\ \theta_0^{-j} \mid \Sigma,\mathscr{G},\mathbb{X}\right)} \cdot \frac{q\left(\theta_0^{(j)} \mid \left(\theta_0^{-j}\right)^*\right)}{q\left(\left(\theta_0^{-j}\right)^* \mid \theta_0^{(j)}\right)} \right\}$$

where $\theta_0^{-j} = \left\{\theta_0^{(k)}, k \neq j\right\}$ denotes the collection of all cut-offs excluding the j-th.

4 Conclusions

We have presented a Bayesian methodology for learning dependence relations among multivariate ordinal binary data. Our method assumes that the ordinal cate-

gorical data are generated by thresholding of latent Gaussian data whose sampling distribution is Markov w.r.t. to a graph. Main advantage of the proposed method is that, differently from alternative methods based on Multinomial-Dirichlet models, we can provide a correlation-type measure between each pair of ordinal variables, which is encoded in the covariance matrix of the latent variables, Σ.

An extension of the method to ordinal variables $X_1, \ldots, X_q$, each with an arbitrary number of levels is possible and requires a suitable adaptation of the proposed framework. In particular, assuming that $X_j \in \{0, 1, \ldots, K_j\}$, one could introduce for each variable X_j a collection of cut-offs $\theta_0^{(j)}, \ldots, \theta_{K_j-1}^{(j)}$ such that

$$X_j = \begin{cases} 0 & \text{if } -\infty < Z_j \leq \theta_0^{(j)} \\ 1 & \text{if } \theta_0^{(j)} < Z_j \leq \theta_1^{(j)} \\ \ldots & \\ K_j & \text{if } \theta_{K_j-1}^{(j)} < Z_j < +\infty \end{cases} \tag{9}$$

where Z_j is the latent variable associated with X_j, and priors to the new cut-off parameters can be assigned independently following Equation (6).

We remark that this extension may augment the computation cost of the proposed algorithm, especially in high-dimensional (large q) settings, and specifically in the update of the latent data which requires sampling from truncated multivariate Normal distributions. Efficient computational implementations are currently under investigation.

Multinomial Thompson Sampling for adaptive experiments with rating scales

Multinomial Thompson Sampling per esperimenti adattivi con scale di rating

Nina Deliu

Abstract Bandit algorithms such as Thompson Sampling (TS) have been put forth for decades as useful for conducting adaptively-randomized experiments. By skewing the allocation ratio towards superior arms, they can substantially improve participants' welfare with respect to particular outcomes of interest. For example, as we illustrate in this work, they may use participants' ratings for understanding and assigning promising text messages for managing mental health issues more often. However, model-based algorithms such as TS, typically assume binary or normal models, which may lead to suboptimal performances in categorical rating scale outcomes. Guided by our field experiment, we extend the application of TS to rating scale data and show its improved performance in a number of synthetic experiments.
Abstract *Gli algoritmi di tipo multi-armed bandits, quali il Thompson Sampling (TS), rappresentano un metodo efficace per la conduzione di esperimenti adattivi. Adattando automaticamente il rapporto di allocazione verso il braccio superiore (quando questo esiste), essi possono migliorare sostanzialmente sia il welfare dei partecipanti–anche semplicemente rilevando le loro preferenze–che l'efficacia e il costo di uno studio. Tuttavia, algoritmi come il TS assumono generalemnte un modello binario o normale per la variabile di risposta, portando a risultati non ottimali in caso di dati con scale di rating. Motivati da un esperimento reale sulla salute mentale, in questo lavoro si propone un'estensione dell'algoritmo TS per scale di valutazione e si studiano la sue performances in una serie di esperimenti sintetici.*

1 Introduction

Adaptively-randomized experiments have the potential to enhance participants' welfare while collecting high-quality data, resulting in a more flexible, efficient, and ethical alternative compared to traditional fixed studies [1]. In such experiments, allocation ratios are skewed towards more efficient or informative arms, with the goal of assigning superior arms to as many participants as possible.

Multi-armed bandit (MAB) algorithms [2] have been argued for decades as useful to adaptively randomize experiments with the aim of optimizing an outcome of interest. In MAB problems, an *agent* chooses at each time t one of the available *arms* for which a *reward* is then provided. The goal is to maximize the cumulative reward, or equivalently minimize regret, under uncertainty on the best arm. As rewards are generally stochastic, and they might vary between arms, the agent must balance *exploring* each arm to gain information with *exploiting* the information gained so far by choosing arms with the higher expected reward. *Thompson Sampling* (TS) is a highly-interpretable randomized MAB strategy that allocates arms in proportion to their posterior mean reward. Due to its empirical and theoretical optimality [3], it has received renewed attention in recent years and have been successfully applied in a wide variety of domains, going from recommendation to education [4].

In many real-world applications, arms are a set of recommendations or explanations, that are allocated according to users' preferences. In this work, for example, we are motivated by mental health experiments we deployed on the Amazon Mechanical Turk [5], in which participants were asked to rate two types of messages in terms of how helpful they would be for managing their mood. Results of a primary experiment (MTurk I), based on a fixed design with an equal allocation ratio for gaining benchmark knowledge, are reported in **Fig. 1**.

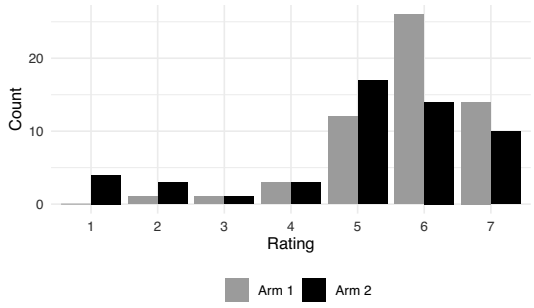

Fig. 1 Arms' ratings distribution in the two-armed *MTurk I* experiment, based on a 7-point Likert scale. A small superiority of Arm 1 vs Arm 2 is shown: sample means $\hat{\mu}_1 = 5.81$ vs $\hat{\mu}_2 = 5.08$, sample standard deviation $\hat{\sigma}_1 = 1.04$ vs $\hat{\sigma}_2 = 1.72$, for a sample size $N = 110$.

Subsequent experiments [6] have then been conducted adaptively with TS and a Gaussian model, in absence of more adequate modeling procedures for rating data within TS. Notably, despite the vast array of MAB and TS variants, most of them assume either binary or Gaussian rewards, and a shortage of MAB methodologies to handle rating scale data persists. The general practices in such cases consist in either dichotomizing the ordinal reward with a threshold (often arbitrary) rule and

then using a binary model, or using a normal model directly on the rating outcomes, as in our MTurk study. Such practices have been long recognized as suboptimal in terms of both reward efficiency [7] and statistical inference [8].

In this work, we extend the applicability of TS to rating scale data, introducing the *Multinomial TS*, which can be easily implemented with the *Dirichlet* conjugate family [9]. Then, guided by our motivating experiment, we evaluate its performance compared to the standard Gaussian TS in a number of synthetic experiments.

2 Problem Setting and Methods

Experimental set-up We consider a two-armed T-time horizon experiment, in which participants are accrued in a fully-sequential way, with a total experiment sample size $N = T$. At accrual, each participant $t = 1, \dots, T$ is assigned one of the two available arms, say $A_t \in \{1,2\}$, and an outcome or reward $Y_t(A_t)$ associated with that arm is subsequently observed before the next time $t+1$. Arms are drawn according to a policy $\boldsymbol{\pi_t} \doteq \{\pi_{t,k}, k = 1,2\}$, where $\pi_{t,k}$ is the allocation probability of arm k at time t. Given the history of selected arms and associated rewards $\mathscr{H}_t \doteq \{A_\tau, Y_\tau(A_\tau), \tau = 1, \dots, t\}$, the goal of an adaptive experiment may be to find an allocation policy so as to maximize the expected cumulative reward over T.

In line with MTurk I, we consider a 7-points rating scale outcome, i.e., $Y_t \in \{1,2,\dots,7\}$ for all t's, with higher values indicating better outcomes. We assume they are drawn independently from a fixed distribution that depends on the arm but not on t (*stochastic stationary bandits*; [2]), with the following conditional mean:

$$\mathbb{E}(Y_{t,i}(A_{t,i})|\mathscr{H}_{t-1}) = \mathbb{E}(Y_t|A_t) = \mu_1 \mathbb{I}(A_t = 1) + \mu_2 \mathbb{I}(A_t = 2), \tag{1}$$

with (β_1, β_2) the unknown arm parameters. In the next sections we will make an additional assumption on rewards distribution, maintaining the parameters unknown.

Thompson Sampling Rooted in a Bayesian framework, TS allocates arms in proportion to their posterior probability of being associated with the maximum expected reward at each round t. In a two-armed setting, denoting by π_{t1}^{TS} TS's allocation probability of arm 1 at step t, and considering Eq. (1), we have that:

$$\pi_{t1}^{\text{TS}} = \mathbb{P}\Big(\mathbb{E}\big(Y_t(A_t = 1)\big) \geq \mathbb{E}\big(Y_t(A_t = 0)\big)|\mathscr{H}_{t-1}\Big) = \mathbb{P}\Big(\mu_{t1} \geq \mu_{t2}|\mathscr{H}_{t-1}\Big), \quad \forall t.$$

The typical way for implementing TS, involves drawing at each round t a sample from the posterior distribution of each of the unknown arms' parameters in Eq. (1), say $\tilde{\mu}_{tk}$, with $k = 1,2$, and then selecting the arm associated with the highest posterior estimated mean reward $\mathbb{E}(\tilde{Y}_t|A_t = k) = \tilde{\mu}_{tk}$, i.e., $\tilde{a}_t \doteq \text{argmax}_{k=1,2}\mathbb{E}(\tilde{Y}_t|A_t = k) = \text{argmax}_{k=1,2}\tilde{\mu}_{tk}$. A conjugate family is generally assumed for the reward variable, with the most common ones being the Binomial and the Gaussian [3].

2.1 Our Proposal: Multinomial Thompson Sampling

The multinomial distribution is the extension of the binomial distribution for categorical outcomes with more than two response categories [10]. Given J mutually exclusive categories of an outcome Y, among which one and only one category is observed at each time t (i.e., $\sum_{j=1}^{J}\mathbb{I}(Y_t=j)=1$ and $\sum_{t=1}^{T}\sum_{j=1}^{J}\mathbb{I}(Y_t=j)=T$), it models the probability of counts $X_{tj}=\sum_{\tau=1}^{t}\mathbb{I}(Y_t=j), \forall j\in[1,J], \forall t\in[1,T]$. At a given time t, the probability mass function of a multinomial, denoted by Multinom$(t;\boldsymbol{p})$, with $\boldsymbol{p}=(p_1,\dots,p_J)=\Big(\mathbb{P}(Y_t=1),\dots,\mathbb{P}(Y_t=J)\Big)$ the unknown parameters, is given by:

$$f(x_{t1},\dots,x_{tJ};t;p_1,\dots,p_J)=\left(\frac{t!}{\prod_{j=1}^{J}x_{tj}!}\right)\prod_{j=1}^{M}p_j^{x_{tj}}, \tag{2}$$

where $t=\sum_{j=1}^{J}x_{tj}$. For a multinomial distribution, we have that $\mathbb{E}(X_{tj})=tp_j$. In case of ordinal, real valued categories (e.g., $j=1,\dots,7$ as in our rating scales), we can compute the mean of the outcome Y_t at each t, as $\mu_t=\mathbb{E}(Y_t)=\sum_{j=1}^{J}jp_j$.

Eq. (2) can be also expressed using the gamma function Γ, directly showing its resemblance to the Dirichlet distribution, which is its conjugate prior. Given $\boldsymbol{\alpha}=(\alpha_1,\dots,\alpha_J)$, with $\alpha_j>0, \forall j\in[1,J]$, this is denoted by Dir$(\boldsymbol{\alpha})$, and models our beliefs/knowledge on the unknown parameters as:

$$f(p_1,\dots,p_J;\alpha_1,\dots,\alpha_J)=\left(\frac{\prod_{j=1}^{J}\Gamma(\alpha_j)}{\Gamma(\sum_{j=1}^{J}\alpha_j)}\right)\prod_{j=1}^{M}p_j^{\alpha_j-1}, \tag{3}$$

where $\boldsymbol{p}$ belongs to the standard $J-1$ simplex ($\sum_{i=1}^{J}p_j=1$ and $p_j\geq 0, \forall j\in[1,J]$).

We then update our beliefs on the parameters based on the observed outcomes, by updating their posterior distribution as $\alpha_j\leftarrow\alpha_j+c_{tj}$, $\forall t$'s and $\forall j$'s, where $c_{tj}=\mathbb{I}(y_t=j)$ states whether category j was observed at time t or not (see Algorithm 1).

Algorithm 1 Multinomial TS pseudocode

Input: Time horizon T, prior parameters $\boldsymbol{\alpha_k}=(\alpha_{1k},\dots,\alpha_{Jk})$, with J the overall number of categories of the rating scale outcome, and $k=1,2$ the study arm.

for $t=1,2,\dots,T$ **do**
  for $k=1,2$ **do**
    Sample $\tilde{\boldsymbol{p}}_{\boldsymbol{k}}=(\tilde{p}_{1k},\dots,\tilde{p}_{Jk})\sim\text{Dir}(\alpha_{1k},\dots,\alpha_{Jk})$
    Compute $\tilde{\mu}_{tk}=\sum_{j=1}^{J}j\tilde{p}_{jk}$
  end for
  Select arm $\tilde{a}_t=\text{argmax}_{k=1,2}\tilde{\mu}_{tk}$ and observe the reward y_t.
  for $j=1,\dots,J$ **do**
    Compute $c_{tj}=\mathbb{I}(y_t=j)$
  end for
  for $k=1,2$ **do**
    Update posteriors: $(\alpha_{1k},\dots,\alpha_{Jk})\leftarrow(\alpha_{1k},\dots,\alpha_{Jk})+(c_{t1},\dots,c_{tJ})$
  end for
end for

3 Synthetic Experiments and Results

For our empirical evaluation, we focus on the set-up introduced in Section 2, with $T = 1000$, and simulation scenarios defined according to the MTurk I motivational study in **Fig. 1**. We evaluate the proposed Multinomial TS with equal Dirichlet priors for the two arms with parameters $\alpha_{jk} = 1$ for $j = 1, \ldots, 7$ and $k = 1, 2$, and compare it to a Gaussian TS with variances set according to the results of the MTurk I experiment and Normal $N(0, 10)$ priors. We also illustrate the behavior of an *Oracle* that always allocates the best arm–when one exists–or both of them with equal probability–when they are identical. We look at standard MAB performance measures.

Regret and Optimal Arm Allocation under a unique optimal arm The unique optimal arm scenario is simulated with $\mu_1 = 5.81 > \mu_2 = 5.08$ ($\sigma_1 = 1.04$, $\sigma_2 = 1.72$), and individual scale frequencies given by the MTurk sample estimates: $p_1 = (0.00, 0.02, 0.02, 0.05, 0.21, 0.45, 0.24)$ and $p_2 = (0.08, 0.06, 0.02, 0.06, 0.33, 0.27, 0.19)$. Results in **Fig. 2** show the increased performance of the proposed Multinomial TS over Normal TS.

Arm Allocation under identical arms In addition to the aforementioned scenario reflecting the MTurk experiment, we now evaluate the behavior of the proposed strategy in an identical arms scenario for understanding how it balances the allocation of one arm over the other one, when no one should be preferred. This scenario is simulated with $\mu_1 = \mu_2 = 4$ ($\sigma_1 = \sigma_2 = 2$) and symmetric scale frequencies: $p_1 = p_2 = (0.02, 0.09, 0.23, 0.31, 0.23, 0.09, 0.02)$. The latter resembles a Gaussian distribution for ensuring higher comparability between the two TS alternatives. Results in **Fig. 2** show that Multinomial TS is more balanced in arms' allocation compared to a Gaussian TS, which can be very extreme–allocating one arm almost the totality of the times–even when this is not superior.

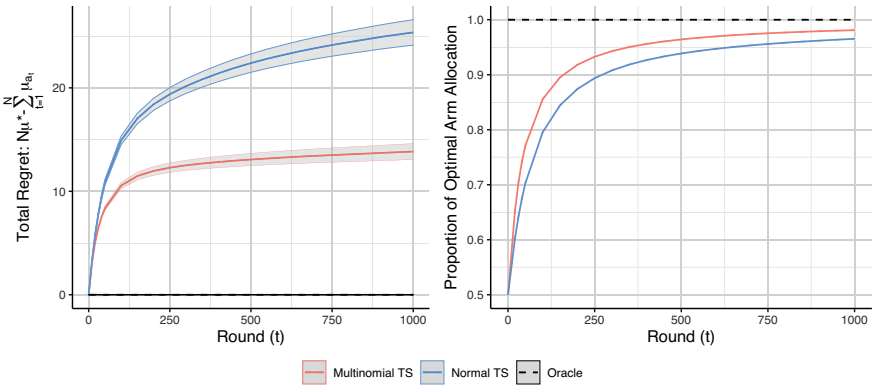

Fig. 2 Regret and proportion of optimal arm allocation in the proposed Multinomial TS vs a Gaussian TS. Values are obtained by averaging across 10^4 independent TS trajectories.

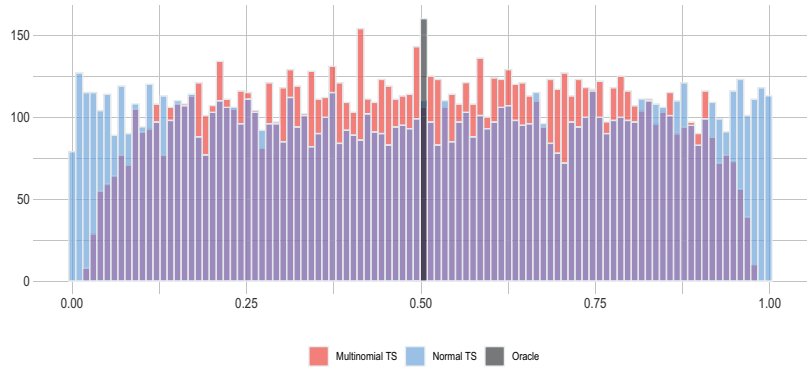

Fig. 3 Empirical allocation of one of the two identical arms (Arm 1). Values are obtained by averaging across 10^4 independent TS trajectories.

4 Conclusion

In this work, motivated by the MTurk field experiment, we extended the applicability of TS to rating scales data, introducing the Multinomial TS. We demonstrated that it can outperform the widely used TS with a Gaussian model in scenarios with a unique optimal arm, and that it is a more balanced solution–that can translate into inferential advantages, due to a lower imbalance in the allocation (see e.g., [6])–when arms are identical. Further work is required to understand how the proposed version would behave in a multi-armed setting or under non-stationarities.

Ranking extraction in nested partially ordered data systems

Estrazione di ranking in sistemi annidati di dati parzialmente ordinati

Marco Fattore, Barbara Cavalletti, Matteo Corsi, Alessandro Avellone

Abstract We propose a novel procedure for extracting rankings from nested systems of partially ordered data, a kind of data structure often encountered in multi-indicator system analysis and multi-criteria decision making, e.g. when units or alternatives are pairwise compared or when preferences are expressed within different contexts, or in view of different goals, which are themselves partially ordered. We develop the procedure through a real example, pertaining to the prioritization of public interventions, to support small companies in the food sector.

Abstract *L'articolo presenta un nuova procedura per l'estrazione di ranking da sistemi annidati di insiemi parzialmente ordinati, una struttura dati tipica nell'analisi di sistemi multi-indicatore e in processi di decision-making e prioritizzazione, quando oggetti, alternative o preferenze vengono confrontati in diversi contesti, o rispetto a obiettivi differenti, a loro volta parzialmente ordinati. La procedure viene sviluppata attraverso un esempio reale, relativo alla prioritizzazione degli investimenti pubblici, per il supporto alle piccole imprese, nel settore agro-alimentare.*

Key words: Nested posets, Partially ordered set, Preferences, Prioritization, Ranking extraction

1 Introduction

The issue of ranking extraction from partially ordered data occurs in a variety of fields and contexts, usually for prioritization and decision-making purposes [2]. Here, we address it considering a particular but typical setting, where partially ordered data are *nested* in a two-level hierarchy. More precisely, the data structure we consider is composed of a higher level *partially ordered set* (*poset* for short) π_s on k objects $s_1, \ldots, s_k$ (e.g., strategies or goals to be pursued with different priorities) and of k lower level posets $\pi_a^1, \ldots \pi_a^k$, *on the same objects* $a_1 \ldots, a_h$, each poset being associated to an element of π_s (e.g. possible actions, partially ordered by importance, to be taken in view of the strategies or the goals). Technically, the problem is to produce a ranking of $a_1 \ldots, a_h$, taking into account both the information provided by their different lower level orderings and that comprised in the higher level partial order of $s_1, \ldots, s_k$. We want to do this in a *purely ordinal way*, i.e. avoiding the use of numerical weights and of metric or aggregative procedures that, although often employed, would be inconsistent in an ordinal setting.

2 Real example: prioritization of public economic interventions

To make the issue more concrete, we consider the following real case. Liguria Region, in the North of Italy, launched a survey among small producers of typical regional food products, to identify the key strategic areas they deemed more relevant to improve, for their economic sustainability, among the following five: 1 - *Management&Accounting*, 2 - *Product Quality*, 3 - *Marketing*, 4 - *Distribution&Sales channels* and 5 - *Innovation&Technology*. Producers were also asked to compare the relevance of five possible public actions, for improving the strategic areas, namely: 1 - *Traininig*, 2 - *Creation of networks*, 3 - *Providing technical/ICT support*, 4 - *Implementing product certifications* and 5 - *Promoting exchange meetings*. Based on the expressed preferences, to each producer a priority poset of the strategic areas and five priority posets (one, for each area) of the actions have been associated, as exemplified in Figure 1. Given the priorities expressed, how can a ranking of actions be generated, for each producer? (Notice that here we do not consider how to synthesize the priorities expressed by all the producers, into a global ranking and just focus on the issue of getting single action rankings for single producers).

3 The ranking procedure

We now describe the ranking extraction procedure and, to ease the exposition, we do this by applying it to the economic intervention example, just introduced. The procedure is organized into three main steps: (i) turning the input data into a multi-indicator system (below called the “ranking MIS”), where the strategic areas play

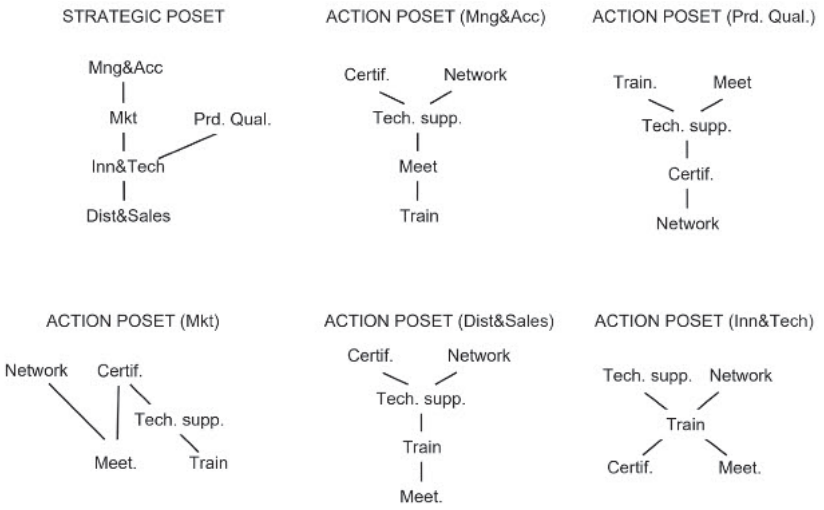

Fig. 1 Top left panel: Poset of strategic areas; other panels: posets of the actions for each strategic area. The diagrams must be read from top to bottom; if a downward edge path exists between two nodes, than the higher is "preferred" to the lower one; otherwise, the two nodes are *incomparable* and no priority between them is explicitly stated.

the role of "indicators" which order the actions as less or more relevant; (ii) turning the MIS into a poset of actions, incorporating the priorities expressed in the "strategic" poset and (iii) finally extracting a ranking out of it. The key feature of the procedure is that these steps are taken consistently with the ordinal nature of the input data. In particular, this holds true for the way the priorities on the strategic areas (i.e., the relevance of the "indicators" in the ranking MIS) are accounted for, without introducing any numerical weights, as shown below.

1. *Building the ranking MIS*. For each action poset in Figure 1, a ranking of the actions is extracted, by using the *SVD*-based algorithm described in [5], which ranks poset elements based on their so-called *mutual ranking probabilities* (*mrps* for short) and where the *mrp* p_{ij}^r $(r = 1,\ldots,k)$ of action j over action i in the action poset π_a^r is defined as

$$p_{ij}^r = \frac{|\ell \in \Omega(\pi_a^r) : \textit{action } j \textit{ is ranked higher than action } i \textit{ in } \ell|}{|\Omega(\pi_a^r)|} \qquad (1)$$

   denoting by ℓ a *linear extension* of π_a^r, by $\Omega(\pi_a^r)$ the set of all of its linear extensions and by $|A|$ (for any finite set A) the cardinality of A. Collecting the ranks of each of the five actions in each of the five rankings (one for each strategic area), the MIS reported in Table 1 is obtained.
2. *Turning the ranking MIS into a poset*. The MIS of Table 1 is turned into a poset by comparing action ranking profiles (i.e. MIS rows) component-wise, i.e. stating that action a_j is *more relevant* than action a_i (written $a_i \lhd a_j$) if and only if

Table 1 Multi-indicator system of the actions (rows), built from their rankings, relative to the five strategic areas (columns). The integer in entry ij is the position of action a_i, in the ranking relative to the strategic area s_j; lower scores mean greater relevance, i.e. higher positions in the ranking (notice that some actions are tied, in some rankings)

	Mng&Acc	Prd. Qual.	Mkt	Dist&Sales	Inn&Tech
Training	1	5	2	2	3
Networks	5	1	4	5	5
Tech. Support	3	3	3	3	5
Certifications	5	2	5	5	1
Meetings	2	5	1	1	1

its position in the five rankings is not lower and, in at least one, is higher than the corresponding position of a_i. We apply this condition to all of the $5^5 = 3125$ possible ranking profiles that can be built considering five indicators (the strategic areas) on five degrees (the possible ranking positions of five actions). This way, a big "component-wise" poset π_{cmp} is built, comprising 3125 elements, five of which are actually observed in the data. The reason why this larger poset is built is to provide a "context", where to set the evaluation of the relative importance of the actions, whose comparison outside of it would be much less informative. Poset π_{cmp}, however, treats strategic areas as equally important. To account for the priorities among them, as expressed by the strategic poset, we follow the *extension* principle introduced in [4] and generate a new ranking profile poset π_{ext}, by turning some incomparabilities of π_{cmp} into comparabilities, according to the following natural criterion. Let a_i and a_j be two actions, whose ranking profiles in the component-wise poset are incomparable due to conflicting scores on only two areas, e.g. $a_i = 23421$ and $a_j = 32421$ (so, the two actions are tied on the last three rankings). Suppose that, in the strategic poset, area s_2 is deemed more important than area s_1; then a_j, being placed higher on the second ranking (recall that lower scores correspond to higher positions), is deemed more relevant than a_i and the original incomparability between these profiles is resolved, by putting $a_i \lhd a_j$. By performing this operation for each pair of ranking profiles in π_{cmp}, many new comparabilities are added to it (and none is removed), producing the *extended* poset π_{ext}, which provides the new evaluation context incorporating the information comprised in the partial order of strategic areas. Notice that the extension criterion adopted here is weaker than that described in [4], which would add much more comparabilities to the component-wise poset. This choice aims at reducing as much as possible the degree of arbitrariness, somehow unavoidable in any "weighting" procedure.

3. *Extracting the final ranking*. To rank the observed actions, i.e. their corresponding ranking profiles, we compute their mutual ranking probabilities *within* π_{ext}, getting the matrix reported in Table 2. By computing the SVD of this matrix, as in Step 1 (see again [5]), each action is assigned a *dominance* score, which is then used to get the final ranking, which turns out to be as follows (in parenthesis, the scores):

$$\overset{(0.19)}{Meet.} \lhd \overset{(0.40)}{Train.} \lhd \overset{(0.45)}{Certif.} \lhd \overset{(0.53)}{Tech.\ supp.} \lhd \overset{(0.56)}{Networks}\ .$$

Being just interested in the ranking, the absolute value of the dominance scores is of less interest; however, it is noticeable that action *Meetings* has a very low score, compared to those of the other actions, showing that it is considered of far less impact. In any case, here we do not provide any interpretation to the results, the data being used only to describe and exemplify the procedure.

The whole ranking procedure is represented in Figure 2.

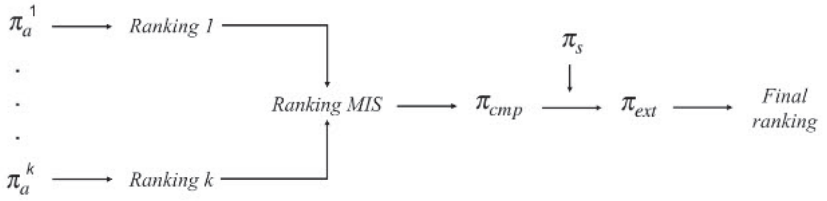

Fig. 2 The schematic flow of the ranking procedure.

Remark. The above procedure involves some heavy computations, for the construction of the extended poset π_{ext}. To lessen the computational burden, a random subset of 805 profiles, out of 3125 (comprising the observed ones), has been generated, getting a random subposet of π_{ext}, over which the mutual ranking probabilities have been computed. This introduces some probabilistic uncertainty in the results; but while this may affect the precise numerical expressions of the dominance scores, it does not alter the big picture and, in particular, the final ranking which is likely to be fairly robust against the sampling process.

Table 2 Mutual ranking probabilities of the actions, computed in π_{ext}

	Training	Networks	Tech. supp.	Certif.	Meet.
Training	1.00	0.91	0.86	0.68	0.00
Networks	0.09	1.00	0.38	0.17	0.00
Tech. support	0.14	0.62	1.00	0.26	0.00
Certifications	0.39	0.83	0.74	1.00	0.00
Meetings	1.00	1.00	1.00	1.00	1.00

4 Software implementation

While the ranking procedure is new, its implementation is essentially a composition of existing algorithms available in the `R` language, namely in packages `parsec` or

`POSetR` [1]. The first provides various functions to manipulate posets, while the second implements efficient algorithms for the computations of the mutual ranking probabilities, which are involved in the computation of the rankings, in the first and the last step of the procedure. The only function not available yet in the two mentioned packages is that providing the extension of the component-wise poset, which is however easy to implement with basic `R` functions.

5 Conclusion

In this paper, we have introduced a new purely ordinal procedure for generating rankings, from nested poset systems, a kind of data structure often encountered in multi-criteria decision-making and in synthetic indicator construction. The entire ranking process exploits just the ordinal information comprised in the data, without requiring exogenous weights and avoiding aggregative and compensative approaches, that would be inconsistent with the relational and non-numerical nature of the inputs. The procedure shows how complex systems of ordinal and partially ordered data can be consistently treated, by using the right mathematical setting, i.e. order theory [3], which provides a firm basis to this novel and growing area of multidimensional data analysis. The ranking procedure can be applied to more complex datasets, than that used here for exemplification purposes, although its natural application field remains that of the typical indicator systems used in socio-economics (or even in psychometry) and not that of the large datasets of big data analysis. As usual with combinatoric structures, the computational issues are not trivial. The development of new and more efficient algorithms to treat posets is, thus, a main research avenue, together with the theoretical deepening of the mathematical properties of the entire process and of its sensitivity to the unavoidable approximations involved in the computations.

Towards the definition of distance measures in the preference-approval structures

Un nuovo approccio per definire misure di distanza nell'ambito dei preference-approval

Alessandro Albano, Mariangela Sciandra and Antonella Plaia

Abstract The task of combining preference rankings and approval voting is a relevant issue in social choice theory. The preference-approval voting (PAV) analyses the preferences of a group of individuals over a set of items. The main difference with the classical approaches for preference data consists in introducing, in addition to the ranking of candidates, a further distinction; candidates are subsetted in "acceptable" and "unacceptable", or also in "good set" and "bad set" (a way to express the approval/disapproval). This work introduces the definition of a new measure to quantify disagreement between preference-approval profiles. For each pair of alternatives, we consider the two possible disagreements in approvals and rankings and merge them through a function $h(\cdot)$ increasing in each component. We show that our approach allows to emphasize particularly those cases in which both ranking and approval show simultaneously the maximum discordance. .

Abstract *Il modello preference-approval (PAV) analizza le preferenze di un gruppo di invidui su un insieme di elementi. Questo modello può essere considerato una generalizzazione dei classici studi di preferenza, poichè oltre all'ordinamento dei candidati (rankings) viene fatta una distanzione tra candidati "accettabili" e candidati "non accettabili" (approval). In questo lavoro proponiamo una nuova distanza per misurare il grado di disaccordo tra i profili di preference-approval. Per ogni coppia di candidati, consideriamo congiuntamente le discordanze tra approval e rankings e le combiniamo attraverso una funzione $h(\cdot)$ crescente in ogni componente. Il nostro approccio, contrariamente alla letteratura, enfatizza in particolar-*

mente i casi in cui occorre contemporanemente massima discordanza tra ranking e approval.

Key words: Preference rankings, Approval Voting, Preference-Approvals, Kemeny distance

1 Introduction

In social choice theory, preference rankings and approval voting are two popular ways to collect the preferences of a group of subjects on a set of elements. Preference rankings order the candidates from best to worst without distinguishing between acceptable and unacceptable. That is, if a is ranked before b, we can only infer that a is preferred over b, but we cannot infer anything about their absolute acceptability. In contrast, the approval voting system consists of drawing an ideal line separating the set of "good" objects from the set of "bad" objects without considering the ordering of the objects. Rankings and approvals are related, but they are basically different types of information and cannot be inferred from each other. However, in some situations, it is appropriate to gather both information simultaneously. For example, suppose a committee has to express their preferences over some candidates based on their scientific production. In this case, preference-approvals are helpful. Indeed, the committee outcome needs to include both candidates ranking and the division between "qualified" (good) and "unqualified" (bad).
Extensions to preference rankings mainly focus on the definition of weighted distances Plaia et al. 2018; Albano and Plaia 2021, while less effort has been devoted to the preference-approval settings. Brams and Sanver (2009) faced, for the first time, the issue of combining rankings and approval in a hybrid voting system called Preference-Approval Voting (PAV). In the PAV system, raters express candidate rankings and draw a line between good and bad candidates. In their study, the authors explain the various desirable properties that PAV meets and analyze the candidates who can and cannot win with this system. The problem of measuring agreement between preference-approval profiles is an open issue in the literature, distance-based approaches Erdamar et al. 2014; Dong et al. 2021 have gained increasing attention over the last years. The state-of-the-art methods compute the ranking distance and the approval distance marginally and eventually aggregate them by their linear combination. In this paper, we propose a new approach to define the distance between preference-approval profiles, simultaneously taking into account the disagreement in ranking and approval for each pair of candidates. Finally, our proposal is compared with approaches in the literature to highlight the differences.

2 Notation

Suppose n voters are asked to order m different alternatives, the ranking π is a mapping function from the set of items $X = \{x_1, \ldots, x_m\}$ to the set of ranks $\pi = (\pi(x_1), \pi(x_2), \ldots, \pi(x_m))$, where $\pi(x_i)$ is the rank given by a judge to item x_i. If the m items are ranked in m different ranks, a complete (full) ranking or linear ordering is achieved (Cook, 2006). In certain cases, some items could receive the same preference, then a tied ranking or a weak ordering is obtained.
In the framework of PAV modelling, each preference ranking, π, is paired with an approval vector, A. For any given set X of candidates, we define approvals by partitioning X into G, the set of good alternatives, and $U = X \backslash G$ the set of unacceptable alternatives, where G and U can be empty sets.
We represent a voter's preference-approval profile by a top-down order of candidates with a horizontal bar: candidates above the bar are approved, those below rejected.

$$\begin{array}{c} x_1 \\ \underline{x_2} \\ x_3 \\ x_4. \end{array}$$

The previous representation indicates that the voter's two top-ranked candidates, x_1 and x_2, are approved, and the voter's two bottom-ranked candidates, x_3 and x_4, are disapproved. The preference-approval profile is codified as follows:

$$\pi_1 = (1,2,3,4) \quad A_1 = (1,1,0,0).$$

3 Marginal distance-based approach

Measuring agreement between preference-approval profiles has been so far solved by a linear combination of a ranking distance and an approval distance calculated marginally. Erdamar et al. (2014) proposed to measure disagreement between preferences using the Kemeny distance (Kemeny, 1959), d_k, and to measure approval disagreement using the Hamming distance, d_H, (Hamming, 1950). The two distances are normalized into [0,1] (d_R, d_A), and eventually aggregated in a final preference-approval distance d_λ:

$$d_\lambda = \gamma\, d_R(\pi, \pi^*) + (1-\gamma) d_A(A, A^*), \tag{1}$$

where π, π^* are two m-size rankings, A, A^* are the two m-size approval vectors, and $\gamma \in [0,1]$ is a parameter used to control the relative relevance of the two components. Similarly, Dong et al. (2021) defined a new distance d_{PAS} using an L_1 metric both to compare preferences and approvals:

$$d_{PAS} = \sum_{i=1}^{m} \gamma \left|\pi(x_i) - \pi^*(x_i)\right| + (1-\gamma)\left|A_1(x_i) - A_2^*(x_i)\right|. \tag{2}$$

The two measures share the same "marginal" approach that consists of deriving the final distance through the additive effect of the sub-components involved. In other words, d_λ, d_{PAS} perfectly depend on the values of d_K, d_H, L_1 computed marginally.

4 Pairwise approach: d_{AP}

This section illustrates our proposal, d_{AP}. Given two preference-approval profiles (π, A) and (π^*, A^*) on m alternatives, the problem of measuring the disagreement between them is broken down into $m(m-1)/2$ easier sub-problems, i.e. one for each pair of items. Thus, the total distance d_{AP} is obtained by multiplying the two possible disagreements, in approvals and in preferences, for each pair of items $i, j \ \forall i > j \in [1, \ldots, m]$.
The ranking disagreement, for each pair of items, is computed by creating a *score matrix* of a ranking. A rank vector π with m objects can be transformed into a symmetric $m \times m$ score matrix, whose elements a_{ij} are defined by:

$$a_{ij} = \begin{cases} 1 & \text{if } i \text{ is preferred to } j \\ 0 & \text{if } i = j \text{ or } i \text{ is tied with } j \\ -1 & \text{if } j \text{ is preferred to } i. \end{cases} \tag{3}$$

The disagreement in approval, for each pair of items, is measured using an L_1 metric between the 2-dimensional approval vectors.

$$p_{ij} = |A_i - A_i^*| + |A_j - A_j^*|. \tag{4}$$

The formula of the aggregated distance d_{AP} between two m-size preference approval profiles $(\pi, A), (\pi^*, A^*)$ with score matrix a_{ij}, and b_{ij} respectively (defined as in Eq.3), and p_{ij} (defines ad in Eq.4):

$$d_{AP} = \sum_{i<j} h(\left|a_{ij} - b_{ij}\right|, p_{ij}), \tag{5}$$

where $h(\cdot)$, increasing in each component, merges both disagreements.

$$h(x,y) = \begin{cases} 0 & \text{if } x = 0, y = 0 \\ x \cdot \gamma & \text{if } x \neq 0, y = 0 \\ y \cdot \gamma & \text{if } x = 0, y \neq 0 \\ x \cdot y & \text{if } x \neq 0, y \neq 0, \end{cases} \tag{6}$$

where $0 < \gamma < 1$. It can be proved that $d_{AP} \in [0, 2m(m-1)]$.

4.1 Illustrative example

This section clarifies the practical impact of the pairwise distance, d_{AP}, and highlights the differences with the marginal approaches d_λ, d_{PAS}. Let us consider four preference-approval profiles as defined in table 1.

(π_1, A_1)	(π_2, A_2)
$x_1\ x_2\ x_3$	x_3
	$x_1\ x_2$

(π_3, A_3)	(π_4, A_4)
x_1	x_2
x_2	x_1
x_3	x_3

Table 1: Preference-approval profiles

The preference-approvals are codified as follows:

$$I = [\pi_1 = (1,1,1),\ A_1 = (1,1,1)]$$

$$II = [\pi_2 = (2,2,1),\ A_2 = (0,0,1]$$

$$III = [\pi_3 = (1,2,3),\ A_3 = (1,0,0)]$$

$$IV = [\pi_4 = (2,1,3),\ A_4 = (0,1,0)].$$

Table 2 compares the distances between the preference-approval profiles *I-II* and the profiles *III-IV*, assuming $\gamma = 0.5$.

Preference-	*Rank-dist*		*Approval-dist*		*Aggregated-dist*		
Approval	d_K	L_1	L_1	d_H	d_λ	d_{PAS}	d_{AP}
I-II	2	2	2	2	0.5	2	**3**
III-IV	2	2	2	2	0.5	2	**5**

Table 2: Preference-approval distances, $\gamma = 0.5$

It should be noted that:

- $d_\lambda(I,II) = d_\lambda(III,IV)$
- $d_{PAS}(I,II) = d_{PAS}(III,IV)$
- $d_{AP}(I,II) < d_{AP}(III,IV)$.

This is due to d_{AP} being sensitive to *double disagreements*. A double disagreement occurs when two profiles agree neither on the ranking nor on the approval of two items. In order to get a clearer view of the d_{AP} distance, let us break down the calculation into its sub-components.

$$d_{AP}(I,II) = d_{AP}[(\pi_1,A_1),(\pi_2,A_2)] = \sum_{i<j} h(\left|a_{ij}-b_{ij}\right|, p_{ij}) =$$
$$= h(0,2)+h(1,1)+h(1,1) = 1+1+1 = 3$$

$$d_{AP}(III,IV) = d_{AP}[(\pi_3,A_3),(\pi_4,A_4)] = \sum_{i<j} h(\left|a_{ij}-b_{ij}\right|, p_{ij}) =$$
$$= \mathbf{h(2,2)}+h(0,1)+h(0,1) = \mathbf{4}+0.5+0.5 = 5$$

The profile pair $(III\text{-}IV)$ exhibits a double disagreement on x_1 and x_2, **h(2,2)**, that is, there is maximum discordance in both components simultaneously. In other words, the presence of a double disagreement heavily amplifies the final d_{AP} distance.
Note that in the case of completely disagreement between two subjects, the three distances d_λ, d_{PAS}, d_{AP} reach their maximum value:

$$\begin{array}{cc} x_1 & \overline{x_4} \\ x_2 & x_3 \\ x_3 & x_2 \\ \underline{x_4} & x_1. \end{array}$$

5 Conclusions

This work introduces a new approach for computing the distance between preference-approval profiles. We consider the two possible disagreements in approvals and preferences for each pair of alternatives and merge them through a function $h(\cdot)$ increasing in each component. The aggregated distance, d_{AP}, differs from the distances in the literature in his sensitivity to double disagreements. In fact, our approach strongly penalizes the cases of maximum discordance in both components simultaneously. Therefore, while the state-of-the-art approaches only depend on the marginal distances between rankings and approvals, our proposal also depends on how many double disagreements occur. Future works should be devoted to the definition of a *consensus ranking-approval* defined as the closest preference-approval profile (i.e. with the minimum distance or maximum correlation) to the whole set of profiles.

Covid-19 Assessment and Evaluation 1

Covid-19 impact assessment and inequality decomposition methods

La valutazione dell'impatto del COVID-19 e i metodi di scomposizione della disuguaglianza

Federico Attili and Michele Costa

Abstract The first aggregate assessment of the impact of COVID-19 is usually made on the basis of a comparison of averages. Our goal is to combine the comparison between the averages with inequality decomposition methods. In particular, we refer to three measures of inequality between subgroups that allow an effective assessment of the inequality factors. Our analysis compares 2019 and 2020 IT-SILC consumption micro data in order to assess the impact of COVID-19 with respect to main inequality factors such as age, gender and geography.

Abstract *La prima valutazione aggregata dell'impatto del COVID-19 viene usualmente effettuata sulla base di un confronto tra medie. Il nostro obiettivo è quello di affiancare a tale confronto i metodi per la scomposizione della disuguaglianza. In particolare, facciamo ricorso a tre misure della disuguaglianza tra i gruppi che consentono una valutazione efficace dei fattori di disuguaglianza. Analizziamo i micro dati IT-SILC sui consumi per il 2019 e il 2020 per valutare l'impatto del COVID-19 rispetto a fattori chiave quali età, genere e ripartizione territoriale.*

Key words: Inequality decomposition, Gini index, Covid-19 impact

1 Introduction

The severity of the COVID-19 pandemic represented a very strong shock with serious health, psychological, social and economic consequences. The need to evaluate its effects on inequality has immediately been recognized. It led to a thriving literature (see e.g. [7] for a review), to which we wish to contribute by including the methods related to inequality decomposition in the methodological toolbox of researchers and policy makers.

Federico Attili, Michele Costa
Department of Economics, University of Bologna, e-mail: federico.attili2@unibo.it; michele.costa@unibo.it

COVID-19 impacted Italian households consumption in 2020 through different channels. The principal ones are income reduction [4], lockdown, restrictions, behavioural changes ([5], [6]). Except for lockdown, which flattened household consumption to unprecedented levels in all the society strata, the other channels shaped the distribution of consumption (and income) with heterogeneous intensity along its deciles and subgroups. To fully understand the heterogeneous changes that have taken place, it is therefore important to measure the inequality between subgroups at all points of the distribution.

We investigate household consumption during summer 2019 and 2020. From July to September 2020 the government removed the shutdown of most activities and many of the restrictions on social distancing and travels. By focusing on summer consumption, we improve the identification of the (potentially structural) effects of income losses and behavioural changes from 2019 and 2020.

With respect to three different partitions, which define subgroups based on age, gender and geographical factor, we compare how different can be the picture of household consumption inequality when considering decompositions that follow different paradigms. We show that the increase of age and gender gaps is much smaller if measured by comparing the whole subgroup distributions; the impact of COVID-19 on household consumption is instead homogeneous among the Italian regions and the different points of their distributions, therefore decompositions of inequality agree on modest reduction of geographical divide in consumption.

2 Inequality factors and inequality decomposition

Traditionally, the most direct and immediate way to measure the relevance of an inequality factor and the gap between subgroups j and h, refers to the (relative) difference between the subgroups means, such as $\Delta\bar{y}_{jh} = (\bar{y}_j - \bar{y}_h)/\bar{y}_h$ which provides an aggregate indicator. A more detailed framework can be developed on the basis of the comparisons between n quantiles of subgroup j (y_{ji}, $i = 1,\ldots,n$) and the corresponding quantiles of subgroup h (y_{hi}) that is $\Delta y_{jhi} = (y_{ji} - y_{hi})/y_{hi}$ with their synthesis given by $d_{jh} = \sum_{i=1}^{n} |\Delta y_{jhi}|/n$. The extension to the case of more than two subgroups involves a series of binary comparisons and their synthesis.

In this paper, we want to combine the differences between the means with the methods for the inequality decomposition, where the inequality between plays a key role in evaluating the importance of the underlying inequality factors and the gap between the subgroups. We focus on the Gini index G and on three of its decompositions. Our first reference [2] is the decomposition proposed by Bhattacharia and Mahalanobis, where the inequality between k subgroups is evaluated on the basis of the subgroup means as

$$G_b = \sum_{j=1}^{k} \sum_{h=1}^{k} p_j p_h |\bar{y}_j - \bar{y}_h|/2\bar{y} \qquad j \neq h. \tag{1}$$

where p_j is the share of population in subgroup j. A further relevant contribution to the Gini index decomposition literature [8] is proposed by Yitzhaky and Lerman, who suggest to evaluate the inequality between subgroups as

$$G_b = 2cov(\bar{y}_j, \bar{F}_j)/\bar{y} \tag{2}$$

where F indicates the cumulative distribution.

Alongside these two well-known decompositions of the Gini index, our third reference [1] is represented by a recent and innovative proposal by Attili, which, not being as well known as the previous ones, deserves some introductory notes. The main intuition of Attili's decomposition is to measure the between component by comparing the income of individuals belonging to different subgroups instead of comparing subgroup means. We present the paradigm of the decomposition by a simple scheme involving four units divided in two groups (Fig. 1). The Gini index of the four values normalises the sum of all the absolute differences indicated by the arrows. The vertical and horizontal arrows refer to the inequality within and between, respectively; the decomposition is finalised disentangling contributions to within and between inequality from the diagonal arrows. E.g., for the diagonal difference $(8-2)=6$, we split it in $(8-3)+(3-2)=6$, attributing the first (vertical) difference to inequality within and the second (horizontal) difference to inequality between. In the case of grey diagonals, the two differences are rescaled so that their sum equates the diagonal difference. This is achieved by a rescaling factor, calculated dividing the diagonal difference by the sum of the vertical and the horizontal one. Likewise, black arrows are rescaled by 1.

As in the example, the decomposition of G in within and between components singles out the sum of vertical from the sum of horizontal differences, where each difference is weighted by the sum of the related rescaling factors. Generalising to the case of n quantiles instead of two units for each subroup, the between component reads

$$G_b = \sum_{j=1}^{k}\sum_{h=1}^{k}\sum_{i=1}^{n} \left|y_{ji} - y_{hi}\right| w_{jhi}/(2\bar{y}n^2k^2) \tag{3}$$

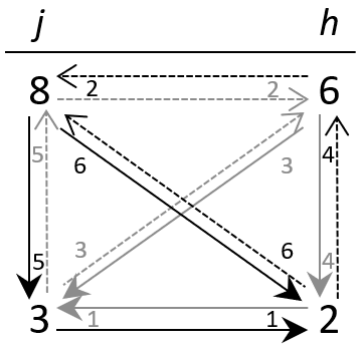

Fig. 1 Illustration of the Gini index in the case of four units divided in two groups. Arrows represent absolute pairwise differences between the four values.

It compares each quantile of subgroup j (y_{ji}) with the corresponding quantile of the other subgroups (y_{hi}) and the weights w_{jhi} ensure correspondence with the Gini index in a fully informative within-between decomposition scheme. A comprehensive presentation is given in Attili. Here we just point out that this measure of G_b is strongly correlated with the *distance between income distributions* proposed by [3], which observes a rigorous axiomatic approach.

3 Data and results

Our analysis is based on the EU-SILC survey for Italian households in 2019 and 2020. We focus on surveys carried out in July, August and September (4650 and 6964 households in 2019 and in 2020, respectively). Household consumption is equivalised for the number of members by using the square root equivalence scale.

In Table 1 we investigate three different bi-partitions based on age, gender and geographical factor. The first panel compares Young-(< 65) and Old-headed(≥ 65) households. In 2019 the former are richer than the latter but in the extreme deciles. Consumption of all groups and deciles decreases in 2020, but COVID-19 more evidently reduces rich old-headed households consumption. Higher values notoriously have impact on the means, so the difference between subgroup means ($\Delta\bar{y}_{jh}$) increases by 71.1% from 2019 to 2020. However, some of the deciles get closer in 2020 (see columns (C)-(D)), which is captured by much smaller increase of d_{jh} (+3.6%). The second panel explores gender divide in households consumption. In 2019 Male-headed households are richer than Female-headed households; again, extreme deciles are an exception. In the same deciles gender divide increases a lot in 2020. As before, $\Delta\bar{y}_{jh}$ is more sensible (+155.8) than d_{jh} (+99.7) to fluctuations of richer households. As for territorial divide, which is investigated in the third panel, the impact of COVID-19 on household consumption is stronger for households in the Centre and the North, but it is distributed quite homogeneously across deciles. Therefore, the reduction of the distance between subgroups is measured at around 7% by both $\Delta\bar{y}_{jh}$ and d_{jh}.

Table 2 reports Gini index decompositions for the three bi-partitions. Consistently with previous results, the increase of age divide is above 70% using eq. (1)-(2), but is more than ten times lower using eq. (3). A similar pattern involves gender divide, where the relevance of the inequality factor increases by 153.2% and 313.2% using eq. (1)-(2), and just by 57.4% with eq. (3). Territorial divide is the most relevant inequality factor and causes from 7.7% to 20.8% of total inequality in 2019. The three decompositions substantially agree on small reduction of the between component share (column (E)), thus suggesting a slightly smaller territorial divide.

To sum up, when the means are influenced by variations in top deciles, and when deciles vary heterogeneously, the change of the difference between subgroup means does not fully account for the evolution of the distance between the subgroup distributions. The latter is better captured by the average change of the differences

Table 1 Italian households monthly consumption. Deciles and means of the subgroups defined by age, gender and geographical factors. Columns (C) and (D) compare different groups in 2019 and in 2020, while column (E) evaluates the 2019-2020 dynamic.

	(A)		(B)		(C)	(D)	(E)

between quantiles (d_{jh}). When Attili's between component evolution differs from the others, it does so in the proportion of d_{jh} to $\Delta\bar{y}_{jh}$.

4 Conclusions

We analyze the COVID-19 impact on inequality with respect to three factors: age, gender and geography. Age and gender gaps increase, while territorial divide (which is confirmed as the most important inequality factor in Italy) slightly decreases.

The assessment of these dynamics strongly depends on the employed measure. If it is based on averages, the evaluation reflects an aggregate effect, which may be at-

Table 2 Evolution of the between component from 2019 to 2020 for three partitions by age, gender and geographical factor. A, BM, YL stand for the three Gini index decompositions compared here.

		(A)		(B)		(C)	(D)	(E)
		$G \cdot 100$		$G_b \cdot 100$		G_b/G		(D-C)/(C)
		2019	2020	2019	2020	2019	2020

	BM	30.2	29.7	6.6	6.2	21.8%	20.8%	-4.5%
	YL	30.2	29.7	2.3	2.0	7.7%	6.9%	-10.2%

tributable to some aspects of the distribution only. This is the case of age and gender gaps in Italian household consumption: the average change is driven by the group of households consuming more. When, on the other hand, the measure of variation refers to the whole distribution, we have a more complete representation of the intervening dynamics. Inequality decomposition methods include both mean-based measures, such as [2] and [8], and measures referring to the whole distribution, such as [1], and represent an excellent choice for measuring the effects on inequality of phenomena such as COVID-19.

Multiversal methods for model selection: COVID-19 vaccine coverage and relative risk reduction

Metodi multiversali per la selezione dei modelli: la copertura vaccinale da COVID-19 e la riduzione relativa del rischio

Venera Tomaselli, Giulio Giacomo Cantone

Abstract Multiversal methods are used for assessment of misspecification risk in the scientific research. In this study, the Relative Risk Reduction after full COVID-19 vaccination is estimated in populations subjected to lockdown measures. While the multiverse model suggests a positive estimate of the effect of vaccination on risk reduction, apparently trivial alternative analyses in model specification reduce the estimate. Absurdly, some model specifications support a significant negative estimate. This is regarded as a case of Janus effect. Causes of Janus effect are identified in adoption of both Oxford Stringency Index as control variable and Negative Binomial instead of Quasi Poisson model. In some literature, these alternatives are characterised as equivalent. The multiversal methodology is further proposed to enhance countermeasures of Janus effect and risk of misspecification.

Abstract *I metodi multiversali sono utilizzati per l'accertamento del rischio di cattiva specificazione nella ricerca scientifica. In questo studio, la riduzione del rischio relativo a seguito del ciclo completo di vaccinazione anti COVID-19 è stimata in popolazioni soggette a misure di lockdown. Il modello multiversale indica una stima positiva dell'effetto della vaccinazione sulla riduzione del rischio, ma specificazioni del modello alternative, apparentemente ininfluenti, ne riducono la stima. Per assurdo, alcune specificazioni del modello indicano una stima negativa significativa. Questo è considerato un caso di effetto Giano, le cui cause sono identificate nell'adozione dell'Oxford Stringency Index come variabile di controllo congiuntamente all'adozione del modello Binomiale Negativo, invece del modello Quasi Poisson. In letteratura, queste alternative sono talvolta considerate come equivalenti. La metodologia multiversale è infine proposta per definire misure di contrasto rispetto all'effetto Giano ed al rischio di cattiva specificazione.*

Key words: multiverse methods, specification curve analysis, relative risk reduction, COVID-19 vaccine coverage.

1 Introduction

Multiversal methods are statistical and graphical tools for assessment of risk of misspecification in a study or in a meta-analysis. They share relevant features:

- an intellectual debt to original methodologies for sensitivity analysis [9] and their computational intensive developments;
- authors invested in improving methodological robustness of scientific studies, mostly as a reaction to the crisis of credibility of null hypothesis testing in experimental social science and clinical medicine [8, 17];
- instead of rejecting null hypothesis in hypothesis testing, lowering α, or limiting analytical freedom of the researcher [15], multiversal methods enhance structural variability in analytical choice of the researcher, the so-called *degrees of freedom of the research* in [5], to reduce arbitrariness of findings only to robust results.

All multiversal methods generate a 'multiverse' of estimates $\hat{\beta}$ in a relation between predictor and outcome ($x \rightarrow y$). Each estimate is associated to a p-value.

The methods differ in the way the multiverse is generated:

- Vibration models [12] are focused on model specification through identification of an extensive set of control variables Z, of which the presence or absence is considered to have equivalent weight in the model selection strategy. This approach has been criticised for being prone to fall into M-collider bias [3].
- Multiverse analysis [14] and Specification Curve analysis [13] are focused on alternating equivalent operationalizations of the empirical measures (e.g., using Mercalli instead of Richter scale) or equivalent regression models (e.g., logit *vs* probit).
- Young and Holsteen [18] use a multiverse for estimation of model variance, that is the variability in estimation across different modeling of the underlying problem. Model variance is positively correlated to the risk of elicitating false-positive associations of variables.

In the present study, a multiverse has been generated to model the effectiveness of relative risk reduction ($\hat{RRR}$) in people full vaccinated against COVID-19 in 2021, that is, the inferred reduction of likelihood to die infected by COVID-19 and not recovered, after full vaccination.

Vaccine effectiveness is a special case of confirmatory ecological inference, since the estimate of $\hat{RRR}$ is a function of the relative frequency of full vaccinated people in a country (*vaccine coverage*) as a predictor x, and the observed outcome y is the variety over time in the number of deaths with infection. A reduction of y when vaccine coverage raises, would raise the $\hat{RRR}$, too:

$$R\hat{R}R = 1 - e^{\hat{\beta}_x}, \tag{1}$$

where $\hat{\beta}_x$ is the estimate of the coefficient in the Poissonian regression.

The two salient features for an observational study on $R\hat{R}R$ are:

1. The link function is modeled after a member of Poisson family.
2. y (and, possibly x) not only variate over time but variate also across territories G, for a set of fixed over time determinants.

The variance across G can be accounted in two ways:

1. by Within estimation, that is, demeaning y across territories $((y \mid G) - \bar{y_G})$;
2. by a pooled strategy, that is, controlling *per* an identified set of covariates fixed within G. The most obvious covariate would be the recorded population of the territory for that year.

This covariance structure induces overdispersion in y, compared to the assumption for finite samples of Poisson model: $\frac{s^2(y)}{\bar{y}} \sim 1$. Two Poissonian models account for overdispersion: Negative Binomial and Quasi Poisson. For both of them, it holds the assumption for location of a Poissonian model: $\mathbb{E}(Y) = \mu$.

In Negative Binomial, the variance is not equal to the location and it assumes to be corrected through a quadratic relation to an overdispersion parameter θ:

$$\sigma^2(Y_{NB}) = \mu + (\theta \cdot \mu)^2 \tag{2}$$

differently, in Quasi Poisson, the correction is linear:

$$\sigma^2(Y_{QP}) = \theta \cdot \mu \tag{3}$$

Even if the literature sometimes dismisses this point [4], identification for the of link function of θ in Poissonian panels is not trivial. The multiverse for the present study shows that, conditioned on other choices, the results may be extremely sensible to this decision, to the point that alternative models would justify totally opposite scientific findings. Multiverse methodology helps to check one's own models and possibly to visualize the risk of misinformed decision making.

2 Materials

The data sources are the "Our World in Data COVID-19" vaccination dataset [11], the COVID-19 DataHub[6] and the Oxford COVID-19 Government Response Tracker (OxCGRT) [7].

Oxford's Stringency Index (STRG) is a composite measure in the unit interval of the overall pandemic-countering measures (not necessarily limitations) activated in the countries, while Lockdown (LCKD) is a record of the pandemic limitations to mobility in an ordinal scale. Conditions of sample eligibility for a country are:

- $>$ 350 daily reports on deaths with COVID-19 in 2021

- > 1 daily report on vaccine coverage.

174 eligible countries were sampled for a sum of $63,510$ vectors of observations over 365 days (t), even if the sample had missing data on vaccine coverage (x_t) and other covariates. All the missing data before the first chronological recorded $x_t = 0$ are natural zeros. Other missing data are true *missing* and can eventually be substituted by linear interpolation. The choice whether to interpolate or not is exemplary about how a multiverse follows organically the necessary decision making for data analysis.

2.1 Multiverse Model

The multiverse combines:

- raw y_t *vs.* smoothed y_t, mobile averages at day ± 1;
- raw x_t *vs.* natural zeros-filled x_t *vs.* zero fill plus interpolation of x_t;
- 10 lags for x_{t-lag}: from 13 days to 22 days before y_t.

Adopting a multiversal approach, the combined models to estimate the relative risk reduction $\hat{RRR}$ are the following eight:

- QPW-STRG: Quasi Poisson, Within Estimation, control for STRG;
- QPW-LCKD: Quasi Poisson, Within Estimation, control for LCKD;
- NBW-STRG: Negative Binomial, Within Estimation, control for STRG;
- NBW-LCKD: Negative Binomial, Within Estimation, control for LCKD;
- QPFP-STRG: Quasi Poisson, control for the logarithm of population, for the % of people older than 65, and for STRG;
- QPFP-LCKD: Quasi Poisson, control for the logarithm of population, for the % of people older than 65, and for LCKD;
- NBFP-STRG: Negative Binomial, control for the logarithm of population, for the % of people older than 65, and for STRG;
- NBFP-LCKD: Negative Binomial, control for the logarithm of population, for the % of people older than 65, and for LCKD.

All the models account for a total of 480 combinations of estimates of $\hat{RRR}$ (see 1) with p-values $> .05$ or $< .05$. STRG and LCKD, while relatively invariant across time, were still lagged of 14 days.

3 Results and discussion

Smoothing the deaths and vibrating the lags of vaccine coverage held no impact on $\hat{RRR}$. However, the coexistence in the same multiverse of red and blue estimates in Fig. 1 implies a Janus effect in the multiverse model, that is a severe risk of

misspecification given seemingly equivalent analytical alternatives [12]. Figure 1 shows the source for Janus effect in two choices: STRG and Negative Binomial.

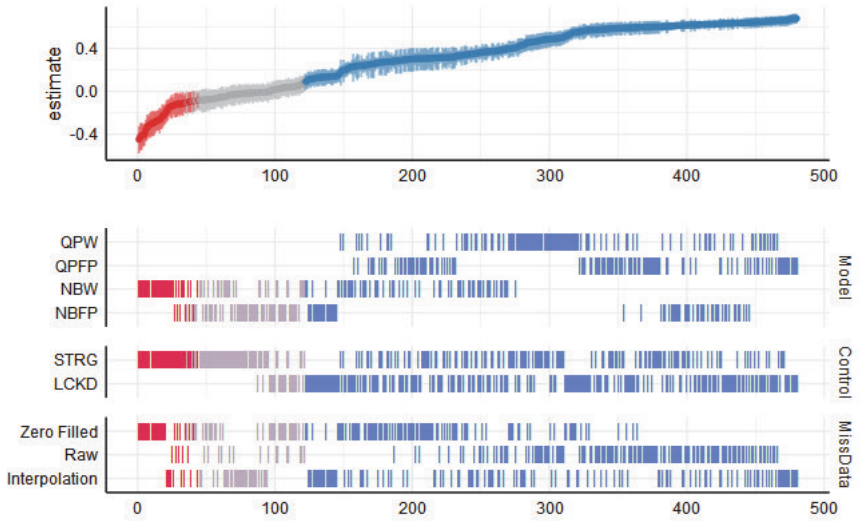

Fig. 1 Specification Curve: in grey the $R\hat{R}R$ estimates associated with not significant p-values $> .05$, in blue the significant (p-values $< .05$) and positive $R\hat{R}R$ estimates, and in red the significant (p-values $< .05$) and negative $R\hat{R}R$ estimates.

An explanation of why Negative Binomial is biased for panel data is that it is very sensible to bias of incidental parameters [1]. NB-models amplify by an exponent the estimated effect in observations with small n, compared to observations with a much larger n [16]. In this case, the Janus effect would be triggered by the control for a composite Oxford Stringency Index. The argument here would be to avoid composite indexes as controls in regressions.

Specification Curve also helps to measure the impact of operationalizations on raw data: filling the natural zeros, while logically appropriate, would induce a statistical bias, that is then corrected only after interpolation of the other missing values.

According to original proponents [13], the slope of the Specification Curve is informative about the robustness of the results. In particular the flat sections are the true *statistical signal* in the multiverse: the existence of flat section implies that as much as the researcher's decisions allow a certain model variance [18], the variance in the estimate will still be minimized within the flat section. In other words, a flat section is informative of convergence of methods towards a likely estimate. If this is true, then the best estimate of $R\hat{R}R$, controlled by mobility limitations, should lie between .45 and .55, since it is the flattest section in Figure 1.

Efficiency and feasibility of two stage sampling designs for estimating SARS-CoV-2 epidemic

Efficienza e fattibilità di disegno di campionamento a due stadi per la stima dell'epidemia di SARS-CoV-2

Pietro Demetrio Falorsi, Vincenzo Nardelli and Giuseppe Arbia

Abstract. Spatial information and aggregate data on the number of verified infected, either hospitalized or in compulsory quarantine, are utilized to improve a standard two-stage sampling design broadly adopted for studying human populations. The basic strategy, is based on spatially balanced sampling. The conditions for their efficiency are analytically proven. The relative advantages are shown through a simulation study.

Abstract. *Le informazioni spaziali e i dati aggregati sul numero di infetti ricoverati in ospedale o in quarantena obbligatoria, vengono utilizzati per migliorare un disegno standard di campionamento a due stadi ampiamente adottato per lo studio delle popolazioni umane. La strategia di base si basa su un campionamento spazialmente bilanciato. Le condizioni per la sua efficienza definite. I vantaggi relativi sono mostrati attraverso uno studio di simulazione.*

1 Introduction

The aim of this paper is to improve the current practice in epidemic data collection. This work examines two-stage sampling, a technique widely used by the National Statistical Institutes to conduct surveys involving direct interviewing (such as large-scale household surveys) in estimating the critical parameters of the Sars-Cov2 epidemic. We first define the conditions for achieving a theoretical efficiency under a

[1] Pietro Demetrio Falorsi, International Consultant – Roma - piero.falorsi@gmail.com

Giuseppe Arbia, Università Cattolica del Sacro Cuore – Roma – giuseppe.arbia@unicatt.it

super-population model which foresees the phenomenon's spatial correlation. We then examine practical sampling choices that allow us to approach the theoretical efficiency but are feasible in practice.

Spatially balanced sampling in the first stage (Grafström et al., 2012; Grafström and Lundström, 2013; Tillé, 2020) and a simple random sampling in the second stage is the basic sampling design here examined. This strategy merge efficiency and feasibility. Since the phenomenon of infection is positively correlated, spatial sampling allows gaining efficiency by spreading the first-stage sample over space; moreover, the balancing strategy leverages aggregated open data on the number of people hospitalized or in a compulsory quarantine. Simple random sampling in the second stage ensures the feasibility of the proposed strategy because the sampling mechanism is simple and does not require information at the unit level. We carried out a comparative analysis of different sampling designs to verify the effectiveness of the proposed strategy using simulated data.

2 The basic sampling framework

We define U as the population of individuals of size N. Suppose that U can be partitioned into M subpopulations, called clusters, denoted as $U_1, \dots, U_i, \dots, U_M$. The clusters are the first-stage sampling units such as neighbourhoods, hospitals or cities. The set of clusters is symbolically represented as $U_{\mathrm{I}} = \{U_1, \dots, U_i, \dots, U_M\}$. Cluster U_i has N_i individuals, being $N = \sum_{i \in N_i} N_i$. Let v_{ij} $(i = 1, \dots, M;\ j = 1, \dots, N_i)$ be the value of the variable v on the verified status of infection for person j in cluster U_i, where $v_{ij} = 1$ if person ij has a verified state of infection and $v_{ij} = 0$ otherwise. The people with $v_{ij} = 1$ could be either hospitalized or in compulsory quarantine. Let $\mathcal{V}_i = \sum_{j=1}^{N_i} v_{ij}$ *and* $\mathcal{V} = \sum_{i=1}^{M} \mathcal{V}_i$ be the known totals of the verified infected people in cluster U_i and in population U. In most situations, public health authorities know the aggregate quantities $\mathcal{V}_i$ and often disseminate such amounts as open data.

Let y_{ij} be the value of variable $\mathcal{y}$ for person j in cluster U_i, where $\mathcal{y}$ is equal to 1 if the person is infected and 0 otherwise. If $v_{ij} = 1$, $y_{ij} = 1$; and if $v_{ij} = 0$, it is possible that either $y_{ij} = 1$ (an infected person for whom the infection has not yet been verified) or $y_{ij} = 0$ (a healthy person). The target parameter, Y, is the total number of infected people, that is,

$$Y = \sum_{i \in U_{\mathrm{I}}} \sum_{j \in U_i} y_{ij} = \sum_{i \in U_{\mathrm{I}}} Y_i \qquad (2.1)$$

where Y_i indicates the number of infected people of cluster i.

We select a sample S using a two-stage sampling design without replacement. A first-stage sample, S_{I}, of fixed size m is selected without replacement from U_{I}, with inclusion probabilities $\pi_{\mathrm{I}i}$ $(i = 1,2 \dots, M)$. A standard solution is to select cluster U_i with Probability Proportional to Size (PPS): $\pi_{\mathrm{I}i} = m\frac{N_i}{N}$.

A second-stage sample, $S_{\mathrm{II}i}$, of fixed size, $\bar{n}$, is drawn from each sampled cluster U_i by *drawing the units* without replacement and with equal probabilities. The second-

stage inclusion probability, $\pi_{\mathrm{II}i}$, of people in the sampled cluster U_i is $\pi_{\mathrm{II}i} = \frac{\bar{n}}{N_i}$. The final inclusion probability of person *j* being selected from cluster U_i is $\pi_{ij} = \pi_{\mathrm{I}i}\pi_{\mathrm{II}i} = m\frac{N_i}{N}\frac{\bar{n}}{N_i} = m\frac{\bar{n}}{N}$. The sampling process is *self-weighting* in the sense that all the units in U have an equal probability of being selected, irrespective of their cluster. The Horvitz-Thompson estimator of Y is

$$\hat{Y} = \sum_{i\in S_{\mathrm{I}}}\sum_{j\in S_{\mathrm{II}i}}\frac{1}{\pi_{ij}}y_{ij} \qquad (2.2).$$

The sample S_{I} is approximately balanced on the d_{I} variables if $\sum_{i\in S_{\mathrm{I}}}\frac{d_{\mathrm{I}i}}{\pi_{\mathrm{I}i}} \cong \sum_{i\in U_{\mathrm{I}}} d_{\mathrm{I}i}$. A well spread sampling avoids the selection of neighbouring units and it is said to be spatially balanced. As for the algorithms that carry out the spreading of the sample, Grafström (2012) introduced the Local Pivotal (LP) method, which enables the selection of unequal probability samples that are well spread over the population. The method uses the distance between units to create small joint inclusion probabilities for nearby units, forcing the samples to be well dispersed. Grafström and Tillé (2013) proposed the Local Cube (LC) method, which selects a sample that is both spread out geographically and balanced in terms of auxiliary variables, LC is an extension of the LP method.

3 Efficiency vs feasibility

Consider the following generalized linear model *M*:

$$y_{ij} = \tilde{y}_{ij} + u_{ij}$$

where $\tilde{y}_{ij} = \Pr(y_{ij} = 1)$, and u_{ij} is a random error where $E_M(u_{ij}) = 0$, $V_M(u_{ij}) = \sigma_u^2$, $Cov_M(u_{ij}, u_{\ell k}) = \sigma_u^2\rho_{ij,\ell k}$, in which $E_M(\cdot)$, $V_M(\cdot)$, and $Cov_M(\cdot,\cdot)$ are expectation, variance and covariance under the model and σ_u^2 is the homoscedastic variance of errors. The correlations $\rho_{ij,\ell k}$ are supposed to be decreasing in function of the distance $\delta_{ij,\ell k}$ between units ij and ℓk. The probability $\tilde{y}_{ij}$ can be modelled as a Lipschitz continuous function $\tilde{y}_{ij} = g(\boldsymbol{x}_{ij})$, where $\boldsymbol{x}_{ij}$ is a column vector of auxiliary variables specific for unity ij. The accuracy of the proposed sampling strategies may be measured by the anticipated variance given by

$$AV(\hat{Y}) = E_P E_M(\hat{Y} - Y)^2 = A + B + C + D + E - V_M(Y)$$

where $E_P(\cdot)$ denotes the expectation over repeated sampling, and

$$A = \sigma_u^2\sum_{i\in U_{\mathrm{I}}}\sum_{\ell\neq i}\frac{N_i}{\pi_{\mathrm{I}i}}\frac{N_\ell}{\pi_{\mathrm{I}\ell}}\pi_{\mathrm{I}i,\mathrm{I}\ell}\bar{\rho}_{i,\ell} \qquad B = V_{\mathrm{I}P}\left(\sum_{i\in S_{\mathrm{I}}}\tilde{Y}_i\frac{1}{\pi_{\mathrm{I}i}} - \sum_{i\in U_{\mathrm{I}}}\tilde{Y}_i\right),$$

$$C = \sum_{i\in U_{\mathrm{I}}}\sum_{j\in U_i}\sum_{k\neq j}\sigma_u^2\rho_{ij,ik}\frac{1}{\pi_{\mathrm{I}i}}\frac{\pi_{\mathrm{II}ij,\mathrm{II}ik}}{\pi_{\mathrm{II}i}^2},$$

$$D = \sum_{i\in U_{\mathrm{I}}}\frac{1}{\pi_{\mathrm{I}i}}N_i\left(\frac{N_i - \bar{n}}{\bar{n}}\right)\sigma_{\mathrm{II}\tilde{y}}^2, E\sum_{i\in U_{\mathrm{I}}}\frac{1}{\pi_{\mathrm{I}i}}\frac{N_i}{\bar{n}}\sigma_u^2,$$

where $V_{1P}(.)$ denotes the first-stage sampling variance, $\pi_{1i,1\ell}$ is the joint inclusion probability of selecting clusters U_i and U_ℓ in the first-stage sampling, $\pi_{2i|j,2i|k}$ is the second-stage joint inclusion probability of selecting units i and j in cluster U_i,

$$\text{and } \tilde{Y}_i = \sum_{j\in U_i} \tilde{y}_{ij} = \sum_{j\in U_i} g(\boldsymbol{x}_{ij}) \quad , \qquad \sigma^2_{2i|\tilde{y}_i} = \frac{1}{N_i - 1}\sum_{j\in U_i}\left(\tilde{y}_{ij} - \frac{\tilde{Y}_i}{N_i}\right)^2 ,$$

$$\bar{\rho}_i = \frac{1}{N_i(N_i-1)}\sum_{j\in U_i}\sum_{k\neq i}\rho_{ij,ik} , \qquad \bar{\rho}_{i,\ell} = \frac{1}{N_i N_\ell}\sum_{j\in U_i}\sum_{k\in U_\ell}\rho_{ij,\ell k}.$$

If we adopt a sampling algorithm for the first stage sampling to ensure that joint inclusion probabilities $\pi_{1i,1\ell}$ are small whenever $\bar{\rho}_{i,\ell}$ is large, we minimize the term A. As demonstrated in theorem 1 in Grafström and Lunsdström (2013), if the first-stage sampling is well-spread on the totals $\boldsymbol{d}_{1i} = \sum_{j\in U_i}\boldsymbol{x}_{ij}$, and we balance on the same totals, then we obtain the balancing on the theoretical unknown values $\tilde{Y}_i$. In this way the term B tends to be negligible. We may diminish the term C geographically spreading the second-stage sampling in the clusters. If we adopted a spatial sampling mechanism geographically spreading the sampling in each unit, the joint inclusion probabilities $\pi_{2i|j,2i|k}$ become very small when the units are close, and the correlation $\rho_{ij,ik}$ is high. Eventually, if we spread geographically the second stage sampling on the $\boldsymbol{x}_{ij}$ values and balance on the same variables, then we obtain the balancing on the theoretical unknown values $g(\boldsymbol{x}_{ij})$. In this way the term D tends to be negligible. In synthesis, taking as fixed the first-order inclusion probabilities π_{1i} and $\pi_{2i|i}$, the maximum efficiency is obtained by spreading and balancing each of the two stages of sampling selection so the term E becomes the dominant term of the AV.

Spreading and balancing in the second stage may not be practicable. Therefore, a feasible strategy should ensure that the second stage selection is carried out autonomously in each sample cluster. In this case, it would be better to adopt a simple SRSWOR design. Spreading and balancing the second-stage sampling would necessitate the availability of a central population register containing as many records of the geographical and balancing variables as there are units in the population. Realistically, this is not the case for most situations that we may encounter in practice.

A feasible strategy is to individuate a $\boldsymbol{z}_i$ vector of known auxiliary variables at the cluster level reasonably correlated to the dissemination of pandemic. We may then define a suboptimal model $y_{ij} = \tilde{y}_{(z)i} + u_{(z)ij}$, where $\tilde{y}_{(z)i} = h(\boldsymbol{z}_i)$ denotes a Lipschitz continuous function, which returns the same value for all the people in the same cluster, and the residual $u_{(z)ij}$ is given by $u_{(z)ij} = u_{ij} + g(\boldsymbol{x}_{ij}) - h(\boldsymbol{z}_i)$.

We can spread the first-stage sampling directly on the z_i variables and balance on the same totals to have a balancing effect on the unknown function $h(z_i)$, and hence also have a small $\pi_{1i,1\ell}$ when $\bar{\rho}_{i,\ell}$ is large. With this strategy we have

$$AV(\hat{Y}) \cong R_z + C + D + E - V_M(Y),$$

$$\text{where } R_z = V_{1P}\left[\sum_{i\in S_1}\left(\tilde{Y}_i - N_i h(z_i)\right)\frac{1}{\pi_{1i}} - \sum_{i\in U_1}\left(\tilde{Y}_i - N_i h(z_i)\right)\right].$$

More the terms $N_i h(z_i)$ are close to the theoretical values $\tilde{Y}_i$ more the variance R_z of residuals is close to zero, and we gain in the efficiency.

In the context of the pandemic, possible and reasonable choices of z_i are:

$$z_i = \bar{V}_i \ (3.1); \quad z_i = k_i \quad (3.2); \quad \text{and} \quad z_i = (\bar{V}_i, k_i')' \quad (3.3)$$

where $\bar{\mathcal{V}}_i = \mathcal{V}_i / N_i$ and k_i is the vector of the geographical coordinates of the cluster U_i.

4 Empirical results

We test the proposed sampling methodologies on a generated dataset representing an artificial population. in which people are free to move around the territory randomly and, according to their social network, can meet other people and eventually become infected. Each individual of the population can be classified as susceptible, infected or removed according to the framework known as the "SIR model". We considered six categories of individuals: susceptible (S), exposed to the virus (E), infected with symptoms (I) and without symptoms (A), and removed from the population either because the individual is healed (R) or dead (D). In the present experiment, we considered the subjects belonging to group (I) to be "known" infected (identified by a positive swab from health screening) and those belonging to group A to be "unknown infected", i.e., those who were not aware of being infected. The simulation algorithm is detailed described in Alleva et al. (2022) and available in the epidsample R package (Nardelli, 2020).

In the experiment we consider the two stage PPS sampling design illustrated in Section 2. The following six schemas of selection are examined: (1) Fixed-size Probability Proportional to Size (FPPS); (2) the LP method; (3) the LC method Based on Verified Infected (LCBV) where the balancing variables are based on specification 3.3a of the z variables; (4) the LC method Based on Verified Infected (LCBG); the balancing is based on specification 3.3b of the z variables; (5) the LC method Based on Verified infected and on Geography (LCBVG) where the balancing is based on specification 3.3c of the z variables; (6) the LC method Based on the $g(\cdot)$ Model at the unit level which best explains the generation of the spread infection (LCBBM). The model g(·), considered in the LCBBM design is based on the following variables: the number of people, the total distance and number of travels, the total number of contacts and the rate of the known infected.

Using the artificial population generated as described previously, we simulated a sample survey at multiple time points during different phase of the epidemic and lockdown periods. For each combination of the simulation parameters, we repeated the Monte Carlo exercise for 10,000 runs so as to ensure the convergence of the sampling methods. We simulated second-stage sampling with a Monte Carlo experiment for different sample cells with different numbers of people sampled in each cell. For simplicity, in Table 1 we report the results for day 15 (3 people for 80 cells) and display the true value, the estimate obtained as the mean of the simulations, the relative bias expressed in absolute terms (RAB) and the standard error (SE). The results of the simulations obtained using other parameter combinations do not add any further insight with respect to those presented here. All the sampling methods considered produce unbiased estimates, as expected. Furthermore, they show consistency, although with very different convergence speeds and a significantly lower standard error (SE) than proportional sampling. The sampling balanced with

model at the unit level which best explains the generation of the spread infection (LCBBM) is the most efficient and displays the lowest standard error. However, as discussed in the previous section, this method collides with feasibility so the second best method is the balanced one on verified infected (LCBV) which has a very similar standard error.

Table 1. Simulation results for day 15 (3 people – 80 cells)

Sampling method	True value	Estimate	RAB	SE
FPPS	1,035	1,048	0.0125	0.37
LP	1,035	1,035	0.0001	0.34
LCBV	1,035	1,034	0.0006	0.25
LCBG	1,035	1,037	0.0015	0.34
LCBVG	1,035	1,028	0.0071	0.32
LCBBM	1,035	1,031	0,0032	0.23

5 Conclusion

The suggested technique has the benefit of being more efficient than the benchmarking case of a regular PPS sampling design while maintaining feasibility. With spatially correlated data, we created an explicit definition of the expected variance. Furthermore, we identified the requirements for increasing efficiency in the two-stage sample design that takes use of the available auxiliary variables, resulting in a promising empirical outcome. This methodology might be applied to the tracing of COVID-19 variants. Future methodological advances will concentrate on determining the relative impact of the AV components on both actual and artificially generated data.

Evaluating the impacts of Covid-19 on the overall Italian death process via Functional Data Analysis

Valutazione degli impatti dell'epidemia di Covid-19 sul processo di mortalità in Italia, via Functional Data Analysis

Riccardo Scimone, Alessandra Menafoglio, Laura M. Sangalli, and Piercesare Secchi

Abstract We propose a novel approach to modeling daily death counts in Italian administrative units, namely Provinces and Municipalities. In particular, starting from data collected by ISTAT during the period 2011-2020, we look at the mortality density along single years, in each province, embedding the analysis in a compositional framework, whose geometry provides a natural amplitude alignment, allows for comparison among differently populated Provinces, and gives interesting insights on the temporal dynamic of the death phenomenon during the years. The majority of the analysis is carried out in an infinite dimensional compositional framework, namely in the Hilbert space B^2 of strictly positive density functions. Combining functional linear models in this Hilbert space with spatial techniques developed in the framework of Functional Geostatistics, we are able to precisely quantify how the structure of the overall death process has been affected by the pandemic waves during 2020. All the results illustrated in this talk are based on [1].

Abstract *Proponiamo un approccio originale alla modellazione del numero di morti giornaliere nelle unità amministrative Italiane, ovvero Province e Comuni. In particolare, a partire dai dati raccolti da ISTAT negli anni dal 2011 al 2020, ci con-*

centriamo sulle densità di mortalità nei singoli anni, in ogni provincia, inserendo l'analisi in un contesto di analisi dati composizionale, la cui geometria consente un naturale allineamento, permette di confrontare province con popolosità variabile e apre interessanti prospettive sulla dinamica temporale della mortalità negli anni. Gran parte dell'analisi viene svolta in un contesto composizionale e infinito dimensionale, ed in particolare nello spazio di Hilbert B^2, costituito da funzioni di densità strettamente positive. La combinazione di modelli lineari funzionali in tale spazio di Hilbert, unita all'applicazione di tecniche di statistica spaziale provenienti dall'ambito della Geostatistica per dati funzionali, ci permette di quantificare come la struttura del processo di mortalità sia stata colpita ed alterata dalle ondate pandemiche. Tutti i risultati illustrati in questa presentazione sono basati sul lavoro [1].

1 Introduction

In order to properly analyze the impacts of the Covid-19 pandemic on the Italian mortality process, we deem appropriate to focus the analysis not only on deaths directly attributed to the disease and its variants, rather favoring a broader point of view by looking at death counts for all causes, as collected by the Italian Statistical Institute[1]. These data contain information about any shock which the Italian death process underwent, be it directly caused by the pandemic, an indirect consequence of it, or even totally unrelated to Covid-19. Several practical reasons also drive this choice: daily death counts from all causes are very high quality data, being scarcely affected by problems of missing data or controversial attribution of the cause of death; in addition they have fine temporal and spatial granularity, being collected at the Italian municipality level. We show in Fig. 1 the death counts referring to people more than 70 years old, at the province level, for the years spanning from 2017 to 2020: we will focus on this elderly class for the talk, because this is the most affected by the effects of Covid-19; analyses and insights regarding other age classes are available at https://github.com/RiccardoScimone/Mortality-densities-italy-analysis.git. A somewhat stable seasonal behavior can be identified, during 2017-2019, by a simple visual inspection: in particular, higher death tolls characterize the coldest and hottest period of the year. On the other hand, this stability is clearly broken during 2020, in which many provinces present abnormal behaviors in correspondence of the first and second waves: for instance Bergamo, drawn in orange, is dramatically affected only by the first wave, Naples and Rome only by the second one, while Milan faced both.

[1] All the data object of our work can be freely downloaded at https://www.istat.it/it/archivio/240401

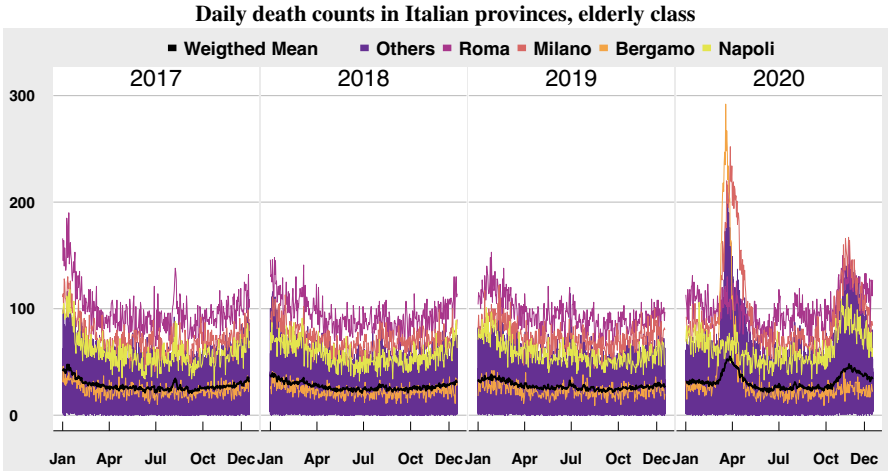

Fig. 1 We show the total amount of deaths in each day, in each year, for each Italian province, referring only to the elderly class (70+ years), it being the most affected by the pandemic. All provinces are drawn in purple, but for some particularly significant provinces which are highlighted in different colors.

Rather than directly analyzing death counts we center our analysis on the empirical distributions

$$p_{iyt} = \frac{d_{iyt}}{\sum_t d_{iyt}} \qquad \text{for } t = 1, \ldots, 365,$$

where d_{iyt} stands for the death count registered in province (or municipality) i in the day t during year y. The collection $\{p_{iy}\}_{iy}$ of discrete distributions can be seen as the empirical distribution functions of the absolutely continuous random variables T_{iy}, each one modeling the time of death of a person who passed away in province i during year y. Analyzing the $\{p_{iy}\}_{iy}$ corresponds to a *compositional data analysis* framework ([6, 7]), i.e., analysis of vectors whose component are parts of a given total. We show in Fig. 2 such family, for the elderly class in Italian Provinces, during 2017-2019. Is it clear that such representation provides a natural alignment with respect to the raw death counts shown in Fig. 1. Moreover, looking at densities highlights different temporal dynamics: the most striking example is the density corresponding to the province of Bergamo, whose peak during the first pandemic wave appears much sharper and dramatic with respect to bigger provinces as Milan, while in the raw counts representation this was less evident.

2 Summary of results

In this talk we will review the main results of our analysis, which is extensively described in [1]. Here follows a short list of our key results:

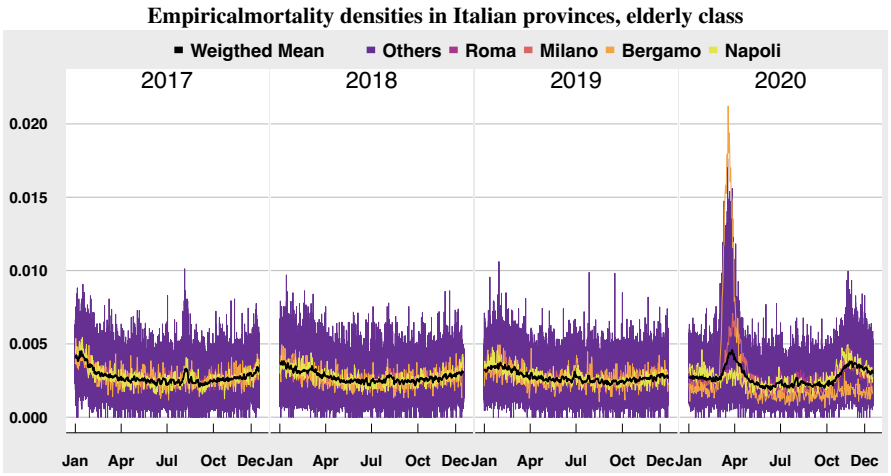

Fig. 2 We plot the $p_{iy_{iy}}$ for Italian provinces, in purple, but for some selesected provinces which are represented with different colors. The black solid line is the weighted mean density, where the weight for each province has been set to be proportional to its population.

- Starting from the $\{p_{iy}\}_{iy}$, we deliver an exploratory analysis based on the *Wasserstein distance* ([5]) for probability density functions, using it as a tool to investigate the stability of the death density process along the years.
- We go beyond the metric embedding, developing the compositional analysis in the Hilbert space B^2 of density functions ([2, 4, 3]). In particular, we smooth the $\{p_{iy}\}_{iy}$ via *compositional splines* ([8, 9]), formulating then a family of function-on-function linear models ([14]) in B^2 to decouple the mortality densities in a *predictable* and an *unpredictable* component.
- We use the previous decoupling as a starting point for a spatial analysis: via functional variography ([10, 11]) and Principal Component Analysis in the B^2 space ([13]) we are able to consistently attribute to the pandemic waves the perturbation of the spatial correlation structure of the death process.
- Finally, we use *spatial downscaling* techniques ([12]) to perform analysis and anomaly detection at the very granular scale of Italian municipalities.

Domestic Violence in Africa: A Glance Through the DHS Survey

La Violenza Domestica in Africa: Uno Sguardo Attraverso l'indagine DHS

Micaela Arcaio,[1*] Daria Mendola,[1] Anna Maria Parroco[1]

Abstract Recent data states that 33 per cent of women in Sub-Saharan Africa are survivors of domestic violence. This work aims at assessing the association between women's characteristics, their environment, and their history of violence in fifteen African countries. Three kinds of violence were explored: physical, emotional, and sexual, each one exerted by the current partner. The data are from the Demographic and Health Survey, in which a special module assessed domestic violence in female respondents. Using three independent logistic regression models, we found that experiencing violence of any kind is associated with a history of past violence, and while women empowerment is not protective, partners with high education are less likely to be violent.

Abstract *Dati recenti provano che il 33% delle donne in Africa Sub-Sahariana è vittima di violenza del partner. Questo studio mira a valutare l'associazione tra le caratteristiche delle donne, il loro ambiente, e la loro storia di violenza in quindici paesi africani. In particolare, lo studio si focalizza su tre tipi di violenza: fisica, emotiva e sessuale. I dati derivano dalla Demographic and Health Survey, in cui un modulo speciale indaga la violenza domestica tra le intervistate. Usando tre modelli indipendenti di regressione logistica, emerge che subire abusi di qualsiasi tipo è associato con un passato di violenza e, nonostante l'empowerment femminile non sia un fattore protettivo, partner con un elevato livello di istruzione sono meno violenti.*

1 Domestic Violence

Domestic or intimate partner violence (IPV) is defined by the United Nations as a behavioural model of relationships in which one of the partners seeks to either obtain or keep power and control over the other [1]. There are different kinds of domestic violence: physical abuse refers to causing harm; emotional abuse points out not only to verbal abuse but also to social isolation from friends and family; finally, sexual abuse involves forcing a partner into sexual acts without their explicit consent [1]. All countries in the world experience IPV but at different rates and women are overall the most targeted group. Sub-Saharan Africa has the second-highest rate (33%) of lifetime IPV for women aged 15-49, following the 35% in Southern Asia [2].

The analysis of IPV requires more than the study of victims' characteristics [3]. Several studies control for education, both of victims and their partners, with people with higher education being less likely to either perpetrate or suffer IPV [4, 5]. Wealth is also considered a protective factor [6]. There is also evidence of a complex interplay between context and personal characteristics: e.g., as women's access to education and the labour market increases, so does IPV within that nation [7]. Religious women are more protected than atheists, given they can rely on a broader social network; however, there is no clear evidence of differential effects among religious affiliations [12]. IPV is also associated with women's approval of wife-beating [4, 8, 9]. Furthermore, history of violence decidedly plays an important role: women who have a history of violence between parents – i.e., their fathers used violence on their mothers – are much more likely to be abused later in life, due to assimilation of acceptability of this kind of aggressions and perpetuation of the same patterns of violence [10,11]; similarly, men who had violent fathers or witnessed violence become perpetrators as well [6].

2 Data and Methods

This paper focuses on violence against women by their heterosexual partners. Data are drawn from the Demographic and Health Survey (DHS), a nationally representative household survey, covering over 90 countries and 40 years. In particular, we focussed on fifteen surveys in Africa for which the module on domestic violence was administered: Angola, Burundi, Cameroon, Chad, Ethiopia, Gabon, Kenya, Liberia, Mali, Malawi, Rwanda, Senegal, Togo, Zambia, and Zimbabwe. Surveys range from 2015 to 2018, with some exceptions for some countries where available data were less recent.

Information on IPV is collected only among women ever partnered, selected at random in those households involved in the main survey. Questions are both referred to violence perpetrated by the respondent's current partner and to past violent experiences. We restricted our analyses to a sample of almost 40,000

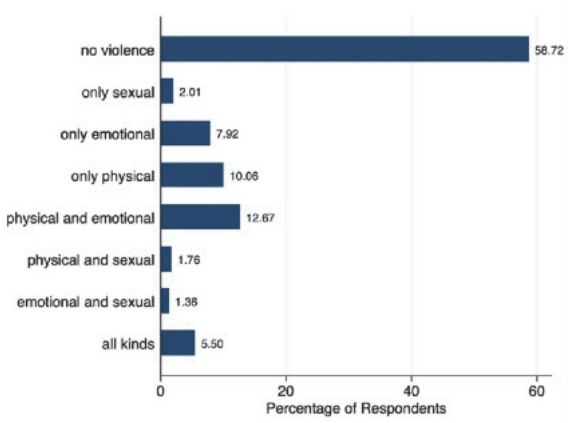
currently partnered women, aged 31 years on average, pooled across the 15 countries.

Domestic violence, our response variable, is assessed via three indicators, made dichotomous:

- "Physical Violence", which takes value 1 if the respondent has been pushed, shook, slapped, punched, threatened at gunpoint by her partner;
- "Emotional Violence", which takes value 1 if the respondent's partner has ever humiliated, threatened with physical harm or insulted her;
- "Sexual Violence", which takes value 1 if the respondent has ever been forced into sexual acts by her partner.

Figure 1 shows the percentages of women who might have experienced any form of the three types of IPV by their partner. More than 40% of respondents have experienced at least one form of abuse by their partner, with almost 6% of them having experienced all three and more than 15% having experienced two.

Figure 1: *Occurrence of the three kinds of violence – percentages*



Given the nature of the phenomenon, and of the response variables, three logistic regression models were defined to assess the effect of the selected regressors, which are the same for all models to improve comparability. These were classified into five different dimensions: 1) *History of Violence*: father used violence on mother; respondent has ever been raped (not by her current partner); no. of people who used violence on the respondent (except for partner); 2) *Respondent's characteristics*: education level, employment status, age, age at first intercourse, religious affiliation, no. of justifications for wife-beating;[1] 3) *Partner characteristics*: partner's age (in terms of age difference among partners), education level and no. of partner's control

[1] Her husband is justified in beating her for: burning the food, arguing, going out without telling him, neglecting her children, refusing sex.

issues;[1] 4) *Household characteristics*: she is the head of the household, quintiles of household's wealth, no. of living children under five years of age; 5) *Context variables*: whether the respondent lives in a rural/urban setting, and the country she lives in. These last country dummies account for regional specificity.

3 Results

The models provide the odds for women to have experienced at least one physical, emotional, or sexual violence by their current partner (estimates in Table 1). History of violence plays a crucial role in predicting every kind of IPV [10,6,11]. Noticeably, women are almost twice as likely to be physically abused if their father harmed their mother, and thrice as likely to be sexually violated by their partners if they had been previously raped. The greater the number of abusers in women's lives the higher the odds to be abused by the current partner.

As for the respondent's characteristics, older women are more likely to experience violence, while there are no significant effects of their education, nor of their age at first intercourse. However, as debated above, women who work are 10% more likely to experience physical or emotional abuse. The religious environment also matters despite but not for every kind of violence: atheist women are 25% more likely than Christian women to be physically abused by their partners, whereas Muslim women are 25% and 30% less likely to be physically or emotionally abused than Christian women respectively. Interestingly, the number of justifications that women provide for wife-beating does contribute to increasing the odds of each form of violence.

Partners with a higher education level are also associated with women being 20% less likely to be physically or emotionally abused, and almost 30% less likely to be sexually abused. Those who tend to control their partners more are more likely to act violently. When he is older than her, the odds of being abused lower by about 2% per year but only for physical and sexual violence.

When it comes to household characteristics, women in the richest quintile are less likely to be either physically or sexually abused. Moreover, when the respondent is herself the head of her household, her odds of experiencing physical abuse lower by 10%. The presence of young children affects the odds of physical violence, by increasing it by about 5% for each child. Finally, women who live in rural areas are less likely to report physical and emotional abuse than those who live in a city.

Furthermore, other things being equal, violence is not equally spread across countries, with Burundi being the riskiest country for physical and sexual violence and Senegal for the emotional violence (with respect to Rwanda, assumed as reference).

[1] The respondent's partner is jealous, accuses her of unfaithfulness, does not allow her to visit female friends, insists on knowing where she is at all times, does not trust her.

a) controlled for country dummies; b) controlled for covariates found not statistically significant: Respondent's education; respondent's age at first intercourse

4 Conclusions

Domestic violence against women is a worldwide issue. However, it is much more pervasive in some regions of the world, like Sub-Saharan Africa, where social and economic systems in place allow the persistence of discriminatory norms and inequalities. Our analysis offered a glance over factors associated with reported

violence, pointing out the relevance of the phenomenon in some African countries. Our findings indicated that women who have lived in a violent environment in the past tend to be more involved in the same kind of violence.

Noticeably, in contrast with our expectations, women's empowerment (in terms of education and employment) does not act as a protective factor. Indeed, having a paid job outside her house increases women's odds of being abused, and education is not statistically significant. This was observed in some other studies (see [7]) and should deserve further investigation. On the other side, richer families, with highly educated male partners, show less violence.

This study is not free from limitations, the main one likely being the reliability of collected data on violence, often biased by social desirability and the tendency of victims to deny experienced violence. However, we believe that the results offer an interesting contribution to the development of policies to fight violence against women. They suggest that the promotion of a model of women's emancipation in accordance with the cultural and social environment of the country could be successful in reducing violence only in association with more inclusive education and general better living conditions.

Inequalities in undernutrition among Roma and non-Roma children in Western Balkans: an analysis of the determinants

Diseguaglianze nella malnutrizione infantile tra Rom e popolazione maggioritaria nei Balcani Occidentali: un'analisi delle determinanti

Annalisa Busetta[1], Valeria Cetorelli[2], Chiara Puglisi[3]

Abstract
Childhood undernutrition affects physical and cognitive growth and is strongly associated with morbidity and mortality. Roma children in Western Balkans display to date incomparably higher levels of undernutrition, compared to non-Roma children. Employing logistic regression models, we explore the determinants of such dramatic differences using Multiple Indicator Cluster Surveys carried out in Bosnia-Herzegovina, Kosovo, Macedonia, Montenegro, and Serbia in the period 2011-2013 and 2018-2020. Children's age, number of children in the household, type of place of residence and age of the mother at birth are found be especially important factors. In particular, we find substantial differences in the role played by child age on the risk of undernutrition among Roma and non-Roma children.

Abstract
La malnutrizione infantile influenza negativamente lo sviluppo fisico e cognitivo degli individui, ed è fortemente correlata con i livelli di morbilità e mortalità. I bambini Rom che vivono nei Balcani Occidentali mostrano ad oggi livelli di malnutrizione sproporzionatamente più alti rispetto al resto della popolazione. Attraverso modelli di regressione logistica, abbiamo esplorato le determinanti di tali disuguaglianze sulla base di Multiple Indicator Cluster Surveys condotte in Bosnia-Herzegovina, Kosovo, Macedonia, Montenegro e Serbia nei periodi 2011-2013 e 2018-2020. I risultati evidenziano l'importanza dell'età del bambino, del numero di bambini conviventi, del tipo di residenza e dell'età della madre alla nascita del figlio. In particolare, si rilevano sostanziali differenze nel rischio di malnutrizione per età del bambino tra la popolazione Rom e il resto della popolazione.

1 Introduction

Despite some declines, undernutrition remains a serious problem in low- and middle-income countries, with lasting social, economic and health implications. Undernutrition hinders children from reaching their physical and cognitive potential and makes them much more vulnerable to disease and death [12;17].

The United Nations Sustainable Development Agenda aims at ending all forms of hunger by 2030, ensuring that all people –especially children– have sufficient and nutritious food. The pledge to 'leave no one behind' requires the prioritization of policies that tackle inequalities and reach the most marginalized communities [13]. Roma settlements in the Balkans are known to suffer from persistent social exclusion [11;18;7]. This paper focuses on prevalence of undernutrition among Roma and non-Roma children over the last decade, and sheds light on the main determinants of inequalities with the intent of informing policies.

Literature on the determinants of undernutrition is wide and has significantly increased in the last few decades. Recent studies highlight that economic growth is not always a sufficiently powerful element to reduce undernutrition, neither are interventions focused only on nutrition, health and water, sanitation, and hygiene [2]. Indeed, several studies emphasize the importance of a multifactorial framework for understanding child undernutrition [1] that includes more social and structural factors (wealth, socioeconomic status, and maternal education) associated with child nutritional outcomes.

Literature on undernutrition shows that several maternal characteristics affect the nutritional status of children, among which education, age at marriage and at childbirth. Maternal education has been identified in other populations as a strong protective factor for undernutrition [14]. Young maternal age at childbirth is also a risk factor for child undernutrition and is associated with an inverted U-shaped birth weight [15]. An increased risk of stunting is observed in event of young age at marriage/union [4].

As for child characteristics, sex has been showed to be an important determinant of undernutrition, with males consistently displaying higher risk of stunting [10], while the relationship between child age and undernutrition seems to follow an inverted U-shape pattern [3]. Household income, too, appears to have a substantial impact on children's nutrition, with children growing in households with higher socioeconomic status displaying a lower probability of stunting, wasting and underweight [6].

2 Data and Descriptive Statistics

The analysis is based on 18 Multiple Indicator Cluster Surveys (MICS) covering national and Roma settlements representative probabilistic samples in Bosnia-Herzegovina, Kosovo, Macedonia, Montenegro, and Serbia in the period 2011-2013

and 2018-2020. These surveys were designed by UNICEF to collect comparable data on key indicators on the well-being of women and children. The MICS questionnaire consisted of three core modules. A household module was administered to a responsible adult in the household, with the main purpose of gathering information regarding the age and sex of all household members. All women between ages 15 and 49 who were reported in the household module were eligible for individual interview. Mothers or caretakers of children aged less than 5 at the date of the survey were also asked to complete a child health module. The latter included an anthropometric section which involved recording height and weight of each child using standard measuring boards and electronic scales.

Following the WHO guidelines [16], we calculate three different measures of undernutrition. Children whose height-for-age was more than two standard deviations below the median height-for-age of the WHO Child Growth Standards were classified as stunted. Those whose weight-for-height was more than two standard deviations below the median weight-for-height of the WHO Child Growth Standards were classified as wasted. Those whose weight-for-age was more than two standard deviations below the median weight-for-age of the WHO Child Growth Standards were classified as underweight.

Overall, in 2011-2013 the weighted prevalence of stunting among children under 5 years was 10.8%, the prevalence of underweight 3.7% and the prevalence of wasting 3.4%, whereas in 2018-20 they were respectively 9.0%, 3.5% and 2.9%. The inequalities between Roma and non-Roma children are substantial in all the five Balkan countries under study (particularly for stunting and underweight) and persistent over time. The worst nutritional status is found in Bosnia-Herzegovina, Montenegro, and Serbia, with nearly one Roma child out of five being stunted.

3 Research Method and Preliminary Results

To investigate differences in undernutrition among Roma and non-Roma children, this study employs a logistic regression model with country and year fixed effects. The main independent variable is a binary variable, classifying children into non-Roma or Roma. Specifically, we look at the prevalence of underweight, wasting and stunting among Roma and non-Roma children, controlling for a number of important factors identified by the literature.

The stepwise inclusion of variables shows that the differences between Roma and non-Roma children persist even when controlling for the economic conditions of the household, as well as for selected mother- and child-level socio-demographic characteristics.

Despite most Roma families living in relative poverty, the wealth index shows a strong and significant effect. In particular, there is a clear risk gradient in the relationship between wealth index and stunting, with children in the top quintile

of the wealth index distribution displaying a lower risk of being stunted, compared with those at the bottom of the distribution,

As literature showed, undernutrition measures are strongly related with some socio-demographic characteristics of the mother, and with the quality of childcare. Having a higher-educated mother protects children from undernutrition both in the Roma and non-Roma community. Indeed, despite the low number of mothers who attended secondary school in the Roma samples, our models show that mother's education is a strong and significant protective factor for all the measures of child undernutrition. As expected, age at first union or marriage, age of woman at childbirth, and short birth interval all affect undernutrition (although some effects disappear once we include the interaction terms). The quality of childcare measures, too, displays a significant effect. The lack of breastfeeding and vaccination are associated with a higher risk of stunting, wasting and underweight. Similarly, being left alone or with other (older) children, as well as not having any children's books in the household, are both factors associated with one or more measures of undernutrition.

To understand whether the analyzed determinants play different roles among Roma and non-Roma children, we tested some interactions. The analysis reveals relevant differences in the role played by the age of the mother at birth and the type of place of residence among Roma and non-Roma children. Interestingly, we also find a significant, strong but opposite age gradient among Roma and non-Roma children (Figure 1). Specifically, while Roma children display a low probability of stunting during the first six months of life, comparable to the one displayed by non-Roma children, differences in the stunting risks among the two groups arise at age 6-11 months. Moreover, while non-Roma children's stunting risk starts decreasing during the second year of life, Roma children's risk of undernutrition steadily increases, and only slightly decreases between the fourth and the fifth birthday. It has been suggested that this result could be attributed to the lifestyle of nomads: in Roma settlements, children who are able to walk and thus exit the barracks are exposed to a greater risk of infections and consequent debilitation [5]. A further reason for these inequalities could be related to the different treatment that Roma mothers and their children are exposed to in health institutions, as well as to physical or linguistic barriers [8;9]: such factors could hinder Roma mothers from seeking medical help, making a delicate moment like the weaning phase an even more critical one.

Figure 1: *Adjusted predicted probabilities of stunting by age among Roma and non-Roma children (90% Confidence Interval)*

The manual, communicative and quantitative abilities of native and foreign workers according to their level of education in Italy

Le abilità manuali, comunicative e quantitative dei lavoratori nativi e stranieri in base al loro livello di istruzione in Italia

Camilla Pangallo[1], Oliviero Casacchia[2] e Corrado Polli[3]

Abstract Many studies address the labour market consequences of immigration flows. A branch of them argues that native workers respond to immigration by specializing in jobs where they have a comparative advantage, thus protecting themselves from labour market competition and possible wage losses. In order to examine this dynamic in the Italian labour market, we analysed the characteristics of jobs in Italy in terms of skills and tasks performed. The results show that foreigners hold more manual jobs, while natives hold jobs with more communicative and quantitative content.

Abstract Molti studi affrontano le conseguenze sul mercato del lavoro dei flussi migratori. Secondo alcuni i lavoratori nativi, per proteggersi dalla competizione sul mercato del lavoro e possibili perdite salariali, rispondono all'immigrazione specializzandosi in lavori dove hanno un vantaggio comparativo. Al fine di studiare questa dinamica sono state esaminate le caratteristiche dei lavori svolti in Italia in termini di abilità e compiti effettuati. Dai risultati emerge che gli stranieri svolgono professioni più manuali mentre i nativi svolgono professioni con maggiore contenuto comunicativo e quantitativo.

Key words: foreigner workers in Italy, specialization activities, level of education, abilities.

1 Background and Object

In recent decades, increasing migration flows have influenced labour market dynamics in most developed countries. Several studies have investigated the relationships between immigrant flows, workers' income and educational qualifications; Peri and Sparber (2011) argue that "…*when the proportion of foreign workers with high educational level increases in the U.S., native workers choose jobs with less analytical and more communicative content*". Zavodny (2014) emphasize that the jobs held by immigrants are more physically laborious than jobs held by U.S. natives. In other research, Peri and Sparber (2009) emphasize that "… *foreign-born workers specialize in occupations intensive in manual-physical labour skills while native pursue jobs more intensive in communication-language tasks*". Other authors [2] suggest that native workers respond to immigration by specialising in occupations requiring skills in which they have a comparative advantage. Few studies however have examined the differences between the foreign and native components in terms of requirements and characteristics of workers and work in Italy. In this paper, the Italian and foreign employed population in 2019 in Italy were analysed by detecting both specific information regarding the characteristics and requirements of the worker, their profession, and some socio-demographic data. The analyses refer to a period before the traumatic effect of the pandemic due to SARS-COV-2; for this reason, it does not reflect the impact of Covid-19 related changes on employment flows and outcomes.

2 Data and Methods

The data used for the analysis were those of the Survey on Italian Occupations (ISTAT and INAPP, 2013), provided by INAPP at a level of detail equal to 3 digits and the micro-data for public use of the Labour Force Survey–RCFL (ISTAT, 2019). The Survey on Italian Occupations (ICP) describes, with high analytical detail, all the professions existing in the Italian labour market, with particular reference to the content of the work performed and the organizational context in which the work takes place [3]. The ICP, borrowed from the Occupational Information Network (O*NET) survey, adopts the US conceptual model, the *content model*, which provided the basis for the creation of the contents of the questionnaire. The questionnaire is formulated by translating the one from the O*NET survey and, where necessary, adapting it to the Italian situation.

We have built an integrated database to simultaneously detect both specific information regarding the characteristics and requirements of the worker and the profession, and socio-demographic data of the workers, through statistical matching between the Sample Survey on Professions (INAPP, 2013) and the Labour Force Survey (ISTAT, 2019). We have also developed two methods for the construction of composite indicators, which allow us to analyze the world of professions in Italy in terms of workers' skills and work activities. The first methodology has referred to

the study by Peri and Sparber (2009) and the eight indicators (one Manual, two Communicative, three Quantitative, one Interactive and one Analytical) represent a weighted average value for each profession. The second method is the one proposed by Autor, Levy and Murnane (2003), and, in this case, the five indicators (Non-Routine Analytical Tasks, Non-Routine Interactive Tasks, Routine Cognitive Tasks, Routine Manual Tasks, Non-Routine Manual Tasks) were obtained using principal component analysis. The methodology developed by Autor, Levy and Murnane (2003) used the information present in the Dictionary of Occupational Titles (DOT), subsequently, Warman and Worswick (2015) incorporated the method proposed by the three authors to the data of the O*NET database as the latter has over time replaced the DOT; for this reason, in this work, the composite indicators were obtained with the variables suggested in Warman and Worswick's (2015) study.

Furthermore, in order to make the indicators constructed using the two methodologies described above comparable, composite indicators designed by Autor, Levy and Murnane (2003) were constructed, adopting the mathematical method used by Peri and Sparber (2009).

3 Results

The world of professions has been analyzed in terms of both the attitudes and skills of the worker and the activities and styles of work, according to sex, level of education, and citizenship.

This paragraph presents some of the main results relating to the indicators obtained by applying the methodology of Peri and Sparber (2009). In this case, the "Manual" and "Communicative" indicators are considered because they represent the most interesting results and for which the greatest differences have emerged between Italian and foreign workers. The comparison is between the Italian and foreign employed populations from developing countries; the employed of developed countries were excluded from the study as the results obtained are similar to those of Italian employed people. The analysis was carried out separately by sex and level of education: the workers without a school certificate or in possession of an elementary or middle school certificate are included in the low qualification group, while the workers with a university degree were in the high qualification group. Graduated workers have been excluded in this part of the analysis to highlight the differences between less-educated and highly educated workers.

As shown in Table 1 for employed men, the Italians with low educational qualifications engage in activities with a moderate manual content (the score is 27,71), which is higher than that observed for Chinese (22,81) and those employed in Latin America and Oceania (27,47), but lower than all the others.

Table 1: *Employed men: manual and communicative indicators by educational level and citizenship. Years 2019 (RCFL) and 2013 (ICP).*

Citizenship groups	Manual indicator		Communicative indicator		Relative difference between low and high levels of education[1]	
	Low level of education	High level of education	Low level of education	High level of education	Manual indicator	Communi-cative indicator
Italy	27,71	10,47	57,63	68,83	90,3%	17,7%
Developing countries:						
EU	33,46	23,11	45,04	53,59	36,6%	17,3%
Not- EU Eastern Europe	34,30	23,65	43,80	51,73	36,8%	16,6%
Asia (excluding China)	27,78	16,66	43,04	58,05	50,0%	29,7%
China	22,81	16,93	50,05	61,26	29,6%	20,1%
North Africa	31,65	21,50	44,63	51,16	38,2%	13,6%
Sub-Saharan Africa	28,95	17,56	44,65	56,30	49,0%	23,1%
Latin America and Oceania	27,47	20,84	43,94	54,52	27,5%	21,5%

Own elaboration on ISTAT-INAPP data.

Italian workers with high educational qualifications carry out activities - as expected - with a minimum manual content (10,47). Furthermore, it is observed that Italians with both low (57,63) and high (68,83) educational qualifications carry out more communicative occupations than all other groups of foreigners. The relative differences by educational qualification in exercising activities characterized by high manual skills are high in the case of Italians (90,3%), much more moderate for the other groups. Conversely, the differences in the degree of education when it comes to activities characterized by high levels of communicativeness are more limited for Italians (17,7%), and the same is true for the other groups of foreign workers, except Asians (almost 30%).

Regarding employed women, Italian women with low educational qualifications as well as foreign women work in occupations with a moderate manual content. The same result was found for men, although the differences by citizenship are even smaller in the case of women. Italian women workers with high qualifications also work in occupations with low manual content, showing lower values than all other groups of foreign workers; again, the result is very similar to that seen for men.

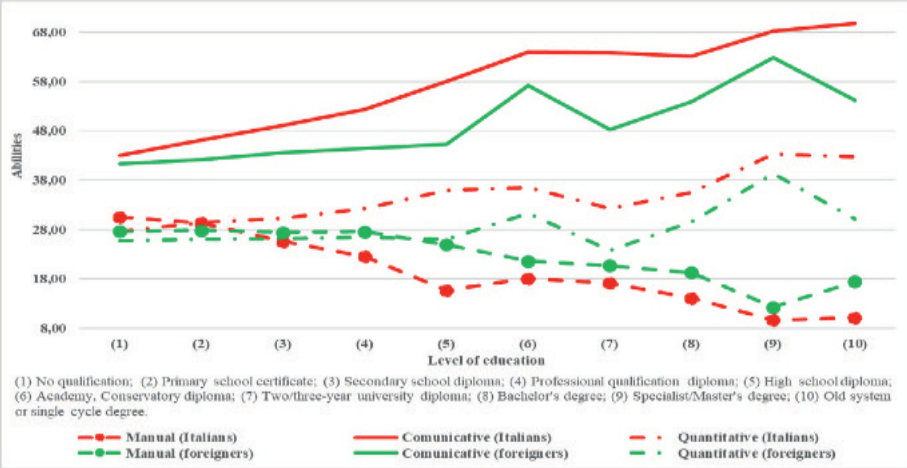
The second type of indicators (Autor, Levy and Murnane) also show greater differences between Italian and foreign workers in terms of content of manual and non-manual occupations, and the study was analysed further by adopting Peri and Sparber's Manual, Communicative and Quantitative indicators.

[1] Relative difference between low and high levels of education relative are calculated considering the average between the two values as denominator.

Data from the Survey on Italian Occupations (INAPP) confirms how the use of the attitudes and skills contained in the various occupations varies according to the level of education of employees; it is possible, using this database linked to the Labour Force Survey, to also test the hypothesis of a variation in this use according to citizenship.

Figure 1 shows the value of manual, communication, and quantitative skills by educational qualification for Italian and foreign workers. Communication and quantitative skills tend to increase with higher educational qualifications, while the use of manual skills decreases.

Figure 1: *Average abilities of Italian and foreign employed people in Italy by the level of education. Years 2019 (RCFL) and 2013 (ICP).*



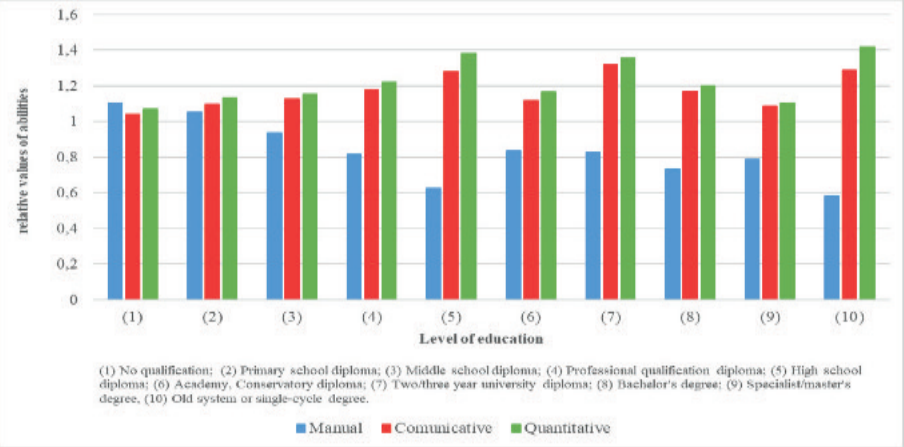
Own elaboration on ISTAT-INAPP data.

Employed people with high educational qualifications are unsurprisingly employed in jobs with high communication content. In some cases, however, there is also a high level of manual work: for example, workers in professions such as health technicians have a manual indicator value of 21,12 (6th decile) and a communication indicator value of 63,56 (7th decile) and doctors have a manual indicator value of 18,69 (5th decile) and a communication indicator value of 73,43 (10th decile). The professions with greater communication skills held by workers with university degrees are, for example, university lecturers (86,92) and researchers and technicians with university degrees (84,52). Educated workers in highly quantitative professions are Engineers and related professions (62,70) and quantitative, physical, and chemical science technicians (63,07). Native workers show an advantage in communication and quantitative skills, foreign workers an advantage in manual work.

Absolute skill levels have to be converted into relative values in order to obtain the comparative advantage in terms of skills of native workers over foreigners (Figure 2). The intensity of communicative and quantitative skills is higher for Italians at practically all levels of education: Italians show a systematic comparative advantage in communicative and quantitative skills compared to manual skills. Italians also show even higher levels of quantitative skills than communicative

skills, which is an unexpected result. Immigrants present a comparative advantage in manual work compared to other skills at all levels of education with the exception of the 'no qualification' category.

Figure 2: *Ratio between the average abilities of Italian and foreign workers. Years 2019 (RCFL) and 2013 (ICP).*



Own elaboration on ISTAT-INAPP data.

4 Conclusion

Thus, the results obtained in this work would seem to confirm part of the conclusions of Peri and Sparber's studies: in Italy, foreign workers would be complementary to native workers because they specialize in different tasks having different skills.

HIV Prevalence in some African Territories: Socio-Economic Drivers

La Prevalenza di HIV in alcuni Territori Africani: Fattori Socio-Economici

Micaela Arcaio,[1*] Daria Mendola,[1] Anna Maria Parroco[1]

Abstract In 2020, 35% of all HIV-positive people in the world lived in Eastern and Southern Africa. This work aims at assessing the relationship between socio-economic drivers and HIV prevalence at the sub-national level in these countries. The data used are drawn from the Demographic and Health Survey, in which a subset of respondents is tested for HIV. Using a fractional logistic regression model on clusters of individuals, middle-to-high wealth is positively associated with higher HIV prevalence, while a higher average number of children acts as a protective factor; moreover, higher proportions of people who have never been in sexual relationships lower their cluster's HIV prevalence but HIV-positive people are more likely to use condoms at last intercourse.

Abstract *Nel 2020 il 35% delle persone sieropositive nel mondo era concentrato in Africa del Sud e dell'Est. Questo studio mira a valutare la relazione tra fattori socio-economici e prevalenza di HIV a livello sub-nazionale in questi paesi. I dati derivano dalla Demographic and Health Survey, in cui un sotto-campione viene sottoposto al test dell'HIV. Utilizzando un modello di regressione logistica frazionaria su cluster di individui, il benessere medio-alto è associato positivamente a prevalenza di HIV più alta, mentre un numero medio di figli maggiore agisce da fattore protettivo; inoltre, maggiori proporzioni di persone che non hanno mai avuto relazioni sessuali abbassano la prevalenza del loro cluster ma persone sieropositive utilizzano con maggiore probabilità il profilattico.*

Key words: HIV, socio-economic status; fractional logistic regression; sexual behaviours.

1 Introduction

In 2020 an estimated 38 million people were living with HIV in the world. Among these people, about 50% are adult women (age 15+) and 5% are children aged 0-14 [1]. When it comes to HIV prevalence, it is estimated to be globally at around 0.7% among adults aged 15-49, with varying prevalence between both regions and countries. Indeed, the regional prevalence ranges between less than 0.1% in North Africa and the Middle East and 6.5% in Eastern and Southern Africa.

As for socio-economic drivers of the HIV epidemic, there is no evidence for an unequivocal relationship between some socio-economic characteristics of a certain population and HIV infection. Different authors have found both positive and negative association with education and wealth, with employment status and age, highlighting the heterogeneity in the relationship [3]. Indeed, some studies have found that higher standards of living, as well as higher household wealth, are positively associated with higher odds of HIV infection [4, 5, 6], while others have found that poorer people incur to income-generating strategies that put them at risk of seropositivity [7]. Education has also been shown to reduce vulnerability to HIV [6].

Focusing on the sexual transmission of HIV, this work aims to assess the relationship between socio-economic drivers and HIV prevalence at the sub-national level.

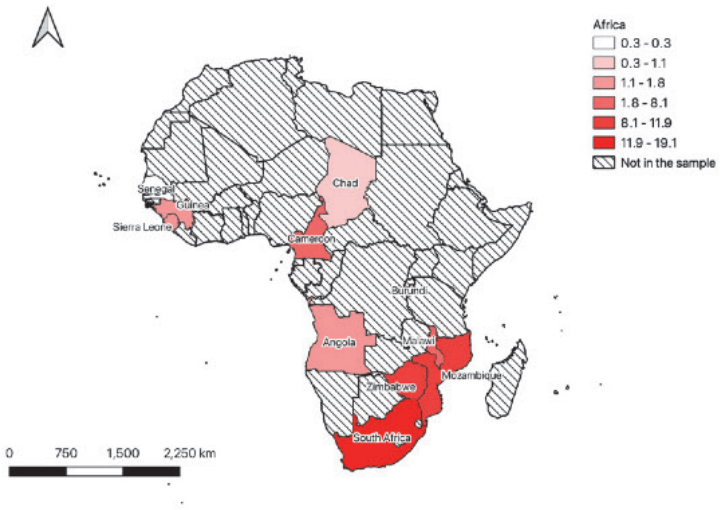
2 Data and Methods

The data used in this analysis are drawn from the Demographic and Health Survey (DHS). It is a nationally representative household survey that has covered over 90 countries in more than 350 surveys in the last forty years [8]. Standardized questionnaires are employed to improve comparisons in time and space on fertility, mortality, family planning, reproductive health, and HIV/AIDS – sub-samples are subjected to ELISA (enzyme-linked immunosorbent assay) tests to determine respondents' serostatus.

In this study, data are from 11 African countries: Angola, Burundi, Cameroon, Chad, Guinea, Malawi, Mozambique, Senegal, Sierra Leone, South Africa, and Zimbabwe. These were selected due to the availability of surveys in a period ranging from 2015 to 2019, choosing one survey (the most recent) for each country.

Indeed, despite accounting only for 3.21% of the global population in 2020 [2], these countries reached a total of 13.5 million cases in that year, accounting for almost 36% of all global HIV-positive patients [1]. The HIV prevalence in these countries ranges from 1% in Burundi to 19.1% in South Africa (see Figure 1).

Figure 1: *HIV Prevalence in the chosen countries*



Our sample is made of almost 150,000 people, aged 15-64, belonging to 11 countries. In the original dataset, households that participated in the survey are grouped in the so-called "clusters"; they are 5,960 with size from 2 to 113 individuals. The original DHS clusters were combined into purposive territorial areas with a greater demographic size to keep the analysis at a territorial level. A spatially-aware k-means clustering method was employed to group the original clusters. Here, the mean point is represented by the barycenter of the clustered geographical coordinates. The procedure [9] was iterated on QGIS for all countries in the dataset, so that the number of macro-clusters would amount to about 50 per country, with a mean population of 270 individuals. The final sample is made of 549 macro-clusters. All variables are aggregated at the macro-cluster level to check for macro socio-economic drivers of HIV.

HIV prevalence at the macro-cluster level is the response variable of the model in this study. It ranges from 0-3.73% in Burundi to 0.19-35.43% in Mozambique, with a total average 5.41% (SD = 7.10).

All variables in the model – including the response – are either presented as means (for continuous variables) or as proportions (for dichotomous variables). Given the nature of the phenomenon, and the way the response variable was built, a fractional logistic regression model was implemented to evaluate the effect of the selected covariates [10]. The log-likelihood function for this model is:

$$\ln L = \sum_{j=1}^{N} y_j \ln\left(\frac{\exp\left(\mathbf{x}_j'\boldsymbol{\beta}\right)}{1+\exp\left(\mathbf{x}_j'\boldsymbol{\beta}\right)}\right) + (1-y_j)\ln\left(1-\frac{\exp\left(\mathbf{x}_j'\boldsymbol{\beta}\right)}{1+\exp\left(\mathbf{x}_j'\boldsymbol{\beta}\right)}\right) \quad (1)$$

in which N stands for the number of territorial units, y_j is the local HIV prevalence, and $\mathbf{x}_j$ is the set of regressors for each territorial unit j.

The option "clustered standard errors" was used so to account for macro-clusters being nested in countries.

Regressors were classified into three different domains: 1) *Socio-demographic characteristics of the macro-cluster:* average age; average no. of years of education; proportion of middle-to-high wealth people; proportion of workers; 2) *Sexual behaviours:* proportion of people who have never had sexual relationships; proportion of married people; proportion of people who used a condom during their last intercourse; 3) *Context variables:* proportion of respondents in a rural setting; country dummies. Country dummies also account for regional specificity.

3 Results

Table 1 shows odds ratio estimates for the model in equation (1). Among socio-demographic characteristics of the macro-clusters, the average number of children is a particularly interesting characteristic, with more children on average lowering the odds for respondents' to be HIV positive – probably due to women having access to prevention education during antenatal care. While the model does not show any significant association between HIV and age at the territorial level, it shows that more educated areas are less likely to be affected by HIV. However, as expected, wealthy areas are twice as likely to have a higher prevalence of HIV.

As for sexual behaviours, a higher proportion in the area of people who have never been in sexual relationships lowers their cluster's HIV prevalence (83% less likely), and a higher prevalence of HIV-positive people is associated with higher proportions of people using condoms at last intercourse. On the other hand, being married is not statistically significant at the territorial level in explaining HIV prevalence.

Rural areas are not statistically different from urban ones in terms of HIV prevalence, while differences among countries emerge with, other things being equal, Burundi, Senegal, and Sierra Leone showing lower levels of HIV prevalence concerning Angola (assumed as a reference country).

Table 1: Fractional logit model for HIV prevalence (odds ratio estimates)

Domains	*Covariates*	*OR estimates*
Socio-demographic characteristics	Age (avg.)	1.001
	No. of years of education (avg.)	0.884***
	No. of children (avg.)	0.786***

	Observations	549

*** p < 0.01, ** p < 0.05, * p < 0.10 *Note: controlled for country dummies*

4 Conclusions

This study is focused on eleven African countries, which, despite only accounting for 3% of the global population, represented more than 35% of all global HIV cases. This analysis aimed to assess the relationship between socio-economic drivers and HIV prevalence at the sub-national level, focusing exclusively on sexual transmission and the socio-economic background of the territorial areas.

Literature on determinants of HIV prevalence has found discordant results. Using a fractional logit model on aggregated data, our findings showed that while age and employment rates do not seem to have an effect on a macro level, a highly educated population is less likely to be HIV positive, but richer people are more likely to drive forward this epidemic.

This mechanism may be due to social networking: richer people have higher chances of having more encounters, which in turn increases their odds of being HIV positive. Social relationships and conventions may also explain why higher proportions of people using condoms during their last intercourse are highly associated with people being HIV positive: people aware of their serostatus are more conscious and, thus, try to avoid infecting their partners by using correct preventative methods.

There is no doubt that these effects need to be further investigated. The erratic way the socio-economic status affects HIV is a sign that the relationship between these two dimensions depends not only on the territories where these data are collected but also on how each population changes over time.

This study is not free from limitations, among these: the arbitrariness of aggregation of territorial clusters; a poor structure of context-level variables. Further steps include robustness tests to different spatial aggregation strategies and a deep reflection on such methodological and substantive aspects.

A longitudinal cross country comparison of migrant integration policies via Mixture of Matrix-Normals

Un confronto longitudinale tra paesi sulle politiche di integrazione degli immigrati attraverso Mixture of Matrix-Normals

Leonardo Salvatore Alaimo, Francesco Amato and Emiliano Seri

Abstract In recent decades, there has been a growing research interest in comparative studies of migrant integration, assimilation and the evaluation of policies implemented for these purposes. With this aim, the Migrant Integration Policy Index (MIPEX) measures policies to integrate migrants in 52 countries all over the world, over time. However, the comparison of very different countries on complex and multidimensional phenomena can lead to misleading interpretations and evaluations of the results. In this paper, we improve and facilitate the comparison between the treated countries on 7 MIPEX dimensions, applying a Mixture of Matrix-Normals classification model for longitudinal data. Trough the analysis, 5 clusters of countries have been discovered, allowing us to add new levels of interpretation of the data.

Abstract *Negli ultimi decenni, c'è stato un crescente interesse di ricerca negli studi comparativi sull'integrazione dei migranti, l'assimilazione e la valutazione delle politiche attuate per questi scopi. Con questo obiettivo, il Migrant Integration Policy Index (MIPEX) misura le politiche di integrazione dei migranti in 52 paesi di tutto il mondo nel tempo. Tuttavia, il confronto tra paesi molto diversi su fenomeni complessi e multidimensionali può portare a interpretazioni e valutazioni fuorvianti dei risultati. In questo articolo miglioriamo e facilitiamo il confronto tra i paesi trattati su 7 dimensioni MIPEX, applicando un modello di classificazione Mixture of Matrix-Normals per dati longitudinali. Attraverso l'analisi sono stati individuati 5 cluster di paesi, permettendoci di aggiungere nuovi livelli di interpretazione dei dati.*

1 Introduction

Immigration regulation and immigrant assimilation have been a salient political issue in all industrialised countries for many decades [1]. The growing interest in comparative analyses of immigration has led to a variety of attempts to quantify immigration policies, i.e. to assess and put into numerical form what countries are doing to foster the integration and assimilation of immigrants. However, the study of these phenomena from a quantitative point of view is rather recent, due to the previous lack of data. Moreover, quantifying migrant integration is a difficult challenge, due to its complex nature and lack of uniformity in migration policies of many countries, which is based on multiple criteria. In the present work, we focus on the Migrant Integration Policy Index (MIPEX) [1]. The project informs and engages key policy actors about how to use indicators to improve integration governance and policy effectiveness. Its aim is to measure policies that promote integration in both social and civic terms, evaluating trough a survey the migration policies of each considered country, to construct a multi indicator system, first aggregated in 8 dimensions, each aggregated in one single composite indicator. The aim of this paper is to add new perspectives on the MIPEX data while respecting the complexity of the phenomenon under consideration by discovering structures and patterns in the behaviour of the considered countries. The research question from which this paper starts is:

- *Given the complexity of the phenomenon under consideration, in order to improve the comparison between the surveyed countries, is it possible to identify homogeneous groups over time among them, i.e. groups of countries which behave similarly across and within time?*

To answer this question, a *Finite Mixture of Matrix-Normals model* has been applied to cluster the units, taking into account the time dimension. The MIPEX includes 52 countries and collects data from 2007 to 2019, in order to provide a view of integration policies across a broad range of differing environments. It considers a system of 58 indicators (for more information, please consult [1]) covering 8 policy areas that have been designed to benchmark current laws and policies against the highest standards through consultations with top scholars and institutions[1]. The policy areas of integration covered by the MIPEX are the following:

[1] The highest standards are drawn from Council of Europe Conventions, European Union Directives and international conventions (for more information see: http://mipex.eu/methodology)

- Labour Market Mobility
- Family Reunion
- Education
- Political Participation
- Long-term Residence
- Access to Nationality
- Anti-discrimination
- Health[2]

Each dimensional synthetic indicator is bounded between $[0,100]$, in which the maximum of 100 is awarded when policies meet the highest standards for equal treatment. These values are chosen by experts from each country, by means of a questionnaire. The analysis carried out in the present work uses the listed above dimensions[3] excluding health.

2 Mixture of Matrix-Normals

Finite Mixture of Matrix-Normals (MNN), as introduced in [2], can be a useful tool to cluster time-dependent data. Let $\mathbf{Y} = \{Y_i\}_{i=1}^{N}$ be a sample of $J \times T$-variate matrix observations (i.e. $Y_i \in R^{J\times T}$), arose from studies with J-variate vector observations measured repeatedly over T time points, as in a longitudinal study case[4]. Assume that each Y_i follows a matrix-normal distribution, $Y_i \sim \mathscr{MN}_{(J\times T)}(M,\Phi,\Omega)$,where $M \in R^{J\times T}$ is the matrix of means, $\Phi \in R^{T\times T}$ is a covariance matrix containing the variances and covariances between the T occasions or times and $\Omega \in R^{J\times J}$ is the covariance matrix containing the variance and covariances of the J variables. The matrix-normal probability density function (pdf) is given by

$$f(Y \mid M,\Phi,\Omega) = (2\pi)^{-\frac{TJ}{2}} \mid \Phi \mid^{-\frac{J}{2}} \mid \Omega \mid^{-\frac{T}{2}} \exp\left\{-\frac{1}{2}\mathrm{tr}[\Omega^{-1}(Y-M)\Phi^{-1}(Y-M)]\right\} \tag{1}$$

The matrix-normal distribution is a natural extension of the multivariate normal distribution, since if $Y \sim \mathscr{MN}_{(J\times T)}(M,\Phi,\Omega)$, then $\mathrm{vec}(Y) \sim \mathscr{MVN}_{TJ}(\mathrm{vec}(M),\Phi\otimes\Omega)$, where $\mathrm{vec}(.)$ is the vectorization operator and $\otimes$ denotes the Kronecker product. Being a special case of the multivariate normal distribution, the matrix-normal distribution shares the same various properties, like, for instance, closure under marginalization, conditioning and linear transformations [3]. The pdf of the MMN model is given by

$$f(Y \mid \pi,\Theta) = \sum_{k=1}^{K} \pi_k \phi^{(J\times T)}(Y \mid M_k,\Phi_k,\Omega_k) \tag{2}$$

[2] Health data are only available for years 2014 and 2019, therefore this dimension could not be used in the analysis

[3] An extensive explanation of the MIPEX dimensions is given in [1]

[4] The three-way data time arrays analysed are represented as: $\mathbf{Y} \equiv \{y_{ijt} : i = 1,\ldots,N; j = 1,\ldots,J; t = 1,\ldots,T\}$, where $i = 1,2,\ldots,52$ indicates the generic country, $j = 1,2,\ldots,7$ the generic MIPEX dimension and $t = 2014,2015,\ldots,2019$ the generic year.

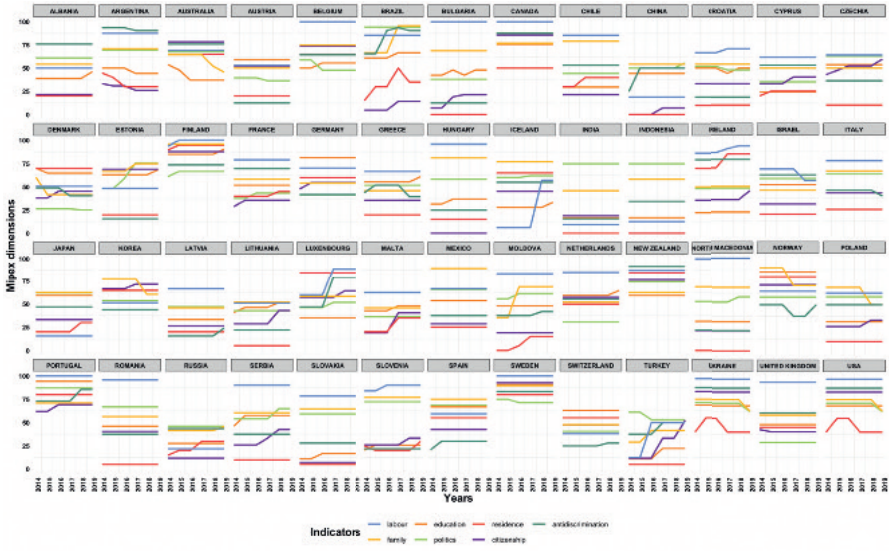
where K is the number of mixture components, $\pi = \{\pi_k\}_{k=1}^{K}$ is the vector of mixing proportions, subject to constraint $\sum_{k=1}^{K} \pi_k = 1$ and $\Theta = \{\Theta_k\}_{k=1}^{K}$ is the set of component-specific parameters with $\Theta_k = \{M_k, \Phi_k, \Omega_k\}$.

In [4], carrying forward from the previous papers, the over-parametrization issue is addressed. For identifiability issues of the model, the determinant of the time-covariance matrix must be restricted to be $\mid \Phi_k \mid = 1$.

3 Results

Figure 1 outline that most of the countries does not change much the values of their indicators through time. Following, the MNN will be used to model together the changes between and within time, grouping together the units which behave similarly across and within time[5].

Fig. 1 Country trajectories of the 7 MIPEX dimensions over time

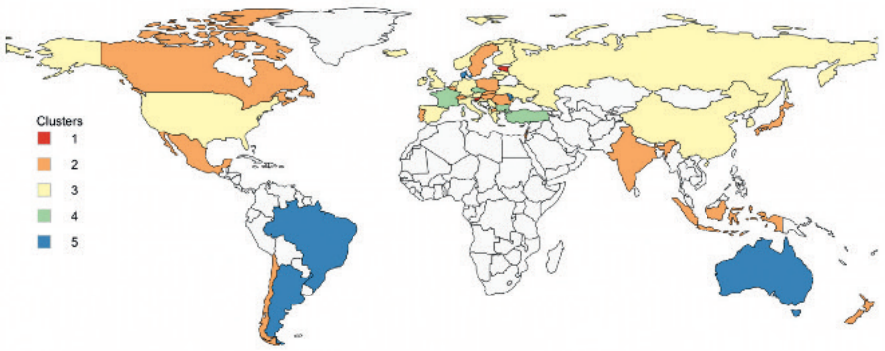


Since our dataset is composed by 52 units, we carried out the MMN model for K ranging from 1 to 8, and choose the best number of clusters by means of the BIC. The selected K is 5. According to BIC, the selected parametrization of the model is A-VEV-VV, which means that the means are better parsimoniously parametrized in additive way, Ω_k with varying volume, equal shape and varying orientation and

[5] The analyzes have been carried out using the package of the softaware R, MatTransMix [4]

Φ_k has both varying shape and orientation. Because of the matrices Φ_k Ω_k, each MMN component models not only the conditional means, but also covariances of the response variables and the covariances among times. In this way, each cluster provides a broad profile of units belonging to it. We report graphically the countries that belongs to each cluster in Figure 2 and the interpretation of the results is as follows:

Fig. 2 MIPEX dimensional indices: MMN clusters' composition of MIPEX countries. Years 2014 – 2019



- **Cluster 1:** *Estonia and Slovenia*. This cluster presents lower correlations in time between the first three years (2014-2016) and the second ones (2017-2019). Moreover, it has negative correlation between labour and the other dimensions, except for family reunification policies. Countries in this cluster have the lowest score for the access to citizenship and rank low for political participation as well, while ranking average for labour mobility, educational policies and high for family reunification, long-term residence and anti-discrimination legislation.
- **Cluster 2:** *Belgium, Canada, Chile, Hungary, India, Indonesia, Israel, Japan, Mexico, New Zealand, North Macedonia, Poland, Portugal, Romania, Slovakia, Sweden, Switzerland*. During the study period, countries belonging to this cluster did not change much their policies, and countries that rank high in some areas tend to rank high in the others as well. The countries of this group tend to have good policies for long-term residency, family reunification and anti-discrimination, but rank low for education and political participation.
- **Cluster 3:** *Albania, Austria, China, Croatia, Cyprus, Finland, Germany, Greece, Iceland, Ireland, Italy, Korea, Latvia, Lithuania, Luxembourg, Malta, Netherlands, Norway, Russia, Serbia, Spain, Ukraine, UK, USA*. Countries in this cluster represents the group that reformed less their immigration legislation during the study period. They tend to rank average in most of the policies areas, with the exception of residence and anti-discrimination laws, where they tend to rank

higher. However, low correlation among variables signals that countries do not move homogeneously among the policies areas.

- **Cluster 4:** *Bulgaria, Czech Republic, France, Turkey*. Despite ranking generally high for anti-discrimination policies, countries within this cluster tend to rank low for policies in education, access to citizenship and labour market mobility, while scoring average for long-residence legislation. Yet, low correlation among variables indicates that countries do not move homogeneously among the dimensions, with the exception of policies regarding access to long-term residence and anti-discrimination, that have high positive correlation. These countries have seen their score moderately changing in time, indicating that some changes in the legislation have happened.
- **Cluster 5:** *Argentina, Australia, Brazil, Denmark, Moldova*. Countries belonging to this cluster have high-correlation in time, but they tend to decrease faster with time, meaning that some changes in the policies have been made especially in the last years. They generally rank low in policies related to educational support for foreign pupils and political participation, average for legislation related to access to labour market and high in family reunion, residence, access to citizenship and anti-discrimination. The policies' dimensions have low correlation, meaning that the countries tend not to move homogeneously among them.

4 Conclusions

This paper has explored immigrant integration policies, analyzing 7 dimensions of the MIPEX from the year 2014 to 2019, to identify groups of units with similar behaviour, to improve the ease of reading of the phenomenon. We addressed this issue trough the application of an unsupervised approach to clustering for longitudinal data namely Mixture of Matrix-Normals model, that accounts simultaneously for the within and between time dependency structures. The analysis, allowed the comparison of clusters with each other and of the countries within each cluster. Also, the correlations in time shown the general trend of each indicator over time in each cluster, and the correlations between variables purified from time effect shown the behaviour of each indicator in relation to the others within each cluster.

Measuring happiness at work with categorical Principal Component Analysis

Misurazione della felicità aziendale attraverso l'Analisi delle Componenti Principali categorica

Kocollari, U., Cavicchioli, M., Demaria, F.

Abstract Despite the large number of contributions on happiness at work, accurate measures are still missing. In this realm, our study investigates the influence of happiness drivers in the workplace, considering the core elements related to both hedonia and eudaimonia, on the most commonly used outcome variable in the management literature that analyses happiness, i.e., the sum of positive feelings. We first explored the drivers of happiness using categorical PCA to find the latent dimensions able to summarize original variability. Then, we analyzed their configuration within a binary regression framework to identify their relative contribution in predicting the probability of employee happiness.

Abstract *Nonostante l'ammontare di contributi sulla felicità aziendale, mancano ancora misure accurate. In questo ambito, il nostro studio indaga l'influenza dei driver di felicità sul posto di lavoro, considerando gli elementi fondamentali relativi sia all'edonia che all'eudaimonia, sulla variabile più comunemente usata nella letteratura manageriale che analizza la felicità, cioè la somma dei sentimenti positivi. Abbiamo prima esplorato i driver della felicità utilizzando la PCA categorica per trovare le dimensioni latenti in grado di riassumere la variabilità originale. Poi, abbiamo analizzato la loro configurazione in un framework di regressione binaria per identificare il loro contributo relativo nel predire la probabilità di felicità dei dipendenti.*

Key words: happiness at work, categorical PCA, optimal scaling, employee well-being.

1 Introduction

Even though happiness in the workplace has been considered critical in management and organizational research, accurate measures for happiness at work are still missing (Fisher, 2010, Salas-Vallina et al., 2020).

In general terms happiness is a subjective experience, closely related to psychological well-being (Grant et al., 2007), which consists of the eudaimonic aspect of happiness (Ryff, 1989). Such well-being depends upon both person-level aspects (e.g. values, attitude, goals) and organization-level characteristics like work environment and culture (De Sousa & Porto, 2015). Moreover, Fisher (2010) identifies three main measures for employee happiness: engagement, job satisfaction and affective organizational commitment. Thus, the happiness construct does not have a single agreed-upon definition, requiring an exploratory and multidimensional approach able to capture the nuances of the term.

1.1 Literature review

The relevance of happiness at the workplace has been examined through different concepts. Research has conceptualized happiness as a multidimensional construct (Ryan & Deci, 2001), considering two main dimensions: hedonic happiness (hedonia) and eudaimonic happiness (eudaimonia). Many authors focus on the hedonic experiences of pleasure and liking, and/or positive beliefs about a certain object i.e. affective commitment, the experience of positive emotions while working (Gaston-Breton et al., 2021). Other investigations include both hedonic and eudaimonic content, the latter involving learning/development, growth, autonomy, and self-actualization (Salas-Vallina et al., 2020).

Fisher (2010) reviewed the concept of 'happiness at work', including both hedonic and eudaimonic orientations. In our study we incorporate both hedonia and eudaimonia, seeing happiness as the sum of positive feelings (Kahneman et al, 1999; Wright & Cropanzano, 2004). We first investigated the drivers of happiness in organizations using categorical PCA to explore the latent dimensions of happiness. Then, we analyzed their configuration within a Logistic regression model that answers to our research question: which are the drivers of happiness in organizations that can positively influence the level of employee happiness?

2 Methodology

Principal Component Analysis, also known by the acronym PCA, is a dimension reduction technique which aims to reduce the number of variables 'm' to a number of 'p' uncorrelated principal components. This technique, however, assumes only linear relationships between variables, requiring a numeric level of measurement (interval or ratio) for all the variables analyzed. In nonlinear PCA all variables are handled as categorical and we perform optimal scaling to assign a numeric value to each of the category label, in a way that maximizes the variance in the quantified variables (Linting & van der Kooij, 2012). In the following we will provide the fundamental aspects of nonlinear PCA. For an extensive review of the procedure and its historical developments we refer to Gifi (1990).

Let **H** be the *n*x*m* observed data matrix, where 'm' is the number of ordinal variables measured on 'n' individuals (objects). Let $\mathbf{h}_j$ be a categorical variable of the matrix **H**, with $j = 1,\ldots, m$, and **G** be an indicator matrix of order nxk_j, where $\mathbf{k}_j$ represents the number of possible categories of variable j. Categorical variables require nonlinear (optimal) scaling, which assigns category quantifications to $\mathbf{h}_j$ through the nonlinear function $\mathbf{q}_j = \varphi_j(\mathbf{h}_j)$. In the following we assume a weight of 1 for all the variables. $\mathbf{Y}_j$ is the category quantification matrix (k_jxp) of variable j, $\mathbf{y}_j$ denotes the vector (of $\mathbf{k}_j$ order) of category quantifications, and $\mathbf{q}_j$ is the associated transformed variable. Thus, the transformed variable $\mathbf{q}_j$ can be denoted by $\mathbf{G}_j\mathbf{y}_j$. Let **A** be the *m*x*p* component loading matrix, where $\mathbf{a}_j$ is the vector of coordinates (component loadings) to represent the j^{th} variable. Let **X** denote the *n*x*p* object scores matrix, containing the coordinates to represent *n* objects in a p-dimensional space. Nonlinear PCA solution is derived by minimizing the least-square loss function σ (X;Y;A), which ultimately minimizes the difference between object scores and original data. To obtain the solution, original data matrix **H** is replaced by the *n*x*m* matrix **Q**, which contains the set of optimally transformed variables $\mathbf{q}_j$. Hence, the loss function can be derived as follows:

$$\sigma(\mathbf{X};\mathbf{Y};\mathbf{A}) = \frac{1}{\mathrm{m}} \sum_{j=1}^{\mathrm{m}} tr\,(\mathbf{X} - \mathbf{G}_j\mathbf{y}_j\mathbf{a}_j^{\mathrm{T}})^{\mathrm{T}}(\mathbf{X} - \mathbf{G}_j\mathbf{y}_j\mathbf{a}_j^{\mathrm{T}}) \qquad (1)$$

where *tr* is the trace function and the product $G_j\, y_j\, a_j^T$ provides the coordinates to represent the j^{th} variable in a p-dimensional space. The minimization of such loss function is performed by an Alternating Least Squares algorithm under normalization conditions and restrictions (Gifi, 1990). Imposing $\mathbf{q}_j^T\,\mathbf{q}_j = n$ we derive that transformed variables are standard scores, and component loadings ($\mathbf{a}_j$) constitute the Pearson correlation between principal components and transformed variables.

2.1 Data collection and variables

Because of the subjective nature of happiness, we opted for a data collection based on self-reported measures. In particular, we viewed happiness as the outcome of five interacting dimensions — economic aspect, interpersonal relationships, personal and professional growth, shared values, and innovative behavior. We conceptually defined these dimensions as potential contributors to employee happiness, and we grounded the questionnaire items design on principles and theories drawn from literature (Warr, 2007). These items were included in an-online questionnaire that was distributed to employees by email. Employees participated on a voluntary basis and confidentiality of responses was assured.

The questionnaire consisted of two sections: the first one gathered demographics and occupational data whereas the second one contained the main variables of the study, measuring the individual work-related experience. All the items were measured on a five-point Likert scale, ranging from total disagreement (1) to total agreement (5) with the question statement.

In addition, we included four multiple-choice questions with the aim to evaluate employees working experience and collect personal thoughts on the organization. One of these questions were used to build a proxy variable for happiness at work. In particular, we defined the proxy variable for happiness at work the multiple-choice question *"Describe your experience in the workplace"*, in which respondents could tick three out of nine possible statements describing their experience.

To build our proxy variable we coded as 1 all the answers including the statement *"I am happy to work for my company"*, and as 0 otherwise. Thus, we dummy-coded happy workers as 1 and non-happy workers as 0.

2.2 Respondents and procedure

The study's sample comprises a total of 201 workers across 13 companies of different industries (e.g. steel industry, industrial machineries, insurance, research and development, etc.) in the Northern Italy. Sex is equally represented as half of respondents are male and half female. Most of them (91) are between 36 and 50 years old and have secondary (47.8%) or higher education (44.3%). The average organizational tenure is 9.35 years.

For the purpose of our study we considered 39 variables, arranged on a five-point Likert scale (i.e. 1-5). The first goal is to find latent dimensions among variables which represent the drivers of happiness at work. In order to check for multicollinearity between variables and justify the adoption of Categorical PCA, association between variables was checked by using Spearman's Rank Correlation All the Spearman's Correlation coefficients were statistically significant at 5%. Correlation between groups of variables was checked through Kendall's Tau-b, which was performed for pairs of variables between groups. All the correlations are within the range 0.204 to 0.356, suggesting that between different groups correlations are from low to moderate. Hence, we can assume that more than one component is needed to summarize the information in the data.

All the 39 Likert-scale variables were scaled at ordinal level, so that φ_j is a monotonic function and transformed categories in $\mathbf{q}_j$ respect the rank order of $\mathbf{h}_j$. Transformation plots showed monotonic and non-decreasing curves, so ordinal treatment is appropriate. The whole analysis was run considering a weight = 1 for all the variables. To maximize Variance Accounted For (VAF) across Principal Components while keeping the orthogonal constraint, *Varimax* rotation (with Kaiser Normalization) was chosen.

3 Results

As can be seen from Table 1, the total variance explained resulting from CATPCA varies from 49.05% with two Principal Components to 65.18% with six latent factors.

Table 1: *VAF comparison*

	Eigenvalue						
DIMENSIONS	λ_1	λ_2	λ_3	λ_4	λ_5	λ_6	**% VARIANCE**
2	14.045	5.085					**49.050**
3	9.658	7.791	3.477				**53.655**
4	8.445	6.765	4.691	2.736			**58.040**
5	7.321	5.963	4.393	3.741	2.731		**61.922**
6	7.373	6.121	4.288	2.755	2.459	2.426	**65.183**

The choice of the number of components was based on VAF, which should always be considered in the light of interpretability and compared across different dimensions (Linting et al., 2007). In our case study we selected four principal

components as the leap in VAF between three and four dimension was the greatest, whereas after four components the marginal increment was not substantial. Overall, the four dimensions explain 58% of the observed variance. We then compared results assuming the least (i.e. nominal) and the most (i.e. numeric) restrictive analysis level. The difference between the variance in the nominal (49.057) and numeric (46.986) analysis is 2.07%, suggesting that when nonlinearity is assumed, the proportion of explained variance increases. Moreover, the graphical inspection of the object plot highlighted 5 outlier observations, which were removed from the analysis.

Table 2: *Model Summary of CATPCA*

	Variance Accounted For		
Dimension	**Cronbach's Alpha**	**Total (Eigenvalue)**	**% of Variance**
1	.955	8.445	21.653
2	.950	6.765	17.346
3	.936	4.691	12.027
4	.842	2.736	7.014
Total	.981[b]	22.636	58.040

a. Rotation Method: Varimax with Kaiser Normalization
b. Total Cronbach's Alpha is based on the total Eigenvalue

The model summary indicates that the four components extracted account for the 58.04% of the quantified variables. Cronbach's Alpha scores confirm the good internal consistency between items, with values greater than 0.842. We only retained in the analysis variables with a VAF greater than 0.25, that is, at least 25% of the variance in a quantified variable is explained across the principal components

Based on the common traits of the variables selected for each dimension, we labeled them as follows. Dimension 1, which explain 21.65% of variance, is related to self-realization through work and skills and is labelled 'Envisioning'. Dimension 2 captures 17.35% of variance and was labelled 'Equity' as it refers to financial reward and career advancement, traditional HR management, and work-life balance. The third dimension, 'Empowerment', covers 12% of variance and includes non-ordinary matters management, critical issues, and teamwork aspects. Finally, the fourth dimension captures 7% of observed variance, and represents interpersonal relationships aspects ('Empathy').

4 Conclusions

Considering the positive effects associated with happiness at work for both employees and organizations (Fisher, 2010; Wright & Cropanzano, 2004), it is worth investigating its drivers and how to improve it.

The first goal was to find the latent dimensions underlying the original data that could be used to build a data-driven happiness construct. Data were gathered through a questionnaire in which the (39) variables measuring the happiness construct were measured by close-ended questions based on a five-point Likert scale. Such questionnaire was administered by email to 201 employees of 13 different small and medium companies in the North of Italy. The data from the survey of self-reported happiness were submitted to a factor analysis using nonlinear principal components extraction. The resulting four-factor solution was subject to the orthogonal Varimax rotation, since the four dimensions were envisaged to be conceptually distinct. The four components extracted capture almost 60% of original variability (58.04%) and the Cronbach's Alpha score indicate a good internal

consistency between items. The variables included in each factor guided their interpretation. PC1 refers to self-realization through work and was labelled 'Envisioning'. PC2 was named 'Equity' as reflects aspects like financial reward and career growth. The third component, 'Empowerment', includes critical matters management and teamwork. Finally, the last dimension ('Empathy') represents interpersonal relationship with peers. Then, we used the extracted components as explanatory variables to predict the probability of being happy by means of a logistic regression model. The response variable of our model was a proxy variable for happiness at work, dummy-coded 1 for happy workers and 0 otherwise.

To conclude, the exploratory and data-driven approach of the present work produced a multifaceted construct of happiness, which is comprised of four main drivers with different contributions on the probability of happiness at work.

Early and accurate: a Machine Learning approach to predict students' final outcome with registry data

In tempo e accurato: un approccio di Machine Learning per prevedere i risultati finali degli studenti utilizzando i dati del registro elettronico

L. Rossi, M. Cannistrà, T. Agasisti

Abstract
Early prediction of students' outcomes represents a challenge for scholars and practitioners. Predicting the final performance of students represents a valuable support for a more informed (and in time) intervention from schools. This paper aims at predicting student performance for a high school in Italy.
Random Forest algorithm is adopted to find the optimal moment to have accurate predictions of students' final grades, as earlier as possible during the academic year. Models adopt data from electronic registers, updated weekly. Results show that predictive models after four months of schooling, on the middle of the academic year, carry out correctly for more than 75% of students based on the final grades average and on the final grade in three subjects (Maths, Italian and English).

Abstract *La previsione corretta e puntuale dei risultati degli studenti rappresenta una sfida per studiosi e professionisti in ambito scolastico. La predizione del rendimento finale degli studenti è un valido supporto per un intervento più informato (e tempestivo) delle scuole. Questo articolo mira a prevedere il rendimento degli studenti di una scuola superiore in Italia.*
L'algoritmo di Random Forest viene adottato per trovare il momento ottimale per avere previsioni dei voti finali degli studenti in modo accurato e tempestivo. I modelli adottano dati provenienti da registri elettronici, aggiornati settimanalmente. I risultati mostrano che i modelli predittivi dopo quattro mesi di scuola, a metà anno accademico, funzionano

correttamente per oltre il 75% degli studenti sulla base della media dei voti finali e del voto finale in tre materie (Matematica, italiano e inglese).

Key words: Learning Analytics; High school Students' performance prediction; Machine Learning

1 Introduction, motivation and research questions

Predicting student academic performance is an important research topic in Learning Analytics (LA) field [1]. Accurate prediction of students' school performance can be useful to evaluate a student's academic performance in advance, which allows to plan and apply personalized and on-time learning intervention. These plans are useful for improving student performance for both those who already have a high academic achievement and for students considered to be at risk of failure [7]. The increasing academic interest over these topics, favours the application and the study of Early Warning Systems (EWS) in the educational domain. The idea of EWS is to use the available data to predict students' school performance early on time and to propose personalized interventions aimed either at their improvement or at the prevention of failure [5] [3] [9]. However, measuring students' academic performance is challenging due to the various factors influencing it: they can be psychological and personal, demographics or academic, as well as concerning family, economic context, or educational setting [10] and they are often correlated in a complex and non-linear way. The complexity of the factors influencing students' achievements and the increasing available information led to the development of new technologies and information systems to study and predict students' career. Machine learning approaches can be adopted in this context to formulate accurate predictions and deal with highly complex data [2] [8]. In this work, an in-depth study using data from the electronic register of an Italian high school is carried out. The objective is the classification of students based on the final average or on the final evaluation in three specific subjects (Mathematics, Italian and English). The main research questions this work aspires to answer are the following:

How **accurately** and how **early** Machine Learning models are able to predict students' final grades in the academic year?

2 Data

The data used for the present research refer to the students enrolled in a private high school in Milan in the academic year 2018/2019. In particular, data are about students' characteristics and come from administrative database and electronic register's data. The variables used for the study can be classified in three categories:

- Static data. This group includes all information known before the beginning of the academic year regarding the personal characteristics of students, information about classes and students' academic performance of the previous year. This group of variables contains demographic information such as gender, citizenship, age (compared to that of peers) and PEI and PDP that indicates if the student follows some personalized plans due to minor or major certified disabilities. The total number of teachers in the class and how many of them are tenured is also known. This set of variables includes prior academic results. Among these, there is a variable indicating whether the student was promoted in June the previous year or he/she had some specific restorative exams in September for being promoted or he/she was rejected or transferred. Also, the average of marks (on a scale between 0 and 10) and the final grade obtained by the students in Mathematics, Italian and English. Lastly, data indicates the school track in which the student is enrolled (the high school system in Italy includes various types of schools: scientific, linguistic, etc...).
- Time-variant information. Information deriving from the electronic registry during each school week. These variables concern the grades' average in Mathematics, Italian and English, the number of delays (i.e. entry at school when the lesson already started), of absences, of merit, diligence and disciplinary notes.
- Output variables. This set of variables includes students' performance, which in the Italian Educational system has a 10-level scale. The variables included in the dataset are the final grade in Mathematics (range of values: 3-10), Italian (range of values: 5-10) and English (range of values: 5-10) and the mean final mark, ranging from 6 to 10.

Table 1 describes variables distributions.

Table 1: Descriptive statistics

Name	***Mean or proportion***	***Standard deviation or range***
Age (-1)	13%	
Age (0)	81,5%	
Age (+1)	5,3%	
Gender (1=Male)	51,1%	
Citizenship (1=Italian)	97,7%	
PEI (1=Yes)	0,7%	
PDP (1=Yes)	16%	
Sector (L. Scientifico Paritario)	25,3%	
Sector (L. Classico Paritario)	15,8%	
Sector (L. Scienze Umane Paritario)	24,9%	
Teachers	18,00	3,42
Tenured teachers	14,96	2,46
Final status 2017/2018 (1=Promoted in June)	82,2%	
Marks average 2017/2018	7,546	0,837
Mathematics final grade 2017/2018	6,68	1,45
Italian final grade 2017/2018	7,14	1,06
English final grade 2017/2018	7,41	1,05
Absences	5,627	0-59
Merit notes	0,563	0-6
Diligence notes	0,847	0-19
Disciplinary notes	0,146	0-7
Delays	2,960	0-31

Mathematics grades	6,504	1.5-10
Italian grades	7,033	3-10
English grades	7,255	3-10
Final grades average (<=5 / at risk)	0	
Final grades average (>=8 /high score)	60,5%	
Mathematics final grade (<=5 / at risk)	9,8%	
Mathematics final grade (>=8 / high score)	36,1%	
Italian final grade (<=5 / at risk)	1,4%	
Italian final grade (>=8 / high score)	42,5%	
English final grade (<=5 / at risk)	0,9%	
English final grade (>=8 / high score)	57,5%	

3 Methodology

In this paper a Machine Learning approach (Random Forest algorithm) is used for the empirical analysis. This study is part of the supervised learning field, it has predictive goals and concern classification. The paper also provides robust checks with alternative algorithms: Classification Trees and Neural Networks, the results are consistent and similar to the ones obtained using RF. To evaluate the results of the study, two important indices will be considered about the performance of the prediction models: accuracy and AUC [4] [6]. A Monte Carlo simulation is also done to test results with a more numerous dataset.

4 Results

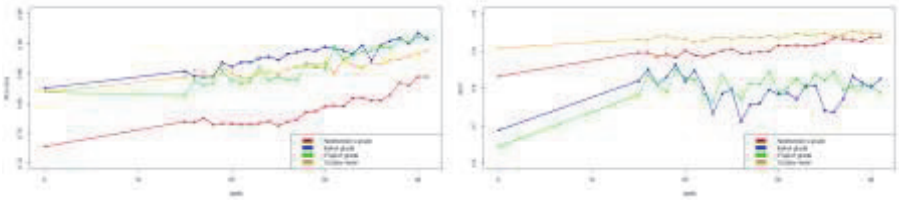
At first the evolution during the year of accuracy and AUC value are evaluated on the original dataset then on the simulated one. Finally, to investigate determinants, the variable importance is considered.

4.1 The performance of the algorithm for predicting students' results

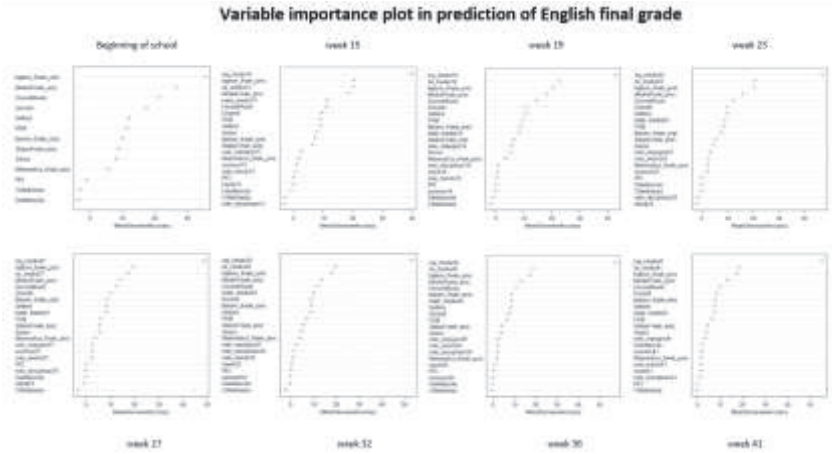
When considering the classification of students based on grades average, initially there is an accuracy of about 82% and an AUC of 0.908, at the end of the year an accuracy of 88.8% is reached and an AUC of 0.946. Already in the 15th week of school out of 41, i.e. the week of December 1st, the accuracy increase about of 3% with the inclusion of registry's data in the analysis.
As for the prediction of the final grade in mathematics, it is initially predicted with lower performance indices than the previous case (73% of accuracy and AUC value equal to 0.833); at the end of the academic year the accuracy is equal to 84.4% and the AUC to 0.939. Already with the addition of the December data 4% in accuracy

is added, exceeding the 75% of accuracy; 80% is reached after 33 weeks. Data of the register increase the accuracy more than 10%.
The final grade of Italian is already correctly predicted at the beginning of the year for about 83% of students, at this time of the year the AUC is equal to 0.689. These values reach respectively the values 90.7% and 0.825 at the end of the academic year. In December the threshold of 85% in accuracy is exceeded with the respective AUC value of 0.802, while after 36 weeks 90% accuracy is reached with AUC value 0.736. After 24 weeks from the beginning of the academic year more than 5% in accuracy is added by using information of the electronic register for the predictions.
Finally, regarding the classification of students based on their final grade in English, at the beginning of the academic year about 82\% of students are correctly classified, with an AUC value of 0.645. The prediction improves more and more until it reaches an accuracy of 91.2% and an AUC value of 0.788; at this time data of the register increase the accuracy of about 10% while of 5% from the 31th week.
Evolution of these indices are reported in Figure 1.

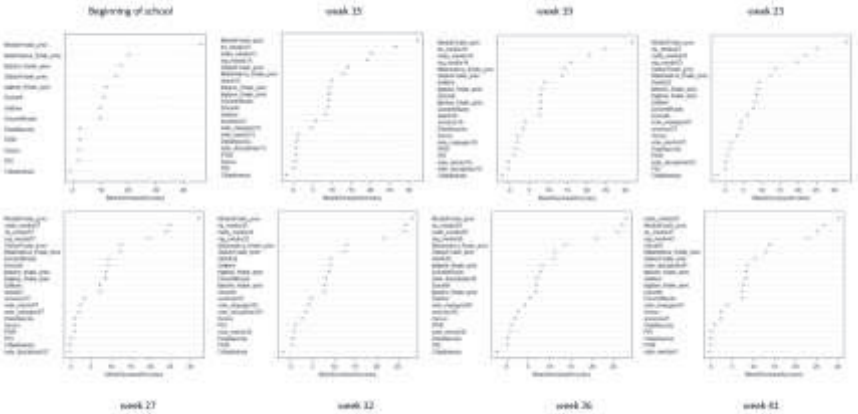
Figure 1: Evolution over the year of Accuracy and AUC value



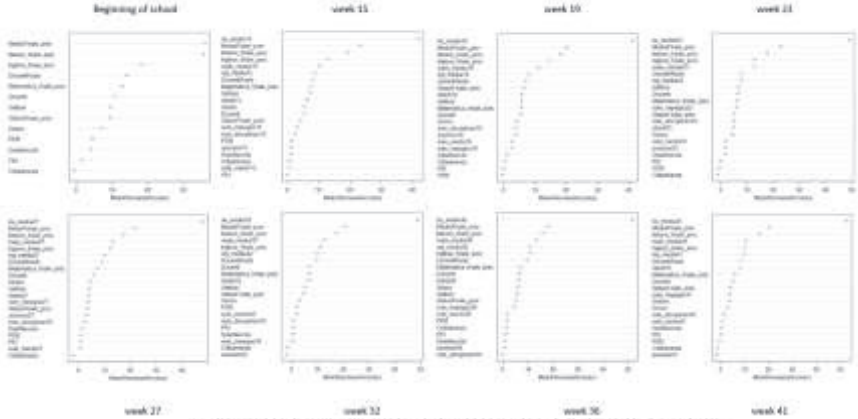
Using variable importance plot of Random Forest on the original dataset the evolution over time of variable importance in the prediction of each output variable is evaluated at the beginning and at the end of the academic year and every first of the month starting from December until June. Results show that grade of the current year and performances of the previous year are always determinants.



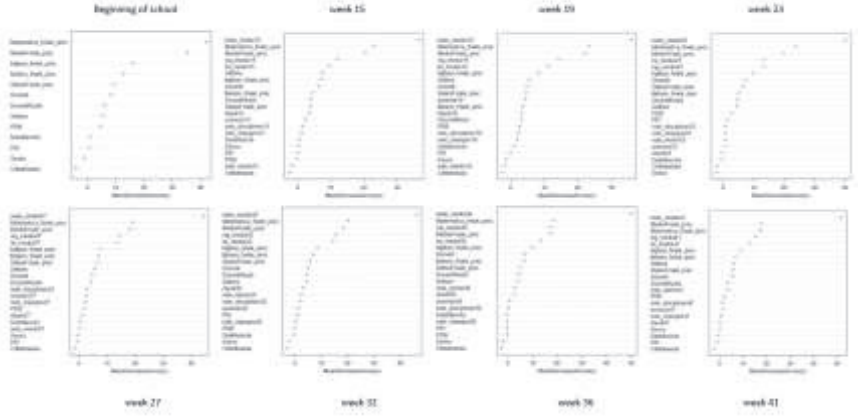
Variable importance plot in prediction of final grade mean



Variable importance plot in prediction of Italian final grade



Variable importance plot in prediction of Mathematics final grade



4.2 A Monte Carlo Simulation

One limitation of this study comes from the low number of observations (as data is available for about 440 students). To test the results obtained with a larger dataset, a data simulation is implemented starting from the original dataset. With the sim_df command on R software data are reproduced with the same distributions and correlations as the original dataset. The simulated dataset consists of 2,000 observations and has the same distributions as the original dataset. The obtained results show indices that are lower than the one obtained using the original dataset but consistent with them and a greater variation in terms of accuracy added by registry's data.

5 Concluding remarks and implications

This paper employs a machine learning approach to realize an EWS finalized at predicting students' academic results. The main innovation proposed here is the use of weekly data extracted from the registry, merging this information with administrative data. The immediate potential use of the EWS proposed here is to realize informative dashboards which can be at disposal of teachers and principals. This information can help teachers to reflect critically on interventions for the students of their classes, also with a specific attention to personalized interventions, that might be personalized over time. A dashboard built at school level can instead be at disposal of the school principal, with the aim of an overview of current academic performance of students as projected at the end of the school year.
A potential limitation of the present study is that the output variable predicted are somehow predicted by the intermediate grades assigned by the teachers - so creating a potentially endogenous circle. In this vein, it would be very useful to check the validity of EWSs in contexts in which the output can be measured by means of external evaluations, as for example standardized test scores.

Students' experience with distance learning during Covid 19 pandemic in Southern Italy

Una esperienza di didattica a distanza in alcuni studenti del Sud Italia durante la pandemia Covid 19

Angela Maria D'Uggento and Nunziata Ribecco

Abstract Approximately two years after the Covid19 pandemic, researchers are interested in assessing its impact on society, mental health, and education. To ensure continuity of instruction, students participated in classes from home. While the technical problems were somehow manageable, the deterioration of mental health was undoubtedly more difficult to cope with and, likely, had traumatic effects on many young people. With a survey of 1,887 high school students in the city of Bari (Italy) we aimed to investigate relevant aspects of social well-being, mental health, and relationships between distance learning and student performance. The results showed that students maintained their performance in distance learning despite suffering from psychological weakness, restlessness and anxiety. This could have interesting implications for school administrators and students.

Abstract *A due anni dalla pandemia, i ricercatori stanno valutandone l'impatto sulla società, in particolare sulla salute mentale e sull'istruzione. Per garantire continuità nella formazione, le scuole hanno adottato la didattica a distanza e, se i problemi tecnici sono risultati in qualche modo gestibili, il peggioramento dello stato psicologico degli studenti è stato senza dubbio più difficile da affrontare. Attraverso un'indagine su 1.887 studenti delle scuole superiori di Bari, una città del Sud Italia, si è cercato di approfondire i temi del benessere sociale e mentale e delle relazioni tra didattica a distanza (DL) e performance scolastica. I risultati hanno rivelato prestazioni invariate, pur in uno stato di disagio psicologico, ansia e paura. Lo studio può risultare di interesse per dirigenti scolastici e studenti.*

Key words: distance learning, high school performance, Covid19 pandemic, mental health, classification trees.

1 Introduction

At the end of 2019, an unknown pandemic is spreading around the world, causing many deaths and changing people's lives by drastically limiting their social activities. Movie theatres, restaurants, sports centres, and schools were closed to avoid physical contact between people that could promote the spread of the Covid 19 virus. Education was no exception, and classes were taught by distance learning (DL), although this was unusual for Italian schools, which normally teach face-to-face. This alternative approach was introduced abruptly and without prior preparation for students and teachers and caused no fewer difficulties. It was to be expected that students' academic performance would deteriorate in such a context (Engzell et al, 2021). One of the main critical issues, that was certainly unavoidable in the initial phase of the lockdown, concerned how DL could be implemented.

The Italian Statistical Office's report on the availability of learning tools and IT devices at home shows that 12.3% of school-age children do not have a computer at home, a figure that is close to 20% in the South, i.e., about 850,000 young people between 6 and 17 years old (ISTAT, 2020). Another 57.0% have a PC at home but have to share it with other family members. Only 6.1% of children aged 6-17 live in families where there is at least one computer per component. In addition, about 41.9% of minors live in crowded housing.

To find out if this context affects students' learning, the results of the National Organization for the Evaluation of Educational Achievement (INVALSI) are useful. They report that the learning skills of high school students in Italian and Mathematics have decreased in the pandemic period compared to 2019, and the existing territorial differences between Italian regions have even widened. Most importantly, the INVALSI report confirms a stable correlation between student performance and socioeconomic environment, with students in unfavourable socioeconomic circumstances losing almost twice as many points as students in more favourable circumstances (Mascheroni et al., 2021). The territorial distribution of the INVALSI analysis shows that the educational gap between the richer regions in central and northern Italy and those in the south is widening.

This paper focuses on the DL experiences of 1,887 high school students from a large city in southern Italy, one of the regions that, according to INVALSI results, experienced increased learning difficulties during the pandemic. The aim of the study is to understand the students' opinions on DL and to find out if their emotional situation during the pandemic affected their performance.

The paper is organized as follows. After a brief introduction to the framework, Section 2 describes the survey and statistical methods. Section 3 presents the main results, which contribute to a better understanding of the phenomenon. Finally, brief conclusions are drawn in Section 4.

2 Data and methods

A web questionnaire was sent to high school students in the city of Bari. 1,887 questionnaires were collected while the students participated in the Statistics Project within the National Plan for Scientific Degrees (PLS), supported by the Ministry of Education and Research for the academic year 2020-2021. Their high schools, as well as other Italian high schools, participated in the PLS program, which is conducted every year by some Italian universities to promote the acquisition of scientific and statistical skills through laboratory activities.

The questionnaire was divided into six sections dealing with different aspects: 1. Sociodemographic information 2. Sources of information 3. Social well-being and mental health 4. Opinions on lockdown rules 5. DL and school performance 6. Future perspective. Of all the aspects investigated, this paper deals with those related to DL and school performance, also in relation to students' main concerns. The research hypotheses were based on evaluating possible differences in performance between the two periods and whether the socioeconomic context might have influenced them in some way. Since household income was not available, the educational level and employment status of the household head were used as indicators of economic conditions. Specifically, the study examined students' opinions of DL, the factors that might lead them to prefer face-to-face education to DL, and their performance compared to the previous year. In addition, the possible relationship between psychological condition and the possibility of making extremely dangerous decisions, such as dropping out of school due to the threat of a pandemic, was examined using the chi-square test and the Classification tree method.

3 Main results

Students expressed a preference for face-to-face classes, citing as the main reason the higher level of attention despite the various sources of distraction at home and the opportunity to interact with the teachers and the class, followed by the better comprehensibility and clarity of the teachers and the lower learning effort. The only reason for preferring distance learning was anxiety about oral exams, which is lower when activities occur through a filter such as the screen (see Table 1). However, when asked for a general preference among the three options (DL or face-to-face instruction or no preference), the gap between distance education (39.5%) and face-to-face instruction (36.6%) narrowed significantly in favour of the former. These data suggest that there are some aspects that were not directly considered in the questionnaire, such as the distance to the school attended, the use of transportation to reach the school, or other factors that made students slightly prefer DL. The fact that more than one-third of respondents preferred the traditional approach indicates a desire for greater social and educational involvement that only the school can provide. In fact, 72.9% of them said they greatly missed social activities with

classmates and 48.6% preferred face-to-face classes (p-value=0.000). We also tried to find out if students' performance deteriorated during the pandemic. 74.9% of the students surveyed reported that their performance had remained unchanged (see Table 2). Relationships with classmates had also not changed for 62.2% of respondents and had actually improved for another 22.4%. When asked about relationships with teachers, the percentages were almost the same, 67.1% and 12.5% respectively, although 55.1% of students defined their teachers more strictly in their evaluation than before. Overall, DL received an average score of 6.7 (SD =1.91; range 1-10) from respondents.

Table 1: Motivations and preferences for distance learning or face to face learning

Motivations	***DL***	***Face to Face***	***No difference***
Better understanding of lessons	11.3	47.0	41.7
Attending lessons more carefully	10.7	58.3	31.1
Ease of participation	20.3	47.8	31.9
Heavier study load	54.1	14.6	31.3
Greater anxiety for oral tests	12.7	53.4	33.9

Table 2: Comparison between the school performance before and during pandemic

Performance before pandemic	***Performance during pandemic***				
	Scarce	Sufficient	Good	Excellent	Total
Scarce (D)	5	15	8	0	28
Sufficient (C)	29	183	146	1	359
Good (B)	15	123	954	63	1,155
Excellent (A)	1	11	60	273	345
Total	50	332	1,168	337	1,887

Following these results, we sought to understand whether they remained unchanged when the influence of the socioeconomic context or the respondents' opinions about DL problems, was considered. As shown in Figure 1, there are no major differences in the proportions of respondents' preferences depending on the father's employment status (χ^2 p-value=0.133). This result is consistent with the previous ones. More likely, all students had either a device (smartphone/tablet/PC) or an Internet connection at home that allowed them to participate in lessons from DL without much effort; in particularly critical cases, schools loaned their students the devices. A similar result emerges by the question *"Have you ever thought about dropping out of school because of distance learning?",* as responses are not affected by father's employment status (χ^2p-value=0.053, combining "not employed" and "retired" categories to meet testing assumptions). Overall, 45.7% of respondents felt that DL was not a reason for dropping out of school, although this response depended on the possibility of returning to "normal life" at the end of the year (χ^2p-value=0.005).

Figure 1: Respondents' preferences and father's employment status

The importance of the experience of DL as a predictor of the possible decision to drop out and, at the same time, the null influence of the respondent's economic conditions are confirmed by the Classification tree (see Fig.2). It allows us to draw two paths: on the right side are the students who had a negative DL experience, so that 33.4% of them sometimes/often thought about dropping out of school. They were also characterized by very low hope (node 6) and serenity (node 10). In contrast, respondents who scored a serenity level of 3 to 4 showed undifferentiated ratings of DL (node 14). On the left are the more resilient students who were able to view the experience of DL in a positive light. Among them, those who felt strongly lonely accounted for the highest percentage of dropout thoughts (28.1%, node 5). In contrast, those who felt less lonely and never experienced psychological fragility had the lowest percentage (5.5%, node 8) of this thought. Finally, the percentage of students who did not feel sustained by hope, although they tended to be satisfied with DL, increased to 22.3%, as shown in terminal node 12. Respondents who experienced positive feelings such as little loneliness and sometimes mental fragility, but saw the future with hope and serenity, repressed negative decisions as they never thought of dropping out of school (92.4%, as can be seen in terminal node 16).

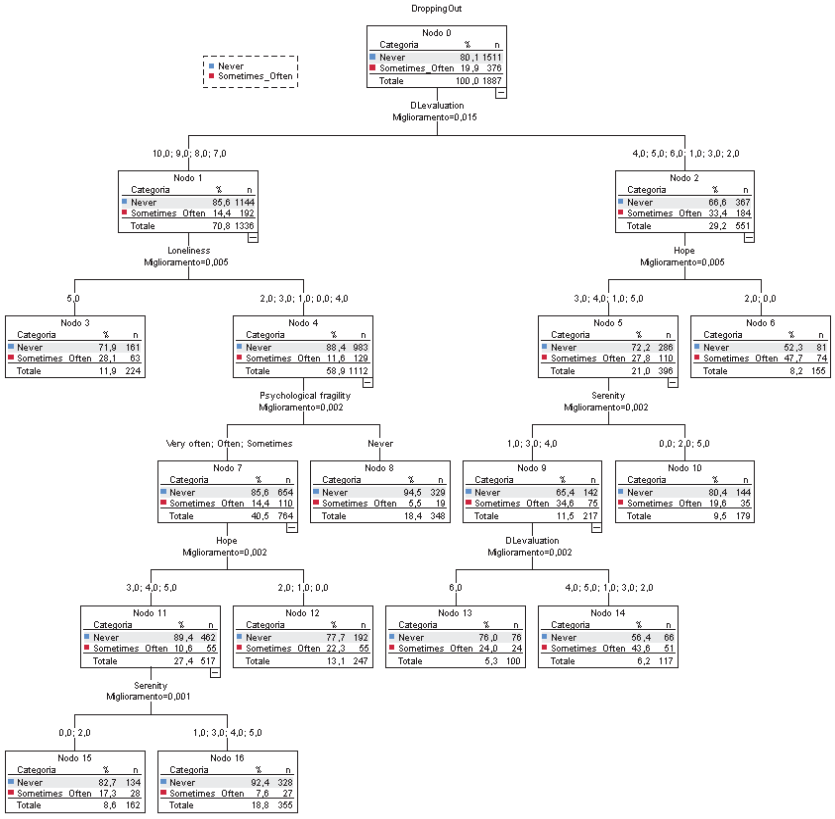

Figure 2: Classification tree for decision of dropping out of school because of distance learning

4 Final remarks

Despite all the concerns mainly expressed during the pandemic period of learning from home, the results of our survey show an overall positive balance. About 39% of respondents preferred it to face-to-face instruction. Logistical and organizational issues probably played some role in the overall positive assessment. Undoubtedly, students also faced some difficulties. It emerged that most students had difficulties in understanding the lessons and interacting with the teachers. In terms of teaching effectiveness, then, the traditional face-to-face form of teaching offers undeniable advantages, which were also acknowledged by the students themselves.

It is also reassuring that about 80% of students have never thought about dropping out of school. Among those who "sometimes" or "often" thought about it, we noted the influence of the emotional state of psychological fragility caused by the inconvenience and difficulties of parents during the pandemic: their proportion decreases when students report being more hopeful and relaxed about the temporary situation and it is high among those who suffered more.

Italian high schools were not really prepared for this emergency in terms of adequate IT equipment and staff preparation. This is certainly one of the factors that could have had the greatest impact on the achievement of the educational objectives offered. Be that as it may, our survey showed that the performance of the students did not deteriorate but remained quite stable during DL.

Undoubtedly, this study deals with a convenience sample, composed of students living in a major city, but it provides evidence that students' online learning experiences can vary widely. This may have policy implications that can help policymakers and schools improve online learning. The pandemic has plunged Italy into crisis, but there have also been many economic and consequently digital inequalities in the past. School attendance represents a fundamental moment of growth in a person's life, and education must be guaranteed without economic or social inequalities.

Time series methods and Applications

Trend and cycle decomposition in nonlinear time series

Decomposizione in trend e ciclo di serie storiche nonlineari

Maddalena Cavicchioli

Abstract In this work we derive the Beveridge-Nelson decomposition and the state space representation for multivariate (co)integrated time series subject to Markov switching in regime. Then we provide explicit matrix expressions for the trend and cyclical components which improve computational performance since they are readily programmable. Further we develop impulse-response function analysis. Applications illustrate the feasibility of the proposed approach.

Abstract *In questo lavoro si ottengono una decomposizione di tipo Beveridge-Nelson e una rappresentazione state-space di serie storiche multivariate (co)integrate soggette a cambiamenti di regime. Inoltre si sviluppano espressioni matriciali esplicite della decomposizione in trend e del ciclo che migliorano le performance computazionali essendo facilmente programmabili. Infine si analizzano le funzioni impulso-risposta. La fattibilitá dell'approccio proposto é illustrata tramite applicazioni.*

Key words: Beveridge-Nelson decomposition, trend and cyclical component, Markov switching (co)integrated processes, Impulse-response function.

1 Introduction

Since the influential works [9] and [10] , Markov switching (MS) models have attracted considerable interest among econometricians to model various nonlinear time series and to capture the business cycle asymmetries (see, for example, [5] and [6]). Moreover, the problem of decomposing a time series into unobservable components having meaningful interpretation has always been very important in econometrics. For example, macroeconomists are interested in modeling the behaviour of aggregate output to analyze the characteristics of trends and cycles in

Maddalena Cavicchioli, Department of Economics Marco Biagi, University of Modena and Reggio Emilia, Viale Berengario 51, 41121 Modena (Italy); e-mail: maddalena.cavicchioli@unimore.it

the economy (see [4], [11], [8] and [2]). Thus, linear models have been augmented with MS processes, so as to incorporate asymmetries associated with business cycle or other macroeconomic nonlinearities. [7] modified the BN decomposition to the univariate MS AR model proposed by [9], and showed that this modified decomposition can be carried out without the necessity of truncating an infinite sum. [3] incorporated MS into a BN decomposition formulated in a single source of error state space form, allowing regime shifts in the long-run multiplier as well as in the short-run parameters. [13] specified a time series with MS to model business cycle phases in permanent and transitory components of post-war US real GNP and consumption. [17] introduced a new approach to trend/cycle decomposition of MS time series, which they called the regime-dependent steady-state (RDSS) decomposition. This procedure extends the BN decomposition to the setting where the reduced form dynamics of a given series can be captured by a MS forecasting model. [12] provided exact calculation of the BN trend and cyclical components for certain classes of univariate and multivariate MS autoregressive sequences. The key to exact BN decomposition is to recognize that the latent first-order MS process in the model has an AR(1) representation, and that the model can be cast into a state space form. From this, he showed that impulse-response function analysis can be processed with respect to a symmetric continuous shock (from the given process) and an asymmetric discrete shock (to the latent MS variable in the model).

We contribute to the existing literature in threefolds. First, we provide a unified framework for the BN decomposition and the state space representation for multivariate (co)integrated MS time series, which include those considered in [12], [15], [16] and [1]. Then we give a state space representation of the process, and derive explicit expressions for the BN trend and cyclical components in terms of the matrices involved in such a representation. Our matrix expressions in closed-form improve computational performance since they are readily programmable and greatly reduce the computational cost. Second, impulse-response function analysis can be developed within our multivariate context by using the proposed matrix calculus. Third, the theoretical results are illustrated via applications.

2 Integrated processes with Markov switching

Let $\mathbf{y}_t$ be a K-dimensional random vector with values in $\mathbb{R}^K$ with $\mathbf{y}_t \sim I(1)$. Suppose that the first difference of $\mathbf{y}_t$ is driven by the following MSI(M) VAR(p) model

$$\Phi(L)\,\Delta\mathbf{y}_t = \nu_{s_t} + \mathbf{u}_t$$

where $\nu_{s_t} \in \mathbb{R}^{K\times 1}$, $\Phi(L) = \mathbf{I}_K - \Phi_1 L - \cdots - \Phi_p L^p$ is a $K \times K$ matrix polynomial in the lag operator L and $\mathbf{u}_t \sim \text{i.i.d.}\, N(0,\Sigma_{\mathbf{u}})$ being $\Sigma_{\mathbf{u}} \in \mathbb{R}^{K\times K}$ positive definite.
Such MS models serve well to depict the business cycle of various industrialized economies as shown, for example, in [14]. We introduce the following assumptions:

Assumption 1. The roots of the equation $\det \Phi(z) = 0$ lie outside the unit circle.

Assumption 2. The process (s_t) is an irreducible, aperiodic and ergodic Markov chain with values in the set $\{1,\dots,M\}$, stationary transition probabilities $p_{ij} = Pr(s_t = j|s_{t-1} = i)$ for $i, j = 1,\dots,M$, and unconditional (or steady state) probabilities $\pi_i = Pr(s_t = i)$ for $i = 1,\dots,M$.

Collect p_{ij} and π_i into a $M \times M$ matrix $\mathbf{P} = (p_{ij})$ and a $M \times 1$ vector $\pi = (\pi_1 \cdots \pi_M)'$, called the *transition probability matrix* and the *stationary vector* of the chain, respectively.

Assumption 3. The shock $(\mathbf{u}_t)$ is independent of the Markov chain (s_t).

The MSI(M) VAR(p) model has the following state space representation

$$\begin{cases} \Phi(L)\,\Delta\mathbf{y}_t^* = \widetilde{\Lambda}\,\delta_t + \mathbf{u}_t \\ \delta_t = \mathbf{F}\,\delta_{t-1} + \mathbf{w}_t \end{cases}$$

where:

$$\begin{aligned} \Delta\mathbf{y}_t^* &= \Delta\mathbf{y}_t - E[\Delta\mathbf{y}_t] \\ E[\Delta\mathbf{y}_t] &= \Phi(1)^{-1}\,\Lambda\,\pi \\ \Lambda &= (\nu_1 \ \cdots \ \nu_M) \in \mathbb{R}^{K\times(M)} \\ \widetilde{\Lambda} &= (\nu_1 - \nu_M \cdots \nu_{M-1} - \nu_M) \in \mathbb{R}^{K\times(M-1)} \end{aligned}$$

and $\mathbf{w}_t$ is the asymmetric discrete shock of the latent state variable $\delta_t \in \mathbb{R}^{M-1}$. Finally, $\mathbf{F}$ is the $(M-1)\times(M-1)$ transition matrix associated with δ_t:

$$\mathbf{F} = \begin{pmatrix} p_{11} - p_{M1} & p_{21} - p_{M1} & \cdots & p_{M-1,1} - p_{M1} \\ p_{12} - p_{M2} & p_{22} - p_{M2} & \cdots & p_{M-1,2} - p_{M2} \\ \vdots & \vdots & \cdots & \vdots \\ p_{1,M-1} - p_{M,M-1} & p_{2,M-1} - p_{M,M-1} & \cdots & p_{M-1,M-1} - p_{M,M-1} \end{pmatrix}.$$

3 Trend and cycle decomposition

As in the case of a linear VAR process, the BN trend component (i.e., the value of the series would take if it were on its long-run path) is given by

$$\mathbf{y}_t^{TR} = \mathbf{y}_t + \sum_{j=1}^{\infty} E(\Delta\mathbf{y}_{t+j}^*|I_t)$$

where I_t is the information set up to time t.

The second summand (whose opposite is the cyclical component $\mathbf{y}_t^c$) can be explicitly calculated from the following state space representation of the basic MSI(M) VAR(p) model (with $n = pK + M - 1$):

$$\widetilde{\mathbf{X}}_t = \widetilde{\boldsymbol{\Phi}}\,\widetilde{\mathbf{X}}_{t-1} + \widetilde{\mathbf{e}}_t$$

where

$$\widetilde{\mathbf{X}}_t = (\Delta\mathbf{y}_t^{*'} \quad \Delta\mathbf{y}_{t-1}^{*'} \cdots \Delta\mathbf{y}_{t-p+1}^{*'} \quad \boldsymbol{\delta}_{t+1}^{'})^{'} \in \mathbb{R}^n$$
$$\widetilde{\mathbf{e}}_t = (\mathbf{u}_t^{'} \quad 0^{'} \cdots 0^{'} \quad \mathbf{w}_{t+1}^{'})^{'} \in \mathbb{R}^n$$

and

$$\widetilde{\boldsymbol{\Phi}} = \begin{pmatrix} \boldsymbol{\Phi}_1 & \boldsymbol{\Phi}_2 & \cdots & \boldsymbol{\Phi}_{p-1} & \boldsymbol{\Phi}_p & \widetilde{\Lambda} \\ \mathbf{I}_K & 0 & \cdots & 0 & 0 & 0 \\ 0 & \mathbf{I}_K & \cdots & 0 & 0 & 0 \\ \vdots & \vdots & & \vdots & \vdots & \vdots \\ 0 & 0 & \cdots & \mathbf{I}_K & 0 & 0 \\ 0 & 0 & \cdots & 0 & 0 & \mathbf{F} \end{pmatrix} \in \mathbb{R}^{n\times n}.$$

Proposition 1. *Under the above Assumptions, the above state space representation of the first difference stationary process* $(\mathbf{y}_t)$*, following the basic MSI*(M) *VAR*(p)*, is stable.*

This follows from the Assumptions and $\rho(\mathbf{F}) < 1$, which imply $\rho(\widetilde{\boldsymbol{\Phi}}) < 1$.

Starting from the latter state space representation of the basic MSI(M) VAR(p) model, we derive an explicit expression for the BN trend $\mathbf{y}_t^{TR}$ (and hence for the cyclical component $\mathbf{y}_t^c$) which involves the matrix $\widetilde{\boldsymbol{\Phi}}$ and the vector $\boldsymbol{\delta}_{t|t}$.

Proposition 2. *Let* $(\mathbf{y}_t)$ *be the first difference stationary process, driven by the basic MSI*(M) *VAR*(p) *model. Under the above Assumptions, the permanent or trend component of the BN decomposition of* $(\mathbf{y}_t)$ *is given by*

$$\mathbf{y}_t^{TR} = \mathbf{y}_t + \mathbf{L}\,\widetilde{\boldsymbol{\Phi}}\,(\mathbf{I}_n - \widetilde{\boldsymbol{\Phi}})^{-1}\,\widetilde{\mathbf{X}}_{t|t}$$

where

$$\mathbf{L} = (\mathbf{I}_k \quad 0 \cdots 0) \in \mathbb{R}^{K\times n}$$
$$\widetilde{\mathbf{X}}_{t|t} = E(\widetilde{\mathbf{X}}_t|I_t) = (\Delta\mathbf{y}_t^{*'} \quad \Delta\mathbf{y}_{t-1}^{*'} \cdots \Delta\mathbf{y}_{t-p+1}^{*'} \quad \boldsymbol{\delta}_{t+1|t}^{'})^{'} \in \mathbb{R}^n$$
$$\boldsymbol{\delta}_{t+1|t} = E(\boldsymbol{\delta}_{t+1}|I_t) = \mathbf{F}\,\boldsymbol{\delta}_{t|t}$$

and $n = pK + M - 1$.

4 Impulse-Response Analysis

In the considered MS model there are two independent (under Assumption 2) shocks: a symmetric continuous shock $\mathbf{u}_t$ and an asymmetric discrete shock $\mathbf{w}_t$. Given the latter state space form, we find the impulse-response with respect to these shocks:

Proposition 3. *Let* $(\mathbf{y}_t)$ *be the first difference stationary process drive by the basic* MSI(M) VAR(p) *model. Under the above Assumptions, the impulse-response function analysis for* $(\mathbf{y}_t)$ *with respect the two independent shocks* $\mathbf{u}_t$ *and* $\mathbf{w}_t$ *is given by*

$$\frac{\partial \mathbf{y}_{t+j}}{\partial \mathbf{u}_t'} = \mathbf{L}\,(\mathbf{I}_n - \widetilde{\boldsymbol{\Phi}}^{j+1})\,(\mathbf{I}_n - \widetilde{\boldsymbol{\Phi}})^{-1}\,\mathbf{L}' \in \mathbb{R}^{K\times K}$$

$$\frac{\partial \mathbf{y}_{t+j}}{\partial \mathbf{w}_t'} = \mathbf{L}\,\widetilde{\boldsymbol{\Phi}}\,(\mathbf{I}_n - \widetilde{\boldsymbol{\Phi}}^{j+1})\,(\mathbf{I}_n - \widetilde{\boldsymbol{\Phi}})^{-1}\,\mathbf{R}' \in \mathbb{R}^{K\times(M-1)}$$

where $\mathbf{L} = (\mathbf{I}_k \quad 0\cdots 0) \in \mathbb{R}^{K\times n}$ *and* $\mathbf{R} = (0\cdots 0 \quad \mathbf{I}_{M-1}) \in \mathbb{R}^{(M-1)\times n}$ *(with* $n = pK + M - 1$*).*

5 A numerical example

We simulate a MS VAR process such that $M = K = 2$ and $p = 1$, that is, a 2–state bivariate AR(1) model:

$$\mathbf{y}_t - \boldsymbol{\Phi}\,\mathbf{y}_{t-1} = \nu_{s_t} + \mathbf{u}_t \qquad\qquad \mathbf{u}_t \sim \text{NID}(0, \boldsymbol{\Omega})$$

where

$$\nu_1 = \begin{pmatrix} -1 \\ 0 \end{pmatrix} \qquad \nu_2 = \begin{pmatrix} 2 \\ 4 \end{pmatrix} \qquad \boldsymbol{\Phi} = \begin{pmatrix} 0 & 0.4 \\ -0.3 & 0.8 \end{pmatrix} \qquad \boldsymbol{\Omega} = \begin{pmatrix} 1.36 & 1.2 \\ 1.2 & 1.36 \end{pmatrix}$$

where $s_t \in \{1,2\}$. The transition probability matrix is $\mathbf{P} = \begin{pmatrix} p_{11} & 1-p_{11} \\ 1-p_{22} & p_{22} \end{pmatrix}$ where $p_{11} = 0.8$ and $p_{22} = 0.1$. The unconditional probabilities are $\pi_1 = 0.8182$ and $\pi_2 = 0.1818$. We generate $T = 100$ observations of $\mathbf{u}_t$ by using Gaussian deviates with zero mean and variance $\boldsymbol{\Omega}$. Then the bivariate process $\mathbf{y}_t$ is obtained from the above model by using true parameters. Trend and cycle components of the two processes included in $\mathbf{y}_t$ are reported in Figure 1: the trend of the first process is more pronunced than the second (first row) and cycles are reported in the second row.

Asymptotic properties of the SETAR parameters: a new approach

Un nuovo approccio per derivare le proprietà asintotiche dei parametri dei modelli SETAR

Marcella Niglio and Guy Mélard

Abstract A new method for obtaining the asymptotic properties of self-exciting threshold autoregressive models estimators is introduced. Like for most non-linear models, the usual method for obtaining the asymptotic properties for such models is based on the stationary and ergodicity of the model. A new method for obtaining these asymptotic properties was recently proposed by the authors for threshold models with exogenous threshold variable independent of the innovations. This method is based on the asymptotic theory for scalar or vector time-dependent ARMA (*td*ARMA) models, where the coefficients are deterministic functions of time and of a small number of parameters. These results cannot be directly extended to the self-exciting threshold models, where the coefficients are random, so we propose a different approach that can be adapted to this particular class of models.

Abstract *In questo contributo si presenta un nuovo approccio per esaminare le proprietà asintotiche del modello autoregressivo a soglia con variabile soglia endogena (SETAR). A differenza dei metodi usualmente impiegati in questo contesto, qui non si farà uso della stazionarietà ed ergodicità del processo. Il metodo è basato sull'uso di alcuni risultati recentemente presentati dagli autori per il modello a soglia con variabile soglia esogena ed è fondato sulla teoria asintotica sviluppata per i modelli ARMA con parametri dipendenti in modo deterministico dal tempo. La struttura del modello SETAR non consente il diretto uso di questi risultati che devono essere adattati al modello soglia in esame.*

1 Introduction

In this paper is proposed a new method to obtain the asymptotic properties of the autoregressive coefficients of the non-linear self-exciting threshold autoregressive (SETAR) model (among others, see [8], [9], [3]).

This model belongs to the wide class of threshold models that are non-linear structures with k regimes for a time series $x_t, t = 1, ..., n$, where the switching among them depends on the value assumed by an exogenous or endogenous (as the self-exciting case) threshold variable. If each regime follows a first-order autoregressive model, we deal with the so-called TAR(2; 1) model whose simplest form is:

$$x_t = \begin{cases} \phi^{(1)} x_{t-1} + \varepsilon_t, \text{ if } y_{t-d} \leq r, \\ \phi^{(2)} x_{t-1} + \varepsilon_t, \text{ if } y_{t-d} > r, \end{cases} \tag{1}$$

where $\phi^{(1)}$ and $\phi^{(2)}$ are the autoregressive coefficients, $\{\varepsilon_t\}$ is a sequence of independent random variables with mean zero and variance σ^2, d is the threshold delay, y_{t-d} is the threshold variable and r is the threshold value. When $y_{t-d} \equiv x_{t-d}$, the endogeneity of the threshold variable gives rise to the SETAR model.

In non-linear time series analysis the usual method for obtaining the asymptotic properties of such models consists in exhibiting a stationary and ergodic solution of the model and using ergodicity to prove the consistency and the asymptotic normality of the estimators. In this domain, [2] shows the consistency and the asymptotic distribution of the least squares estimators of the SETAR autoregressive coefficients and further investigates the consistency and limiting distribution of the estimator for the threshold r. A new approach has been recently proposed by [5, 6] that establish the asymptotic properties of the autoregressive coefficients of a TAR model with an exogenous threshold variable, y_{t-d}, independent of the innovations ε_t. These results are mainly based on the asymptotic theory developed for the ARMA models with time-dependent coefficients, also called tdARMA (see [1, 4]), where the autoregressive coefficients are deterministic functions of time and a few parameters. [5] give evidence that these results can be extended not only to TAR models but even to threshold models with ARMA regimes, shortly called TARMA models in [8], and that these extensions can be considered both in the univariate and multivariate domain (where each regime follows a Vector ARMA structure), provided that the threshold variable remains exogenous.

When the threshold variable is endogenous, $y_{t-d} \equiv x_{t-d}$, the autoregressive coefficients become random variables and then the results of [5] cannot be further used. Nevertheless we can adapt the results of [1] to the SETAR case and even to its SETARMA generalization, both in the scalar and in the vectorial form. There remains that the new approach requires assuming or proving the existence and the non-singularity of the information matrix.

To ease the presentation, we treat here only the SETAR case, leaving the SETARMA and SETVARMA (SETAR model with Vector ARMA regimes) cases for further paper.

2 TAR, SETAR and tdAR models

It will be shown that there is a strict relation among TAR, SETAR and tdAR models and that they can be connected to the same model structure.

Let $x_t \sim \text{TAR}(k;p)$ be a threshold model:

$$x_t = \sum_{i=1}^{k} \left[\sum_{j=1}^{p} \phi_j^{(i)} x_{t-j} \right] \mathbb{I}_{\{y_{t-d} \in \mathbb{R}_i\}} + \varepsilon_t, \tag{2}$$

where the autoregressive parameters $\phi_j^{(i)}$ are the object of our proposal, the innovations ε_t's have been defined before, $\mathbb{R}_i$ defines a partition of the real line $\mathbb{R}$, such that $\bigcup_{i=1}^{k} \mathbb{R}_i = \mathbb{R}$ and $\mathbb{R}_i \cap \mathbb{R}_s = \emptyset$, for $i \neq s$. When $y_{t-d} \equiv x_{t-d}$, we have a SETAR$(k;p)$ model.

The autoregressive model with time-dependent coefficients of order p, tdAR(p), is defined as:

$$x_t = \sum_{j=1}^{p} \phi_{tj} x_{t-j} + \varepsilon_t, \tag{3}$$

where the coefficients ϕ_{tj} are deterministic functions of time and of a vector of parameters β, and the innovations ε_t are like before.

By comparing the models (2) and (3), it can be noted that model (2) can be written in terms of (3) with $\phi_{tj}(\beta) = \sum_{i=1}^{k} \phi_j^{(i)} \mathbb{I}_{\{y_{t-d} \in \mathbb{R}_i\}}$, with β the vector of autoregressive parameters $\beta = (\phi_1^{(1)} \ldots \phi_p^{(1)} \phi_1^{(2)} \ldots \phi_p^{(k)})'$, where $\mathbf{A}'$ is the transpose of $\mathbf{A}$.

Further, let m be the number of the parameters included in β, $e_t(\beta)$ the residuals of the model and β_0 the true value of β, such that $e_t(\beta_0) = \varepsilon_t$, for all t.

Following the results of [5, 6], the SETAR model can be written as a tdVAR(1) model:

$$\mathbf{X}_t(\beta) = \mathbf{A}_t(\beta)\mathbf{X}_{t-1}(\beta) + \mathbf{E}_t(\beta), \tag{4}$$

with

$$\mathbf{A}_t(\beta) = \begin{bmatrix} \Phi_t(\beta) & \underset{p\times 1}{\mathbf{0}} \\ \underset{1\times p}{\mathbf{0}} & 0 \end{bmatrix}, \quad \Phi_t(\beta) = \begin{bmatrix} \phi_{t1}(\beta) & \ldots & \phi_{tp}(\beta) \\ & \underset{(p-1)}{\mathbf{I}} & \underset{(p-1)\times 1}{\mathbf{0}} \end{bmatrix},$$

and

$$\mathbf{X}_t(\beta) = \begin{bmatrix} X_t \\ \cdots \\ X_{t-p+1} \\ e_t(\beta) \end{bmatrix}, \quad \mathbf{E}_t(\beta) = \begin{bmatrix} e_t(\beta) \\ \underset{(p-1)}{\mathbf{0}} \\ e_t(\beta) \end{bmatrix},$$

then the moving average representation becomes (see [4]) :

$$\mathbf{X}_t(\beta) = \sum_{\ell=0}^{t-1} \Psi_{t\ell}(\beta)\mathbf{E}_{t-\ell}(\beta_0), \tag{5}$$

where $\Psi_{t\ell}(\beta) = \sum_{s=0}^{\ell} \left(\prod_{j=0}^{\ell-s-1} \mathbf{J}\mathbf{A}_{t-j}(\beta)\right) \mathbf{K} \left(\prod_{j=0}^{s-1} \mathbf{A}_{t-\ell+s-j}(\beta_0)\right)$, $\mathbf{J}$ and $\mathbf{K}$ are square matrices of dimension $(p+1)$, $\mathbf{J}$ is an identity matrix with $J_{1,1} = 0$ and $J_{(p+1),1} = -1$ and $\mathbf{K}$ is a null matrix with $K_{1,1} = K_{(p+1),1} = 1$.

Noting that $e_t(\beta)$ is the $(p+1)$-th element of $\mathbf{X}_t(\beta)$:

$$e_t(\beta) = \sum_{\ell=1}^{t-1} \psi_{t\ell}(\beta)\varepsilon_{t-\ell}, \tag{6}$$

with $\psi_{t\ell}(\beta) = \mathbf{U}'_{p+1}\Psi_{t\ell}(\beta)\mathbf{U}_1$, where $\mathbf{U}_1$ and $\mathbf{U}_{p+1}$ are two $[(p+1)\times 1]$ vectors of zeroes where the first and the $(p+1)$-th elements are replaced with 1, respectively.

Given $e_t(\beta)$ in (6), its first derivative with respect to β_i becomes:

$$\frac{\partial e_t(\beta)}{\partial \beta_i} = \sum_{\ell=1}^{t-1} \psi_{t\ell i}(\beta)\varepsilon_{t-\ell}, \tag{7}$$

where $\psi_{t\ell i} = \partial \psi_{t\ell}(\beta)/\partial \beta_i$, $i = 1, ..., m$.

Finally note that the theory requires also the second and the third derivatives of $e_t(\beta)$ that can be obtained likewise.

3 Parameters estimation

Assume that the time series x_t, for $t = 1, \ldots, n$, is a realization of the SETAR process (2), so with $y_t \equiv x_t$, and $\beta = \beta_0$. We estimate β using quasi maximum likelihood estimators that are obtained assuming that the innovations ε_t have a Gaussian distribution with $E[\varepsilon_t] = 0$ and $E[\varepsilon_t^2] = \sigma^2$.

Let $\widehat{\beta}_n$ be the estimator for β . We show that, under well-defined conditions, $\widehat{\beta}_n \to \beta_0$ almost surely for $n \to \infty$ and that $\sqrt{n}(\widehat{\beta}_n - \beta_0) \xrightarrow{L} N(\mathbf{0}, V^{-1})$, as $n \to \infty$.

The novelty of these results, if compared to those given in [2] where conditional least squares estimators are obtained for the parameters of the SETAR model, is that x_t is not assumed to be stationary and ergodic. This makes the use of the proposed inferential results more general.

4 Contribution

The results in [5, 6] deal with the estimation of the autoregressive coefficients of a threshold model with an exogenous threshold variable and then the theory given by [1] can be directly applied. On the contrary, in the SETAR case the coefficients $\psi_{t\ell}(\beta)$ of model (6) and consequently the coefficients $\psi_{ti\ell}(\beta)$ in (7) are random variables not independent from ε_t. This makes the SETAR model not only different from the tdAR model but even from the Random Coefficient Autoregressive (RCA)

model where the autoregressive coefficients are random variables also independent from the innovations (see [7]).

It implies that the assumptions considered for the tdAR model need to be changed to cope with the SETAR case. We here discuss only the assumptions that are critical for the SETAR model whereas for the other assumptions we refer to [4] and [6].

First, we need to keep two of these assumptions: the existence of the fourth moment of ε_t and the existence and the invertibility of the Fisher information matrix V, with elements V_{ij} given by $\lim_{n\to\infty} \frac{1}{n\sigma^2} \sum_{t=1}^{n} E_{\beta_0} \left(\frac{\partial \varepsilon_t(\beta)}{\partial \beta_i} \frac{\partial \varepsilon_t(\beta)}{\partial \beta_j} \right)$.

Further, it appears that we need to obtain an upper bound for quadratic forms like

$$E_{\beta_0}\{(\partial e_t(\beta)/\partial \beta_i)(\partial e_t(\beta)/\partial \beta_j)\}$$

(and even quartic forms, that will not be faced here). The main idea was to replace the derivatives making use of (7) and to transform the expression

$$\left| E\left(\sum_{\ell_1=1}^{t-1} \sum_{\ell_2=1}^{t-1} \varepsilon_{t-\ell_1} \psi_{ti\ell_1} \psi_{tj\ell_2} \varepsilon_{t-\ell_2} \right) \right|, \tag{8}$$

with $\psi_{ti\ell} = \psi_{ti\ell}(\beta_0)$, such that it is finite and fulfills the conditions given in [1, Technical Appendix Lemma 4.7].

To do this, we considered the existence of constants N and Φ, $0 < \Phi < 1$ such that $\sum_{k=\nu}^{t-1} \psi_{ti\ell}^2 < N\Phi^{\nu-1}$, for $\nu = 1,...,t-1$ and $i = 1,...,m$.

As said before, the random nature of the coefficients $\psi_{ti\ell}(\beta)$ in the SETAR case does not allow the use of the same arguments, so we need another way to bound (8). Denote $C_{tij\ell_1\ell_2} = \psi_{ti\ell_1}\psi_{tj\ell_2}$ and $D_{t\ell_1\ell_2} = \varepsilon_{t-\ell_2}\varepsilon_{t-\ell_1}$. Then:

$$E\left(\left| \sum_{\ell_1=1}^{t-1} \sum_{\ell_2=1}^{t-1} C_{tij\ell_1\ell_2} D_{t\ell_1\ell_2} \right| \right) \leq \sum_{\ell_1=1}^{t-1} \sum_{\ell_2=1}^{t-1} \{E(|C_{tij\ell_1\ell_2}|^2)\}^{1/2} \{E(|D_{t\ell_1\ell_2}|^2)\}^{1/2},$$

but $\{E(|D_{t\ell_1\ell_2}|^2)\}^{1/2} \leq \sigma^2$ and $|C_{tij\ell_1\ell_2}|^2 = \psi_{ti\ell_1}^2 \psi_{tj\ell_2}^2$.

We further assume that all the roots of all the autoregressive polynomials of the SETAR regimes $(1 - \phi_1^{(i)} z - ... - \phi_p^{(i)} z^p)$, $i = 1,...,k$, are in absolute value greater than 1 (this condition should not be confused with the stationarity of the SETAR model whose conditions are more restrictive).

If Φ exists, with $0 < \Phi < 1$, and if the matrix $\Phi_t(\beta)$ has all its eigenvalues less than Φ, it follows that the Frobenius norm of the coefficients $\Psi_{t\ell}$ included in (5) is almost surely bounded by Φ^{ℓ} up to a constant factor.

We can to verify that a similar bound exists for the coefficients $\psi_{ti\ell}$, $i = 1,...,m$, included in (7), implying the existence of an upper bound for $E(|C_{tij\ell_1\ell_2}|^2)$. Similar arguments can be used for the quadratic forms obtained from the other derivatives of $e_t(\beta)$ and for the other conditions given in [1].

For ARMA regimes, so for a univariate SETARMA model, a more general tdVAR(1) representation than in (4) is required. Also, it may not be obvious from the development given above, but it is possible to handle a vector of $e_t(\beta)$ and a matrix of coefficients $\psi_{ti\ell}$, making it possible to extend our results to vector self-exciting models, without any assumption of stationarity and ergodicity.

Food prices forecast using post-sampled crowdsourced data with Reg-ARMA model: the case of Nigeria

Previsione dei prezzi del cibo usando dati post-sampled crowdsourced con un modello Reg-ARMA: il caso della Nigeria

Ilaria Lucrezia Amerise, Gloria Solano Hermosilla, Vincenzo Nardelli and Giuseppe Arbia

Abstract The current Sars-Cov-2 epidemic has once more highlighted the need of accurate and timely food price information for decision makers, citizen and food supply chain stakeholders, especially in developing countries and in particular in Africa. The conventional methods adopted by official statistical offices do not allow the dissemination of such information in real time. Therefore, we used data collected by the JRC project Food Price Crowdsourcing Africa in Nigeria. In the first stage, we pre-processed data using the Spatial Post Sampling approach, and we then estimated a Reg-ARMA model to provide an accurate forecast of price trends.

Abstract *L'attuale epidemia da Sars-Cov-2 ha evidenziato ancora una volta la necessità di informazioni accurate e tempestive sui prezzi degli alimenti sia per i decisori ed i cittadini sia per le parti interessate della filiera alimentare, in particolare nei paesi in via di sviluppo e segnatamente in Africa. I metodi convenzionali adottati dagli uffici statistici ufficiali non consentono la diffusione di tali informazioni in tempo reale. Abbiamo utilizzato, dunque, i dati raccolti dal progetto Food Price Crowdsourcing Africa del JRC in Nigeria. Nella prima fase, abbiamo pre-elaborato i dati utilizzando l'approccio del Spatial Post Sampling, quindi abbiamo stimato un modello Reg-ARMA per fornire una previsione accurata dell'andamento dei prezzi.*

1 Introduction

Unexpected food price fluctuations can affect the poor and vulnerable in Sub-Saharan Africa, where incomes are low and poverty rates are high. The COVID-19 pandemic has once again underlined the need to predict changes for policymakers planning to adjust food security initiatives, and for food supply chain players [1]. Notably, decisions are made according to price expectations. However, because of delays in the publication of official statistics, the full situation will not be available until some time after the period's end. Nowadays, mobile phone technologies and alternative data collection methods such as crowdsourcing, offer great potential for timely data collection, even in remote areas, to complement official statistics [2] and improve forecasts [3]. As such, it involves a large group of non-professionals volunteers (the crowd) at a lower cost or to a greater extent than traditional, professional data collection methods [4].Two key challenges arise: (i) involving a crowd providing a consistent data flow [5] and (ii) the quality of their inputs, which might be lower than that of professionals [4]. In terms of quality, it is essential that the crowdsourcing tool incorporates automatic quality checks for which the temporal/spatial dimension of the data has proved to be helpful [6]. In this context, the aim of this paper is twofold: firstly, to assess if the use of crowdsourced prices can help producing accurate forecasts, and secondly, to assess if the spatial post-sampled data (SPS prices) may lead to a more accurate prediction than the average of raw data (raw prices). In the remainders of this paper, Section 2 describes the data, Section 3 introduces the time-series forecasting methods, Section 4 includes the empirical application and Section 5 presents the discussion and conclusions.

2 Data

We use data collected from April to December 2021 from Nigeria's European Commission Joint Research Centre FPCA platform. A crowd of 1300 volunteers using a mobile app submitted in Kano, Katsina, Kaduna, and Lagos states daily market prices of several food commodities for a reward given to a maximum of 30 individuals per day. Volunteers owned a smartphone with GPS and the system was built based on Open Data Kit and deployed on a compatible server. Automatic routines (implemented in an R) were in place to process, quality check and validate data, which fed into a daily updated web dashboard [7]. In a first step, based on the auto-recorded time and geo-location, prices were compared to others submitted during the same week within a 12 km radius (cluster). Multiple close price points (in time and space) are expected to be correlated so this allow to filter out spurious data points and confining price values to reasonable ranges. Isolated points (prices that did not find a price in the given neighbourhood) were relocated to a neighbouring cluster, if available, or discarded. In a second step, the data were reweighted to resemble a formal spatial sampling design with the spatial post-sampling procedure [6], attenuating potential effects of sampling bias inherent to the voluntary nature of

crowdsourcing and the non-random distribution of smartphone owners and digital competence. Prices collected in Kano from April 19th to October 3rd act as training period and prices from October 4th to December 5th as validation set. The crowd submitted 10058 garri (derived from cassava) price observations during the period, translating into 6184 valid prices and aggregated in 33 weekly observations.

3 Methods

3.1 Assessing point forecast accuracy

The main problem with assessing the reliability of forecasts is that the magnitude of forecast errors cannot be evaluated until the actual values have been observed. To simulate such a situation, we split the time series into two parts: the "training" period, which ignores a number of the most recent time points and the "validation" period, which comprises only the ignored time points. Eight weeks of observations ($H = 8$) are set-aside to serve as a benchmark for forecasting purposes. There are a number of indices that assess predictive accuracy. For our current purposes, we choose the relative absolute error of forecast (RAEF), which is an index that varies in a fixed interval and makes good use of the observed residuals. Its formal expression is the following:

$$RAEF = 100\left[1 - H^{-1}\sum_{h=1}^{H} A_{n+h} - \widehat{A}_{n+h}A_{n+h} + \widehat{A}_{n+h} + \varepsilon\right] \quad h = 1,2,\cdots,H \quad t = 1,2,\cdots,n \tag{1}$$

where ε is a small positive number (e.g. $\varepsilon = 0.00001$) which constitutes a safeguard against division by zero. Coefficient (1) is independent on the scale of the data and, due to the triangolar inequality, ranges between zero and 100. The maximum is achieved in the case of perfect forecasts: $L_{n+h} = \widehat{L}_{n+h}$ for each h. The lower the $RAEF$ is, the less accurate the model is. The minimum stands for situations of inadequate forecasting such as $\widehat{H}_{n+h} = 0$ or $\widehat{L}_{n+h} = -L_{n+h}$ for all h.

3.2 Simultaneous prediction intervals

When forecasting pricing for marketing, planning, development, and policy-making, it is critical to not only create point predictions for several steps ahead, but also to provide an evaluation of the uncertainty associated with projections. Thus, the challenge is to combine point forecasts with prediction intervals (PIs) which apply simultaneously to all possible future values of the predictors. There is an extensive literature on simultaneous prediction intervals for autoregressive time series (see, for example, [8] and reference therein).

A reasonable strategy can be as follows. Given the availability of H future values, we can construct two bands such that, under the condition of independent Gaussian distributed random residuals, the probability that consecutive future prices $A_{n+h}, h = 1,2,\cdots,H$ lie simultaneously within their respective range is at least is γ

$$P\left[\bigcap_{h=1}^{H}\left(A_{1,h,\gamma} \leq A_{n+h} \leq A_{2,h,\gamma}\right)\right] \geq \gamma \tag{2}$$

where

$$\left\{A_{1,h,\gamma} = \widehat{A}_{n,h} - \theta_{H,\nu,\gamma}\widehat{\sigma}_h A_{2,h,\gamma} = \widehat{A}_{n+h} + \theta_{H,\nu,\gamma}\widehat{\sigma}_h.\right.$$

(3)

The multiplier $\theta_{H,\nu,\gamma}$ is the γ-th quantile of the of the maximum absolute value t of the H-variate Student t probability density function with ν degrees of freedom. See [9]. In short, $\theta_{H,\nu,\gamma}$ is the solution of

$$\int_{-\theta}^{\theta}\int_{-\theta}^{\theta}\cdots\int_{-\theta}^{\theta} f(t_1,t_2,\cdots,t_h;\nu)\,dt_1 dt_2\cdots dt_H = \gamma \tag{4}$$

The critical values can be found solving iteratively $u_{H,\nu,\gamma}$ using the command *pmvt* of the *R* package *mvtnorm*, which provides the multivariate t probability. See [10].

The most important characteristic of PIs is their actual coverage probability (PIAC). We measure PIAC by the proportion of true prices of the validation period enclosed in the bounds

$$PIAC_\gamma = 100H^{-1}\sum_{h=1}^{H} c_{h,\gamma} \quad \text{where } c_{h,\gamma} = \left\{1 \quad \text{if } A_{n+h} \in \left[A_{1,h,\gamma}, \quad A_{2,h,\gamma}\right] 0 \quad \text{otherwise}\right. \tag{5}$$

If $PIAC_\gamma \geq \gamma$ then prices tend to be covered by the constructed bounds, but this may also imply that the estimates of the variances in the forecast errors are positively biased. A $PIAC_\gamma < \gamma$ indicates under-dispersed forecast errors with overly narrow prediction intervals and unsatisfactory coverage behavior.

Ceteris paribus, narrow PIs are desirable as they reduce the uncertainty associated with forecasts. However, high accuracy can be easily obtained by widening PIs. A complementary measure that quantifies the sharpness of PIs might be useful in this context. Here, we use the score function.

$$R_{h,\gamma} = (\gamma 2)\left(C^2_{h,\gamma} - C^1_{h,\gamma}\right)A_{n+h}, \quad h = 1,2,\cdots,H. \tag{6}$$

This expression reflects a penalty proportional to the narrowness of the intervals that encompass the true values at the nominal rate. The penalty increases as γ decreases, to compensate for the tendency of prediction bands to be broader as the confidence level increases. Of course, the lower $R_{h,\gamma}$ is, the more accurate PI will

be. The average value of the score width across time points

$$ASW_{\gamma} = 1H \sum_{h=1}^{H} R_{h,\gamma} \tag{7}$$

can provide general indications of PIs performance.

4 Empirical analysis

Table 1 shows the results obtained with the Reg-ARMA method applied to the data of the training period for the prices in the validation period.

The Reg-ARMA approach offers several improvements. The temporal autocorrelation is almost inexistent because the p-value of the LB statistics is now larger that 99%. Also, the quality of the fitting is increased as proven by a lower AICc and a higher $\bar{R}^2$.

Table 1 Reg-ARMA estimation and forecasting.

		β_0	t	$\gamma_{1,1}$	$\gamma_{2,1}$	$\gamma_{1,2}$	$\gamma_{2,3}$	$\gamma_{1,5}$	RAEF	PIAC	ASW
Raw prices											
	Reg-A	419.9	374.6	-135.3	-175.4	278.8	219.8	157.0			
	$\bar{R}^2$:	0.879	AICc:	207.1	LB:	7.7			72.1%	65.5%	11.6
SPS prices											
	Reg-A	415.2	390	-169.9		284.7	-287.1				
	$\bar{R}^2$:	0.981	AICc:	195.4	LB:	6.7			89.7%	99.0%	3.1

In both cases the improvement is quite substantial. In addition, as can be readily seen from Figure 1, the coverage rate is now significantly higher compared to raw prices. The cost of these enhancements is a larger width of the simultaneous forecast intervals, which, as it is well known, determine broader brackets. Furthermore, the stability of the RAEF index across the estimation methods of the two time series, is a demonstration that the predictive accuracy does not deteriorate when Reg-ARMA method is used. Nonetheless, we must remark that, the Reg-ARMA method, yields prediction intervals whose actual coverage rate resulted to be less than the nominal level (95%). We explain this result as due to a change in the evolutionary trajectory of prices, which in the last year, has not been following the trends of previous years. This is an obvious consequence of the need of bracketing future values within the same scheme used for past observations. Thus a constraint is imposed on the forecasting tool: strong local fluctuations or outliers cannot appear in the set of future values even if we know that they are there; thus, some failures are inevitable.

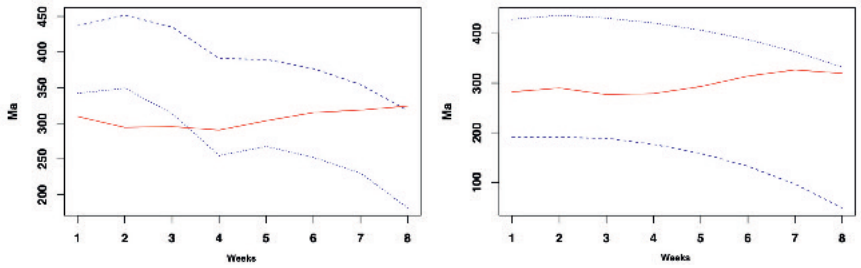

Fig. 1 Prediction intervals (PIs) of garri raw prices (left) and SPS prices (right) in Kano state (Nigeria)

5 Conclusion

Our work is an example of using crowdsourcing and quality control methods for accurate food price predictions to help governments and other actors in decision-making processes. The results show that the raw data are not sufficient to correctly forecast price trends. A two-stage procedure (spatial pre-processing and temporal modelling) solves most of these problems, ensuring greater reliability both in the data collected and in the predictions. Further research could exploit the combination of high-frequency crowdsourced prices with official prices released at lower frequencies also focusing on spatio-temporal modelling.

Universal change point testing for dependent data

Test d'ipotesi universale per punti di cambio in dati dipendenti

Federica Spoto, Alessia Caponera and Pierpaolo Brutti

Abstract One of the main interests in time series analysis is the detection of the so called change-points, defined as timestamps where the model parameters experience a substantial shift in value. Once a candidate change-point is identified, we may want to test whether there is a significant difference in distribution before and after the structural break. In this work we approach the problem from a split-sample perspective and we implement and test on both simulated and real data a two-sample test for time dependent streams that we call *universal change-point testing.*

Abstract *Uno dei problemi principali nell'analisi di serie storiche è l'individuazione dei cosiddetti punti di cambio (change-points), definiti come quegli istanti temporali in cui i parametri del modello vanno incontro ad una sostanziale variazione. Più specificatamente, una volta individuato un valore candidato per il punto di cambio, ci possiamo chiedere se c'è sufficiente evidenza sperimentale a favore dell'esistenza di una differenza significativa nella distribuzione dei dati prima e dopo tale valore. In questo lavoro affrontiamo il problema con delle opportune tecniche di suddivisione del campione, implementando e testando su dati, sia simulati che reali, un test a due campioni per serie dipendenti che chiameremo "test universale per il punto di cambio".*

1 Introduction

In temporal processes analysis, one of the main interests is the detection and the analysis of the so called change-points, defined as timestamps where the model parameters have a change in value.

Once a change-point is given as an endogenous information, one may want to test whether there is a significant difference in distribution before and after the structural break. To do so, in this work we approach the problem from the split-sample perspective discussed in [5] (mostly for i.i.d samples) and we implement a two-sample test for time dependent streams of data. We refer to such procedure as *universal change-point testing* and the key steps are formally described in Section 2 for the case of an autoregressive change-point model.

This basic procedure can also be seen as the stepping stone for building a more structured *sequential change-point detection*, which finds important applications for instance in industrial quality control, environment surveillance, computer network security (see among others [4]).

2 Materials and Methods

In this section, we introduce the autoregressive change-point model and the main steps to build the universal change-point testing procedure in this context. For the sake of simplicity, our arguments are presented for a AR(1) model, allowing a single change-point; however, the analysis can be generalized to higher autoregressive orders and multiple change-points. In this setting, the model is written as the composition of two stationary AR segments and takes the form

$$X_t = \begin{cases} \phi_1 X_{t-1} + \varepsilon_{1t} & t \leq \tau \\ \phi_2 X_{t-1} + \varepsilon_{2t} & t > \tau \end{cases}, \tag{1}$$

that, given τ, are assumed to be independent. We consider centered X_t's, but clearly one can allows for changes also in the mean, thus including two different intercepts in the model. We also assume that the errors ε_{jt} are Gaussian with mean zero variance σ_j^2, $j = 1,2$.

We assume to be able to observe a finite stretch $\{X_1,\dots,X_N\}$ and to know that a change-point occurred at $1 < \tau < N$. Our goal is to test whether there is a significative difference among the set of parameters before and after the structural break. Hence, formally, define $\theta_1 = (\phi_1, \sigma_1^2), \theta_2 = (\phi_2, \sigma_2^2) \in (-1,1) \times (0,\infty)$ and consider the following set of hypotheses:

$$\begin{cases} H_0 : \theta_1 = \theta_2 \\ H_1 : \theta_1 \neq \theta_2 \end{cases}.$$

Then, split $X_1,\dots,X_\tau$ into two segments A_0, A_1, and $X_{\tau+1},\dots,X_N$ into other two segments B_0, B_1, that is,

$$A_1 = (X_1,\dots,X_\gamma), \qquad A_0 = (X_{\gamma+1},\dots,X_\tau),$$
$$B_1 = (X_{\tau+1},\dots,X_{\tau+\gamma}), \qquad B_0 = (X_{\tau+\gamma+1},\dots,X_N),$$

for some integer $1 < \gamma < \tau$. We can hence define $D_0(\tau) = A_0 \cup B_0$, $D_1(\tau) = A_1 \cup B_1$ and the *conditional likelihood*

$$L_{0|1}(\theta_1,\theta_2) = p_{\theta_1,\theta_2}(D_0|D1) = p_{\theta_1,\theta_2}(B_0|B_1)p_{\theta_1,\theta_2}(A_0|A_1).$$

In particular for the autoregressive model (1), we have

$$p_{\theta_1}(A_0|A_1) = p_{\theta_1}(X_{\gamma+1},\dots,X_\tau|X_1,\dots,X_\gamma) = \prod_{t=\gamma+1}^{\tau} p_{\theta_1}(X_t|X_{t-1})$$
$$= \prod_{t=\gamma+1}^{\tau} \frac{1}{\sqrt{2\pi\sigma_1^2}} \exp\left\{-\frac{1}{2}\frac{(X_t-\phi_1 X_{t-1})^2}{\sigma_1^2}\right\},$$

and similarly,

$$p_{\theta_2}(B_0|B_1) = p_{\theta_2}(X_{\tau+\gamma+1},\dots,X_N|X_{\tau+1},\dots,X_{\tau+\gamma}) = \prod_{t=\tau+\gamma+1}^{N} p_{\theta_2}(X_t|X_{t-1}),$$
$$= \prod_{t=\tau+\gamma+1}^{N} \frac{1}{\sqrt{2\pi\sigma_2^2}} \exp\left\{-\frac{1}{2}\frac{(X_t-\phi_2 X_{t-1})^2}{\sigma_2^2}\right\}.$$

Under H_0, $\theta_1 = \theta_2 = \theta$ and we can compute the MLE of θ based on D_0 as

$$\widehat{\theta} = \arg\max_{\theta} L_{0|1}(\theta,\theta).$$

Let then $\widehat{\theta}_1, \widehat{\theta}_2$ be any estimators based on D_1 (under the alternative hypothesis).

$$\text{Reject } H_0 \text{ if:} \quad \frac{L_{0|1}(\widehat{\theta}_1,\widehat{\theta}_2)}{L_{0|1}(\widehat{\theta},\widehat{\theta})} > \frac{1}{\alpha}.$$

This is essentially a modified version of the usual likelihood ratio statistic with an *out-of-sample* estimator in the numerator and a "universal" threshold, in the sense that it does not rely on approximations based on limiting distributions, but ensures finite sample guarantees (without additional regularity conditions). Indeed, it is possible to show that the Type-I error can be (conservatively) controlled at level α.

We stress that this method is general and can be applied to different contexts, as long as the conditional likelihood can be computed. The idea is then to extend the result to more general dependency structures, and also to implement a multiple

testing procedure that jointly test different values of τ, to then obtain a complete detection procedure.

The present framework could be also generalized to the so-called *spherical functional autoregressive model*, defined for collections of time dependent random fields on a spherical domain (see for instance [1]). In this setting, an alternative change-point analysis is discussed in [3]. All these topics are the object of current ongoing research.

3 Results

We tested the performance of our proposal on synthetic time series and then on a real data-set collecting the *wave heights* in the East Scotian Slope, Canada.

The simulation study has been carried out on two different scenarios to explore *size* and *power* of the universal LRT. In the first scenario we work under the null with $\theta_1 = \theta_2 = (\phi = 0.4, \sigma^2 = 0.3)$, and the observations are generated from the following AR(1) model:

$$X_t = 0.4 \cdot X_{t-1} + \varepsilon_t \qquad 1 \leq t \leq N,$$

where ε_t are Gaussian with zero mean and variance $\sigma^2 = 0.3$. We evaluated the Type I error probability based on $M = 10{,}000$ runs with increasing sample size N and $\alpha = 5\%$. In this scenario $\tau = \frac{N}{2}$ and $\gamma = \frac{\tau}{2}$. The results are shown in Table 1.

N	Test Size
100	0.0009
500	0.0004
1000	0.0001

Table 1: Type I error probability at different sample sizes.

The second scenario follows the alternative hypothesis $\theta_1 \neq \theta_2$. We considered three different settings, increasing the distance between the parameters vectors $\theta_1 = (\phi_1, \sigma_1^2)$ and $\theta_2 = (\phi_2, \sigma_2^2)$. More specifically, we kept the model parameters of the first segment fixed at $\theta_1 = (\phi_1 = 0.4, \sigma_2^2 = 0.2)$ while varying the parameters of the second segment from $\theta_2 = (\phi_2 = 0.6, \sigma_2^2 = 0.3)$ in *Setting 1*, to $\theta_2 = (\phi_2 = 0.8, \sigma_2^2 = 0.4)$ in *Setting 2*, and finally $\theta_2 = (\phi_2 = -0.8, \sigma_1^2 = 0.5)$ in *Setting 3*. For each setting we generated $N \in \{100, 500, 1000\}$ observations with $\tau = \frac{N}{2}$, and $\gamma = \frac{\tau}{2}$. Each setting has been simulated $M = 10{,}000$ times and we evaluated the power of the test with $\alpha = 5\%$. Table 2 contains the results.

As anticipated, we also applied our universal change-point test on the publicly available time series of wave heights collected by Fisheries and Oceans

	N	Power
Setting 1	100	0.010
	500	0.297
	1000	0.696
Setting 2	100	0.117
	500	0.907
	1000	0.996
Setting 3	100	0.781
	500	0.999
	1000	1.000

Table 2: Power of the test for different settings.

Canada (more specifically by the East Scotian Slope buoy), and contained in the `changepoint R` package (see the Github repository). The observations were taken at hourly intervals from January 2005 until September 2012. Here we focus only on the period January - September 2005. The detection of change-points in this time series is helpful to get a better understanding of the variability of the ocean in a certain period of the year, a crucial information for planning operations on offshore infrastructures whose risk of failure strongly increase in the presence of larger wave heights. Quite understandingly, we expect a transition point when moving fro winter to summer, but its exact timing is unknown.

This dataset has been previously used by [2] to test the performance of their algorithm. The analysis there focused on the first order difference of the original data and, between January and September 2005, they detected a change-point at the beginning of April 2005 (dashed blue line in Fig. 1), a result that is consistent with the seasonal behaviour of wave heights. As a confirmatory step, we applied our technique to test the presence of a significant change in the data by setting $\tau = \{\text{April } 1^{\text{st}}\}$. On the log-scale, the rejection rule is then:

$$\text{Reject } H_0 \text{ if:} \quad \log\left(L_{0|1}(\widehat{\theta}_1, \widehat{\theta}_2)\right) - \log\left(L_{0|1}(\widehat{\theta}, \widehat{\theta})\right) > -\log(\alpha).$$

The test confirmed the detection in early April, rejecting the null hypothesis and estimating the model parameters as $\widehat{\theta}_1 = (\widehat{\phi}_1 = 0.012, \widehat{\sigma}_1^2 = 0.048)$, and $\widehat{\theta}_2 = (\widehat{\phi}_2 = 0.029, \widehat{\sigma}_2^2 = 0.019)$

Change point detection in fruit bioimpedance using a three-way panel model

Rilevamento del punto di cambiamento nella bioimpedenza della frutta utilizzando un modello panel a tre vie

F. Marta L. Di Lascio and Selene Perazzini

Abstract We propose a three-way dynamic threshold panel model defined without time-varying covariates. The model is thought to detect changes in fruit ripeness observed at several frequencies of electrical impedance spectroscopy. The transition variable is the lagged dependent variable, which is fruit bioimpedance, and the threshold parameter varies by the level of the third way, which is the electrical frequency of the spectroscope. Consistently with the applied aim, we assume cross-independence in the third way. We apply the model to an innovative dataset containing bioimpedance measurements on on-plant strawberries. Our findings suggest that there is a physio-chemical change in the observed strawberries during days 6-7 of the maturation process irrespective of the electrical frequency.

Abstract *Proponiamo un modello panel a soglia dinamica a tre vie definito senza covariate variabili nel tempo. Il modello è pensato per rilevare i cambiamenti di maturità della frutta osservati a diverse frequenze della spettroscopia di impedenza elettrica. La variabile di transizione è la variabile dipendente ritardata, che è la bioimpedenza della frutta, e il parametro di soglia varia con il valore della terza via, che è la frequenza elettrica dello spettroscopio. Coerentemente con l'obiettivo applicato, assumiamo l'indipendenza trasversale nella terza via. Applichiamo il modello a un set di dati innovativo contenente misure di bioimpedenza relativa a fragole su pianta. I nostri risultati suggeriscono che c'è un cambiamento fisico-chimico nelle fragole osservate durante i giorni 6-7 del processo di maturazione, indipendentemente dalla frequenza elettrica.*

1 Introduction

The reliable assessment of fruit quality is extremely important in order to meet production and consumer demands, and at the same time drastically reduce food waste. Bioimpedance analysis for fruit quality control is currently severely limited by the lack of an accurate method for modeling fruit ripeness. For these reasons, innovative and reliable statistical methods able to assess fruit physio-chemical changes from the bioimpedance response are needed.

Change point detection methods [1] for panel data are suitable for this kind of issues as the bioimpedance of the fruits is detected over time using a bench-top impedance analyser set at different frequencies. Hence, [2] proposed a three-way dynamic threshold panel model as change detection method by extending the work by [5] to the three-way framework and defining a criterion to detect the change point. Here we consider a particular version of the model proposed by [2] and we show its performance in assessing fruit ripeness.

In summary, in Sect. 2 we describe the fruit bioimpedance data to which we applied the three-way dynamic threshold panel model described in Sect. 3. Empirical findings are shown in Sect. 4, while conclusions are presented in Sect. 5.

2 Fruit bioimpedance data

Bioimpedance typically refers to the measurement of the electrical impedance of a biological tissue that is a physical quantity describing the ability of an object to oppose, or impede, a flow of electrical current caused by an external voltage [4]. Biological tissues are composed of complex liquids containing structures separated by diverse membranes, through which the electric current can travel depending on the frequency of the applied signal. Therefore, bioimpedance measurements are dependent on the electrical frequency. For this reason, in order to assess the quality of a fruit, multiple frequencies should be considered.

The innovative dataset used for the proposed analysis has been collected during the development of an interdisciplinary research project between the Faculty of Economics and Management and the Faculty of Science and Technology of the Free University of Bozen-Bolzano by the Sensing Technologies Laboratory. The original dataset contains bioimpedance measurements on 99 on-plant strawberries observed twice a day at frequencies ranging from 20 to 13668764.956 Hz. Data have been collected from the fruiting of the plants until fruit deterioration. Since strawberries ripened at different times, the dataset constitutes an unbalanced panel where the three ways are given by the strawberry $i = 1,\dots,n$, the electrical frequency $j = 1,\dots,J$, the time of observation $t = 1,\dots,T$.

Data have been pre-processed in order to increase the data quality. First of all, a huge variability in the bioimpedance of the strawberries has been observed during the first 4 times of observation. This may trace back to data collection: bioimpedance is measured by means of electrodes placed on the surface of the fruit, and the small-

est volumes might have affected the measurements. Therefore, for all fruits, the first 4 time observations, i.e. the first two days of observation, have been discarded. Then, we selected the subset of strawberries with similar time to deterioration. We thus restricted the analysis to 61 strawberries, for which at least 16 and at most 30 times of observation were available. Finally, no missing data or outliers were detected.

Preliminary analyses showed very similar bioimpedance patterns at close frequencies. Therefore, sufficiently different frequencies should be considered. Furthermore, bioimpedance time series at low frequencies appear highly random, and tend to flatten at higher frequencies. Neither one of the two extreme cases is suitable to change point detection. As far as the observed strawberries concern, we identified the following 9 electrical frequencies that well capture regime switches in the fruit maturation process: 8690.783, 23635.120, 74152.869, 201663.287, 548435.709, 1043389.435, 1720663.222, 2290015.458, 3047761.311 Hz, and restricted the analysis to them. The final dataset we analyse is therefore a balanced panel with $i = 1,\dots,61$, $t = 5,\dots,16$, and $j = 1,\dots,9$.

3 Three-way dynamic panel threshold model

Di Lascio and Perazzini [2] developed a three-way dynamic panel threshold model with the aim of detecting change points. Here we present their proposal in a simplified version that do not use any time-varying covariate. Hence, we work with the following three-way dynamic panel threshold model

$$y_{ijt} = \phi_{1j}\mathbb{1}\left\{y_{ij(t-1)} \leq \gamma_j\right\} + \phi_{2j}\mathbb{1}\left\{y_{ij(t-1)} > \gamma_j\right\} + \varepsilon_{ijt} \tag{1}$$

where y_{ijt} is the value of variable Y observed on the i-th statistical unit at time t for the level j of the considered factor, and ϕ_{1j} and ϕ_{2j} are the two slope parameters associated, respectively, to the lower and upper regimes of the j-th category. Moreover, $\mathbb{1}$ is the indicator function that captures the change in regime and is defined by the threshold parameter γ_j, which depends on the j-th category, the lagged dependent variable $y_{ij(t-1)}$ is the transition variable, and ε_{ijt} is the error term. The latter is defined as the sum of three components

$$\varepsilon_{ijt} = \mu_i + \lambda_t + \nu_{ijt} \tag{2}$$

where μ_i is the unobserved individual fixed effect, λ_t is the unobserved time fixed effect, and ν_{ijt} is a zero mean random error.

We assume that the J levels of the third way are independent to each others and they represent the categories of a variable. This is due to the nature of data analysed in Sect. 4 where observations on the same statistical unit by varying the third level, i.e. the frequencies of electrical impedance spectroscopy, do not have any effect each other, i.e. are independent.

The model in Eq. (1) is estimated through the generalized method of moments [3] based on the first-difference transformation and on the use of instrumental variables

(IV-GMM). This estimation method has been developed by [2] extending the one in [5] to the three-way model case. The extensive Monte Carlo study in [2] proved the ability of the three-way dynamic threshold panel model to both detect the time and the extent of the regime switch and provide reliable estimates. These results support the application presented here.

4 Findings on fruit bioimpedance

We apply the three-way dynamic panel threshold model in Eq. (1) to the strawberries bioimpedance data presented in Sect. 2. Observations at $t = 5, \dots, 7$ have been selected as instrumental variables and have therefore been excluded from the estimation of the thresholds. The IV-GMM estimates of the threshold parameters and of the difference between the slope parameters are shown in Tab. 1. Coherently with the spectroscopy, the estimated values of both the parameters of interest decrease as j increases. Fig. 1 shows the observed time series for each considered frequency j

Table 1: Estimation results: j indicates the used electrical frequency, $\hat{\gamma}_j$ is the IV-GMM estimate of the threshold parameter, $\hat{\delta}_j = \hat{\phi}_{2j} - \hat{\phi}_{1j}$ is the IV-GMM estimate of the difference between slope parameters associated with the two different regimes.

j	$\hat{\gamma}_j$	$\hat{\delta}_j$

23635.12	3871.95	719.61
74152.87	2091.80	344.89
201663.29	1493.37	587.34
548435.71	1086.95	569.00
1043389.44	918.67	460.52
1720663.22	910.33	433.78
2290015.46	876.74	418.97
3047761.31	798.19	359.79

together with the corresponding threshold value estimated. As one can notice, the strawberries time series are highly heterogenous in terms of bioimpedance irrespective of the frequency j, but they show more clearly a negative trend in ripeness if lower frequencies are used. Nevertheless, the method appears to be able to identify successfully the thresholds as shown by the change point detection presented in Fig. 2.

In order to detect a change point common to all the observed series, they have been averaged over i once fixed the value of j. Hence, the change point has been computed as the minimum value of t such that $\frac{\sum_{i=1}^{n} Y_{ijt}}{n} > \hat{\gamma}_j$, for $j = 1, \dots, 9$. The three-dimensional plot in Fig. 2 shows that, on average, the regime switch occurs at time $t = 12, 13, 14$ by varying j. Therefore, these results suggest that there is a

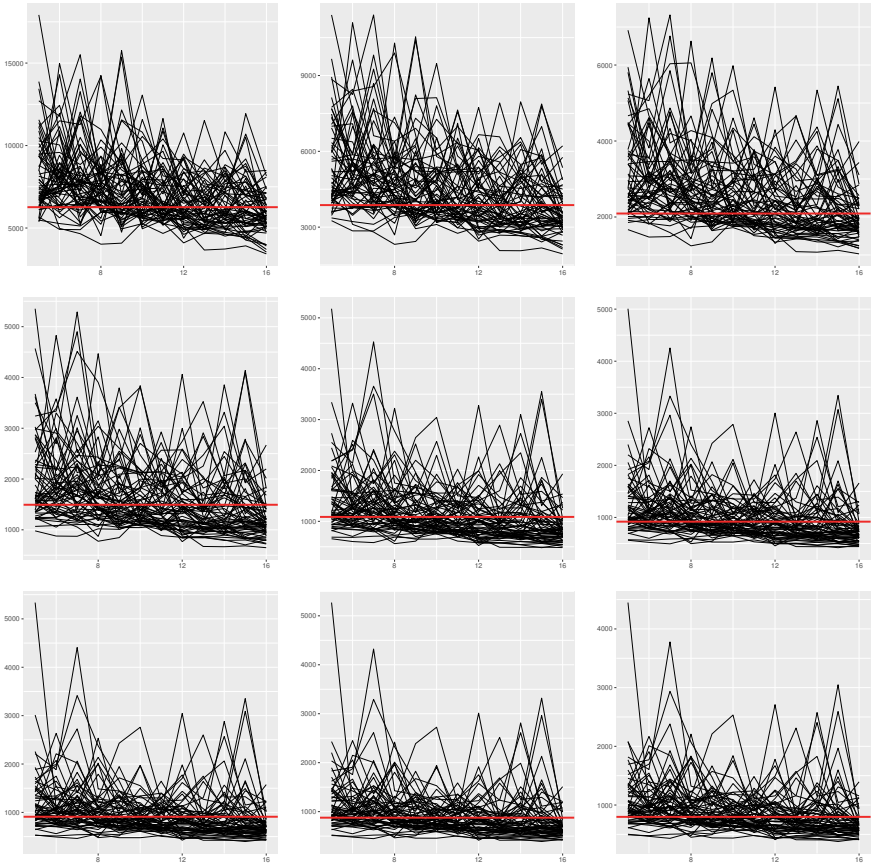

Fig. 1: Strawberries bioimpedance (y-axis) observed over time $t = 5,\ldots,16$ (x-axis) and estimated thresholds $\hat{\gamma}_j$ (red lines). Each plot refers to a different electrical frequency: from left, $j = 8690.783, 23635.120, 74152.869$ (top panel); $j = 201663.287, 548435.709, 1043389.435$ (middle panel); $j = 1720663.222, 2290015.458, 3047761.311$ (bottom panel). Note that the y-axis range varies among the plots to better show the time series behaviour.

physio-chemical change in the observed strawberries during days 6-7 of the on-plant maturation process irrespective of the electrical impedance spectroscopy frequency.

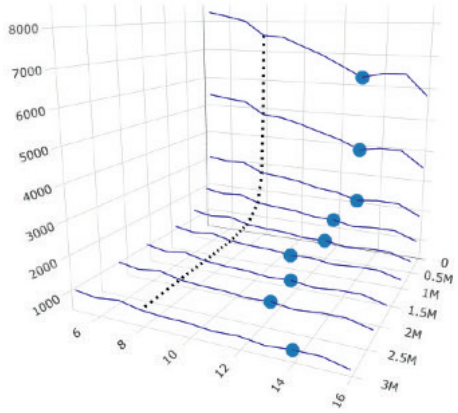

Fig. 2: Average strawberries bioimpedance (y-axis) per frequency j (z-axis) (blue lines) observed over time $t = 5, \ldots, 16$ (x-axis) and detected change points (blue dots). The black dotted line separates the observations used as instrumental variables from those used in the threshold estimation.

5 Conclusion

In this paper we presented an application of the three-way dynamic panel threshold model proposed by [2] in the special case where the dependent variable is self-excited and there are no other regressors. We showed the ability of the model to detect changes in fruit ripeness that is useful to fruit industry for quality control.

Bayesian modelling and inference 3

A dynamic power prior approach to non-inferiority trials for normal means with unknown variance

Power prior dinamiche in prove cliniche di non-inferiorità per medie normali con varianza incognita

Francesco Mariani, Fulvio De Santis, Stefania Gubbiotti

Abstract Non-inferiority (NI) trials compare new experimental therapies to standard ones (active control). Since historical information on the control treatment is often available, a Bayesian approach to NI trials allows to exploit results from past studies and, eventually, to improve accuracy of inference. Here, we propose the use of a dynamic power prior: the active control treatment's endpoint is modelled by a power prior distribution, whose informativeness is tuned by a measure of similarity between past and current information. The methodology is evaluated and compared to the frequentist method by simulation; an application to real drug data is available as well.

Abstract *I test clinici di non-inferiorità (NI) confrontano una terapia sperimentale e una standard (controllo attivo). Un approccio di tipo bayesiano ai test NI permette di sfruttare negli studi correnti i risultati degli studi passati e, eventualmente, di migliorare l'accuratezza dell'inferenza. Qui viene proposta una metodologia bayesiana in cui il parametro relativo all'effetto del controllo attivo è modellato con una power priori informativa, la cui informatività è modulata secondo una misura di similarità tra informazione storica e corrente. Mediante studi di simulazione, la metodologia è valutata con criteri frequentisti; viene infine presentata un'applicazione a dati reali.*

1 Introduction

Non-inferiority (NI) clinical trials aim to establish if a new experimental therapy is not worse than a standard treatment (active control), which is known to be effective. Since much controversy exists regarding the ethic of placebo-controlled trials [11, 13], NI tests are quite popular because they do not require a placebo arm. As past information on the control arm is often available, the Bayesian paradigm offers an ideal framework for the inclusion of historical information in a current experiment [3, 4, 6, 10, 12]. On the one hand, by borrowing historical data more trial resources can be devoted to the novel treatment while retaining accurate estimates of the current control arm parameters [12]; on the other hand, the potential lack of full homogeneity between current and previous data may recommend their down-weighting. At the same time, regulatory agencies [1, 2] recommend that novel statistical methodologies for analysing trial results parallel to the frequentist strategy [6, 7].

Formally, let us consider a NI trial in which an experimental therapy E is compared to an active control C. The latter is known to be effective since in past studies the control (C_0) has been tested with a placebo P_0. We are interested in studying drug average effects by assuming that the treatment responses in historical and current trials are distributed as mutually independent normal random variables, i.e. $X_i \sim N(\mu_i, \sigma_i^2)$ where μ_i is the unknown parameter of interest, σ_i^2 is the variance, for $i \in \{C_0, P_0, C, E\}$. NI of the experimental therapy with respect to the active control is declared by rejecting the null hypothesis of the test $H_0 : \mu_E - \mu_C \leq -\delta$ vs $H_1 : \mu_E - \mu_C > -\delta$ where $\delta > 0$ is the so-called NI margin. Its choice is not trivial, since it may depend on past performances of the active control and it may be modified according to medical judgment. The test is implemented as follows. First, we determine the p^* credible intervals for $\mu_E - \mu_C$ and for $\mu_{C_0} - \mu_{P_0}$, whose lower bounds are denoted by L_{E-C} and $L_{C_0-P_0}$, respectively. Then, we set $\delta = (1-\lambda) \times L_{C_0-P_0}$, where $\lambda \in [0,1]$ allows to involve potential clinical judgement in the NI margin determination. If $L_{E-C} > -\delta$, we reject H_0 declaring NI of the experimental treatment. We assume that no prior information on $\mu_{P_0}, \mu_{C_0}, \mu_E$ is available. As a result, the initial distributions for μ_{P_0}, μ_{C_0} and μ_E are non-informative. From standard conjugate results, the posterior distributions are also normal conditional on σ_i^2's.

Past data regarding the active control C_0 can be exploited as prior knowledge over μ_C. As a consequence, the prior distribution of μ_C is informative and, following [9], it is modelled by the *power prior*

$$\pi^{PP}(\mu_C|C_0) \propto L(\mu_C; C_0)^{a_0} \times \pi_0(\mu_C), \tag{1}$$

where $\pi_0(\mu_C)$ is a non-informative starting prior, $L(\mu_C; C_0)$ is the likelihood function of μ_C with the observed historical data C_0, $a_0 \in [0,1]$ tunes the amount of borrowed historical information. For $\pi_0(\mu_C) \propto 1$, the power posterior distribution of μ_C is based on Equation (1). Following the dynamic power prior approach of [4], we define

$$a_0(C,C_0) = \kappa(1 - d_H[\pi_c(\mu_C|C), \pi_0(\mu_C|C_0)]),$$

where d_H denotes the Hellinger distance between the posterior distributions of μ_C obtained by updating $\pi(\mu_C)$ with C and C_0, $\kappa \in [0,1]$ is a static coefficient which provides an upper limit to the quantity of information that we borrow. Since d_H is a relative measure, a_0 ranges in $[0,1]$: $a_0 = 0$ corresponds to ignoring historical information, $a_0 = 1$ implies the full incorporation of the past information in the current experiment, whereas intermediate values of a_0 represent partial borrowing. In this paper we generalize this approach by assuming unknown variances: we assume independent Jeffrey's non-informative priors for $\sigma^2_{P_0}$, $\sigma^2_{C_0}$, σ^2_C and σ^2_E; then posterior distributions are independent inverse gamma. The topic of this paper is related to the literature on the following fields: *(i)* Bayesian approaches to NI clinical trials for normal means [6]; *(ii)* power priors and their use in Bayesian design [3, 8, 9]; *(iii)* use of the Hellinger distance in Bayesian analysis of clinical trials [4, 10]. The main contribution of the present article is to apply the dynamic power prior approach to the context previously introduced by [6].

2 Simulation studies

As requested by regulatory agencies [1, 2], frequentist properties of the proposed methodology are analysed via simulation. Moreover, results are compared to the ones obtained through the frequentist fixed-margin approach [6]. Indeed, in the NI margin, $L_{C_0-P_0}$ is computed following the frequentist method even under the Bayesian paradigm; we let λ vary, thus taking into account potential clinical judgements in the determination of δ. Simulations are conducted under the unknown variance case according to the following scheme:

1. **Specify** $n_{P_0}, n_{C_0}, n_C, n_E, \mu_{P_0}, \mu_{C_0}, \mu_C, \sigma^2_{P_0}, \sigma^2_{C_0}, \sigma^2_C, \sigma^2_E$;
2. **Generate historical data** from $X_{P_0} \sim N(\mu_{P_0}, \sigma^2_{P_0})$ and $X_{C_0} \sim N(\mu_{C_0}, \sigma^2_{C_0})$.
3. **NI margin computation**: compute $\delta = (1-\lambda) \times Ł_{C_0-P_0,1-\frac{\alpha}{2}}$ following the frequentist fixed-margin methodology [6];
4. N-steps iteration:
   - **Simulate current data** from $X_C \sim N(\mu_C, \sigma^2_C)$ and $X_E \sim N(\mu_E = \mu_C - \delta + \xi, \sigma^2_E)$;
   - Compute the **Hellinger distance** using current data and historical data;
   - **Gibbs Sampling**: generate M posterior values for μ_E, σ^2_E, μ_C, σ^2_C using posterior distributions. Initial values are set equal to the true parameters values;
   - Once M empirical values for μ_E and μ_C are obtained, compute L^{sim}_{E-C} as the $\frac{\alpha}{2}$ quantile of the empirical distribution of $(\mu_E - \mu_C)$;
5. Once N values for L^{sim}_{E-C} are obtained, compute the fraction of $L^{sim}_{E-C} > -\delta$ and obtain the empirical **Type-I error** (if $\xi = 0$) or the **empirical power** (if $\xi > 0$).

The following two scenarios are considered.

- **Scenario 1**: Let $\mu_{C_0} = 1$, $\mu_{P_0} = 0$, $\mu_C = 1$ and $\mu_E = \mu_C - \delta + \xi$, $\sigma_{C_0} = \sigma_{P_0} = \sigma_C = \sigma_E = 1$, $n_{C_0} = n_{P_0} = 600$, $n_C = n_E = 30$, and $p^* = 95\%$. We simulate

7000 MCMC samples for the parameters of interest and we remove a burn-in of 2000 elements ($M = 5000$). The procedure is repeated for $N = 10000$ times so that we obtain N decisions. The estimated type-I error is the total number of rejections over N. Type-I error is computed for different values of the NI margin δ by changing $\lambda = 0, 0.3, 0.6, 0.9$; moreover, we involve different specifications of the power prior parameter a_0 (Table 1). Figure 1 (left panel) shows the power functions for $\lambda = 0.3$.

- **Scenario 2**: using the same parameters values, sample sizes and credibility/confidence level as in Scenario 1, we now add to the active control historical data a certain percentage of noise ν simulated from a uniform distribution $Unif(-5,5)$. The goal is not only to analyse the procedure under new heterogeneous scenarios, but also to assess the impact of the discount parameter a_0. For $\lambda = 0.3$, type-I error is computed for several noise levels in the historical data ($\nu = 15\%, 12.5\%, 10\%, 7.5\%, 5\%$) and for different values of a_0 (Table 2). Moreover, Figure 1 (right panel) shows the power function for $\nu = 5\%$.

3 Application to drug data

In this section, we consider an example used in [6]: the proposed approach is applied to a dataset for drug A which is indicated for the treatment of iron deficiency anemia in adult patients with chronic kidney disease. The parameter of interest in this study is the mean change in hemoglobin (Hgb) from baseline to day 35. Drug A is dosed at 510mg per injection for a total of two daily injections. Results from previous placebo-controlled trials are available. The aim of our study is to show that the Bayesian approach with partial borrowing gives similar results to those of the frequentist approach in a NI test for a new dosage (255 mg four times daily). Results are provided in Table 3.

Table 3 Bayesian and frequentist rejection decisions with drug A (1: reject H_0; 0 otherwise).

	Probability		Decisions		
λ	$\kappa = 0.8$ (partial borrow)	$a_0 = 1$ (full borrow)	Bayesian $\kappa = 0.8$	Bayesian $a_0 = 1$	frequentist
0.4	0.982	0.990	**1**	**1**	**1**
0.5	0.969	0.983	**1**	**1**	0
0.6	0.948	0.971	0	**1**	0
0.7	0.917	0.952	0	**1**	0
0.8	0.873	0.924	0	0	0

4 Discussion

We presented a Bayesian methodology which mirrors the frequentist fixed-margin approach in construction but uses an informative power prior [9] for the active control mean effect. This informative prior depends on a measure of divergence between the historical and the current information, which is quantified by a function of the Hellinger distance: this approach was first introduced by [10] and then developed by [4] for testing NI trials with binary endpoints. The present paper re-adapts these notions to pinpoint a dynamic Bayesian methodology for testing NI trials with normal responses in the case of unknown variances.
Regulatory agencies require new statistical methodologies for the analysis of clinical trials to be evaluated in terms of their frequentist properties, such as the type-I error and the power: in this regard, we simulated data to determine if the proposed method retains the type-I error (size of the test) and if it is as powerful as the frequentist approach. In order to have a clearer idea about the new methodology performances and about the Hellinger distance behaviour, a second numerical simulation with noised data is introduced. On the one hand, under Scenario 1, all the analysed methodologies maintain their size by protecting the type-I error; however, cases in which the historical information is fully or partially borrowed are consistently more powerful than the others. On the other hand, under Scenario 2, for a larger amount of noise in the historical data (15%, 12.5%), none of the methods retains the test size;

nevertheless, for a smaller amount of noise ($10\%, 7.5\%, 5\%$), only the Bayesian approach with partial borrowing maintains its size. Finally, an application to a real case study shows how the proposed and the frequentist methods bring to the same decisions almost all the times, in contrast with the full borrowing methodology.
In conclusion, the proposed methodology controls type-I error and parallels the frequentist strategy; it is simple in construction and its greatest advantage lies on its power to declare NI when the experimental treatment is indeed non-inferior; finally, it allows to wisely borrow past information in the current study by accounting for the discrepancy between the current and the historical data. Results are encouraging and some futher developments can be foreseen: (i) in simulation studies, one might take into account potential randomness of C_0 and study its impact on the performances in terms of type-I error and power; (ii) in noised-data simulations, it would be interesting to modify the historical data with a noise which favours the null hypothesis while the current data favours the non-inferiority hypothesis; (iii) the methodology can be improved by modelling an informative dynamic power prior distribution for the active control variance.

Bayesian Change-Point Detection for a Brownian Motion with a Total Miss Criterion

Rilevazione Bayesiana del Punto di Cambiamento per un Moto Browniano con un Criterio di Errore Complessivo

Bruno Buonaguidi

Abstract We study the following problem of sequential analysis: we observe a Brownian motion which has a zero drift initially; at a an unknown and random time θ, known as change-point, the Brownian motion takes a non-zero drift. Since the Brownian motion is observed in real time, we want to estimate θ optimally by means of a stopping time which minimizes a total miss criterion, namely the linear combination between the expected advance in detecting θ wrongly and expected delay of a late detection. This problem is solved in the Bayesian formulation, where θ is assumed to follow an exponential prior distribution.

Abstract *Studiamo il seguente problema di analisi sequenziale: osserviamo un moto Browniano che ha inizialmente un drift nullo; ad un ignoto e casuale istante θ, chiamato punto di cambiamento, il moto Browniano assume un drift non nullo. Poiché il moto Browniano é osservato in tempo reale, vogliamo stimare θ in modo ottimale mediante un tempo di arresto che minimizzi un criterio di errore complessivo, dato dalla combinazione lineare tra l'anticipo e il ritardo attesi nel rilevare θ. Il prblema é risolto nella formulazione Bayesiana, dove θ segue una distribuzione a priori di tipo esponenziale.*

Key words: Brownian motion, change-point/disorder problem, optimal stopping, sequential analysis, total miss criterion.

1 Introduction

In a change-point detection problem for a sequentially observed stochastic process the goal is to estimate the moment θ, known as *change-point* or *disorder time*, at which the process suffers an abrupt modification of its statistical properties. This

Bruno Buonaguidi
Università Cattolica del Sacro Cuore di Milano e-mail: bruno.buonaguidi@unicatt.it

problem arises in several fields: in quality control, where goods produced by a machine are sequentially analyzed in order to identify when the latter moves from an "in-control" to an "out-of-control" state; in internet surveillance problems, where data are analyzed in real time to identify hacker attacks that turn legitimate traffic into malicious traffic; in credit card fraud detection, where the expenditures pattern of a credit card holder is monitored to identify rapidly the moment at which it is hit by fraud (see, e.g., [2]); in finance, where the asset prices are analyzed to detect the appearance of an arbitrage in the market due to insider trading; in epidemiology, where one wants to identify promptly the onset of the spread of a certain disease; in biomedicine, where signals recorded by means of electroencephalograms and electrocardiograms could reveal the appearance of altered health conditions. We refer to [8] for a broader overview.

In this short paper we consider the following problem. Let X be a Brownian motion having a zero drift initially; at the unknown change-point θ, X takes a non-zero and known drift μ. The change-point detection problem for X aims at estimating θ efficiently, by relying on the observation of X only. By efficient estimation we mean that the occurrence of θ is declared so that a risk function, given by the linear combination of the expected costs due to an early and late detection, is minimized. The problem is studied in the Bayesian formulation, where θ is assumed to be independent of X and to follow an exponential distribution with an atom at 0. The risk function we consider is given by

$$R(\pi,\tau) := \mathbb{E}_\pi[(\theta-\tau)^+] + c\mathbb{E}_\pi[(\tau-\theta)^+], \tag{1}$$

where $\pi \in [0,1]$ is the prior probability that θ has already occurred at time 0 and τ is a stopping time of X, which we use to estimate the occurrence of θ and at which we interrupt the observation of X. In the expression above, $\mathbb{E}_\pi[(\theta-\tau)^+]$ is the expected advance in detecting θ wrongly, while $\mathbb{E}_\pi[(\tau-\theta)^+]$ is the expected detection delay since the occurrence of θ; the constant $c>0$ is given and weights the importance attributed to the two sources of cost. We refer to (1) as the expected *total miss* criterion.

When the first addend in (1) is replaced by the probability of a false alarm, namely $\mathbb{P}_\pi(\tau<\theta)$, we obtain the classic Shiryaev change-point disruption problem for a Wiener process (see, e.g., [7, Ch. 4.4]). Let us also observe that the risk function (1) was analyzed in [5] by setting $c=1$. Here, unlike the latter article, we reduce the optimal stopping problem associated to (1) to a new and equivalent optimal stopping problem by abandoning the original measure $\mathbb{P}_\pi$ and we provide the corresponding solution for any $c>0$.

2 The Model

A standard Brownian motion $W := (W_t)_{t\geq 0}$ and an independent and non-negative random variable θ are defined on the probability space $(\Omega,\mathscr{F},\mathbb{P}_\pi)$. The probability

measure $\mathbb{P}_\pi$ is given by

$$\mathbb{P}_\pi := \pi\mathbb{P}^0 + (1-\pi)\int_0^\infty \mathbb{P}^s \lambda e^{-\lambda s} ds, \tag{2}$$

where $\mathbb{P}^s$ is the probability measure under which $\mathbb{P}^s(\theta = s) = 1$, $s \geq 0$, and $\pi \in [0,1]$ and $\lambda > 0$ are two given and fixed values. Then, it readily follows that $\mathbb{P}_\pi(\theta = 0) = \pi$ and $\mathbb{P}_\pi(\theta > t | \theta > 0) = e^{-\lambda t}$, for $t > 0$. The researcher is allowed to observe the process $X := (X_t)_{t\geq 0}$, defined by

$$X_t = \mu(t-\theta)^+ + W_t, \quad \mu \neq 0 \text{ and known.} \tag{3}$$

This means that X is a standard Brownian motion taking a non-zero drift at θ. Then, solving the Bayesian change-point detection problem for X with a total miss criterion means computing the value function

$$V(\pi) := \inf_\tau R(\pi, \tau), \quad \pi \in [0,1], \tag{4}$$

and determining the optimal estimate $\tau_\star$ of θ, at which the infimum in (4) (searched among all the stopping times τ of X) is reached.

To approach the problem (4) we need the following quantities:

$$L_t := \frac{d\mathbb{P}^0}{d\mathbb{P}^\infty}\bigg|_{\mathscr{F}_t^X}, \quad \Pi_t := \mathbb{P}_\pi(\theta \leq t | \mathscr{F}_t^X), \quad \Phi_t := \frac{\Pi_t}{1-\Pi_t}, \tag{5}$$

where $\mathscr{F}_t^X$ is the sigma-algebra generated by X up to $t \geq 0$ and $\mathbb{P}^\infty$ is the probability measure under which the drift of X never changes (i.e., $\mathbb{P}^\infty(\theta = \infty) = 1$). The processes $L := (L_t)_{t\geq 0}$, $\Pi := (\Pi_t)_{t\geq 0}$ and $\Phi := (\Phi_t)_{t\geq 0}$ are known as likelihood ratio process, posterior probability process and posterior probability odds process, respectively, for obvious reasons. Girsanov's theorem and well known arguments (see, e.g., [4]) show that the explicit expressions of L_t and Φ_t for $t \geq 0$ are

$$L_t = \exp\left(\mu X_t - \frac{\mu^2}{2}t\right), \quad \Phi_t = e^{\lambda t} L_t \left(\frac{\pi}{1-\pi} + \lambda \int_0^t \frac{e^{-\lambda s}}{L_s} ds\right). \tag{6}$$

3 Change of Measure and optimal estimation of θ

Under the probability measure $\mathbb{P}^\infty$, the process X from (3) boils down to the standard Brownian motion W and this leads to a substantial simplification of the expressions in (6), which become independent of θ. Moreover, under the measure $\mathbb{P}^\infty$, the problem (4) can be equivalently expressed as

$$V(\pi) = (1-\pi)\left(\frac{1}{\lambda} + c\hat{V}\left(\frac{\pi}{1-\pi}\right)\right), \quad \pi \in [0,1), \tag{7}$$

being

$$\hat{V}(\varphi) := \inf_{\tau} \mathbb{E}_{\varphi}^{\infty} \left[\int_0^{\tau} e^{-\lambda t} \left(\Phi_t - \frac{1}{c} \right) dt \right], \tag{8}$$

where the infimum is taken over all the stopping times τ of X and the probability measure $\mathbb{P}_{\varphi}^{\infty}$ is such that $\mathbb{P}_{\varphi}^{\infty}(\Phi_0 = \varphi) = 1$, for $\varphi \in [0,\infty)$ (see [1] for a formal proof).

From the structure of the integrand in (8), we can conjecture that there exists an optimal point $b \geq 1/c$ such that, as soon as Φ_t crosses b from below, we can interrupt the observation to declare the occurrence of θ. Standard arguments (see, e.g., [6, Ch. 3-4] or [7, Ch. 3]) show that the function $\hat{V}$ and the optimal boundary b solve the free-boundary problem

$$(\mathbb{L}\hat{V} - \lambda \hat{V})(\varphi) = -\left(\varphi - \frac{1}{c} \right), \quad \varphi \in [0,b), \tag{9}$$

$$\hat{V}(\varphi) = 0, \quad \varphi \in [b,\infty) \quad \textit{(instantaneous stopping)}, \tag{10}$$

$$\hat{V}'(b) = 0 \quad \textit{(smooth fit)}, \tag{11}$$

where $\mathbb{L}$ is the infinitesimal generator of Φ and is given by

$$\mathbb{L}_{\Phi} = \lambda(1+\varphi)\frac{\partial}{\partial \varphi} + \frac{1}{2}\mu^2 \varphi^2 \frac{\partial^2}{\partial \varphi^2}. \tag{12}$$

Solution methods for ordinary differential equations related to quickest detection problems (see, e.g., [3, Sec. 4-5]) imply that the solution to (9)+(12) and (10) is given by

$$\hat{V}(\varphi) = A(1+\varphi) - \frac{1}{c\lambda} - \frac{2}{\mu^2}(1+\varphi) \int_{\frac{b}{1+b}}^{\frac{\varphi}{1+\varphi}} \left(\frac{1-r}{r} \right)^{\nu} e^{\nu/r} \int_0^r \frac{y^{\nu-1}}{(1-y)^{\nu+2}} e^{-\nu/y} dy dr, \tag{13}$$

for $\varphi \in [0,b]$ and $\hat{V}(\varphi) = 0$ for $\varphi \in [b,\infty)$. In (13) above, A is a constant to be determined and $\nu := 2\lambda/\mu^2$. The instantaneous and smooth fit conditions (10)-(11) at b yield $A = 1/(c\lambda(1+b))$ with b which solves

$$\frac{e^{\nu(1+b)/b}}{b^{\nu}} \int_0^{\frac{b}{1+b}} \frac{y^{\nu-1}}{(1-y)^{\nu+2}} e^{-\nu/y} dy = \frac{1}{c\nu}. \tag{14}$$

Figure 1 below shows the function $\varphi \mapsto \hat{V}(\varphi)$ on $[0,\infty)$ and the optimal stopping point b. Applying finally the Itó-Tanaka formula to $\hat{V}$ obtained above, which boils down to Itô's formula due to the smooth fit (11), and making use of the optional sampling theorem, it is readily verified that the solution to the free-boundary problem (9)-(11) is unique and coincides with that of the optimal stopping problem (8) and that the optimal estimate $\tau_{\star}$ of θ is given by

$$\tau_{\star} = \inf\{t \geq 0 : \Phi_t \geq b\}. \tag{15}$$

From (6) we see that Φ depends explicitly on the observed path of X and is therefore observable. Then, $\tau_\star$ can straightforwardly be computed.

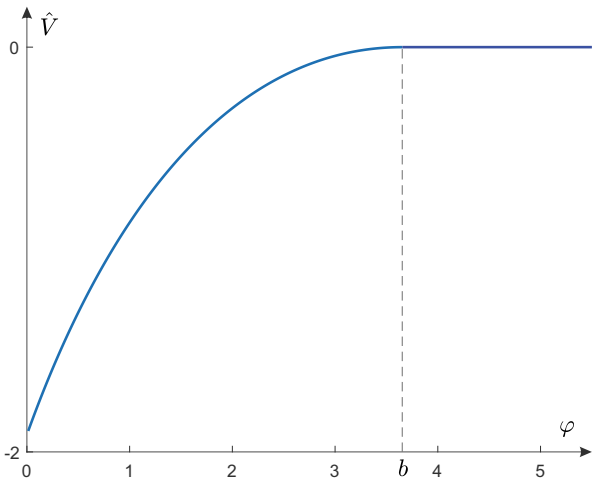

Fig. 1: A computer drawing of the function $\varphi \mapsto \hat{V}(\varphi)$ on $[0,\infty)$ from (8) and (13), and of the optimal stopping boundary point $b = 3.654$ solving (14). We fixed $\mu = 0.5$, $\lambda = 1$ and $c = 0.3$.

On the comparison of alternative Bayesian measures of posterior discrepancy

Fulvio De Santis and Stefania Gubbiotti

Abstract In this paper we consider the problem of quantifying the degree of conflict between posterior distributions of a parameter of interest based on the same data but induced by two alternative prior distributions. This problem has recently received attention in the literature on clinical trials. Specifically, we contrast two interval-based measures of discrepancy using as a reference the Hellinger distance between the posteriors. We perform the comparison in the context of clinical experiments involving binary outcomes and using the normal approximation for the log odds ratio. We provide a real data example.

Abstract *In questo articolo si considera il problema di quantificare il grado di conflitto tra distribuzioni a posteriori per un parametro di interesse basate sugli stessi dati ma indotte da due diverse distribuzioni a priori. Questo problema è stato recentemente oggetto di attenzione nella letteratura nell'ambito delle prove cliniche. In particolare si confrontano due misure di discrepanza basate su intervalli di credibilità prendendo come riferimento la distanza di Hellinger tra le due distribuzioni a posteriori. L'esame comparativo viene effettuato nel contesto di esperimenti clinici con dati binari in cui si utilizza l'approssimazione normale per il log odds ratio. Le caratteristiche delle misure oggetto del confronto sono illustrate mediante un esempio basato su dati reali.*

Key words: Consensus, Credible intervals, Hellinger distance, Normal approximation, Posterior distribution.

1 Introduction

In Bayesian inference extra-experimental information and uncertainty on model parameters are expressed by prior distributions. Sometimes alternative sources of knowledge exist. For example, in a clinical trial setup where the parameter of interest represents a treatment effect or effects difference, two experts may have conflicting opinions (such as skepticism or optimism). Similarly, when two historical data sets are available, the priors based on these sources may produce discordant evidence. Both situations potentially yield contrasting posterior conclusions. In order to quantify the degree of discordance between posterior distributions induced by different priors, several measures of discrepancy have been recently introduced. In this paper we focus on three approaches. The first two methods, respectively proposed by [5] and [3], are based on credible intervals, whereas the third one is a formal distance between posterior distributions (see [4]). All three methods have been originally introduced to define predictive sample size determination criteria. Conversely, the goal of this paper is to compare the posterior behaviour of the interval-based measures with the formal distance between posteriors, regardless of their use in experimental design. Specifically, the comparison is performed in the context of clinical trials involving binary outcomes and using the normal approximation for the log odds ratio (log OR).

The paper is organized as follows. In Section 2 we introduce the three measures of discrepancy between posterior distributions. In Section 3 we specialize the methods for normal models. Section 4 provides an application to a comparative study of two treatments for diabetic patients with coronary artery disease is considered. Finally, Section 5 reports a discussion.

2 Methodology

Let θ be a real one-dimensional unknown parameter and let $\mathbf{X}_n$ be the data based on n observations with density or probability mass function $f_n(\cdot|\theta)$. According to the Bayesian approach, let us assume that θ is a continuous random variable, $\pi(\theta)$ its prior density, $\mathbf{x}_n$ the observed data and $\pi(\theta|\mathbf{x}_n)$ the corresponding posterior density. We also suppose that $\pi(\theta|\mathbf{x}_n)$ is unimodal so that both highest posterior density (HPD) and equal tails (ET) credible sets are intervals. Assume now that two alternative sources of prior information are available and formalized by two prior densities $\pi_a(\theta)$ and $\pi_b(\theta)$ that induce the two posteriors $\pi_a(\theta|\mathbf{x}_n)$ and $\pi_b(\theta|\mathbf{x}_n)$. The experiment shows consensus if a measure of discrepancy between $\pi_a(\theta|\mathbf{x}_n)$ and $\pi_b(\theta|\mathbf{x}_n)$ is small to a prespecified degree. Let us consider the $(1-\gamma)$-level posterior credible interval $C_j = [L_j, U_j]$, i.e. a subset of the parameter space Θ such that $\int_{C_j} \pi_j(\theta|\mathbf{x}_n)d\theta = 1-\gamma$, for $j = a, b$.

In this article we focus on the following three measures of discrepancy:

$$D_1 = \max\{|L_a - L_b|, |U_a - U_b|\}, \tag{1}$$

$$D_2 = \max\{1 - \mathbb{P}_a(C_b), 1 - \mathbb{P}_b(C_a)\}, \tag{2}$$

$$D_3 = \left(1 - \int_\Theta \sqrt{\pi_a(\theta|\mathbf{x}_n) \cdot \pi_b(\theta|\mathbf{x}_n)}d\theta\right)^{\frac{1}{2}}. \tag{3}$$

D_1 has been proposed in [5], D_2 in [3] and D_3 is the Hellinger distance between the posterior densities (see [6] for its first application in the clinical trial context). Therefore, we have *posterior consensus* at degree $\epsilon_i \in [0, 1]$, for $i = 1, 2, 3$, if $D_i < \epsilon_i$. Notice that D_1 is not a relative measure and depends on the measurement unit of θ (see [2]). On the contrary both D_2 and D_3 range in $[0, 1]$, a fact that makes the choice and the interpretation of ϵ_i easier. Furthermore, while D_1 and D_2 are based on specific posterior summaries, D_3 is an overall distance between distributions.

3 Results for normal model

Assume now that data $X_1, \ldots, X_n$ are summarized by a statistic Y_n that, conditional on θ, is approximately normal with parameters $(\theta, \sigma^2/n)$, σ^2 known. Suppose that $\pi_j(\theta)$ is a normal density with mean μ_j and variance σ^2/n_j, where n_j is the prior sample size, $j = a, b$. From standard conjugate analysis the posterior density of θ is normal with parameters $\bar{\mu}_j = (ny_n + n_j\mu_j)/(n + n_j)$, $\bar{\sigma}_j^2 = \sigma^2/(n + n_j)$, $j = a, b$. Under these assumptions, $C_j = [L_j, U_j] = \bar{\mu}_j \pm z\bar{\sigma}_j$, where z is the $1 - \gamma/2$-level quantile of the standard normal distribution. It is easy to check that

$$D_1 = \max\{|(\bar{\mu}_a - \bar{\mu}_b) - z(\bar{\sigma}_a - \bar{\sigma}_b)|, |(\bar{\mu}_a - \bar{\mu}_b) + z(\bar{\sigma}_a - \bar{\sigma}_b)|\}, \tag{4}$$

$$D_2 = \max\left\{1 - \left[\Phi\left(\frac{\bar{\mu}_b + z\bar{\sigma}_b - \bar{\mu}_a}{\bar{\sigma}_a}\right) - \Phi\left(\frac{\bar{\mu}_b - z\bar{\sigma}_b - \bar{\mu}_a}{\bar{\sigma}_a}\right)\right], 1 - \left[\Phi\left(\frac{\bar{\mu}_a + z\bar{\sigma}_a - \bar{\mu}_b}{\bar{\sigma}_b}\right) - \Phi\left(\frac{\bar{\mu}_a - z\bar{\sigma}_a - \bar{\mu}_b}{\bar{\sigma}_b}\right)\right]\right\}, \tag{5}$$

$$D_3 = \left(1 - \sqrt{\frac{2\bar{\sigma}_a\bar{\sigma}_b}{\bar{\sigma}_a^2 + \bar{\sigma}_b^2}} \cdot \exp\left\{-\frac{1}{4}\frac{(\bar{\mu}_a - \bar{\mu}_b)^2}{\bar{\sigma}_a^2 + \bar{\sigma}_b^2}\right\}\right)^{\frac{1}{2}}. \tag{6}$$

D_3 has been proposed and discussed as a measure of posterior discrepancy in [4].

4 Example

The model described in the previous section can be used for instance in phase III two-arms clinical trials with binary data when θ is the log OR and Y_n is the sample

log OR. Specifically, following [7], Y_n is asymptotically $N(\theta, \sigma^2/n)$ with $\sigma = 2$, so that n can be interpreted as the effective number of observations, i.e. the total number of events occuring in the two arms. In this setup we consider an example based on the real trial data discussed in [1] where coronary artery bypass graft (CABG) is compared with percutaneous coronary intervention (PCI) in diabetic patients with multivessel coronary artery disease in terms of survival (with log OR > 0 favouring CABG with respect to PCI). In [1] the prior distribution for the log OR is based on a metanalysis of 8 historical trials and is combined with the likelihood of the data of the FREEDOM trial. The posterior distribution of the log OR shows evidence in favour of CABG (e.g. posterior mean 0.545 with 95% credible interval [0.342, 0.734] corresponding to a reduction in mortality risk between 29%-52%).

Table 1 Posterior credible intervals ($1 - \gamma = 0.95$) and discrepancy measures D_1, D_2, D_3 for increasing values of n (fixed $y_n = 0.69$ and known variance $\sigma^2 = 4$), under the following prior assumptions: (i) π_a historical ($\mu_a = 0.545$, $n_a = 376$) and π_b skeptical ($\mu_b = 0.198$, $n_b = 390$); (ii) π_a discounted historical ($\mu_a = 0.545$, $n_a = 37.6$) and π_b discounted skeptical ($\mu_b = 0.198$, $n_b = 39$); (iii) π_a historical ($\mu_a = 0.545$, $n_a = 376$) and π_b non-informative ($n_b = 0$); (iv) π_a discounted historical ($\mu_a = 0.545$, $n_a = 37.6$) and π_b non-informative ($n_b = 0$).

Let us now discuss the choice of the priors π_a and π_b. As in [4], we first consider the posterior distribution as π_a, e.g. a normal density of parameters $\mu_a = 0.545$, $n_a = 376$. For π_b we follow [1] who also consider a skeptical prior yielding a second posterior distribution for the log OR (e.g. posterior mean 0.198 with 95% credible interval $[0, 0.4]$, corresponding to a reduction in mortality risk between 0%-23%). This results in a normal density of parameters $\mu_b = 0.198, n_b = 390$. To have a better insight on the effect of n_a and n_b on the three discrepancy measures, we also consider priors with the same means μ_a and μ_b but with prior sample sizes discounted, for instance, by a factor 0.1 (thus obtaining $n_a = 37.6$ and $n_b = 39$ respectively). For comparison, we also consider a non-informative prior as π_b ($n_b = 0$) in contrast with the same π_a and its discounted version. In summary, by combining the above mentioned choices of π_a and π_b, we have the following four cases:

(i) π_a historical ($\mu_a = 0.545$, $n_a = 376$) and π_b skeptical ($\mu_b = 0.198$, $n_b = 390$);
(ii) π_a discounted historical ($\mu_a = 0.545$, $n_a = 37.6$) and π_b discounted skeptical ($\mu_b = 0.198$, $n_b = 39$);
(iii) π_a historical ($\mu_a = 0.545$, $n_a = 376$) and π_b non-informative ($n_b = 0$);
(iv) π_a discounted historical ($\mu_a = 0.545$, $n_a = 37.6$) and π_b non-informative ($n_b = 0$).

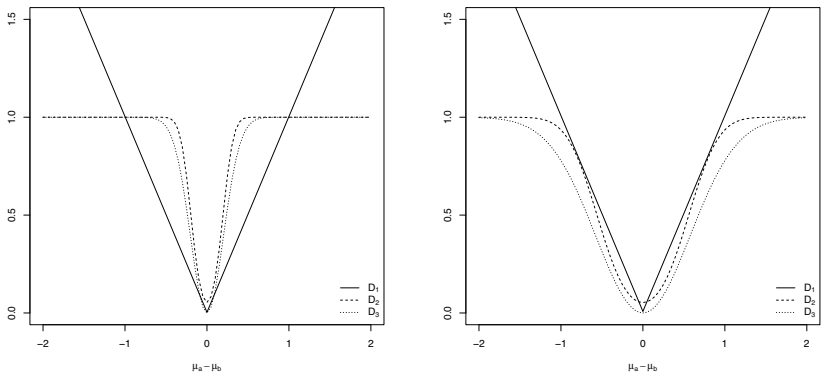

Fig. 1 Plots of D_1, D_2 and D_3 as functions of $\mu_a - \mu_b$ for $n = 10$, $y_n = 0.69$, with $n_a = 376$ $n_b = 390$ (left panel) and $n_a = 37.6$ $n_b = 39.0$ (right panel).

Table 4 reports bounds of 95% posterior credible intervals and values of D_1, D_2 and D_3 for several sample sizes in cases (i)-(iv). Figure 1 shows the plots of D_1, D_2 and D_3 as functions of $\mu_a - \mu_b$ for different choices of the prior sample sizes.
Some comments are in order.

1. As expected, D_i decreases as $n \to \infty$, $i = 1, 2, 3$.
2. As noted in Section 2, $D_i \in [0, 1]$ for $i = 2, 3$, whereas D_1 is not a relative measure (see for instance case (iii) for $n = 10$ where $D_1 > 1$; see also Figure 1).

3. In all the cases we have considered $D_2 > D_3$. As regards D_1, instead, depending on the choice of the prior parameters for each sample size, its values are smaller (see for instance case (i)) or larger (see case (ii) for $n \leq 100$) than those of D_2 and D_3.
4. The more informative the priors (i.e. the larger the values of n_a and n_b), the larger the values of D_i, $i = 1, 2, 3$ (compare (i) vs (ii) and (iii) vs (iv)).
5. In our example the skeptical prior is more in contrast with π_a than the non-informative prior (compare (iii) vs (i) and (iv) vs (ii)). This is shown by the smaller values of D_3, which is the only formal distance between posterior distributions. The values of D_2 follow the trend of D_3, whereas D_1 is not consistent (for instance in case (iii) D_1 is larger than in case (i) for $n \leq 100$).

5 Conclusions

The topic of this article is the comparison of two interval-based measures of conflict between the posterior distributions induced by contrasting priors D_1 and D_2 with the behaviour of the Hellinger distance between posterior distributions D_3. Under the normal model assumptions we have performed the comparison in the context of real clinical trials using several setups of conflicting priors. Results suggest that D_2 has a behavior consistent with D_3, whereas D_1 is more difficult to interpret not only because by definition it is not a relative measure but also because its values do not follow the same trend of D_3 as shown in comment 5 of the previous section. We plan to elaborate on the analytical aspects of the problem in future research.

A Bayesian Test for the comparison of two independent populations

Un test bayesiano per il confronto di due popolazioni indipendenti

Mara Manca, Silvia Columbu and Monica Musio

Abstract In this paper, we propose a testing procedure that allows to compare parameter functions from two independent populations. We address this issue through a test based on the Bayesian Discrepancy Measure, a measure of evidence recently introduced in the literature. This approach is flexible, as it can be adapted to take into account different distributions and different parameter transformations. In addition, this methodology enables us to tackle problems that are not yet covered in the literature.

Abstract *In questo articolo, proponiamo una procedura di test che permette di confrontare funzioni dei parametri di due popolazioni indipendenti. Affrontiamo questo problema attraverso un test basato sulla Misura di Discrepanza Bayesiana, una misura di evidenza recentemente introdotta in letteratura. Tale approccio è flessibile poiché può essere riadattato in modo da prendere in considerazione diverse distribuzioni e diverse funzioni dei parametri. Inoltre, questa metodologia ci permette di affrontare problemi che non sono ancora stati trattati in letteratura.*

Key words: Bayesian test, Bayesian Discrepancy Measure, sharp hypothesis, variance, coefficient of variation, skewness

1 Introduction

In this article we propose a general procedure for testing hypotheses on the comparison of two parameters, or their transformations, from two independent populations. We consider a valutative approach which involves only the specification of one hypothesis without considering the alternative (in the same spirit of Fisher's pure significance test, see [3]). This method is based on a measure of evidence, the Bayesian Discrepancy Measure (BDM), which has been recently introduced in the literature

Dept. of Mathematics and Computer Sciences, University of Cagliari, Via Ospedale, 72, Cagliari

(see [2]). The testing procedure we are going to deal with has a general validity as it allows to perform a variety of tests in a simple way. This problem has been only partially addressed so far, in fact, tests found in the literature usually are defined for specific parameter functions. For example, in the frequentist field, we need "ad hoc" techniques to solve similar problems, which are usually applicable only to specific cases.

In what follows, we propose to use the BDM for comparing variances, coefficients of variation and skewness of two particular independent populations.

The problem of comparing variances has been widely discussed in both the frequentist and the Bayesian fields. Whereas the problem of comparing coefficients of variation, although widely addressed in the frequentist paradigm, has had only few contributions in the Bayesian one (see [1] for all the references). Additionally, to the best of our knowledge, the case of the comparison of two skewness indexes treated here is completely original and has not been addressed before.

2 The Bayesian Discrepancy Measure

Let $X \sim f(x|\theta)$ be a parametric model indexed by a scalar parameter $\theta \in \Theta = \mathbb{R}$, $g(\theta)$ a prior density, $\mathbf{x}$ a sample of *iid* observations and $g(\theta|\mathbf{x}) \propto g(\theta)\, L(\theta|\mathbf{x})$ a posterior density, where $L(\theta|\mathbf{x}) = \prod_{i=1}^{n} f(x_i|\theta)$ is the likelihood function. Let also $G(\theta|\mathbf{x})$ be the correspondent distribution function and $m_1 = G^{-1}\left(\frac{1}{2}|\mathbf{x}\right)$ the posterior median.
We are interested in testing sharp hypothesis $H : \theta = \theta_H$. The BDM is defined as

$$\delta_H = 1 - 2 \cdot \int_{I_E} dG(\theta|\mathbf{x}) = 1 - 2 \cdot \min\left\{\mathbb{P}(\theta > \theta_H|\mathbf{x}), \mathbb{P}(\theta < \theta_H|\mathbf{x})\right\}, \qquad (1)$$

where the external interval is expressed as

$$I_E = \begin{cases} (\theta_H, +\infty) \text{ if } & \theta_H > m_1 \\ (-\infty, \theta_H) \text{ if } & \theta_H < m_1. \end{cases}$$

If $\theta_H = m_1$ this interval can be expressed equivalently as $(-\infty, m_1)$ or $(m_1, +\infty)$, while, if $\Theta \subseteq \mathbb{R}$ then the interval I_E will be redefined consequently.
The more θ_H is far from the median of the posterior distribution $G(\theta|\mathbf{x})$, the more δ_H is large. In this case, H is not conform to G. On the contrary, the smaller δ_H the stronger is the evidence in favor of H.

The approach described previously can be extended to the multiparameter case. Let $X \sim f(x|\theta)$ be a parametric model indexed by a parameter $\theta = (\theta^1, \cdots, \theta^k) \in \Theta \subseteq \mathbb{R}^k$ and $\varphi = \gamma(\theta)$ be the parameter of interest, on which we would like to perform a test, where $\gamma : \Theta \to \Phi \subseteq \mathbb{R}$ is a known continuous function. Suppose, in addition, that there exists a one-to-one transformation between θ and (φ, ζ), with ζ a noise parameter.
For $k \geq 2$, hypothesis of the type $H : \varphi = \varphi_H$ induce a partition $\{\Theta_a, \Theta_H, \Theta_b\}$ of Θ,

through the function γ, where the subsets are defined as

$$\Theta_a = \{\theta \in \Theta \mid \gamma(\theta) < \varphi_H\}, \quad \Theta_b = \{\theta \in \Theta \mid \gamma(\theta) > \varphi_H\},$$
$$\Theta_H = \{\theta \in \Theta \mid \gamma(\theta) = \varphi_H\},$$

through which the BDM is expressed as

$$\delta_H = 1 - 2 \cdot \int_{I_E} \mathrm{d}G(\theta|\mathbf{x}) = 1 - 2 \cdot \min_{a,b} \left\{ \mathbb{P}(\theta \in \Theta_a \mid \mathbf{x}), \mathbb{P}(\theta \in \Theta_b \mid \mathbf{x}) \right\}, \qquad (2)$$

where now the external set is $I_E = \arg\min_{a,b} \left\{ \mathbb{P}(\theta \in \Theta_a \mid \mathbf{x}), \mathbb{P}(\theta \in \Theta_b \mid \mathbf{x}) \right\}$.
Formula (2) can be naturally extended to cases in which we can find a partition of three elements $\{\Theta_a, \Theta_H, \Theta_b\}$ of the parameter space associated to the hypothesis of interest.
The acceptance or rejection of H, that characterise this test, depends on the value of δ_H and its comparison with a threshold $\omega \in \{0.95, 0.99, 0.995, 0.999, \dots\}$, whose choice depends on the researcher.

3 Comparing parameters of two independent populations

The BDM is suitable for comparing two independent populations.
Let us consider two independent random variables $X_\ell \sim f(x_\ell|\theta_\ell)$, $\ell = 1,2$, a prior density $g_\ell(\theta_\ell)$ and a sample $\mathbf{x}_\ell = \{x_{\ell_1}, \dots, x_{\ell_{n_l}}\}$ of n_ℓ *iid* observations. The posterior density is then $g_\ell(\theta_\ell|\mathbf{x}_\ell) \propto g_\ell(\theta_\ell)\, L_\ell(\theta_\ell|\mathbf{x}_\ell)$. We indicate with θ the joint parameter vector $\theta = (\theta_1, \theta_2) \in \Theta_1 \times \Theta_2 = \Theta \subseteq \mathbb{R}^k \times \mathbb{R}^k$ of the two populations parameters. We are interested in testing the hypothesis

$$H : \varphi_1 - \varphi_2 = 0, \qquad (3)$$

with $\varphi_\ell = \gamma(\theta_\ell)$ the parameters of interest ($\ell = 1,2$), which identify the partition $\{\Theta_a, \Theta_H, \Theta_b\}$ of Θ where

$$\Theta_a = \left\{ \theta \in \Theta \;\middle|\; \varphi_1 < \varphi_2 \right\}, \quad \Theta_b = \left\{ \theta \in \Theta \;\middle|\; \varphi_1 > \varphi_2 \right\},$$
$$\Theta_H = \left\{ \theta \in \Theta \;\middle|\; \varphi_1 = \varphi_2 \right\}.$$

To perform the test we can then use formula (2), where

$$\mathbb{P}(\theta \in \Theta_j \mid \mathbf{x}_1, \mathbf{x}_2) = \int_{\Theta_j} g_1(\theta_1|\mathbf{x}_1)\, g_2(\theta_2|\mathbf{x}_2)\, \mathrm{d}\theta_1\, \mathrm{d}\theta_2, \quad j = a, b. \qquad (4)$$

The evaluation of these probabilities demands the computation of multidimensional integrals that can not be solved in a closed form, hence we suggest to approximate them using the Monte Carlo Integration method.

We now consider a variety of distributions and parameters transformations and briefly outline the case-by-case tools needed to calculate the BDM. In particular, we specify the posterior distributions and the subsets of the parameter space that are needed to compute the integrals (4). In all the cases discussed a Jeffreys' prior has been adopted.

Skewness of two Inverse Gaussian populations Let us consider two indipendent Inverse Gaussian random variables $X_\ell \sim IG(x_\ell \mid \mu_\ell, \lambda_\ell)$, $\ell = 1,2$, i.e.

$$f(x_\ell \mid \mu_\ell, \lambda_\ell) = \sqrt{\frac{\lambda_\ell}{2\pi x_\ell^3}} \exp\left\{ -\frac{1}{2}\lambda_\ell \left(\frac{x_\ell - \mu_\ell}{\mu_\ell \sqrt{x_\ell}} \right)^2 \right\}, \quad X_\ell \in \mathbb{R}^+, \ (\mu_\ell, \lambda_\ell) \in \mathbb{R}^+ \times \mathbb{R}^+.$$

Given n_ℓ observations, the posterior distribution of the parameter vector with non-informative prior $g(\mu_\ell, \lambda_\ell) \propto \frac{1}{\sqrt{\mu_\ell^3 \lambda_\ell}}$ is

$$g_\ell(\mu_\ell, \lambda_\ell \mid \mathbf{x}_\ell) \propto \sqrt{\frac{\lambda_\ell^{n_\ell - 1}}{\mu_\ell^3}} \exp\left\{ -\frac{n_\ell \lambda_\ell}{2} \left(\frac{\bar{x}_\ell}{\mu_\ell^2} - \frac{2}{\mu_\ell} + \frac{1}{a_\ell} \right) \right\}, \quad \ell = 1,2,$$

where $\bar{x}_\ell$ and a_ℓ are the arithmetic and harmonic means respectively.
We are interested in comparing the skewness of the two populations. The skewness of a real-valued random variable is defined as the third standardized moment. In this case it assumes the expression

$$\varphi_\ell = 3\sqrt{\frac{\mu_\ell}{\lambda_\ell}}.$$

The hypothesis $H : \varphi_1 - \varphi_2 = 0$ identifies in the parameter space Θ the subsets

$$\Theta_j = \left\{ (\mu_1, \lambda_1, \mu_2, \lambda_2) \in \mathbb{R}^4_+ \;\middle|\; \mu_1 \lambda_2 \lesseqgtr \mu_2 \lambda_1 \right\}, \quad j = a, b.$$

Coefficients of variation of two Negative Binomial populations Let us consider two discrete Negative Binomial populations. It is known that, given $X_\ell | \lambda_\ell \sim$ Poisson$(x_\ell \mid \lambda_\ell)$ with $\lambda_\ell \sim$ Gamma$(\lambda_\ell \mid \alpha_\ell, \beta_\ell)$, then the unconditional random variable X_ℓ follows a Negative Binomial distribution

$$X_\ell \sim NB\left(x_\ell \;\middle|\; \frac{\beta_\ell}{\beta_\ell + 1}, \alpha_\ell \right), \qquad (\alpha_\ell, \beta_\ell) \in \mathbb{R}^+ \times \mathbb{R}^+, \ \ell = 1,2.$$

Assuming the non-informative prior $g_\ell(\alpha_\ell, \beta_\ell) \propto \frac{1}{\beta_\ell} \sqrt{\alpha_\ell \psi^{(1)}(\alpha_\ell) - 1}$, where $\psi^{(1)}(\alpha_\ell) = \sum_{j=0}^{\infty} (\alpha_\ell + j)^{-2}$ is the PolyGamma function (see [5]), the posterior distribution of the parameter vector takes the expression

$$g_\ell(\alpha_\ell, \beta_\ell \mid \mathbf{x}_\ell) \propto \frac{\prod_i (x_{i\ell} + \alpha_\ell - 1)!}{[(\alpha_\ell - 1)!]^{n_\ell}} \left[\frac{\beta_\ell^{\alpha_\ell}}{(\beta_\ell + 1)^{\alpha_\ell + \bar{x}_\ell}} \right]^n \frac{1}{\beta_\ell} \sqrt{\alpha_\ell \psi^{(1)}(\alpha_\ell) - 1}.$$

We want to compare the two populations through their coefficients of variation. For the negative binomial distribution the coefficient of variation is

$$\varphi_\ell = \frac{\sqrt{Var(X_\ell)}}{|E(X_\ell)|} = \sqrt{\frac{\beta_\ell + 1}{\alpha_\ell}}, \quad \ell = 1,2.$$

The hypothesis $H : \varphi_1 - \varphi_2 = 0$ identifies on the parameter space Θ the subsets

$$\Theta_j = \left\{ (\alpha_1, \beta_1, \alpha_2, \beta_2) \in \mathbb{R}^2_+ \times \mathbb{R}^2_+ \;\middle|\; \alpha_2(\beta_1 + 1) \lesseqgtr \alpha_1(\beta_2 + 1) \right\}, \quad j = a, b$$

Variances of two Gamma populations Consider two independent random variables X_ℓ, $\ell = 1,2$, with distributions

$$X_\ell \sim Gamma\big(x_\ell | \alpha_\ell, \beta_\ell\big) = \frac{\beta_\ell^{\alpha_\ell}}{\Gamma(\alpha_\ell)} x^{\alpha_\ell - 1} e^{-\beta_\ell x_\ell}, \quad X_\ell \in \mathbb{R}^+, \; (\alpha_\ell, \beta_\ell) \in \mathbb{R}^+ \times \mathbb{R}^+.$$

We are interested in performing a test on the variances, i.e. $\mathbb{V}ar(X_1) = \mathbb{V}ar(X_2)$ where $\mathbb{V}ar(X_\ell) = \frac{\alpha_\ell}{\beta_\ell^2} = \varphi_\ell$. The posterior distribution of the parameter vector, after assuming the Jeffreys' prior (see [5]), takes the expression

$$g_\ell(\alpha_\ell, \beta_\ell | \mathbf{x}_\ell) = k_\ell \cdot g(\alpha_\ell, \beta_\ell) \cdot L(\alpha_\ell, \beta_\ell \,|\, \mathbf{x}_\ell) \propto \frac{1}{\beta_\ell} \sqrt{\alpha_\ell \psi^{(1)}(\alpha_\ell) - 1} \left(\frac{\beta_\ell^{\alpha_\ell}}{\Gamma(\alpha_\ell)} g^{\alpha_\ell} e^{-\bar{x}_\ell \beta_\ell} \right)^n$$

with k_ℓ the normalising constant. The hypothesis $H : \varphi_1 - \varphi_2 = 0$ identifies on the parameter space Θ the subsets

$$\Theta_j = \left\{ (\alpha_1, \beta_1, \alpha_2, \beta_2) \in \mathbb{R}^2_+ \times \mathbb{R}^2_+ \;\middle|\; \alpha_1 \beta_2^2 \lesseqgtr \alpha_2 \beta_1^2 \right\}, \quad j = a, b.$$

3.1 Example

We present an application to real data for the comparison of skewness indexes of two Inverse Gaussian populations. In the engineering context, river flooding rates have significant economic, social, political implications. The modelling and analysis of such data is an important application of extreme value theory. We consider a study on the Floyd Ever Flood rate data for the years 1935–1954. A more extended version of this dataset was analysed in [4] where it is shown that the exponentiated Weibull model is appropriate for such data, more in general for extreme value analysis, and that the Inverse Gaussian distribution belongs to this family.

In the years 1935–1944 we have that $n_1 = 10$ and $\hat{\varphi}_1 = 2.19$ while in the second group, for the years 1945–1954, $n_2 = 10$ and $\hat{\varphi}_2 = 5.20$. The computation of δ_H, as explained in the prevoius section, depends on the evaluation of two four-dimensional integrals (see (4)), that can be approximated through the Monte Carlo

integration method. Furthermore, since the posterior distribution is known up to a normalizing constant, it is not possible to sample directly from it. We, therefore, applied the random walk Metropolis-Hasting algorithm using a bivariate Normal proposal distribution. In order to obtain a chain that converges to the target distribution, $9 \cdot 10^5$ samples were generated and reduced to $1.2 \cdot 10^5$ after considering a burn-in period and a chain thinning. We, finally, found that the discrepancy measure is $\delta_H \approx 1$, then we can reject the null hypothesis of the skewness indexes equality.

4 Conclusions

In this paper we have proposed a testing procedure to compare parameter functions of two independent populations. Until now, only sharp hypotheses have been considered, but the extension to more complex hypotheses is under study. Theoretical and computational developments in more general contexts, such as linear or generalised models, ANOVA, model selection, are also at an advanced stage of investigation.

A contribution to the L. J. Savage problem

Sul problema di L. J. Savage

Francesco Bertolino, Silvia Columbu and Mara Manca

Abstract The aim of this contribution is to provide an answer, from a subjective Bayesian perspective, to the conceptual problem proposed in 1959 by Leonard Jimmie Savage. For this purpose we propose to apply the Bayesian Discrepancy Measure, which is a new evidence measure recently introduced in the literature.
Abstract *Lo scopo di questo lavoro è quello di fornire una risposta, in ottica bayesiana soggettiva, al problema concettuale proposto nel 1959 da Leonard Jimmie Savage. In questa direzione proponiamo di utilizzare la Misura di Discrepanza Bayesiana, una nuova misura di evidenza che è stata recentemente introdotta in letteratura.*

Key words: Bayesian test, elicitation, Bayesian Discrepancy Measure.

1 Problem description and objective solution

During the Summer Course in Varenna (1959) Savage [4] illustrated three isomorphic conceptual experiments. His explicit aim was to argue against the idea that statistical analysis, in order to be objective, cannot take into account the personal convictions of the statistician.

The first experiment involves a German professor (*GP*), expert in Mozart and Haydn music, who claims to be able to distinguish the two composers' sheets by simply listening to a few notes. The second experiment concerns Mrs Muriel Bristol (*MB*), the "Fisher's lady", who states she is able to distinguish the flavour of a cup of tea in which the tea has been poured first and then the milk later, from a cup in which the opposite happened. The protagonist of the third experiment is a drunk soothsayer (*DS*) who claims to be able to guess the results of flipping a coin by placing it on

Dept. of Mathematics and Computer Sciences, University of Cagliari, Via Ospedale, 72, Cagliari

his arm. The three individuals tested on 10 trials always give the correct answer, resulting in 10 successes.

If, in a frequentist setting, we consider the hypotheses

$$\left\{ H_0 : \theta = \frac{1}{2} \; vs \; H_1 : \theta \neq \frac{1}{2} \right\}, \tag{1}$$

with θ probability of success, we obtain a *p-value* $= \frac{1}{2^9} \cong 0.002$ and H_0 is rejected in the same way for all the three experiments.

Although, the experiment results observed suggest identical conclusions on H_0, it is reasonable to not be confident on the abilities claimed by *DS* in the third case. As a consequence, we may think to include our pre-experimental opinions in the formalisation of the problem.

For the moment, we perform the test under a standard objective Bayesian framework using the Bayes Factor. Since Savage does not specify the stopping rule adopted, two different situations can be considered.

- In the first situation, we fix the number of the trials and the observed successes, i.e. $n = s = 10$. Since $S|\theta \sim Bin(s \mid \theta, n)$, we assume the Jeffreys non-informative (proper) prior
$$g_0(\theta) = \frac{1}{\pi} \cdot \frac{1}{\sqrt{\theta\,(1-\theta)}}.$$
Given the likelihood $L(\theta) = \theta^s$, the Bayes factor is
$$BF_{0,1}(n,s) = \frac{\left(\frac{1}{2}\right)^s}{\pi^{-1} \displaystyle\int_0^1 \frac{\theta^s}{\sqrt{\theta(1-\theta)}}\, \mathrm{d}\theta} = 0.0098.$$
This result forces a strong rejection of H_0 and, again, all three experiments come to the same conclusion.
- In the second situation, we set the number $\nu = 10$ of successes and observe $y = 0$ failures. Given that $Y|\theta \sim NB(y \mid \theta, \nu)$ the Jeffreys non-informative prior is assumed
$$h_0(\theta) \propto \frac{1}{\theta\sqrt{1-\theta}}.$$
Since $h_0(\theta)$ is improper, we consider the proper distribution
$$h_b(\theta) = \frac{c_b}{\theta\sqrt{1-\theta}} \cdot \mathbf{1}_{(b,1)}(\theta), \quad b > 0,$$
where c_b, the normalising constant of the distribution, depends on b and is such that $\lim_{b\to 0} c_b = 0$. Provided the likelihood, $L(\theta) = \theta^\nu$, the Bayes factor is

$$BF^b_{0,1}(\nu, y) \;=\; \frac{\left(\frac{1}{2}\right)^{\nu}}{c_b \cdot \displaystyle\int_b^1 \frac{\theta^{\nu}}{\theta\sqrt{1-\theta}}\,\mathrm{d}\theta} \;=\; \frac{\left(\frac{1}{2}\right)^{\nu}}{c_b \cdot B_b\left(\nu, \frac{1}{2}\right)},$$

where $B_b(\cdot,\cdot)$ is the incomplete beta function. Notice that $\lim_{b\to 0} B_b\left(\nu, \frac{1}{2}\right) = B\left(\nu, \frac{1}{2}\right)$ and $\lim_{b\to 0} c_b = 0$ implies $\lim_{b\to 0} BF^b_{0,1}(\nu, y) \to \infty$. Hence, the hypothesis H_0 cannot be rejected. In addition, in this situation we run into the well known Jeffreys-Lindley paradox.

In conclusion, it can be argued that by using a proper prior the hypotheses are rejected in the same way in all the experiments, whereas the use of an improper prior leads to the Jeffreys-Lindley paradox. Furthermore, we obtain opposite results even though the likelihoods are the same.

It should be pointed out that even when dealing with intrinsic and fractional Bayes factors, which are also part of objective Bayesian methods (see [1] and [3]), Savage's three isomorphic experiments still receive equal results.

2 A subjective solution proposal through the BDT

Following Savage's guidelines, we now attempt a subjective Bayesian analysis in which the three isomorphic experiments are considered separately. To this aim, we propose to use a new Bayesian evidence measure recently introduced in the literature (see [2]).

The Bayesian Discrepancy Measure Let $X \sim f(x|\theta)$ be a parametric model indexed by a scalar parameter $\theta \in \Theta = \mathbb{R}$, we indicate with $G(\theta|\mathbf{x})$ the posterior distribution function and with $m_1 = G^{-1}\left(\frac{1}{2}|\mathbf{x}\right)$ the posterior median.
We are interested in testing the sharp hypothesis $H_0 : \theta = \theta_{H_0}$ and we propose to do it by considering the Bayesian Discrepancy Measure (BDM), defined through the distance between the posterior median and the hypotheses as

$$\delta_{H_0} = 2 \cdot \mathbb{P}(\theta \in I_{H_0}|x) = 2 \cdot \int_{I_{H_0}} dG(\theta|x), \tag{2}$$

where I_{H_0} is the discrepancy interval, expressed as

$$I_{H_0} = \begin{cases} (m_1, \theta_{H_0}) \text{ if } & m_1 < \theta_{H_0} \\ \{m_1\} \quad \text{if } & m_1 = \theta_{H_0} \\ (\theta_{H_0}, m_1) \text{ if } & m_1 > \theta_{H_0} \end{cases}. \tag{3}$$

We have values of δ_{H_0} close to 1 when θ_{H_0} is far from the median of the posterior distribution $G(\theta|\mathbf{x})$. Following this idea the Bayesian Discrepancy Test (BDT), to which this measure is associated, after fixing a threshold $\omega \in \{0.95, 0.99, 0.995, \dots\}$ allows to reject H_0 when we have values above it.

The subjective problem Although Savage's three experiments are isomorphic, they should be treated separately. Considering our beliefs on them we specify the following *Beta* priors.

1. Being confident of *GP*'s capabilities we set the mode in $\theta = 1$ and $\mathbb{P}_{GP}(\theta \geq 0.90) = \frac{1}{2}$.
2. Having less confidence in *MB*'s capabilities we set the prior mean $\frac{\alpha_0}{\alpha_0+\beta_0} = \frac{3}{4}$ and $\mathbb{P}_{MB}(\theta \leq \frac{1}{2}) = 0.15$.
3. Being completely dubious about *DS*'s divinatory abilities we set $\mathbb{E}(\theta) = \frac{1}{2}$, which implies that $\alpha_0 = \beta_0$, and $\mathbb{P}_{SD}\left(\frac{1}{2} - 0.05 < \theta \leq \frac{1}{2} + 0.05\right) = 0.90$.

It should be noticed that it is pointless to evaluate the hypothesis $H_0 : \theta = \frac{1}{2}$ in the first two cases, whereas it is appropriate to evaluate it in the third case. Therefore,

1. the prior probability is $\mathbb{P}_{GP}(\theta \geq 0.90) = \frac{1}{2}$, while the posterior probability is $\mathbb{P}_{GP}(\theta \geq 0.90 \mid n,s) = 0.833$. This outcome indicates a consolidation of our initial opinions, but it is still insufficient to determine the protagonist's flawlessness.
2. In this case we move from a prior probability $\mathbb{P}_{MB}\left(\theta \geq \frac{3}{4}\right) = 0.321$ to a posterior probability $\mathbb{P}_{MB}\left(\theta \geq \frac{3}{4} \mid n,s\right) = 0.865$. This result leads us to conclude that *MB* can boast a tea tasting sensibility that not many people possess.
3. In order to verify the hypothesis $H_0 : \theta = \frac{1}{2}$ we evaluate the BDM that, starting from the posterior median $m_1 = 0.5193$, is

$$\delta_{H_0} \;=\; 2 \cdot \int_{1/2}^{m_1} g_1^{DS}(\theta \mid n,s)\,\mathrm{d}\theta \;=\; 0.466\,,$$

   which indicates that there is not enough evidence to reject H_0.

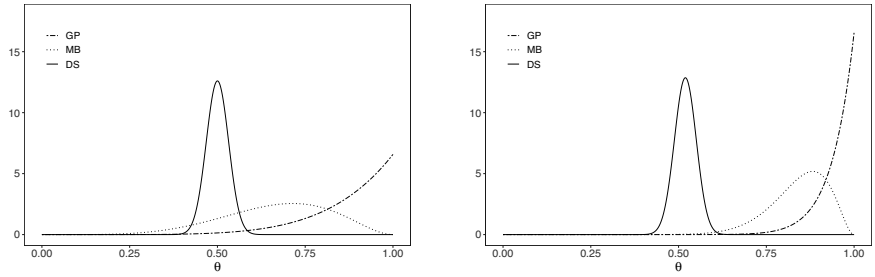
Table 1 shows the prior hyperparameters of the Beta distributions proposed and their posterior values of the conjugate model. The associated distribution plots are shown in Figure 1.

prior			
hyperparameters	*GP*	*MB*	*DS*
α_0	7	6	125
β_0	1	3	125

posterior			
hyperparameters	*GP*	*MB*	*DS*
α_1	17	16	135
β_1	1	3	125

Table 1: Hyperparameters of the prior (left) and posterior (right) distributions.

From a subjective perspective, conclusions about the supposed sensitive faculties of *DS* arise as a combination of an objective fact, $n = s = 10$, and the researcher belief/scepticims towards *DS*, expressed through the choice of the prior hyperparameter α_0.



(a) Prior distributions (b) Posterior distributions

Fig. 1: Probability density functions for *GP*, *MB*, *DS*.

In eliciting the prior we have imposed that $\mathbb{E}(\theta) = \frac{1}{2}$, whence $\alpha_0 = \beta_0$, and we have been conservative in choosing $\alpha_0 = 125$. It should also be taken into account that the higher the disbelief in *DS*, the more concentrated the prior distribution is in $\theta = \frac{1}{2}$.

What happens when the opinions of more than one individual have to be taken into account, i.e. what happens when considering more than one value of α_0? In Figure 2 we have summarised the behaviour of the BDM by varying the hyperparameter values and observed that when α_0 increases, the BDM tends to decrease. In particular, when $\alpha_0 \leq 8.5$ the hypothesis H_0 is rejected since $\delta_{H_0} > 0.95$.

Another aspect that is worth discussing is the dependence of rejection conclusions on the observed sample size. Regarding *DS*'s case, suppose for example to have $n = s = 16$ and consider again the hypothesis test on $H_0 : \theta = \frac{1}{2}$. In this scenario a frequentist analysis, with a p-value of 3×10^{-5}, will again suggest the rejection of the hypothesis. On the other hand, the use of a prior with $\alpha_0 = \beta_0 = 125$, proposed in the former discussion, would not allow such a conclusion as we obtain $\delta_{H_0} = 0.6743$. In this second experimental setting, letting vary α_0 we observe that the threshold of rejection has increased moving from $\alpha_0 = 8.5$ to $\alpha_0 = 26$. In the figure it is also reported the behaviour of the discrepancy measure for a third potential setting where $n = s = 8$.

3 Conclusions

Savage's problem describes a situation in which the pre-experimental information outweighs the one of the experiment. Arguing that under these circumstances any objective procedure (whether frequentist or Bayesian) provides no real help to statistical analysis, Savage suggests that the effort of elicitation is unavoidable.

Moving from Savage's criticism, we proposed to address the problem from a subjective perspective by introducing priors which reflect differing opinions on the three experiments. The BDT has then been applied to test the abilities of *DS* in the

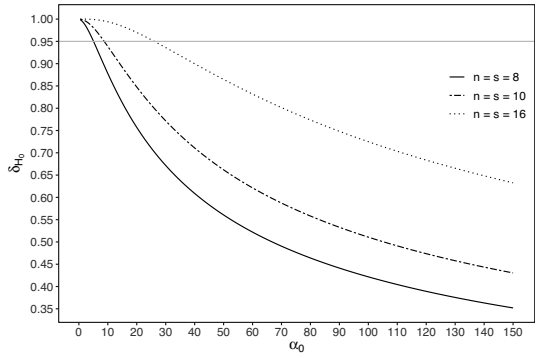


Fig. 2: Sensitivity analysis showing δ_{H_0} values in dependence of α_0.

third experiment. We remark that we have intentionally avoided performing a similar test in the remaining two situations as testing a similar hypothesis would be in contrast with the elicitation. In fact, there is a strict connection between the selection of the hypothesis to test and the opinions expressed through the prior elicitation.

Finally, for Savages' third experiment, we reported a preliminary sensitivity analysis on the hyperparameters' choice. We have also investigated the behaviour of the BDM for different samples sizes with fixed proportion of successes.

Although the subjective analysis was here approached using the BDM, the Bayes factor could also have been applied. We intend to do it in a future work in which the relationship between the BDM and the Bayes factor will be also investigated.

Methods for Complex Data

Optimization of Delayed Rejection Adaptive Metropolis

Ottimizzazione del Metropolis Adattivo con Rifiuto Ritardato

Daniele Raffo and Antonietta Mira

Abstract We present an improved Delayed Rejection Adaptive Metropolis algorithm that significantly speeds up sampling. The computational optimization consists in a remodulation of the covariance updating formula, using Cholesky factors and a closed-form expression for the log-proposal ratio used in the second stage of delayed rejection, for both Gaussian and Student's t proposal distributions. The original and improved samplers are run on a test distribution with a fixed runtime and their results are compared; empirically, the optimized algorithm has an efficiency higher by an order of magnitude with respect to the original one.

Abstract *Presentiamo un algoritmo Metropolis Adattivo con Rifiuto Ritardato migliorato che accelera significativamente il campionamento. L'ottimizzazione computazionale consiste in una rimodulazione della formula di aggiornamento della covarianza, utilizzando la fattorizzazione di Cholesky e un'espressione chiusa per il rapporto della log-proposta utilizzato nel secondo stadio del rifiuto ritardato, per entrambe le distribuzioni di proposta Gaussiane e Student's T. Il campionatore originale e quello migliorato sono impiegati su una distribuzione di test con un runtime fisso e i loro risultati vengono comparati; empiricamente, l'algoritmo ottimizato ha un'efficienza maggiore di un ordine di grandezza rispetto a quello originale.*

1 Introduction

Adaptive Metropolis (AM, [1]) is a variation of the standard Random Walk Metropolis (RWM) algorithm that adapts the covariance matrix of the proposal distribution at each simulation step, using the path of the chain up to that step. In RWM every time we reject the proposal and retain the previous position of the Markov chain autocorrelation increases and, as a result, the asymptotic variance of the resulting MCMC estimator also increases. The mechanism of Delayed Rejection (DR, [2]) produces chains that are guaranteed to be less autocorrelated than those obtained by RWM: if at a certain iteration of the algorithm the proposal is rejected, instead of immediately moving to the next iteration, a second stage move is proposed. The second stage proposal distribution can be updated and may depend on the rejected value as well as on the current position of the Markov chain. Delayed Rejection Adaptive Metropolis (DRAM, [3]) blends these two concepts: the covariance of the proposal at the first stage is adapted as in AM, while that of the second stage is computed as a scaled version of the one used in the first stage as in DR.

The Robust Adaptive Metropolis sampler (RAM, [4]) gave us the inspiration for the optimization of DRAM: instead of directly updating the covariance matrix of the proposal distribution, RAM updates the corresponding Cholesky factor and this translates in a significant speed-up in both the update operation itself and the generation of proposal moves.

Furthermore the proposal ratio which is needed at the second stage of the delayed rejection step can be swiftly computed in closed form for Gaussian and Student's t proposal distributions, avoiding the need to compute the density twice. Since computing the density of these proposal distributions requires the inversion of their covariance matrices, this represents a bottleneck for the efficiency of the algorithm, especially in high dimensions.

2 Methods

Instead of the recursive formula reported in [1], for the update of the covariance matrix in the **Adaptive Metropolis** (**AM**) algorithm we refer to the equivalent formula reported on [5], since the latter is easier to compare to the updated routine used in the optimized version of the algorithm. The covariance matrix $C_n \in \mathbb{R}^{d\times d}$, where d is the number of parameters (or, equivalently, the rank of C_n), used in iteration $n = 1,\ldots,N$ is defined as:

$$C_n = \begin{cases} C_0, & n = 1,2 \\ \frac{n-2}{n-1}C_{n-1} + \frac{s_d}{n}(X_n - \bar{X}_{n-1})(X_n - \bar{X}_{n-1})^T, & n > 2. \end{cases} \tag{1}$$

where $C_0 \in \mathbb{R}^{d\times d}$ is a given initial covariance matrix which may reflect prior beliefs (in all our applications, this is set equal to the identity matrix $I_d \in \mathbb{R}^{d\times d}$), $\bar{X}_n = \frac{1}{n}\sum_{i=1}^{n} X_i$ is the sample mean, the draws $X_n \in \mathbb{R}^d$ being column vectors, and

s_d is a scaling parameter that we take to be $s_d = 2.4^2/d$ following [6]. The sample mean also satisfies a recursive formula:

$$\bar{X}_n = \begin{cases} X_1 & n = 1, \\ \bar{X}_{n-1} + \frac{1}{n}(X_n - \bar{X}_{n-1}) & n > 1. \end{cases} \tag{2}$$

We can reformulate (1) in terms of the Cholesky factor L_n of C_n; we have, for $2 < n \leq n_T$:

$$L_n L_n^T = \frac{n-2}{n-1} L_{n-1} L_{n-1}^T + \frac{s_d}{n}(X_n - \bar{X}_{n-1})(X_n - \bar{X}_{n-1})^T. \tag{3}$$

Solving (3) for L_n is equivalent to perform a rank-one Cholesky update of $\sqrt{\frac{n-2}{n-1}} L_{n-1}$ given a random vector $\sqrt{\frac{s_d}{n}}(X_n - \bar{X}_{n-1})$:

$$L_n = \text{CholeskyUpdate}\left(\sqrt{\frac{n-2}{n-1}} L_{n-1}, \sqrt{\frac{s_d}{n}}(X_n - \bar{X}_{n-1}) \right). \tag{4}$$

The rank-one Cholesky update is a $O(d^2)$ operation (see [7]); hence, it is of the same asymptotic computational complexity as calculating (1), since that involves the sum of two matrices.

At iteration n, a candidate move, Y_1, is generated from a symmetric proposal distribution $q(X_n, C_n)$ and accepted with the usual Metropolis probability

$$\alpha(X_n, Y_1) = \min\left\{ 1, \frac{\pi(Y_1) q_1(Y_1, X_n)}{\pi(X_n) q_1(X_n, Y_1)} \right\} = \min\left\{ 1, \frac{\pi(Y_1)}{\pi(X_n)} \right\}. \tag{5}$$

where $\pi(\cdot)$ is the target distribution. Note that the proposal distribution cancels in the above acceptance ratio because of its symmetry: $q_1(Y_1, X_n) = q_1(X_n, Y_1)$. If we accept we move to Y_1, i.e. $X_{n+1} = Y_1$; otherwise we stay at the current position, i.e. $X_{n+1} = X_n$.

With **Delayed Rejection** (**DR**), if the first proposal move $Y_1 \sim q(X_n, C)$ is rejected, instead of immediately moving to the next iteration and retaining the current position X_n, a second stage move $Y_2 \sim q(X_n, \gamma C)$ is proposed. γ was set to 0.5 in all our applications (i.e., we halve the covariance matrix). The acceptance probability at the second stage depends not only on the current position of the chain, but also on what we have just proposed and rejected:

$$\alpha_2(X_n, Y_1, Y_2) = \min\left\{ 1, \frac{\pi(Y_2) q_2(Y_2, Y_1)[1 - \alpha_1(Y_2, Y_1)]}{\pi(X_n) q_2(X_n, Y_1)[1 - \alpha_1(X_n, Y_1)]} \right\}. \tag{6}$$

Here, the factor $Q = \frac{q_2(Y_2, Y_1)}{q_2(X_n, Y_1)}$ is called proposal ratio and cannot be simplified further. However, it can be computed in closed form for log-Gaussian and log-Student's

t proposals, respectively:

$$Q_{\mathscr{MVN}_{\log}} = -\frac{1}{2}(Y_2 - Y_1)^T \Omega (Y_2 - Y_1) + \frac{1}{2}(X_n - Y_1)^T \Omega (X_n - Y_1), \tag{7}$$

$$\begin{aligned} Q_{\mathscr{MVT}_{\log}} = &-d \log\left(1 + \frac{1}{d}(Y_2 - Y_1)^T \Omega (Y_2 - Y_1)\right) \\ &+ d \log\left(1 + \frac{1}{d}(X_n - Y_1)^T \Omega (X_n - Y_1)\right). \end{aligned} \tag{8}$$

In an iteration of the vanilla implementation of the **Delayed Rejection Adaptive Metropolis** (**DRAM**), the worst-case scenario in terms of computational complexity happens when the first proposal is rejected and the second proposal must be sampled and the acceptance probability must be computed. Table 1 summarizes the operations that are carried out, their computational complexity and how many times each of them is executed; it is shown how the total complexity of the vanilla algorithm is $5O(d^3) + O(d^2) + 2K$[1] (where K varies with the specific target distribution).

Operation	Complexity	Times
Computing target $\pi(X)$	K	xx
Sampling $Y \sim q(X,C)$	$O(d^3)$	xx
Computing the density at a point $q_j(X,Y)$	$O(d^3)$	xxx
Update covariance matrix C_n	$O(d^2)$	x

Table 1 Summary of operations carried out by the vanilla algorithm.

However, if the Cholesky decomposition L_n of the covariance matrix C_n is available beforehand, as in our optimization, we can sample the first proposal Y_1 having distribution $q(X_n, C_n)$ in the following way:

$$Y_1 = X_n + L_n U_1, \tag{9}$$

and the second proposal (if required) as:

$$Y_2 = X_n + \sqrt{\gamma} L_n U_2, \tag{10}$$

where $U_1, U_2 \sim q(\mathbf{0}, I_d)$ are random vectors sampled from the standardized version of the current proposal distribution. Obviously, sampling from a standardized distribution does not require finding the inverse of the covariance matrix, hence it is an $O(1)$ operation, and sampling with in the method in Equations (9) and (10) is therefore an $O(d^2)$ operation, as it involves a matrix-vector multiplication.

Computing the log-proposal ratio eliminates the need of computing the densities $q(X,Y)$ and, as it only involves matrix-vector multiplications (see Equations (7) and (8)), it is $O(d^2)$.

[1] Note that, at each iteration with $n \geq 2$, we have computed $\pi(X_n)$ at the precedent iteration.

We can then summarize the operations carried out in the worst-case scenario by the optimized algorithm in Table 2, and see how the computational cost is brought down to $4O(d^2)+2K$.

Operation	Complexity	Times
Computing target $\pi(X)$	K	xx
Sampling as $Y = X + LU$	$O(d^2)$	xx
Computing log proposal ratio $Q_{\log}$	$O(d^2)$	x
Update Cholesky factor L_n	$O(d^2)$	x

Table 2 Summary of operations carried out by the optimized algorithm.

3 Results

Optimized DRAM was tested against its vanilla implementation, both with Gaussian and Student's-t proposal distribution, on the Rosenbrock probability distribution, also called Banana distribution for its particular shape. The distribution is defined in d dimensions and has the following kernel [8]:

$$f(x) \propto \exp\left(\sum_{i=1}^{d-1}\Big[-100(x_{i+1}-x_i^2)^2-(x_i-1)^2\Big]\right), \tag{11}$$

with $x=(x_1,...,x_d)\in\mathbb{R}^d$ being the random vector. It is a unimodal distribution whose most of the density lies in a narrow, parabolic region of the parameter space. The global maximum is $f(x^*)=1$ at $x^*=(1,\ldots,1)$. In particular, the samplers were used to approximate the distributions for $d=2,3$ on the hypercube $x_i\in[-5,10]$ for all $i=1,\ldots,d$.

We measured the number of iterations performed in 2 seconds of runtime by the different versions of the algorithm. The starting point for each simulation was $x_0=0\in\mathbb{R}^d$. We did not use burn-in as our main focus was to evaluate the efficiency of the "adaptive" iterations. AM and DR were used at each step. Each simulation run was repeated $k=1000$ Monte Carlo times to analyze the distribution of the results and assess their variability. The results are reported in Table 3.

In the 2D case, the mean number of iterations is increased by a factor of about 15-fold for both Gaussian and Student's-t proposal, from the vanilla version to the optimized version; in the 3D case, this gain is already about 75-fold, with the number of iterations performed by the optimized version almost unchanged from 2D to 3D. This highlights how the computational advantages are greater in higher dimensions. Furthermore, the variability of the results is much larger when using the classical implementation.

4 Discussion

We showed how the optimization of the DRAM algorithm improves its speed significantly; this makes it a valid choice in applied settings, especially when the target distribution has a complex shape and/or the acceptance rate of alternative sampling algorithms is low. Optimized DRAM has been used successfully in the estimation of a Markov-Switching GARCH model for the computation of the conditional volatility of financial assets, and proved to be more efficient than other samplers, also producing chains with a higher degree of stationarity.

Dealing with multicollinearity and outliers in multinomial logit model: a simulation study

Una soluzione alla multicollinearità e ai valori anomali nel modello logit multinomiale: uno studio di simulazione

Ida Camminatiello and Antonio Lucadamo

Abstract Multinomial logit model is a powerful tool for modeling the dependence relationship between a set of quantitative regressors and a categorical response variable with more than two categories. However, it necessitates careful consideration of multicollinearity among the regressors and examination for outliers. For dealing with these problems in the multinomial logit model, an approach based on robust principal components has been developed. The robust approach has achieved satisfactory results on real data. This paper aims to validate such an approach by a simulation study.

Abstract *Il modello logit multinomiale é un potente strumento per modellare la relazione di dipendenza tra un insieme di regressori quantitativi e una variabile dipendente nominale con più di due categorie. Tuttavia, richiede un'attenta considerazione della multicollinearitá tra i regressori e l'osservazione dei valori anomali. Per affrontare questi problemi nel modello logit multinomiale, é stato sviluppato un approccio basato sulle componenti principali robuste. L'approccio robusto ha ottenuto risultati soddisfacenti su dati reali. Questo paper mira a convalidare tale approccio mediante uno studio di simulazione.*

1 Introduction

Multinomial logit (MNL) model allows explaining a response variable on nominal scale in terms of the predictors (McFadden, 1974). The model is widely used in many fields, however, it can be affected by multicollinearity and outlier problems.
In presence of multicollinearity, the stepwise selection of the predictors can be performed. Principal component multinomial regression (Aguilera, Escabias, 2008; Camminatiello, Lucadamo, 2010; Lucadamo, Leone, 2015) has been proposed as an alternative way of solving consequences of multicollinearity.
This estimation method solves the multicollinearity problem; however, the results can be affected by extreme values in the continuous predictors, thus there is a need for some robust estimation methods. Camminatiello and Lucadamo (2018) developed an approach based on robust principal components (PCs), called robust principal component multinomial regression (RobPCMR), so that the effect of both multicollinearity and outliers is minimized in the estimation of the MNL model parameters (second section). The robust approach applied for assessing judges' performances (Camminatiello, Lucadamo 2018) showed good results. However, an extensive simulation study is needed to verify that RobPCMR is resistant to many types of contamination, to compare the results with other robust approaches for PCs proposed in the literature, and to select the optimal dimension of the model. For this purpose, the third section presents a first simulation study. The last section concludes with some remarks and perspectives.

2 Robust principal component multinomial regression

When multicollinearity among the regressors exists, the estimation of MNL model becomes inaccurate because of the need to invert nearsingular and ill-conditioned information matrices (Ryan, 1997). Therefore, the covariates of the MNL model could be substituted by a reduced number of PCs of the regressors. Because the PCs are based on the eigenvectors of the empirical covariance matrix, they are very sensitive to anomalous observations. Several methods for robustifying principal component analysis (PCA) have been proposed in literature. RobPCMR considers a recently developed method, called ROBPCA (Hubert, Rousseeuw and Vanden Branden, 2012), for its interesting properties. In a nutshell RobPCMR can be synthesized as follow.
Let $\mathbf{X} = [\mathbf{x}_1, ..., \mathbf{x}_p]$ is the $n \times p$ matrix of the p predictor variables and $\mathbf{y}$ the $n \times 1$ vector of categorical response variable with more than two categories observed on n statistical units.
At first step, RobPCA creates the robust PCs of the regressors $\mathbf{Z} = [\mathbf{z}_1, ..., \mathbf{z}_p]$ which are linear combinations of the original variables, $\mathbf{Z} = \mathbf{XV}$. At second step the MNL model is carried out on the set of p robust PCs. At third step, the number of robust PCs, $a \leq p$, to be retained in the model, is selected according to different tools (Camminatiello, Lucadamo, 2010). Finally the MNL model is carried out on the chosen subset of robust PCs. The MNL model can be expressed in terms of a robust

PCs as:

$$\pi_i^{(a)}(c) = \frac{exp(\sum_{j=1}^{p}\sum_{k=1}^{a} z_{ik} v_{kj} \beta_{jc}^{(a)})}{\sum_{b=1}^{s} exp(\sum_{j=1}^{p}\sum_{k=1}^{a} z_{ik} v_{kj} \beta_{jb}^{(a)})} = \frac{exp(\sum_{k=1}^{a} z_{ik} \gamma_{kc}^{(a)})}{\sum_{b=1}^{s} exp(\sum_{k=1}^{a} z_{ik} \gamma_{kb}^{(a)})} \quad (1)$$

where $\gamma_{kb}^{(a)} = \sum_{j=1}^{p} v_{kj} \beta_{jb}^{(a)}$ are the robust coefficients to be estimated on the subset of a robust PCs and $\beta_{jb}^{(a)}$ are the robust parameters obtained after the extraction of the a components. Finally, the robust MNL parameters can be expressed in function of original variables $(\mathbf{x_1}, ..., \mathbf{x_p})$

$$\mathbf{Z^{(a)}} \gamma^{(\mathbf{a})} = \mathbf{X V^{(a)}} \gamma^{(\mathbf{a})} = \mathbf{X} \beta^{(\mathbf{a})} \quad (2)$$

where $\beta^{(a)} = V^{(a)} \gamma^{(a)}$ is the matrix of robust parameters expressed in function of original variables; $\mathbf{Z}^{(a)}$ is the matrix of selected robust PCs; $\gamma^{(a)}$ is the matrix of robust parameters on a robust PCs for the s alternatives; $\mathbf{V}^{(a)}$ is the matrix of robust eigenvectors for the selected components.
We observe that the approach can be applied to low - $n > p$ - as well as high dimensions - $n \leq p$.
To measure the performance of a model, several criteria can be applied (Camminatiello, Lombardo, Durand, 2017; Camminatiello, Lucadamo, 2010). Here, we focus on rate of well classified which we expect higher compared to Principal component multinomial regression (PCMR) and MNL.

3 A simulation study.

The goodness of the proposed methodology has been investigated through some simulation studies. Analyses have been performed for data with and without outliers and 100 simulations for each scenario have been considered.

Genuine data have been generated according to the following scheme:

1. Building of the matrix $(\mathbf{X})$ of explicative variables: each variable has been generated from a normal distribution with mean 0 and standard deviation 1. Different correlation structures among variables have been considered.
2. Generation of the dependent variable using the multinomial distribution to define the membership to each group.

Contamination has been introduced by replacing a proportion $\varepsilon = 0.1, 0.2$ and 0.4 of genuine observations, by outliers generated from a normal distribution with the same variance than before, but mean equal to 20. The scenario we introduce in this paper is the following:

- number of observations: $n = 1000$
- number of predictors: $p = 20$

- number of modalities of response variable: 3
- correlation among predictors: 0.9

To evaluate the goodness of RobPCMR we can consider table 1, in which the correct classification rate for classical multinomial logit model, principal component multinomial Regression and RobPCMR with different level of resistence (α) to outliers are compared. In this analysis we decided to retain in the analysis, for all the methods, only the significant variables or components, according to a stepwise selection based on AIC.

Table 1 Correct classification rate (%) for different contamination levels

	Methods				
	Multinom.	PCMR	RobPCMR($\alpha = 0.90$)	RobPCMR($\alpha = 0.80$)	RobPCMR($\alpha = 0.60$)
No contamination					
Estimation set	75.66	75.64	74.60	74.53	74.64
Validation set	72.06	72.78	71.84	72.50	72.20
$\varepsilon = 0.1$					
Estimation set	73.68	72.31	71.86	71.50	71.59
Validation set	69.73	68.81	70.01	70.93	70.15
$\varepsilon = 0.2$					
Estimation set	71.74	71.32	69.96	69.96	70.11
Validation set	67.56	67.83	68.03	68.36	67.86
$\varepsilon = 0.4$					
Estimation set	67.79	67.59	66.06	66.39	66.07
Validation set	62.54	61.29	63.77	62.98	63.63

Looking at the values in table, we can see that the rate of well classified for the estimation sample is always higher for the classical multinomial logit model, but we are interested almost to what happens for the validation set. When there is not contamination, it is easy to notice that the PCMR works better than other methods, but the RobPCMR, for all levels α, lead to good results. When we consider data with outliers, the RobPCMR shows, for the validation set, higher performance than other methods, independent of the resistence level. Obviously deeper simulation studies are needed to better understand the validity of the proposed method.

4 Remarks and perspectives

In this paper, we presented a first simulation study to verify that RobPCMR is a valid method for dealing with multicollinearity and outlier problems in MNL. However, further simulation studies are needed to show that RobPCMR is resistant to many types of contamination, to compare the results with other robust approaches for PCs proposed in the literature, to consider different correlation structures among predictors and variations in the numbers of observations, explicative variables, and modalities of the dependent variable and, to select the optimal dimension of the

model.
Moreover, the rate of well classified is a performance measure widely applied in literature, but other criteria - such as the estimator variance or the predicted residual error sum of squares - could be discussed. Finally, a robust method for ordinal logistic regression could be proposed.

A tool to validate the assumptions on ratios of nearest neighbors' distances: the Consecutive Ratio Paths

Uno strumento per validare le assunzioni sui rapporti di distanze fra vicini più vicini: le traiettorie di rapporti consecutivi

Francesco Denti and Antonietta Mira

Abstract The estimation of the intrinsic dimension is an essential step in many data analyses involving, for example, dimensionality reduction. Likelihood-based estimators, which rely on the distributions of the ratios of distances between nearest neighbors, have been recently proposed. However, these distributional results depend on several assumptions. One of the most important is the local homogeneity of the point process characterizing the data-generating mechanism. By exploiting a recent theoretical result, we develop the Consecutive Ratio Paths, a graphical tool to assess the validity of the local-homogeneity assumption in a dataset. This tool is also helpful to uncover the presence of multiple latent manifolds, a potential indicator of the existence of heterogeneous intrinsic dimensions.

Abstract *La stima della dimensione intrinseca è un passaggio essenziale in molte analisi dei dati che comportano, per esempio, la riduzione della loro dimensionalità. Recentemente sono stati proposti stimatori basati sulla verosimiglianza, costruiti partendo dalle proprietà delle distribuzioni dei rapporti delle distanze tra i vicini più vicini. Questi risultati distributivi dipendono da diverse ipotesi. Una delle più importanti è l'omogeneità del processo di punto che caratterizza il meccanismo di generazione dei dati. Sfruttando un recente risultato teorico, proponiamo di monitorare le traiettorie di rapporti consecutivi, fornendo uno strumento grafico per valutare la validità dell'ipotesi di omogeneità locale in un set di dati. Questo strumento è utile anche per scoprire la presenza di molteplici manifold latenti, evidenziando l'eventuale esistenza di dimensioni intrinseche eterogenee.*

1 Introduction

Dimensionality reduction techniques are valuable tools to ensure the feasibility of statistical analyses involving large datasets. These methods are used to obtain parsimonious but meaningful representations of the data over a latent (potentially non-linear) manifold with dimensionality lower than the original one, preserving as much information as possible. We call the dimensionality of the latent manifold the *intrinsic dimension* (`id` from now on). It is essential to rely on an accurate `id` estimate to perform effective dimensionality reduction. Recently, [3] introduced the `TWO-NN` model, a likelihood-based `id` estimator that builds on the properties of the ratios of distances between data points and their first two nearest neighbors (NNs). The `TWO-NN` model has been recently extended in [2], where the authors propose an estimator that relies on the ratios of NN of generic order, called `Gride`. This modeling framework produces reliable estimates for the `id` given that all the underlying modeling assumptions, on which we elaborate more in the next section, are satisfied. However, it is not always trivial to assess the correctness of these assumptions to perform model validation. In this paper, we propose the Consecutive Ratio Paths (`CoRaP`), a graphical tool to assess the compliance of the data to the assumptions mentioned above. The paper proceeds as follows. First, Section 2 briefly presents the modeling framework and the distributional results, which are the foundations of the `CoRaP`, and delineates our contribution. Then, Section 3 discusses the results on simulated data, explaining how to interpret the plots that we propose to assess the assumptions. Finally, Section 4 concludes the article, discussing potential future directions.

2 The modeling background

Consider a dataset $\boldsymbol{X} = \{x_i\}_{i=1}^n$, where $x_i \in \mathbb{R}^D,\ \forall i$. The dataset $\boldsymbol{X}$ is viewed as a realization of a Poisson point process with constant density ρ defined over $\mathbb{R}^d$. We also postulate that the data points take place on a manifold of dimension $d < D$. Then, given a distance function δ taking values in $\mathbb{R}^+$, let $r_{i,l} = \delta(x_i, x_{i,(l)})$ be the value of this distance between observation i and its l-th NN $x_{i,(l)}$. [3] proved that the ratios between the second and first order NNs' distances is distributed as

$$\mu_{i,2} = \frac{r_{i,2}}{r_{i,1}} \sim Pareto(1,d), \qquad \mu_{i,2} \in (1,+\infty), \qquad i = 1,\dots,n. \tag{1}$$

Equation (1) states that one can recover the `id` of a dataset, d, by estimating the scale parameter of a Pareto distribution using the sample of ratios $\boldsymbol{\mu}_{i,2} = \{\mu_{i,2}\}_{i=1}^n$. One can only prove the result in (1) if the density ρ is constant (*global homogeneity*). However, the derived `id` estimator is empirically valid as long as the density is approximately constant on the scale defined by the distance from the furthest of the NNs, $r_{i,2}$. We refer to this weakened assumption as *second order local homogeneity*.

Thus, we can summarize the principal modeling assumptions of the `TWO-NN` in the following three points: (a) the computed ratios of NN distances are independent, (b) the underlying latent manifold on which the data take place is unique, and (c) the data generating mechanism is characterized by a density function that is *second order locally homogeneous*. [2] extended the result in Equation 1, showing that, under the same theoretical framework, one can obtain that, for the ratios of the l-th to the $(l-1)$-th order NN distances, the following is true:

$$\mu_{i,l} = \frac{r_{i,l}}{r_{i,l-1}} \sim Pareto(1,(l-1)\cdot d), \quad \mu_{i,l} \in (1,+\infty) \quad i = 1,\dots,n, \quad l = 1,\dots,L, \tag{2}$$

where $L < n$. Moreover, it can be proved that the entries of the vector $(\mu_{i,2},\dots,\mu_{i,L})$ are all independent.
Equation (2) is important because it provides the link between the `TWO-NN` modeling framework and the likelihood estimators proposed by [4] and corrected in [5]. The estimator derived from (2) would require even more stringent hypotheses since the intensity function has to be approximately constant on the scale defined by the distance from the furthest of the NNs for each point i, $r_{i,L}$, with $L > 2$ (called *L-th order local homogeneity*). These strong hypotheses are unlikely to be completely satisfied in many real scenarios. Nonetheless, in the next section, we show how the distributional result stated in Equation (2) can be exploited to assess the validity of the underlying modeling assumptions.

2.1 The Consecutive Ratios Paths

The previous results states that, under ideal conditions, the consecutive ratios of distances are independent and Pareto distributed. Given well-known properties of the Gamma and Pareto distributions, we consider the transformation $\eta_{i,l} = (l-1)\cdot \log(\mu_{i,l})$, which ensures that $\eta_{i,l} \sim Exp(d)$. Then, for every observation $i = 1,\dots,n$, we compute the vector of running means $\bar{\boldsymbol{\eta}}_i$ over the increasing orders of NNs $l = 2,\dots,L$ defined as

$$\bar{\boldsymbol{\eta}}_i = (\bar{\eta}_i(2),\dots,\bar{\eta}_i(L)), \quad \text{where} \quad \bar{\eta}_i(l) = \sum_{k=2}^{l} \eta_{i,k}/(l-1). \tag{3}$$

We call the vector $\bar{\boldsymbol{\eta}}_i$ the *Consecutive Ratio Path* for the i-th observation (`CoRaP`$_i$), since it summarizes the evolution of the behavior of the distances between x_i and its NNs. If all the required assumptions are met, for each combination (i,l) we have $(l-1)\cdot\bar{\eta}_i(l) \sim Gamma(l-1,d)$, implying that $\mathbb{E}[\bar{\eta}_i(l)] = 1/d$ and $\mathbb{V}[\bar{\eta}_i(l)] = 1/((l-1)d^2)$. In other words, the ideal `CoRaP`$_i$ is a collection of random variables characterized by a constant expected value across i and l, identically equal to the reciprocal of the `id`, and by decreasing variance. Moreover, for l^* large enough, we can exploit the Central Limit Theorem, stating that $\bar{\eta}_i(l^*) \approx \mathcal{N}\left(1/d, 1/((l^*-1)d^2)\right)$,

where with $\mathcal{N}(\mu, \sigma^2)$ indicates a Normal distribution with mean μ and variance σ^2.
Our goal is to compare the behavior of the observed $\texttt{CoRaP}_i$ with the expected theoretical counterpart to detect violation of hypotheses. The ideal case (**Case A**) is displayed in the top left panel of Figure 1, and it is obtained simulating $Exp(d = 5)$ random numbers populating a matrix with $n = 1{,}000$ observations and considering $L = 750$ NN order. We can appreciate how the `CoRaP` concentrate around the true value $d = 1/5$. Also, the left panel of Figure 2 showcases the distribution of $\bar{\eta}_i(1{,}000)$, for which the Gaussian asymptotic approximation holds very well.

3 Detecting violation of assumptions via CoRaP

We discuss the interpretation of the `CoRaP` with the help of three additional synthetic datasets, generated as follows:

- **Case B**: 1,000 data points sampled from a five-dimensional Normal distribution (one manifold, unique `id`);
- **Case C**: 1,000 data points sampled from two bi-dimensional, non-overlapping Normal distributions (two manifolds with identical `id`);
- **Case D**: 1,000 data points sampled from two different Normal distributions with `id` of 2 and 7, respectively (two manifolds with different `ids`).

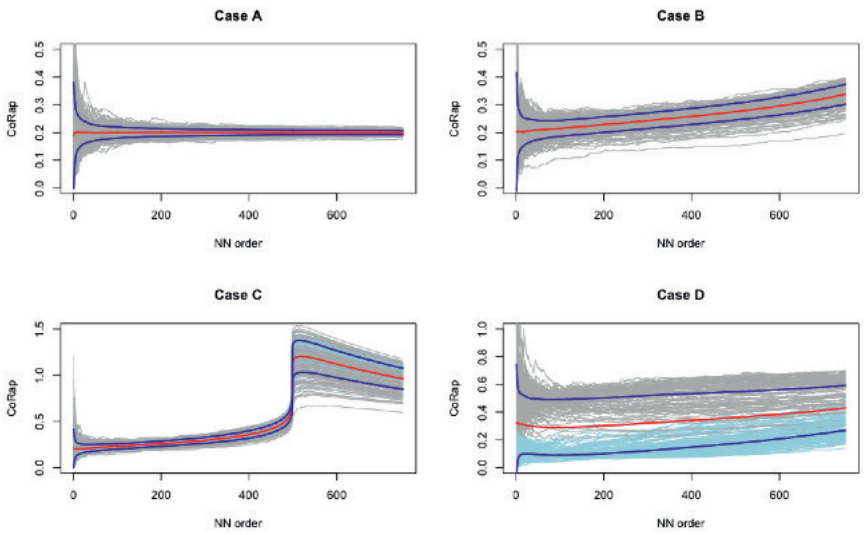

Fig. 1 The `CoRaP` obtained from datasets generated under the four different scenarios (Cases A, B, C, and D) are depicted in gray and/or light blue. The red lines represent the overall ergodic mean (computed point-wise), and the blue lines help quantify the uncertainty ($\pm$ std.dev.).

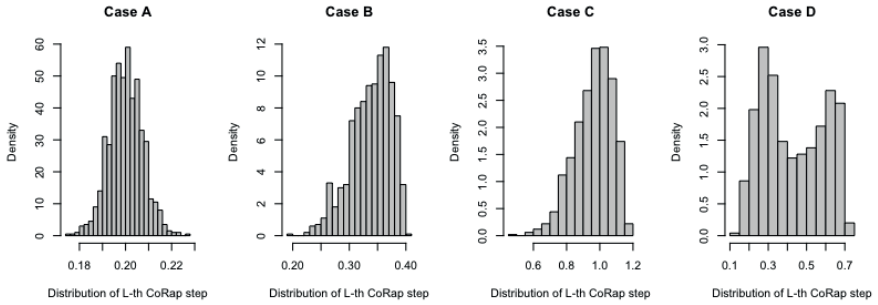

Fig. 2 Histograms of the distributions $\bar{\eta}_i(750)$, under ideal theoretical conditions (Case A) and the other three scenarios considered in the simulation study (B, C, and D).

Figure 1 displays the `CoRaP` for all the observations in the four datasets up to the NN order of $L = 750$. Similarly, Figure 2 reports the histograms of the distributions for $\bar{\eta}_i(L),\ \forall i$. In both figures, the remaining three panels illustrate characteristically different behaviors that the `CoRaP` might manifest in applications. From the top-right panel (Case B) in Figure 1, we notice how the inhomogeneity induced by the tails of the Normal distribution is reflected by a slight departure from the ground truth ($d = 1/5$) as L grows. The shift in the distribution is evident from the corresponding histogram (second panel) in Figure 2.
The bottom two panels (Cases C and D) in Figure 1 unveil more interesting patterns. The former describes data characterized by the same `id` but grouped in different clusters. The corresponding `CoRaP` capture this behavior showing a discontinuity point at $L = 500$. Similarly, the latter panel presents the case where the data possess more than one latent manifold: the resulting `CoRaP` are separated into two clusters, which is evident from the different starting points for low values of l. Each group presents well-behaved `CoRaP`, but pooling the data together produces misleading results (e.g., the overall ergodic mean is not representative of the data). The presence of multiple manifolds is also captured in the right panel of Figure 2: the resulting distribution presents multimodality.

4 Conclusion

In this paper, we introduced the `CoRaP`, a model-based, intuitive graphical summary of a dataset. Monitoring the evolution of the `CoRaP` allows to detect departures from the theoretical assumptions required by the `TWO-NN` and `Gride` models. In particular, we were able to detect the presence of different manifolds with heterogeneous `id`, which represents an important violation of the assumption. This result is a precious indicator that models tailored to identify, for a given dataset, the presence of multiple latent manifolds – each one with its own `id` – should be used. An example

of this type of models is `Hidalgo` [1]. We will extend and improve the preliminary results presented in this contribution. For example, the multimodality encountered in the last histogram of Figure 2 can be exploited to devise a fast algorithm for multiple `id` estimation leveraging on EM for mixtures of Gaussians. Moreover, the model-based nature of our results paves the way for the derivation of statistical tests concerning the topological structure of datasets.

Dimensionality reduction and visualization for interval-valued data via midpoints-ranges principal component analysis

Riduzione della dimensionalità per variabili a intervallo attraverso l'analisi delle componenti principali su centri e raggi

Viviana Schisa, Alfonso Iodice D'Enza, and Francesco Palumbo

Abstract Interval data proved to be a useful coding in big data applications since many individuals can be collapsed into a single unit, so that each cell of the table contains a bounded interval. This contribution presents the Principal Component Analysis (PCA) for interval-valued data based on midpoints and radii approach, where the symbolic standardization is used, along with an ad-hoc Procrustean rotation.

Abstract *I dati ad intervallo rappresentano una codifica efficiente di grandi quantità di dati: numerose osservazioni possono essere sintetizzate in una, che contiene l'intervallo dei valori osservati sulle singole osservazioni. Il presente contributo descrive l'analisi in componenti principali per dati a intervallo, basata sull'approccio centri-raggi e la standardizzazione simbolica.*

1 Introduction

In several statistical analysis problems, uncertainty and imprecision in the data suggest considering interval-valued variables instead of the more classical single-valued variables. There are also situations where data are natively recorded as intervals: e.g., describing a species of plants or animals, and more in general when the data refers to groups of units and not to single units [1]. Therefore, each single interval *datum* is represented by $[x] \equiv [\underline{x}, \overline{x}]$, $\overline{x} \geq \underline{x}$, and $\underline{x}$ and $\overline{x}$ indicate the min and max values of the interval. Then *interval algebra* approach postulates that the knowledge about the interval is limited to its extremes values, and from a geometric point of view, $[x] \subset \mathbb{R}$ (is a closed bounded interval in $\mathbb{R}$). The generic interval value $[x]_i$ is

Department of Political Sciences, Università degli Studi di Napoli Federico II, Naples, Italy

defined as

$$[x]_i = [\underline{x}_i, \overline{x}_i] \qquad\qquad i = 1, \ldots, n,$$

and can equivalently be represented in the center $x_i^c = \frac{1}{2}(\overline{x}_i + \underline{x}_i)$ and the range $x_i^r = \frac{1}{2}(\overline{x}_i - \underline{x}_i)$ notation. So the interval $[x]_i \equiv \{x_i^c, x_i^r\}$. The initial formalization of the PCA for interval data is by [8]: since then, several contributions into the interval-valued data analysis were published, and some of these are referenced in the following suggested reconsidering in a new light the MR-PCA. Recently, from the same authors, an article proposed a new MR-PCA algorithm that is a significant improvement of the method [4]. Moreover, it is worth mentioning that the routines of the new MR-PCA are now available written in the CRAN-R meta-language: no MR-PCA code was officially or unofficially delivered up to now.

The present contribution shortly summarizes the changes in the new MR-PCA algorithm (see for details [4]), and it reports a case study based on the well-known `abalone` dataset (`http://www.uci.edu/`).

2 Interval-valued variables pre-treatment

Data pre-treatment represents a crucial aspect in any factorial analysis. In classical PCA, the most classical pre-treatment consists in centering by the arithmetic mean $\bar{x}$ and scaling the variables by the standard deviation s. Therefore, all involved variables have the mean equal to 0 and variance and standard deviation equal 1. Moreover, scaling produces dimensionless variables and each principal component results as a weighted sum of the scaled variables. The classical pre-treatment cannot be adopted when dealing with interval-valued variables, namely centers and ranges. First, the definition of the classical standard deviation no longer applies to interval data; second, centers and ranges must be treated independently but consistently to reconstruct the best-approximated interval data on the factorial axes. In their revised MR-PCA, to pre-process interval-valued data consistently with their intrinsic nature, [4] used the definition of the *symbolic mean* and the *symbolic covariance matrix* Σ_{symb} for interval-valued variables [7], which guarantees advantages with respect to the original proposal.
Let $[\underline{x}_{ij}, \overline{x}_{ij}]$ be the interval-valued realization of the j-th variable for the i-th observation $(j = 1, ..., p;\ i = 1, ..., n)$, where $\underline{x}_{ij} \leq \overline{x}_{ij}$. Then the *symbolic* mean $\bar{w}_j$ and the *symbolic* variance $\sigma^2_{j_{symb}}$ of $[x]_j$ are defined according to the following formulae:

$$\overline{w}_j = \frac{1}{2n}\sum_{i=1}^{n}(\underline{x}_{ij} + \overline{x}_{ij}) \ \text{ and } \ \sigma^2_{j_{symb}} = \frac{1}{3n}\sum_{i=1}^{n}(\underline{x}^2_{ij} + \underline{x}_{ij}\overline{x}_{ij} + \overline{x}^2_{ij}) - \overline{w}^2_j. \qquad (1)$$

It is worth noting that $\bar{w}_j$ corresponds to the mean of the midpoints for the j-th variable. The variance (1) can be extended to the bivariate case for the covariance for j and j':

$$\sigma_{jj'_{symb}} = \frac{1}{6n}\sum_{i=1}^{n}[2(\underline{x}_{ij}-\bar{w}_j)(\underline{x}_{ij'}-\bar{w}_{j'}) + (\underline{x}_{ij}-\bar{w}_j)(\bar{x}_{ij'}-\bar{w}_{j'}) + (\bar{x}_{ij}-\bar{w}_j)(\underline{x}_{ij'}-\bar{w}_{j'}) + 2(\bar{x}_{ij}-\bar{w}_j)(\bar{x}_{ij'}-\bar{w}_{j'})] \quad (2)$$

Then, the *symbolic covariance matrix* Σ_{symb} has diagonal and extra diagonal elements (1) and (2), respectively.
Let $\tilde{\mathbf{X}}^c$ and $\tilde{\mathbf{X}}^r$ be the midpoint and range matrices $(n \times p)$; in the following $\mathbf{X}^c$ and $\mathbf{X}^r$ denote the centered versions. We propose the *symbolic standardization* of the midpoints and radii as follows:

$$\mathbf{Z}^c = \mathbf{X}^c\mathbf{S}^{-1} = \left(\tilde{\mathbf{X}}^c - \frac{1}{n}\mathbf{1}\mathbf{1}'\tilde{\mathbf{X}}^c\right)\mathbf{S}^{-1};$$
$$\mathbf{Z}^r = \mathbf{X}^r\mathbf{S}^{-1} = \left(\tilde{\mathbf{X}}^r - \frac{1}{n}\mathbf{1}\mathbf{1}'\tilde{\mathbf{X}}^r\right)\mathbf{S}^{-1},$$

where $\mathbf{S}$ is a diagonal matrix and $s_{jj} = \sqrt{\sigma^2_{jj_{symb}}}$, for $j = 1, \ldots, p$.

3 Centers and ranges joint representation on the factors

The other relevant issue in interval-valued variables PCA is the interval data reconstruction into the factor space. To this aim, several approaches have been proposed in the literature [2, 3, 5, 7]. The leading principle in the MR-PCA consists in assuming that the position of each interval data on the factor space depends on the center only. As a consequence, the ranges must be represented as supplementary information in the way that it must be as much as possible consistent with the centers factor subspace. Then the standardized and centered ranges are projected after a suitable rotation that maximize the Tucker congruence index. The revised version proposes a more efficient and more consistent algorithm starting from the one introduced by [8], but maximizing the average congruence [10] with respect to all factors (and not just with the first one, as in the first version).
The rotation matrix $\mathbf{T}$ is such that $\mathbf{Z}^c$ is as close as possible to the rotated version of $\mathbf{Z}^r$. Therefore the definition of $\mathbf{T}$ is obtained solving the following constrained optimization problem:

$$\begin{aligned} \min_{\mathbf{T}}: \quad & tr\left(\mathbf{Z}^c - \mathbf{Z}^r\mathbf{T}\right)\left(\mathbf{Z}^c - \mathbf{Z}^r\mathbf{T}\right)' \\ & tr\left(\mathbf{Z}^c\mathbf{Z}^{c\prime}\right) + tr\left(\mathbf{Z}^r\mathbf{T}\mathbf{T}'\mathbf{Z}^{r\prime}\right) - 2tr\left(\mathbf{Z}^{c\prime}\mathbf{Z}^r\mathbf{T}\right) \quad s.t. \quad \mathbf{T}\mathbf{T}' = \mathbf{I}. \end{aligned} \quad (3)$$

It is easy to see that the problem in (3) can be re-written as

$$\max_{\mathbf{T}}: tr\left(\mathbf{Z}^{c\prime}\mathbf{Z}^r\mathbf{T}\right) \qquad s.t. \qquad \mathbf{T}\mathbf{T}' = \mathbf{I}, \quad (4)$$

which is equivalent to the maximize the correlation coefficient among the columns of the centers matrix and the corresponding columns of the ranges matrix:

$$\sum_{j=1}^{p} \frac{\mathbf{t}_j' \mathbf{Z}^{r\prime} \mathbf{z}_j^c}{(\mathbf{t}_j' \mathbf{Z}^{r\prime} \mathbf{Z}^r \mathbf{t}_j)^{1/2} (\mathbf{z}_j^{c\prime} \mathbf{z}_j^c)^{1/2}},$$

where $\mathbf{t}_j$ and $\mathbf{z}_j^c$ are the j-th column of the $n \times p$ matrices $\mathbf{T}$ and $\mathbf{Z}^c$, respectively. The solution of the optimization problem in (4) is obtained via the iterative procedure proposed by [6].
The coordinates for centers (midpoints) and ranges (radii) are

$$\boldsymbol{\Psi}^c = \mathbf{Z}^c \mathbf{U}_{(d)}^c \quad \text{and} \quad \boldsymbol{\Psi}^r = \mathbf{Z}^r \mathbf{T} \mathbf{U}_{(d)}^r,$$

where $\mathbf{U}_{(d)}^c$ and $\mathbf{U}_{(d)}^r$ are the first d columns of the eigenvector matrices of $\mathbf{Z}^{r\prime}\mathbf{Z}^r$ and $\mathbf{Z}^{r\prime}\mathbf{Z}^r$, respectively.
The projection of the i^{th} range on the α^{th} component is

$$\psi_{i,\alpha} = [(\psi_{i\alpha}^c - \psi_{i\alpha}^r), (\psi_{i\alpha}^c + \psi_{i\alpha}^r)],$$

where $\psi_{i,\alpha}^c$ and $\psi_{i,\alpha}^r$ are the coordinates of the i^{th} center and range on the α^{th} axis. Finally, for interval-valued data the analogue of the PCA relative contributions is given by

$$ctr\_rel_{i\alpha} = \frac{\sum_\alpha (|\psi_{i,\alpha}^c| + |\psi_{i,\alpha}^r|)^2}{\sum_{j=1}^{p} (|z_{i,j}^c| + |z_{i,j}^r|)^2}.$$

4 Application: Abalone data set

The `abalone` data set consists of 4177 observations described through 9 variables: sex (discarded), length, diameter, height, whole weight, shucked weight, viscera weight, shell weight, and number of rings. The observations were aggregated according to the number of rings of each abalone. Note that rings indicate the age of the mollusk and that some groups consist of only one sample implying that units are characterized by *tiny (degenerated) intervals* [8] in the available data set. The example shows that tiny intervals do not impact the analysis feasibility.

For the sake of space, the article reports only the most significant results; in particular, the attention focuses on the first factorial plane plots. To illustrate the MR-PCA results on the Abalone data set, it is worth starting from the maps of the loadings in Figure 1, where arrows represent loadings and the spread of the maps is proportional to the overall variability accountable to centers and ranges, respectively. The more significant proportion of variability comes from the centers. The left-hand side plot in Figure 1 helps to understand the centers' correlation structure and explain the units positioning in Figure 2. In contrast, the right-hand side plot

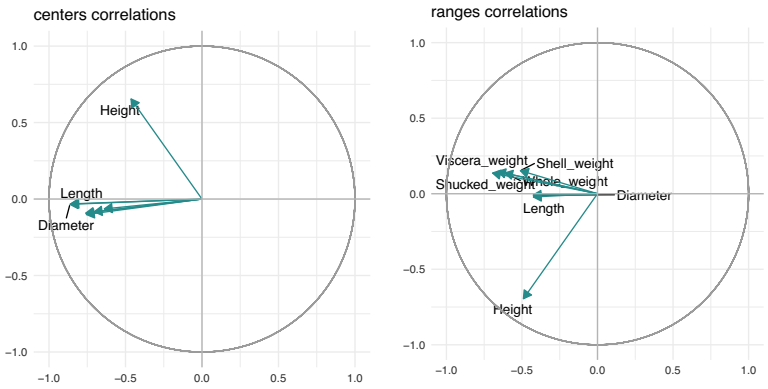

Fig. 1 Symbolic covariance-based standardization: two-dimensional maps of the centers (midpoints) and ranges (radii) loadings.

shows ranges' correlation structure and their orientations and lengths in the plot. In Figure 2, rectangles transparency refers to the quality of the representation, measured by the ratio between the length of the projections of the rotating range and the original length of the standardized range. In this example, the centers-ranges correlation structure allows for high values of quality of the representation on the first two dimensions. Looking at the MR-PCA map, the ranges orientations on the factorial plan allow tracing back the variations to the source variables: e.g., *rings8* and *rings10* ranges have the same direction meaning that they depend on the same variables; *rings3* and *rings8* ranges have opposite orientations. Returning on the un-

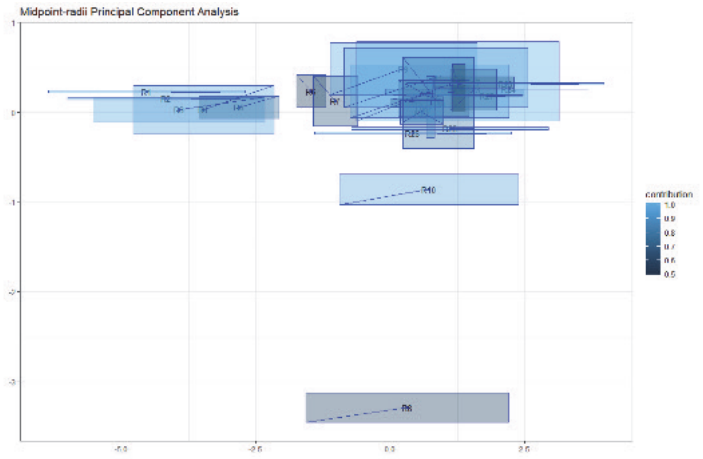

Fig. 2 MR-PCA: observations map (82.90% explained inertia). Procrustean rotation of ranges. Darker rectangles indicate lower relative contributions

rotated ranges representations and having the ranges correlations map, it is possible to identify the variables that have mainly affected the range length and orientations.

5 Concluding remarks and future perspectives

Before the contributions of the Symbolic Data Analysis group [1], at the end of the nineties, the treatment of interval-valued variables was relegated to some applications in the numerical analysis to deal with the round-off error caused from the fixed-point CPUs [9]. Uncertainty and imprecision were and still are, treated under the fuzzy logic paradigm [11]. However, the quick growth of the available data is inducing new interest through interval data analysis. In particular in the processes control. The number of citations to the early papers focused on PCA for interval-valued variables proves it. This new interest also touched our sensibility. First, we realized that software to perform the MR-PCA does not exist; second, we realized that the methodology needed a revision. The article[4] introduces these novelties. However, to validate the efficacy and the consistency, new theoretical results are expected, accompanied by empirical evidence, as the present contribution is.

Data-driven design-based mapping of forest resources

Mappatura di risorse forestali in approccio da disegno

S. Franceschi, R.M. Di Biase, L. Fattorini, M. Marcheselli and C. Pisani

Abstract The mapping of forest resources in a study region is approached when the region is partitioned into spatial units by means of a completely data driven, design-based sampling strategy. When auxiliary variables are available for all the units, the prediction of the densities of an interest attribute can be performed by using an assisting model. Under these circumstances, the model residuals are interpolated using the inverse distance weighting interpolator with a data-driven smoothing parameter selection, and the density of the attribute for each unit is obtained by summing prediction and interpolated error. Finally, densities are rescaled to match the traditional total estimate with the sum of mapped values. The uncertainty is accounted for by a bootstrap procedure. A simulation study is performed and a case study is presented.
Abstract *La mappatura di risorse forestali per le unità spaziali che compongono una regione di studio viene affrontata con un approccio data-driven basato sul disegno. Se sono disponibili variabili ausiliarie, la previsione del valore dell'attributo di interesse può essere effettuata con strategie assistite da modello. I residui del modello vengono previsti utilizzando l'interpolatore inverse distance weighting dove il parametro di smorzamento viene selezionato con una procedura data-driven e le densità dell'attributo vengono ottenute sommando le previsioni e gli errori interpolati. Inoltre le densità vengono riscalate in modo tale che la stima del totale ottenuta sommando i valori previsti coincida con quella ottenuta con approcci tradizionali. L'incertezza delle stime è valutata attraverso una procedura bootstrap. Uno studio di simulazione viene effettuato e viene presentato un caso di studio.*

1 Introduction

Wall-to-wall maps of forest attributes are essential information sources for forest management and most of the methodologies applied for mapping rely on model-based inference, owing to the impossibility to estimate values at non-sampled units without any assumption.

We present an alternative approach to forest mapping, in which an assisting model is used, but uncertainty stems from the adopted sampling scheme, in accordance to a model-assisted perspective [1]. However, any interpolator adopted for mapping can achieve statistical soundness only if it is proven to be design-based asymptotically unbiased and consistent (DBAU&C). Conditions ensuring DBAU&C, derived by [3] for finite populations of spatial units when the sole spatial information is available, are extended to allow for the exploitation of auxiliary sources of information, such as those provided by satellites and aircraft-based sensors, available for each spatial unit (e.g., pixels) partitioning the study area.

In particular, we propose a completely data-driven, design-based strategy for mapping forest attributes. The first step is the selection of a model using an Akaike-type criterion for choosing an appropriate set of available auxiliary variables. Using the least-squares method, the predictions of the attribute densities are obtained for each spatial unit. Then, the inverse distance weighting (IDW) interpolator, which relies on Tobler's first law of geography [9], is adopted for interpolating the residuals for non-sampled units on the basis of the residuals that are known for each sampled unit. Following [5], the leave-one-out cross-validation is used to select the smoothing parameter adopted in the IDW interpolator. Subsequently, the interpolated values at non-sampled units are obtained by summing model predictions and interpolated residuals.

Finally, we rescaled the resulting densities in such a way that the total obtained from the interpolated values matches traditional total estimates [7]. Moreover, a bootstrap technique is used to estimate relative root mean squared errors of the predicted values.

2 Data-driven mapping

Consider a study area partitioned into N spatial units and suppose to be interested in the reconstruction of the whole map of the spatial population, that is the estimation of the density of an interest attribute for each spatial unit, by using a suitably selected sample of units. It is worth noting that usually the size of the spatial units are known and therefore the estimation of the density is theoretically equivalent to the estimation of the total amount in each spatial unit. Furthermore, suppose that a large set of covariates is available, as it is common in forest inventories. To select the assisting model for obtaining predictions, we performed a variable selection using an Akaike-type criterion, as suggested by [2]. Indeed, strongly correlated auxiliary

variables can induce instability in the model while they can exhibit a poor prediction capability when weakly correlated to the interest variable.

Let f_j and $\mathbf{x}_j$ respectively be the density of the interest attribute and the vector of selected covariates for spatial unit j, in such a way that densities can be expressed as $f_j = \boldsymbol{\beta}^t \mathbf{x}_j + e_j(\boldsymbol{\beta})$. The choice of $\boldsymbol{\beta}$ can be made using a least-square criterion to minimize the residual sum of squares. Denoting by $\mathbf{b}$ the ordinary least-squares solution for $\boldsymbol{\beta}$, if $\mathbf{b}$ was known, the residuals for each sampled unit would be $e_j(\mathbf{b}) = f_j - \mathbf{b}^t \mathbf{x}_j$, while the residuals for non-sampled units could be obtained using the IDW interpolator. In particular, the j-th interpolated residual would be given by

$$\hat{e}_j(\mathbf{b}) = Z_j e_j(\mathbf{b}) + (1 - Z_j) \sum_{i=1}^{N} w_{i,j}(\alpha) e_j(\mathbf{b})$$

where Z_j is equal to 1 when the j-th unit is sampled and 0 otherwhise and $w_{ij}(\alpha) = Z_i d_{i,j}^{-\alpha} / \sum_{l=1}^{N} Z_l d_{l,j}^{-\alpha}$, with $d_{i,j}$ denoting the distance between the centroid of unit i and unit j, and $\alpha > 2$ is the smoothing parameter. As consequence, the resulting interpolated value for the density for unit j would be $\hat{f}_j(\mathbf{b}) = \mathbf{b}^t \mathbf{x}_j + \hat{e}_j(\mathbf{b})$.

Unfortunately, the least-square solution $\mathbf{b}$ is unknown, involving the knowledge of the density for each unit. Nevetherless, as suggested by [8], an estimate $\hat{\mathbf{b}}$ can be obtained as a function of Horvitz-Thompson estimators. Then, IDW interpolation can be performed with $\mathbf{b}$ replaced by its sampling estimator $\hat{\mathbf{b}}$ on the basis of the observed residuals $e_j(\hat{\mathbf{b}}) = f_j - \hat{\mathbf{b}}^t \mathbf{x}_j$ so that the interpolated densities are given by $\hat{f}_j(\hat{\mathbf{b}}) = \hat{\mathbf{b}}^t \mathbf{x}_j + \hat{e}_j(\hat{\mathbf{b}})$.

As to the asymptotic properties, $\hat{f}_j(\hat{\mathbf{b}})$ is consistent because, as the extent of the spatial units partitioning the study area decreases and their number increases, $\hat{\mathbf{b}}$ converges to $\mathbf{b}$ and, consequently, $\hat{f}_j(\hat{\mathbf{b}})$ converges to $\hat{f}_j(\mathbf{b})$, which in turn is DBAU&C under conditions derived in [3]: i) the existence of a Riemann integrable function giving the density of the interest attribute at any point of the study area; ii) some sort of regularity in the shape of the spatial units; iii) the use of an asymptotically balanced spatial sampling scheme. Commonly adopted sampling schemes ensuring DBAU&C are simple random sampling without replacement, one-per-stratum stratified sampling and systematic sampling.

Moreover, the IDW interpolator depends on the smoothing parameter α determining the roughness of the surface of interpolated residuals. As suggested by [5], the value of α can be selected by means of the leave-one-out cross-validation and the corresponding IDW interpolator is proven to remain DBAU&C.

Finally, it is worth noting that, in a design-based setting, the total of the interest attribute is commonly estimated by traditional estimators, such as the regression estimator, which necessarily give rise to different total estimates with respect to the one achieved by summing the interpolated values for all the spatial units. To obtain non-discrepant results, a harmonization of the estimated map can be achieved by rescaling density estimates in analogy with [7].

As to the evaluation of precision, each step of the proposed mapping strategy (Akaike-type selection of the assisting model, choice of the smoothing parameter and harmonization of maps with the total estimate) should be considered, since all

of them are sample dependent. The use of bootstrap seems to be the sole way for facing the complexity of this data-driven mapping procedure. More precisely, the map of the interpolated values is taken as a pseudo-population from which bootstrap samples are drawn using the same sampling scheme adopted to produce the original sample, as suggested by [5] and [4]. Under the conditions ensuring DBAU&C, the estimated map converges to the true map, so that the bootstrap distribution should converge to the true distribution, also providing consistent estimators of its mean squared errors.

3 Simulation study

The performance of the proposed data-driven mapping strategy was empirically assessed by means of a simulation study performed on a real survey region located in Calabria (Southern Italy). The values of several auxiliary variables and the value of growing stock volume (interest attribute) were available for each pixel partitioning the study region.

In order to check the improvement as the number of pixels partitioning the study area increases and their size become smaller, the study area was partitioned considering three different pixels sizes and the values of interest and auxiliary attributes were aggregated within those pixels.

From each of the three partitions, $10,000$ samples were independently selected by means of one-per-stratum sampling (OPSS) with a constant sampling fraction of 4%. For each sample, selection of auxiliary variables was performed, the growing stock volume estimate for each pixel was derived by using the IDW interpolator, where the value of the smoothing parameter was obtained by means of leave-one-out cross-validation and, finally, harmonization was implemented. Furthermore, for each simulation run, $1,000$ bootstrap samples were selected from the estimated map by the same OPSS scheme adopted for extracting the original sample, then bootstrapped maps were used to achieve the bootstrap root mean squared error estimates. From the resulting Monte Carlo distributions, several perfomance indexes were computed. Results show that usually 4 or 5 covariates are selected out of the 11 originally available, suggesting that the selecting rule is likely to choose parsimonious models. Also for the choice of the smoothing parameter, small values are the most commonly selected, probably owing to the smoothness of the error surfaces to be interpolated (see Fig. 1). Furthermore, relative bias values and relative root mean squared errors quickly decrease in minima, means and maxima as the spatial grain decreases, with a balance between underestimation and overestimation, showing also a relevant spatial autocorrelation of negative and positive values (see Tab. 1).

As to the bootstrap root mean squared error estimator, underestimation seems to be prevalent. Nevertheless, its tendency to be conservative is more apparent as the spatial grain decreases. Indeed, the number of pixels in which the ratio between the expectation of the bootstrap root mean squared error estimator and the true root

Table 1 Minima, means and maxima of the absolute bias (AB), root mean squared errors (RMSE) and its ratio with the expectation of bootstrap root mean squared error (RAT) achieved for the three populations considered in the simulation study.

	AB			RMSE			RAT		
POP	MIN	MEAN	MAX	MIN	MEAN	MAX	MIN	MEAN	MAX
POP1	0.381	27.400	86.010	28.86	58.59	133.80	0.348	0.652	0.919
POP2	0.038	22.770	81.215	12.93	35.99	92.29	0.221	0.592	1.100
POP3	0.003	14.243	65.035	6.00	23.43	73.88	0.263	0.730	1.809

mean squared error is greater than 1 increases as the spatial grain decreases. It is probable that with a thinner partition conservativeness over the whole area can be achieved.

4 Case study

The proposed mapping strategy was applied to provide the map of densities of wood volume in the forest estate of Rincine (Central Italy), an area partitioned into square cells of $23 \times 23m^2$. For each cell, the values of several auxiliary variables were available. For sampling purposes, the area was partitioned into 50 blocks of cells and, following OPSS, one cell was randomly selected within each block, determining a sample of 50 units. The wood volume of each tree in the selected cells was reckoned to achieve the wood volume density by three size classes: small, medium and large trees.

For each class, variable selection was performed using the procedure adopted in the simulation. Mapping was performed for each size class harmonizing the total of the interpolated values with the regression estimates of the total over the whole survey area. Subsequently, the three estimated maps were taken as pseudo-populations

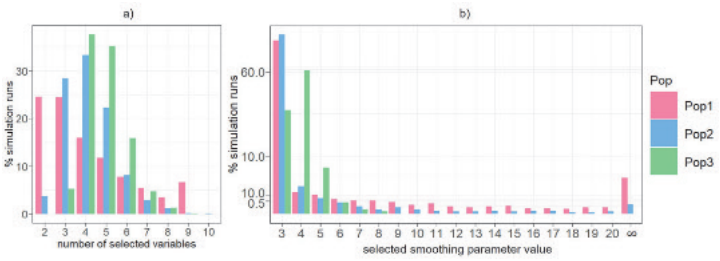

Fig. 1 For each of the three considered populations a) frequencies (expressed as percentage of the number of simulation runs) of the number of variables adopted in the predicting model; b) frequencies (expressed as percentage of the number of simulation runs) of the selected smoothing parameter.

from which 10,000 bootstrap samples were selected by the OPSS scheme adopted to select the original sample. From each bootstrap sample, the three bootstrap maps were achieved for each class repeating the usual steps and the total map was achieved by sum. Then, bootstrap root mean squared errors were computed for each of the four maps. Bootstrap samples were also adopted to achieve the bootstrap root mean squared error of the regression estimator, incorporating uncertainty determined from the variable selection.

The maps of estimated densities within cells show a relevant level of uncertainty for small trees that decreases for medium trees and becomes satisfactory for large trees and for the total. High uncertainty for small trees is mainly due to the high variability in the number of small trees (many of which from scattered forest natural regeneration) within the selected cells, with many cells with 0 small trees and few with more than 150 trees. Consequently, as expected (see e.g. [6]), the precision is deteriorated by the highly clustered spatial pattern.

In order to highlight the improvement when exploiting auxiliary sources of information, those maps were compared to those obtained using the sole spatial information and selecting the value of the smoothing parameter from data as in [5]. From this comparison it is evident that the proposed mapping strategy reduces the excessive smoothing produced by IDW interpolation based on the sole spatial information.

5 Final remarks

Despite being data-driven, the proposed mapping strategy is based on several subjective choices, such as the choice of the linear model for performing regression and the choice of the criterion for implementing the leave-one-out cross-validation. However, it should be also noticed that these choices only impact on the sample statistics adopted for mapping, while the precision of the map is objectively determined by the sampling scheme used for selecting the units partitioning the study area.

A further issue is that two-phase sampling schemes are usually adopted in forest inventories, whereas one-phase OPSS was here proposed. However, [4] proved the consistency of the IDW interpolator if the two-phase scheme continues to provide spatially balanced samples. As consequence, the procedure can be applied also in two-phase large-scale forest inventories.

The proposed design-based, data-driven strategy for mapping forest resources exploiting auxiliary variables, guides the user from the preliminary choice of the assisting model to the final map and the estimation of its precision, through model selection, exploitation of selected covariates for mapping, choice of the smoothing parameter for IDW interpolation, harmonization with traditional estimates of totals and bootstrap resampling from the estimated map. Moreover, this strategy seems to be suitable also for mapping environmental attributes besides forestry.

Ensemble model output statistics for temperature forecasts in Veneto

Ensemble model output statistics per la previsione delle temperature in Veneto

Gaetan Carlo, Giummolè Federica, Mameli Valentina, Siad Si Mokrane

Abstract Post-processing methods are nowadays widely used for limiting the impact of errors in ensemble forecast of meteorological variables. Ensemble model output statistics are an easy-to-apply technique for post-processing, based on a linear regression model. In this paper we use an ensemble model output statistic for the forecast of daily maximum temperatures in Veneto. We calculate estimative and calibrated predictive distributions for a time period of three years. We then compare the different predictive distributions by means of the log-score, the continuous ranked probability score and the coverage of the corresponding predictive quantiles. We show that the calibrated approach improves on the estimative ones as regards both mean scores and coverage probabilities.

Abstract *Al giorno d'oggi, metodi di post-processing vengono ampiamente utilizzati per limitare l'impatto di errori nelle previsioni di variabili meteorologiche che utilizzano ensemble. Gli ensemble model output statistics sono una tecnica di post-processing basata sul modello di regressione lineare. Nel nostro lavoro li abbiamo utilizzati per la previsione delle temperature massime giornaliere in Veneto. Abbiamo calcolato diverse distribuzioni predittive estimative e calibrate per un periodo di tre anni e le abbiamo confrontate fra loro utilizzando log-score, continuous ranked probability score e probabilità di copertura dei rispettivi quantili. I risultati mostrano la superiorità delle distribuzioni predittive calibrate rispetto alle corrispondenti distribuzioni estimative, secondo tutti i criteri considerati.*

1 Introduction

Weather predictions are a critical component of decision support for a wide variety of applications. As a result, there is a significant demand for accurate weather predictions from a diverse variety of stakeholders, including the general public, the corporate sector, and government agencies that issue weather warnings. Forecasts have gradually improved over the previous decades, partly due to breakthroughs in numerical weather prediction (NWP) ([1]; [8]). The advancement of powerful high-performance computers enables more detailed weather simulations. Despite these advances in NWP, forecasts generated by physics-based models, usually provided as forecast ensembles, exhibit systematic bias and are often underdispersive ([2], [7]). Statistical post-processing methods are nowadays widely used for further refining, improving, and calibrating NWPs. The ensemble model output statistics (EMOS, [5]) is among one of the most popular post-processing techniques used to calibrate the ensemble forecasts. EMOS is based on a simple regression model with parameters depending on the ensemble forecasts. It is able to correct for systematic biases and dispersion errors.

This article proposes an adjustment of EMOS based on a bootstrap calibration procedure proposed by [3] and further extended to the EMOS context in [4]. In order to evaluate the performance of the calibrated EMOS and develop a comparison with the classic EMOS, we consider a real case study dealing with maximum daily temperatures at measurement sites located in the Veneto region, northern Italy. The evaluation and comparison of methods are based on measures of goodness for calibration and sharpness, the most desirable properties that characterise predictive models [6]. In particular, we compare different predictive models by means of the log-score, the continuous ranked probability score (CRPS) and the coverage of the corresponding predictive quantiles. These analyses exhibit the accuracy of the calibrated EMOS, with respect to the classic EMOS, in the presented application, and highlight the great potentiality of this new technique to provide calibrated and sharp predictive models.

The paper is organised as follows. In Section 2 we outline the methodology employed in this research. In Section 3 we introduce the data and we assess the performance of the calibrated EMOS in comparison with the classic EMOS. Finally, in Section 4 we present some concluding remarks.

2 The method

The most popular post-processing techniques used to calibrate the ensemble forecasts are EMOS that allow for probabilistic forecasts of weather variables ([5]) in the form of Gaussian predictive distributions. More formally, it is assumed that a weather variable Z depends on the ensemble forecasts $X_1, \ldots, X_m$ in such a way that its mean is equal to $\beta_0 + \beta_1 X_1 + \ldots + \beta_m X_m$ and its variance is equal to $\gamma + \delta S^2$, where $S^2 = \frac{1}{m-1} \sum_{i=1}^{m} (X_i - \bar{X})^2$ denotes the ensemble variance and $\beta_1, \ldots, \beta_m$, γ and

δ are non-negative unknown coefficients. Therefore, under normality assumptions, the distribution of Z is $N(\beta_0+\beta_1X_1+\ldots+\beta_mX_m, \gamma+\delta S^2)$.

For fitting the unknown EMOS coefficients, $\beta_0, \beta_1, \ldots, \beta_m, \gamma, \delta$, [5] proposed to use the method of minimum CRPS estimation, which finds the estimates by minimising the CRPS. The CRPS estimates are then substituted to the unknown parameters in the EMOS normal distribution obtaining what is known as an estimative distribution for the future weather quantity Z. In the introduction we have referred to this procedure as the classic EMOS. Here we also consider for comparison the EMOS estimative distribution obtained with the maximum likelihood estimates (MLE), that minimises the log-score. Unfortunately, estimative distributions may perform poorly, especially when the sample size is small with respect to the number of members of the ensemble. In particular, the important requirement of calibration is hardly attained by estimative distributions. As explained in [6], calibration is a sort of consistency between a predictive distribution and future observations and it can be graphically assessed by means of the histogram of the probability integral transformed (PIT) values. Moreover, a well calibrated predictive distribution provides prediction limits with coverage probability close to the nominal value.

In order to obtain calibrated predictive distributions, we consider the approach presented by [3] and recently adapted to the EMOS context by [4] that propose a simple simulation experiment. Suppose that we want to make prediction on the unobservable variable Z with distribution $G(z;\theta)$ depending on an unknown parameter θ. In our case $Z \sim N(\beta_0+\beta_1X_1+\ldots+\beta_mX_m, \gamma+\delta S^2)$, so that $\theta=(\beta_0,\beta_1,\ldots,\beta_m,\gamma,\delta)$. Let $\hat{\theta}$ be the MLE for θ or an asymptotically equivalent alternative, such as the CRPS estimator, based on an observed sample.

A suitable adjustment of the classic EMOS that yields calibrated predictive distributions can be obtained using the following simple bootstrap procedure:

$$G^{boot}(z;\hat{\theta}) = \frac{1}{B}\sum_{b=1}^{B} G\{z_\alpha(\hat{\theta}^b);\hat{\theta}\}|_{\alpha=G(z;\hat{\theta})}, \tag{1}$$

where $z_\alpha(\theta)$ denotes the α-quantile of Z and $\hat{\theta}^b$, $b=1,\ldots,B$, are the estimates obtained by a parametric bootstrap from the estimative distribution of Z. The goodness of the approximation depends on the efficiency of the bootstrap simulation procedure. We also note that in the case under study it is straightforward to draw random samples and calculate quantiles and probabilities from normal estimative distributions. This makes the bootstrap calibration procedure very easy to apply for improving on EMOS estimative distributions.

3 A case study

For this study, we focus on maximum daily temperature forecasts at surface stations in the Veneto region, northern Italy. Our period of interest spans 3 years from 16 August 2009 to 17 August 2012. Historical maximum daily tempera-

ture forecasts were acquired from the website of the Italian national system for the collection, processing and dissemination of climate data, created by ISPRA (http://www.scia.isprambiente.it/). Ensemble predictions were available from World Climate Research Programme. We use the Coupled Model Intercomparison Project Phase 6 system (CMIP6) that consists of over 100 models of which 29 ensemble members cover the Veneto region. The data in the CMIP6 archive are downscaled to station level using elevation as a base for interpolation. In order to assess and compare the performance of different EMOS predictive distributions, we analyse maximum daily temperatures for the station Cavallino-Treporti (Longitude: 12.48642°, Latitude: 45.45805°), located on the Venetian lagoon. After removing missing observations from the selected station, the sample contains 1091 observations of daily temperatures and 26 ensemble members. According to [5], we use a sliding window of 40 observations as training set, with the remaining 1051 days available as test set. In this temporal window the generating process is supposed to be stationary. First, the EMOS parameters are estimated by optimising both the log-score and the CRPS over the sliding training period. Then, for each of the 1051 days available as test set, the performance of the two estimative distributions obtained by estimating with the log-score and the CRPS, and the corresponding calibrated distributions, are evaluated by means of different measures of goodness for calibration and sharpness. Table 1 summarises the mean and standard deviations of the log-score and the CRPS for the four predictive models. The superior performance of the calibrated models is reflected in the smaller values of the two scores.

Table 1 Log-score and CRPS values of the four predictive distributions. Standard errors in brackets. Est log denotes the estimative EMOS with log-score estimates and Est CRPS the estimative EMOS with CRPS estimates, while Cal log and Cal CRPS are the respective calibrated counterparts.

	Est log	Cal log	Est CRPS	Cal CRPS
Log-score	3.22	2.51	3.65	2.58
	(0.09)	(0.03)	(0.14)	(0.06)
CRPS	1.79	1.64	1.82	1.66
	(0.05)	(0.04)	(0.05)	(0.04)

For properly measuring calibration and sharpness (concentration) of the different predictive models, we have also obtained coverage probabilities and mean lengths of central intervals of level 66.7% (Table 2). Moreover, the coverage probability of upper prediction limits of levels 90%, 95% and 99% for the different predictive models have been obtained, being fundamental quantities for the evaluation of environmental risk (Table 3). The effect of calibration can be clearly seen from coverage probabilities for calibrated predictive models, much closer to target values than those for the estimative ones. Of course, shorter central prediction intervals for the estimative models are due to the loss of corresponding coverage.

Finally, Figure 1 shows the PIT histograms for the four considered predictive models. The effect of calibration can be observed in the flat histogram very close to the uniform one for the calibrated predictive models. Instead the U-shaped

histograms of the estimative models are the consequence of the excessive underdispersion.

Table 2 Coverage probabilities and mean lengths of the central prediction interval of level 66.7% for the estimative predictive models with MLE and CRPS estimates, and corresponding calibrated models. Standard errors in brackets. Est log denotes the estimative EMOS with MLE estimates and Est CRPS the estimative EMOS with CRPS estimates, while Cal log and Cal CRPS are the respective calibrated counterparts.

4 Conclusions

This work proposes a comparison between the classic EMOS and a calibrated EMOS based on a bootstrap procedure, applied to a real case study of temperatures in the Veneto region, Italy. In particular, we have used measurements from a single station, Cavallino-Treporti, in the Venice lagoon. Future work will consider a spatial analysis of temperature data collected all over the Veneto region, including the coast around the Venice lagoon, the low Venetian plan and the Dolomite mountains. Indeed, the Veneto region's height fluctuates from sea level (and also below sea level) up to about 3,300 m, with a corresponding wide variation in the temperatures.

State of the urban Environment in Italy. A comparative analysis of selected composite indicators

Lo Stato dell'ambiente urbano in Italia. Analisi a confronto per la selezione degli indicatori sintetici

Lecardane Giuseppe, Istat, lecardan@istat.it

Abstract The consequences of climate change, depletion of water resources, urban pollution and other environmental crisis involve all the contexts in which human activity is expressed. In this paper, main statistical methods are compared for the synthesis of representative indicators of the set of environmental phenomena. A multidimensional study that offers insights to subjects involved in development policies and environmental sustainability in the urban area.

Abstract *Le conseguenze dei cambiamenti climatici, il depauperamento delle risorse idriche, l'inquinamento urbano e le altre manifestazioni di crisi ambientale coinvolgono in modo trasversale tutti i contesti in cui si esprime l'attività umana. Nel presente lavoro sono messi a confronto alcuni principali metodi statistici per la sintesi di indicatori rappresentativi dell'insieme dei fenomeni ambientali per il monitoraggio delle città italiane. Uno studio multidimensionale che offre spunti di approfondimento a soggetti impegnati su politiche di sviluppo e sostenibilità ambientale nel territorio urbano.*

Key words: environment, synthetic index, urban area.

1. Introduction

Environment quality and social well-being are closely interconnected on a collective and individual level. It is, in fact, a relationship that invests values of primary importance, such as those relating to human health and safety, heritage and resources to be passed on to future generations. Therefore, statistical information, for an in-depth knowledge of environmental issues, it is relevant for everyone. The

[1] Lecardane Giuseppe, Istat; lecardan@istat.it

effectiveness of any action in the environmental field implies an awareness of citizens and the choice of appropriate behaviors. Complex and multidimensional nature of environmental phenomena requires the identification and measurement of indicators for the implementation of more effective and incisive information programs. Due to the number of indicators that represent the different dimensions of the state of the urban environment to be measured, it is also necessary to find a synthesis process to improve comparison and analysis of the observed phenomena. In fact, the synthesis has the advantage of performing simpler and faster analyzes especially in comparative terms and in addition of summarize heterogeneous and multidimensional phenomena.

In this paper, we will proceed to experimental comparison of some main weighting approaches for the composite indicator-construction methods referring to the data on urban environmental quality on issues such as water, air, energy, noise, waste, mobility and urban green for 110 provincial capitals (Istat, 2020).

The aim of this work is not to establish which approach is preferable to another but to analyze the robustness and sensitivity of the results from the different composite methods used. Analysis of the state of the urban environment therefore provides useful measuring tools with the appeal to an awareness of the need for a change of course towards planning a more urban sustainability.

The paper is structured as follows: description and application of the main composite methods used; comparison of the results obtained through cograduation matrices of the rankings, correlation matrices and dispersion matrices of the values obtained with the different methods; summary conclusions.

2. Methodology

The multidimensional nature of the phenomenon and its measurability through a system of elementary indicators allows the targeted construction of a composite technique which is able of acquiring the multiple aspects. Therefore, there is a need to experiment composite methods of elementary data to improve the measurement and communicability of the results.

To identify measurement model the *formative model* was followed, according to which individual indicators are causes of an underlying latent variable, rather than its effects, they are not interchangeable, and their correlations are not explained by the model. Regarding the latest data on the urban environmental (Istat 2020), a set of elementary indicators on environmental themes (water, air, energy, noise, waste, mobility, and urban green) were selected (Tab. 1). These indicators have a high variability and little correlation with each other, characteristics suitable to achieve the aims. It's the basis for the aggregation process through the construction and comparability of some main composite methods. Elementary indicators have been normalized and standardized to obtain data purified from units of measurement and comparison process.

Standardized deviation in the composite index allows the construction of a robust measure and not very sensitive to remove a single elementary index (Mazziotta et al., 2013).

Table 1: Environmental indicators selected, survey Istat "Environmental data of cities". 2020

Environmental Issues	Environmental indicators and polarity (+/-)
Water	a1(-). Household water bill per capita *(liters per day)* a2(-). Household water bill total per capita *(liters per day)* a3(-). Water network losses *(%)*

In addition, *polarity* (positive or negative) of the relationship between indicator and phenomenon was specified. Finally, standardized indicators were aggregated. Following, steps to calculate composite index by comparing the following methods.

Given the matrix $X=\{x_{ij}\}$ with n rows (units) and m columns (indicators), composite methods have the following mathematical properties:

Mean Z-scores *(MZ)*

$Mz_i = \frac{\Sigma_{j=1}^{m} z_i j}{m}$ $Z=\{z_{ij}\}$ transformed matrix for unit *i* and indicator *j*

con $z_{ij} = \pm \frac{(x_{ij} - M_{xj})}{s_{x_j}}$ if the indicator *j* has positive or negative polarity.

M_{xj} e S_{xj} arithmetic mean and deviation standard of indicator *j*.

The *MZ* allows transformation of indicators j into standardized deviations and aggregation with the arithmetic mean.

Mean R-Indices *(MR)*

$Mz_i = \frac{\Sigma_{j=1}^{m} r_{ij}}{m}$ $R=\{r_{ij}\}$ transformed matrix for unit *i* and indicator *j*

con $r_{ij} = \begin{cases} \frac{(x_{ij}-Min_{xj})}{(Max_{xj}-Min_{xj})} \\ \frac{(Max_{xj}-x_{ij})}{(Max_{xj}-Min_{xj})} \end{cases}$ Min_{xj} e Max_{xj} indicator *j*

The *MR* allows standardization with min-max method of the indicators j and aggregation with the arithmetic mean.

Adjusted MPI *(AMPI)*

$MPI_{ci}^{\pm} = M_{ri} \pm S_{r_i} cv_i$

con $r_{ij} = \begin{cases} \frac{(x_{ij}-Mi\ _{xj})}{(Max_{xj}-Min_{xj})} 60 + 70 \text{ if the indicator } j \text{ has positive polarity} \\ \frac{(Max_{xj}-x_{ij})}{(Max_{xj}-Min_{xj})} 60 + 70 \text{ if the indicator } j \text{ has negative polarity} \end{cases}$

$M_{r_i} = \frac{\Sigma_{j=1}^{m} r_{ij}}{m}$ $S_{r_i} = \sqrt{\frac{\Sigma_{j=1}^{m} (r_{ij}-M_{ri})^2}{m}}$ $cv_i = \frac{S_{ri}}{M_{r_i}}$

The *AMPI* is a non-compensatory (or partially compensatory) composite index and allows min-max standardization of the indicators j and aggregation with the arithmetic mean penalized by the "horizontal" variability of the indicators themselves. Normalized values are approximately in the range (70; 130), where 100 is the reference value[1].

3. Results

From the exploratory data analysis, indicators show a pronounced variability (many CV values are close to 1) and little correlated with each other (tabb. 2 and 3), characteristics suitable to achieve the aims. To identify a composite index that represents multidimensionality of the urban environment, some main methods were compared using the transformation of the indicators to obtain data purified from units of measurement and their variability. Figure 1 shows cartograms of the four approaches used in 110 provincial capitals. Result of the analysis is almost uniform for all methods, with the subdivision of decreasing territorial trialism Northern, Center and Southern Italy.

From the ranking of the four composite indicators, it is possible to observe the positioning of the Italian municipalities based on the state of environment which decreases towards the higher ranks. Trento has the best urban environmental performance while Catania is the city with the highest negative impact.

In ranking of the top five cities with low environmental impact, Bolzano, Sondrio, Mantova and Bergamo are also distinguished, cities of small and medium population size in Northern Italy. At the bottom of the ranking with a greater environmental pressure Isernia, Napoli, Frosinone and Campobasso in Southern Italy (Tab. 4). Table 5 shows rank differences compared by means of the absolute difference and Spearman's rank correlation coefficient. Sensitivity analysis shows similar results in the comparison between MR-MPIc$_+$ method and the MR-MPIc$_-$ method with absolute average rank differences 5.19 and 6.36 positions respectively with a strength of the relationship directly proportional and close to 1 (0.98 and 0.96). Linear relationship with R-values is very high too (fig. 2).

4. Conclusions

Study on the multidimensional aspects of the urban environmental through comparison of some composite methods offer an important contribution to the interpretation of the phenomenon. Geography of the environmental state and urban anthropic pressure highlights an unbalanced and negative configuration for most of

the southern cities. At the other end of distribution, higher environmental performances are recorded, especially in the northern small and medium-sized urban areas where investments in environmental projects are constantly growing.

A Functional Data Analysis approach for Climate Model Selection : the case study of Campania Region

Selezione di un modello climatico attraverso l'analisi dei dati funzionali: il caso di studio della Regione Campania

Villani V., Romano E., Mercogliano P.

Abstract In recent years climate projections are available in large number of applicative fields, so the difficulty lies in using them for climate change impact studies. The main aim of this work is to propose a Functional Data Analysis clustering strategy to select a single regional climate model. We will refer to climate projections available within the EURO-CORDEX program and select the one that has the best ability to simulate the observed climate in the studied area.

Abstract Dato il rapido aumento del numero di proiezioni climatiche disponibili negli ultimi anni e la difficoltà di utilizzarle tutte per gli studi sull'impatto del cambiamento climatico, l'obiettivo di questo lavoro è selezionare un unico modello climatico regionale, tra quelli disponibili nell'ambito del programma EURO-CORDEX, che abbia la migliore capacità di simulare il clima osservato nell'area di studio. A tal fine, è stata proposta una strategia di clustering per dati funzionali**.**

Key words: Climate changes, Impact studies, High-resolution climate projections, Functional Data Analysis

1 Introduction

The rapid increase in the number of available climate projections in recent years, especially by adopting high resolution climate models, and the difficulty (in terms of computation costs) in using all of them for the local assessment of climate change impacts studies, make crucial to select a subset of climate models representative of the area of interest. The use of the mean value (called the ensemble mean) of this subset for subsequent climate change impact studies is in direct conflict with the aim of evaluating extreme scenarios to be used in the context of such studies. In fact, in the ensemble mean of climate models, information on climate extremes could be lost. The aim of this work is to select a regional climate model, among those available under the EURO-CORDEX program (Hennemuth et al, 2017; Jacob et al, 2014; Jacob et al, 2020), which has the best skill in simulating the observed climate over the study area. To do this, we used Functional Data Analysis (FDA). Particularly, the FDA allowed us to study the commonalities and dissimilarities between the results of the various simulations and the trend of the station data. Such dissimilarities have been evaluated by calculating the functional distance between the coefficients of the first derivatives of the 18 functional simulations and of each of these with the coefficients of the first derivative of the observed functional data. Since, considering the coefficients of the first derivatives of the functional data, the distance is not influenced by the bias of the simulations considered. Hence, in the case where the calculated distance is small, the functional data show a similar form of temporal changes in the series. Subsequently, a cluster analysis was performed on the dissimilarity matrix obtained as mentioned above, and a characterization of the variability within the classes was performed to identify the simulation showing a more similar form of temporal changes in the series with respect to the time series of observations. The annual cumulative precipitation variable was used, both calculated with the daily series of station data available over the Campania region and with the data of 18 EURO-CORDEX models. As works of literature in which the FDA has been applied to climatological data we find: Holtanova et al. (2019) which used FDA to distinguish time series data related to climatology; Burdejová and Härdle (2019) have suggested a dynamic functional factor for the FDA of climatological data, including precipitation and temperature; Ghumman et al. (2020) which aims to answer the research question that what are the commonalities and dissimilarities in the observed data time series and the results of various GCMs. In this paper we want to show how this approach can be used to get insight into climate data modelling. The aim is to improve the process of climate models selection by comparing the mutual dissimilarities between simulations and observed data using a functional data analysis clustering approach.

2 Data description

This work is based on the use of observational datasets and high-resolution climate projections currently available on the Italian territory. Regarding these latter, CORDEX regional climate model (RCM) simulations for the European domain (EURO-CORDEX) at 0.11° resolution (~12 km) forced by different global climate models (GCM) were used. EURO-CORDEX is the European branch of the international CORDEX initiative, which is a program sponsored by the World Climate Research Program (WRCP, http://wcrp-cordex.ipsl.jussieu.fr/) to organize an internationally coordinated framework to produce improved regional climate change projections for all land regions world-wide. More information on the EURO-CORDEX initiative are available at the following link http://www.euro-cordex.net[1].
RCMs are numerical climate models able to perform an explicit simulation of some of the most important physical dynamics of the climate system, for a limited area. They are nested on the GCMs, usually using a one-way nesting procedure: this technique consists of using the outputs from GCM simulations, conveniently interpolated to provide initial and driving lateral boundary conditions for a high-resolution simulation only for a part of the Earth surface. GCM are forced by Representative Concentration Pathway (RCP) scenarios.
The ensemble of climate simulations used in this work consists of eighteen GCM-RCM combinations carried out in the frame of EURO-CORDEX, as shown in Table 1. The Representative Concentration Pathway scenarios used in this activity are RCP4.5 (Intermediate emissions) and RCP8.5 (High emissions), adopted by the IPCC for its fifth Assessment Report (AR5) in 2014. RCPs are time and space dependent trajectories of concentrations of greenhouse gases and pollutants resulting from human activities, including changes in land use. RCPs provide a quantitative description of concentrations of the climate change pollutants in the atmosphere over time, as well as their radiative forcing in 2100 (specifically, RCP4.5 achieves an overall impact of 4.5 watts per square meter by 2100 and RCP8.5 of 8.5 watts per square meter) (IPCC, 2014a; Moss et al, 2010).
Furthermore, one climate variable has been taken into account: precipitation.

3 Methodology

The main aim of this work is to explore the potential of using functional data analysis (FDA) to facilitate the comparison between simulated climate data and observed climate data. Indeed, what is unique about functional data is the possibility of also using information on the rates of change or derivatives of the curves. Slopes, curvatures, and other characteristics made available can be used because these curves are intrinsically smooth, and we can use this information in many useful ways. In this paper, we use the FDA to analyse the variations and differences over time of the simulated and observed precipitation variable and identify the simulated data that has a trend closer to that of the observed data.

The strategy proposed to identify a regional climate model, among those available under the EURO-CORDEX program, which shows the most similar form of temporal changes in the series compared to the historical series of observations, consists of an analysis with several sequential steps.

The first step is to select the grid points of the models that are representative of the study area. For this purpose, 4 methods have been used, so that a first error was not introduced precisely due to the choice to use only one of these methods. The first method consists in identifying the grid point of the model closest to the station point under examination (closest point method); the second in identifying a 3x3 box centered on the station point under examination (box 3x3 method); the third is the IDW (Watson and Philip, 1982) a deterministic spatial interpolation method which assumes that each point of the model grid has an influence that decreases with increasing distance from the station point (IDW method); the fourth is the Kriging (Bohling, 2005) a geostatistical interpolation method applying weights in measured points, according to a (moderately) data-driven weighting function (Kriging method). Those weights are based not only on distance between points (like in

IDW), but also on the variation between measured points as function of distance. In this work, the ordinary Kriging approach is adopted.
The second step was to convert the observed precipitation data and the simulated precipitation data representative of the study area, obtained with the 4 previously described methodologies, into functional data. Therefore, this step consists in construct the smooth functional curves from their corresponding simulated and observed data obtained discretely over time. In this work, aggregated data on an annual scale were considered for both simulated and observed data. Let there be N curves and let $y_i(t)$ denote the value of the i^{th} curve at time $t \in T$ (for $i = 1, \ldots, N$). The method used to represent smooth functions $y_i(t)$ over time $t \in T$ is through linear combinations of known basis functions as follows:

$$y_i(t) = \sum_{k=1}^{K} c_{ik} \Phi_k(t) = \mathbf{c}_i^{\mathrm{T}} \mathbf{\Phi}(t), \forall\, t \in T, i = 1, \ldots, N$$

where $\Phi_k(t)$ (for $k = 1, \ldots, K$) is the k^{th} known basis functions and c_{ik} is the corresponding coefficient. In the vector-matrix notation, $\mathbf{\Phi}(t)$ is the vector of all K basis functions and $\mathbf{c}$ is a vector that contains all K coefficients. The choice of the basis function is based on the characteristics of the data and the nature of the smooth curve (Ramsay and Silverman, 1997). The most appropriate basis for periodic functions defined on a time interval is the Fourier basis. The degree of smoothness imposed on the curve $y_i(t)$ is controlled by the number K of basis functions. A large K implies more flexibility and smoothness in the estimated curve. Once the basis Fourier object was set up, it was then combined with the discrete observed and simulated annual precipitation data to create the functional precipitation data objects.
The next step is to calculate the first derivative of each functional object created, expressed in the following form:

$$y_i'(t) = \sum_{k=1}^{K} c_{ik}^{'} \Phi_k(t) = \mathbf{c}_i'^{\mathrm{T}} \mathbf{\Phi}(t), \forall\, t \in T, i = 1, \ldots, N$$

The functional distance was then calculated between the coefficients of the first derivatives of the 18 functional simulations and of each of these with the coefficients of the first derivative of the observed functional data, to obtain the functional distance matrix showing the magnitude of dissimilarities. Let the i^{th} and j^{th} estimated curves $y_i(t)$ and $y_j(t)$ be expressed as a linear combination of Fourier basis functions with coefficient vectors $\mathbf{c}_i$ and $\mathbf{c}_j$ respectively. The distance between the curves can then be written as

$$d_{ij}^0 = \left(\mathbf{c}_i - \mathbf{c}_j\right)^{\mathrm{T}} W \left(\mathbf{c}_i - \mathbf{c}_j\right)$$

and $W = \int \mathbf{\Phi}(t)\, \mathbf{\Phi}^{\mathrm{T}}(t) dt$, which is a symmetric square matrix of order K, and K is the number of known basis functions. For each set of basis functions, W can be evaluated by using numerical integration, if necessary, and the functional distance matrix D with entries d_{ij} , as defined above, can be computed. Similarly, the distance between the first derivatives of the curves $y_i(t)$ and $y_j(t)$ is given as follows:

$$d_{ij}^{1} = \left(\mathbf{c'}_i - \mathbf{c'}_j\right)^{\mathrm{T}} W \left(\mathbf{c'}_i - \mathbf{c'}_j\right)$$

and $W = \int \mathbf{\Phi}(t)\, \mathbf{\Phi}^{\mathrm{T}}(t) dt$, which is a symmetric square matrix of order K, and K is the number of known basis functions. The distances d_{ij}^{1} are usually not affected by the bias, whereas the common bias of the simulated data is considered to have impacts on the similarity assessed by distances d_{ij}^{0}. Thus, smaller values of that distances show a similar shape of the temporal changes in the data series.

The last step consisted in applying hierarchical clustering in order to search for clusters of models that show a more similar shape in temporal variations compared to the same time series of the observations. By way of example, Figure 1 shows the dendrogram generated by the hierarchical clustering on the functional distance matrix obtained respectively for each method used to extract the grid points of the climate models representative of the study area, according to RCP4.5 scenario.

Figure 1: Dendrogram generated by the hierarchical clustering on functional distance matrix: closest point method (top left), box 3x3 method (top right), IDW method (bottom left), Kriging method (bottom right).

Evolution of scientific literature on climate change: a bibliometric analysis

Evoluzione della letteratura scientifica sul cambiamento climatico: un'analisi bibliometrica

Gianpaolo Zammarchi[1], Giulia Contu[1], Maurizio Romano[1]

Abstract Climate change represents one of the biggest challenges of our time. We conducted a scientometric analysis of articles on climate change indexed in Web of Science to identify the most productive countries and relevant sources. Through a topic modeling analysis of the abstracts conducted using Latent Dirichlet Allocation (LDA), we identified the main topics and their evolution during time. Through an analysis of 263,197 articles published from 1989 to 2022, we showed an increase of articles related to consequences on living beings and habitats as well as to potential actions against climate change. Our analysis provides a comprehensive picture of studies conducted on this relevant topic in the last thirty years.

Abstract *Il cambiamento climatico rappresenta una delle sfide maggiori del nostro tempo. Abbiamo condotto un'analisi scientometrica degli articoli sul cambiamento climatico indicizzati su Web of Science, per identificare i paesi che hanno prodotto il maggior numero di articoli e le fonti più rilevanti. Tramite un'analisi di topic modeling degli abstract condotta tramite Latent Dirichlet Allocation (LDA), abbiamo identificato i temi principali e la loro evoluzione. L'analisi di 263.197 articoli pubblicati tra il 1989 e il 2022 ha permesso di evidenziare un aumento degli articoli relativi alle conseguenze sugli esseri viventi e gli habitat e alle possibili azioni contro il cambiamento climatico. La nostra analisi offre una panoramica degli studi condotti su questo importante tema negli ultimi 30 anni.*

Key words: climate change, scientometrics, topic modelling, LDA, general sentiment decomposition

1 Introduction

The expressions “climate change” and “global warming” refer to the rapid and recent global rise in temperatures caused by the increase in CO_2 and methane levels due to human activities (e.g. agriculture, industrial production, overbuilding and deforestation). In 2018, the Intergovernmental Panel on Climate Change (IPCC) reported that human activities have increased global temperature from 0.8 to 1.2°C (since the pre-industrial era) and, if current levels of greenhouse gas emissions will not be reduced, the temperature will increase constantly. For these reasons, under the 2015 Paris Agreement, several nations agreed to keep warming under control, but in order not to cross the threshold of 1.5°C, it would be necessary to halve emissions by 2030 and to achieve net-zero emissions by 2050 [1]. Climate change has also profound repercussions on economic outcomes. In fact, extreme events (i.e. floods, droughts, heat waves) and other effects of the climate change (i.e. rising temperatures and sea-level) can cause wealth destruction or reduction of income [2], especially on minorities and other vulnerable groups. In addition, climate change is a problem that affects all countries. Some of its main and most severe repercussions concern anomalous heat waves and other extreme weather events, increasing number of wildfires, ice melting, deserts expansion and extinction of animal species. Human beings will also be in danger as migration flows, diseases, floods, food and water shortages and economic losses will occur in the next decades [3]. It is therefore understandable why the climate change literature has expanded rapidly in recent years [4].

In this work we conducted a scientometric analysis of scientific studies investigating climate change. Through topic modeling of retrieved abstracts, we discuss the most explored aspects as well as trends in their temporal evolution.

2 Materials and methods

We conducted a bibliometric analysis on the Web of Science Core Collection (WoS) online database, searching for studies mentioning the terms “climate change” OR “global warming” in titles, abstracts, author keywords or keywords plus (“Topic” option in WoS), published up to 29th of January 2022. A document type restriction (only Articles) and a language filter (only English) were applied. From each identified article, the following characteristics were extracted: title, abstract, keywords, authors’ affiliations, year of publication, journal title and the number of citations. We used the Bibliometrix package [5] version 3.1 in R version 4.1.1 to

display the annual scientific production, identify the most relevant sources and the most active countries. Next, the corpus of documents was preprocessed with tm [6] and quanteda [7]. A co-cluster analysis of 1,000 randomly sampled abstracts was conducted with blockcluster [8]. We tested a range from 1 to 5 clusters to find the number that allows to maximize the pseudo-likelihood. Next, we used Latent Dirichlet Allocation (LDA) in topicmodels [9] to perform topic modeling on the whole dataset. Topic names of the clusters were defined using K-means clustering over the word embeddings representation [10] in Python for dimensionality reduction (merging words with different representation but the same meaning) [11].

3 Results

We retrieved 263,197 scientific articles published from 1989 to 2022. The scientific production observed an annual percentage growth rate of 26.18 (Figure 1).

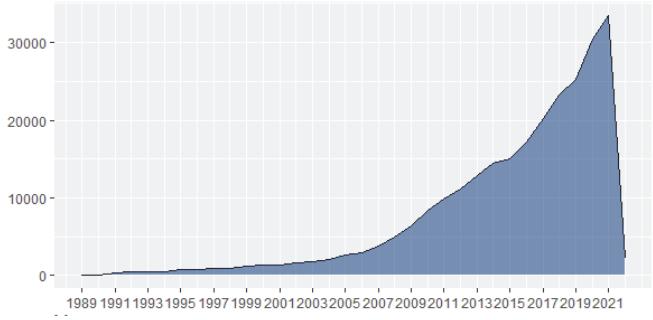

Figure 1. Annual scientific production growth of articles on climate change

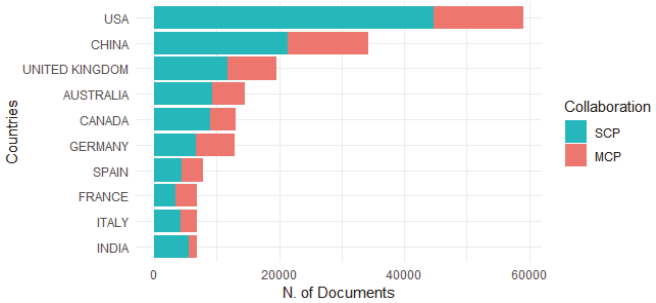

Figure 2. Most productive countries based on the affiliation of the corresponding author

United States were the country in which most articles were published, based on the affiliation of the corresponding authors, followed by China and United Kingdom (Figure 2). Single country publications (SCP) and multiple country publications (MCP) (i.e. articles with international collaborations) are also shown. The five most relevant sources based on the number of published articles are shown in Table 1.

Table 1: Most relevant sources based on the number of published articles

Journal name	Articles
Science of the Total Environment	4,272
Sustainability	3,705
Global Change Biology	3,640
PLOS ONE	3,633
Climatic Change	3,474

Analyses conducted with blockcluster on 1,000 randomly sampled abstracts showed that a five-cluster partition was able to maximize the pseudo-likelihood (Table 2).

Table 2: Pseudo-likelihood for clusters in a range from 1 to 5

Metric	1 cluster	2 clusters	3 clusters	4 clusters	5 clusters
Pseudo-likelihood	-374,555	-373,198	-409,632	-372,792	-340,785

Based on this, we set to five the number of clusters for the topic modeling analysis conducted with LDA on the whole dataset. The first ten words for each topic based on LDA are shown in Table 3. The first 100 words for each topic were used to assign topic names based on the word embeddings representation. The most representative five words based on this representation are also shown in Table 3.

Table 3: Topics and relative words identified by LDA and word embeddings

Topics	LDA	Word embeddings
Topic 1 "Ice"	model, changes, water, temperature, data, precipitation, models, results, study, surface	ice, seasonal, lake, winter, surface
Topic 2 "Community"	species, temperature, may, population, populations, effects, environmental, changes, distribution, habitat	community, populations, habitat, biodiversity, sea
Topic 3 "Fire"	soil, forest, carbon, water, vegetation, growth, increased, temperature, plant, drought	fire, season, response, forest, nitrogen
Topic 4 "Energy"	energy, emissions, carbon, production, environmental, gas, results, study, emission, system	energy, heat, power, fuel, electricity
Topic 5 "Natural resources"	management, research, environmental, adaptation, can, policy, study, risk, development, paper	natural, resources, water, human, environmental

Since LDA is a probabilistic model, any abstract will be assigned to the topics with different probabilities. For each abstract, we selected the topic with the highest probability and then plotted the number of abstracts assigned to each topic (Figure 3). We can observe that Topic 1 ("Ice") is the most represented among our articles, followed by Topic 5 ("Natural Resources") and Topic 2 ("Community").

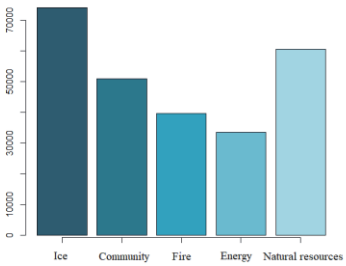

Figure 3: Number of articles for each topic

Next, we plotted the temporal evolution of probability distributions for each topic in order to observe their change over time (Figure 4). It can be observed how the probability of Topic 1 decreased during the years, the probability of Topics 2 and 5 observed an increase while that of Topics 3 and 4 remained somewhat stable, with the latter observing a slight increase from 2020.

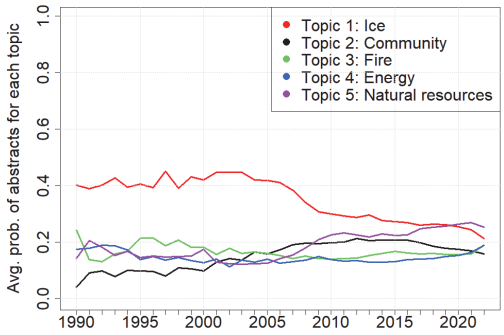

Figure 4: Number of abstracts assigned to each topic

4 Discussion

In this article, we conducted a bibliometric analysis of studies investigating climate change. We reported how the literature has grown, especially in the last two decades. This growth can be explained by the increased relevance that this topic has gained since the Kyoto Protocol signed in 1997. In particular, in recent years, activists such as Greta Thunberg have attracted the attention of newspapers and TV, also shifting the attention of public opinion towards this topic.

We built a corpus using the abstracts of the articles retrieved from the search and used a topic modeling approach to identify the main topics present in the corpus. When we plotted the temporal evolution of the topics' probabilities over the entire time span, we found Topic 2 (including words related to community) and Topic 5

(including words related to natural resources and potential actions) to slightly increase. The latter finding might be explained by the growing international efforts into providing policies and instruments to manage and reduce climate change. On the other hand, while overall Topic 1 (including words related to ice, water and precipitations) was the most represented in our dataset, its probability showed a decrease from 40% to around 20%. Studies assigned to Topics 3 (including words related to fire and vegetation) or Topic 4 (including words related to energy) remained somewhat stable. As future developments, we plan to compare results obtained using different methods for topic modeling, such as seeded LDA.

To conclude, our analysis of the large body of scientific literature on climate change provides an updated and comprehensive picture of studies conducted on this relevant topic in the last thirty years and highlights relevant trends with regards to investigated topics.

Energy and material demand of the Italian Regions

Il fabbisogno di materia e di energia delle regioni italiane

Flora Fullone, Giulia Iorio, Assunta Lisa Carulli

Abstract

Material and energy consumption exerts a general environmental pressure. The economy is in a physical exchange relation with the natural environment via resource and energy flows. There are international statistical standard for measuring material and energy flow and since these concepts are aligned with those of the System of National Accounts, the environmental information can then be integrated with economic information. The work describes the main dynamics of energy and resources consumption, and the regional results obtained. It also highlights that, despite the differences between the methodological references and the sources used for the indicators of materials and energy consumption, there is a coherence at regional level between the two statistical measures.

Abstract

Le pressioni sull'ambiente esercitate dalla crescita economica possono essere descritte attraverso il consumo di materia ed energia. I conti dei flussi di materia, sono finalizzati a dare una misura del consumo di risorse, confrontabile con il PIL per condurre analisi relative alla dimensione ambientale, in parallelo a quella economica. Analogamente la dimensione energetica è descritta attraverso i bilanci energetici realizzati dall'ENEA. Il lavoro descrive le principali dinamiche del consumo di risorse, ed i risultati regionali ottenuti, inoltre evidenzia che, nonostante i riferimenti metodologici e le fonti utilizzate per la costruzione degli indicatori del consumo di materia e di energia siano molto diverse fra loro, si riscontri una coerenza a livello regionale fra le due misure statistiche.

Key words: resources, energy, total energy supply, domestic material consumption

1 Introduction

The indicators of material and energy consumption are provided in the context of sustainable development goals indicators as they represent some environmental pressures exerted by the socio-economic system. Energy consumption is assessed based on the regional energy balances (BER) provided for by law no. 10 of January 9, 1991. The BERs are consistent with the national energy balance and are developed by applying the Eurostat methodology. Similarly, the regional material consumption is evaluated based on the Eurostat methodology of the Economy-wide material flow accounts (EW-MFA), a statistical accounting framework that records, in thousands of tons per year, the material flows in and out of an economy. The work highlights different regional consumption patterns in relation with economic measure of GVA per capita and GVA composition. It also notes some correlations between the indicators relating to material and energy resource demand on regional scale.

2 Regional energy balance

The Regional Energy Balance (BER) allows to see the total amount of energy extracted from the environment, traded, transformed and used by end-users in a year giving an immediate image of the energy situation. BER

- quantifies energy supply and the energy consumption of the whole economy and of individual sectors;
- allows to observe the evolution over time of energy trends;
- allows to make a comparison with the national energy situation highlighting its diversity and problems;
- allows to evaluate the interrelationships with the socio-economic system through energy indicators such as energy intensity;
- allows to monitor the achievement of regional objectives (burden sharing).

BER is the starting point for regional energy strategies and allows monitoring impacts of energy policies.

ENEA produces Regional Energy Balances: the BERs are consistent with the national energy balance and they are developed by applying the EUROSTAT methodology[1] by adopting EUROSTAT definitions and by following EUROSTAT guidelines.

BER reports all statistically significant energy products and their production, transformation and consumption by different types of economic actors (industry, transport, etc.).

The energy flows are grouped into sections that illustrate how the energy is made available and consumed.

In a first step the energy products are evaluated in physical units and only in a second step the quantities produced and consumed are converted into a common energy unit, by multiplying all the data by the appropriate conversion factor: tons of

oil equivalent. The quantity (production+import-export+stock changes- international maritime bunkers -international aviation) is the total energy supply (TES) and it represents the quantity of energy necessary to satisfy inland energy consumption of the territory. Final energy consumption (FEC) is the total energy consumed by end users (industry, services, households, domestic transport and agriculture).

3 Regional Economy-wide material flow accounts

Economy-wide material flow accounts (EW-MFA) give a representation of the overall material inputs into regional economies, the material accumulation within the economic system and the material outputs to other economies or to the environment. These accounts include all materials other than water and air, measured in tonnes per year. Primary resources from domestic extraction and all imported/exported products (raw, semi-finished and finished) have a classification consistent with the prevailing raw material of which they are made. All classifications are based on an international statistical standard for measuring the environment and its relationship with the economy, the SEEA Central Framework[2]. A regional database covering the main material flows was compiled following standardized guidelines [3]. Based on this framework a set of EW_MFA indicators can be calculated: the domestic extraction (DE), that represents the exploitation of natural resources from the regional environment, the physical trade balance (PTB) that means the quantity of goods imported from abroad and from other Italian regions, net of the quantities exported, and finally the domestic material consumption (DMC). This consumption (DMC) takes into account the resources extracted in the territory (DE) and imported net of exports (PTB) which are used in socio-economic processes, mainly accumulated in buildings, in controlled landfills or released as residues into the environment.
The material demand records significant differences between regions and its variability is linked to the main regional structural and socio-economic indicators.[4]

Table 1 - Extensive indicators - 2018

	TES [1000 toe]	***DMC [1000 t]***	***GDP [10^6 euro]***
North	81.042	252.681	969.467
Centre	29.635	85.473	370.055
South	43.937	149.673	379.280
Italy	154.613	487.828	1.718.802

4 Analysis of regional indicators' variability

Socioeconomic processes, described mainly through the indicators of GDP and GVA, are based on the transformation and consumption of natural resources and energy as shown in Figure 1.

Figure 1 - *TES per capita on x-axis, DMC per capita on y-axis, , GVA per capita on bubble surface, the colors represent the services share in GVA: the lighter color of the bubble denotes a greater share of services in GVA, the darker color of the bubble denotes a greater share of primary and secondary activities in GVA - 2018*

The regions where the consumption of materials (DMC) and energy (TES) per capita is higher are concentrated in the upper right quadrant, at the same time there is a greater share of primary and secondary activities on GVA. In these regions, the GVA per capita is generally higher.

Some regions are mainly suited to the extraction and processing of raw materials, in other regions goods and raw materials are mainly imported. In the second case, consumption is lower than the other regions since the finished products imported and consumed have a lower weight than the raw materials used in the production processes. Liguria and Valle d'Aosta[2] have the greater share (more than 65%) of imported goods on the material consumption.

Regarding energy it can be observed that some regions are characterized by relevant energy production sector: for example Puglia consumed in 2018 over 70% of primary fuels TES to produce energy. The energy transformation sector does not have a significant weight on the GVA but involves considerable consumption of energy and material (Fig.1).

The electricity, produced by fossil fuels and biomass, also involves consumption of raw materials. So the regions that satisfy their needs by importing materials,

[2] The per capita DMC of the Valle d'Aosta can be difficult to read as it refers to the smallest region, with the minimum values of per capita extraction, population and population density, it has a strong impact of the import of goods on consumption.

commodities and energy, for the same amount of wealth produced, have lower resource consumption than the producing regions. This aspect must be considered when comparing the indicators of energy and material consumption relating to territorial contexts in which primary and secondary activities prevail, which require high consumption of materials and energy, compared to other situations in which production is outsourced and the service sector prevails (lighter color of the bubble).
Analyzing TES per unit of surface and DMC per unit of surface (Tab3), a strong link arises between the two indicators. (Pearson coefficient = 0.9).

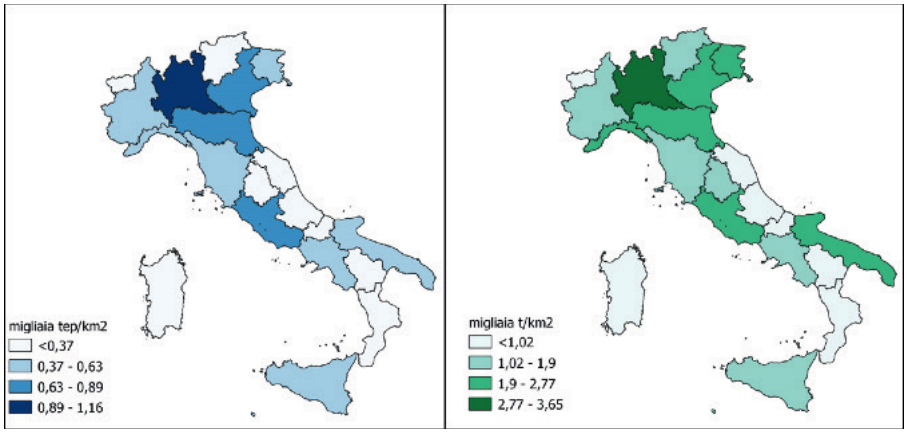

Figure 2 – Left. TES on surface ratio; Right. DMC on surface ratio

Looking at the energy dimension, the no industry FEC indicator (final energy consumption of services, households, agriculture and domestic transport) per capita has a low variability, coefficient of variation 0.25, while the per capita variability of final energy consumption in industry and construction has a medium-high variability, cv = 0.48. Furthermore, the total energy supply per capita of the regions is strongly correlated with the per capita energy consumption of industry and construction (Pearson coefficient 0.83). This suggests that the variability between regions of total energy supply per capita depends more on the industry and construction sector.
Material consumption is described applying the Eurostat EW-MFA methodology, which allows a detailed description of commodities but does not allow for a breakdown in the various sectors of the economy.
The extraction and consumption of non-metallic minerals predominate in Italy, mainly sand, gravel and other building materials directly attributable to the accumulation of infrastructures and buildings on the territory. Moreover, the per capita consumption of materials is meanly correlated with the per capita energy consumption of industry and construction (Pearson coefficient 0.61).
Finally, the efficiency measures linked to the use of materials and energy per unit of GDP are also correlated. As can be noted on Tab.4, even the TES compared to the regional GDP has a strong correlation with the material intensity calculated as the DMC ratio on GDP (Pearson coefficient 0.71).

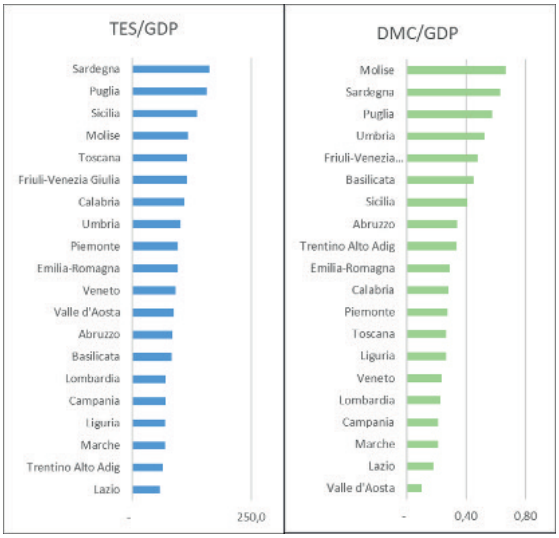

Figure 3 - Left. TES intensity (ktoe/1000 euro); Right. Material intensity (t/1000 di euro)

5 Conclusion

The consumption of energy and materials describes the pressures on the environment exerted by economic growth. The materials and energy demand of the Italian regions were compared in terms of per capita and unit area, and related to the main economic measures (GVA per capita and composition of the GVA) to highlight the dynamics of consumption and environmental pressures. This approach introduces an additional dimension to the analysis in term of sustenaible development on a regional basis, integrating the analysis based on socio-economic measures. Starting from different methodological references and sources, the analysis relating to the materials and energy demand of the Italian regions has also made it possible to find the consistency between the energy/material consumption data.

Health and survivorship

Increasing Inequalities in Mortality by Socioeconomic Position in Italy

Aumento delle diseguaglianze di mortalità per posizione socioeconomia in Italia

Chiara Ardito, Nicolás Zengarini, Roberto Leombruni, Angelo d'Errico, and Giuseppe Costa

Abstract This article assesses the evolution of socioeconomic inequality in life expectancy and mortality in Italy adopting measures of individual socioeconomic position based on income and occupational social class.
The analysis uses a large social security administrative dataset covering the population of private sector employees in Italy for the years 1990-2019 and the population of private and public sector workers from the census of the city of Turin (Italy) for the years 1981-2019. Life table techniques are used to estimate life expectancy at 65 years by different income quantiles and occupational classes. Cox regression analyses are performed to calculate the effect of socio-economic position on mortality controlling for several individual and contextual factors.
We find that inequalities in longevity have increased in recent decades. The redistributive implications are considerable since pension rules based on the average life expectancy in the population implicitly induce a regressive redistribution of pension resources.
Abstract *L'articolo stima l'evoluzione nel tempo delle disuguaglianze sociali nella longevità in Italia adottando misure di posizione socioeconomica basate su reddito e classe sociale professionale.*
L'analisi utilizza dati amministrativi relativi alla popolazione dei dipendenti del settore privato per gli anni 1990-2019 e alla popolazione dei lavoratori del settore

privato e pubblico dal censimento della città di Torino (Italia) per gli anni 1981-2019. L'aspettativa di vita a 65 anni per diversi quartili di reddito e classi occupazionali è stimata tramite le tavole di mortalità. Analisi di regressione di Cox vengono eseguite per calcolare l'effetto della posizione socioeconomica sulla mortalità controllando per numerosi fattori individuali e contestuali.
Troviamo che negli ultimi decenni le disuguaglianze di longevità sono aumentate. Le implicazioni redistributive sono rilevanti in quanto la presenza di regole pensionistiche basate sull'aspettativa di vita media nella popolazione induce implicitamente una redistribuzione regressiva delle risorse pensionistiche.

Key words: Mortality, Inequality, Socio-economic position, Income, Occupational class, Pension system.

1 Introduction

Life expectancy inequalities do not only rise public health concerns, but they also have important consequences in terms of redistribution and equity of pension systems (e.g. [1,2,3,4,5]). Life expectancy deterministically translates in the number of years of retirement, and it is a key parameter used in pension rules. In countries adopting automatic adjustment mechanisms, life expectancy determines the pension benefits as in notional defined contributions-based systems, or the eligibility conditions, in countries like Italy, where raises in average life expectancy automatically translate into equal rises in the eligibility conditions. However, while pension rules focus on the average life expectancy in the population, important differences exist between social groups as more disadvantages categories display systematically lower life expectancy. Hence, pension systems may induce a regressive redistributive mechanism by ignoring the longevity differences across socio-economic groups.

In this work, we present updated evidence on the evolution over the last 30 years of socio-economic differentials in mortality inequality and in life expectancy at 65 in Italy, controlling for individual and contextual factors. Moreover, we exploit comprehensive administrative data from INPS, the Italian National Institute of Social Security, which covers the population of private sector employees, offering highly precise and nationally representative estimates based on the entire population rather than on samples limited to specific subpopulation or geographical areas. Our estimates are based on individual rather than aggregated data, providing very accurate measurements of socio-economic position (SEP) whereas most of previous studies on the evolution of longevity inequalities adopted measures of deprivation based on aggregated indicators at the level of areas. These are important for delivering evaluations on the longevity divide that can inform policy makers around the revision of retirement eligibility conditions for more disadvantaged categories.

2 Data and Methods

2.1 Data and variables

The empirical analysis exploits the administrative archives of the INPS. This data represents the most complete and up-to-date statistical source of information to study socio-economic longevity differentials among workers. We analyse data on the population of private sector employees registered in the INPS archives for the years 1990-2019. Furthermore, the analysis is replicated and tested on an independent information source, the Turin Longitudinal Study (TLS), a census-based database built on the censuses of the municipality of Turin, one of the four largest cities for population in Italy. For both data sources, it is possible to conduct mortality follow-up by linking administrative records with administrative mortality records up to very recent years, i.e., up to 2019. It should be noted that while INPS data allow obtaining results valid for private sector employees in Italy, the TLS database includes all workers residents in the municipality of Turin, thus offering the opportunity to extend the analysis to autonomous work and public sector too, at the cost of lower national representativeness.

For the analysis on INPS, we observe and select private sector employees in three distinct 5-year periods: 1990-1994; 1995-1999 and 2000-2004 (henceforth, we will refer to them as the "1990", "1995" and "2000" cohorts). For each cohort, we selected only individuals born in Italy, aged 15-95 at the start of the period and with at least one job spell lasting for one month or more. Then, individuals were followed until death or end of the follow-up (after 20 years from the start). By piling up all job spells observed during the 5-year periods, for each separate cohort of workers we were able to construct variables describing their work such as: average weekly wage, prevalent geographical area of work, main sector of activity, main occupational class, main firm size, average labour market attachment (% of weeks worked over the period). For TLS data we sample workers from three different censuses, i.e., 1981, 1991 and 2001.

We use two different SEP indicators. The first is occupational social class, categorized according to the European Socio-economic Classification (ESeC) into three categories: executives, white collars, and blue collars. The second is based on average weekly wage and ranks individuals according to income quartile, calculated separately for men and women. To define weekly wage, we took the sum of reported employment inflation-adjusted earnings divided by the total number of weeks worked and constructed an average weekly wage over the 5-year window for every given cohort.

2.2 Methods

Specific mortality rates were calculated for five-year age classes, sex, income, occupational class, and cohort as the ratio between the number of individuals who died in the age interval and the total population-years at risk in that age interval. Subsequently, we constructed abridged life tables using 5-year age intervals with a final age interval of 85+ to estimate life expectancy and confidence intervals (CIs) using the method described by [6], with standard errors formulas proposed in [7]. In the analysis, we focus on life expectancy at an age approaching statutory retirement age, i.e., at 65 years. The differential is computed as the difference in life expectancy between the highest-SEP and lowest-SEP group.

We complement the life expectancy analysis by estimating a set of Cox regression models on the INPS data to assess how the hazard rate (HR) of mortality for the lowest-SEP compared to the highest-SEP group changed over time controlling for work and individual characteristics. The models include two separate measures of socio-economic position simultaneously (occupational class and income quartiles) while adjusting for the following covariates: age (linear and transformed in logarithmic), macro-region of birth (5 categories), macro-region of work (5 categories), economic activity (4 ISIC categories), an indicator of work intensity constructed as the proportion of weeks worked over the 5-year window (divided in tertiles) and firm size (3 categories).

3 Results

3.1 Life expectancy in Italy by socio-economic position

Figure 1 plots the gap in life expectancy at 65 measured between the top and bottom SEP categories in the three cohorts of 1990, 1995 and 2000 using two measures of SEP: occupational social class (panel A) and income quartiles (panel B). The results show that the advantage of life expectancy in favor of workers in high socio-economic groups has increased significantly with time, regardless the indicator adopted, in both genders, although with more pronounced life expectancy gaps found among men. Being more precise, comparing individuals of different occupational class (panel A), we observe that 65-years old male executives could expect to live 1.33 years more than blue collars in 1990 (95% CI 1.23, 1.43) and this gap raised to 2.0 years in 2000 (95% CI 1.90, 2.11). Among women too it is possible to detect a significant increase with time, as the gap was null in the 1990 cohort but positive and significant in the 2000 cohort.

The divide in life expectancy at 65 widened also among individuals of different income levels. Focusing on income quartile (panel B), among men in the lowest 25% of the income distribution, the life expectancy disadvantage increased over the last 30 years, raising from 1.09 years in 1990 to 1.79 years in 2000. Women of different income groups had equal life expectancy at 65 in 1990 while a small but significant advantage of about 2 and 4 months for the richest quartile emerged in the 1995 and in 2000 cohort, respectively.

3.2 Regression analyses on mortality

Regression results are substantially consistent with the findings from the life expectancy analyses, indicating that the socio-economic gradient in mortality

became stronger in the most recent cohorts also when adjusted for several individual and work-related characteristics. Table 1 presents gender-specific HRs and 95% CIs from Cox regression models predicting mortality by SEP in the 1990, 1995 and 2000 cohorts separately, controlling for age, region of birth and several work characteristics. The analysis is mutually adjusted for the two SEP indicators used in the previous section, i.e., occupational social class and income quartile. Mortality follow up is 20 years for all the cohorts.

Focusing on occupational social class, results show a clear time trend in inequality in mortality for both men and women: the HR of mortality for blue collars compared to executives, increased with time, raising from 1.128 (n.s.) to 1.663 ($p<.001$) for men (panel A) and from 1.051 (n.s.) to 1.175 ($p<.001$) for women (panel B). Income inequality seems to widen mortality inequality too, as the HR for the lowest income quartile raised for both men and women comparing the 1990 and 2000 cohorts.

4 Robustness

To test the robustness of results we performed several checks. First, we replicated the life expectancy analysis on a different administrative dataset, i.e., the Turin Longitudinal Study (TLS). TLS is a prospective study of mortality among persons residents in Turin (the fourth largest city of Italy) censused at the 1981, 1991 and 2001 national population censuses. The results from the analysis of the social differential in life expectancy at 65 on TLS confirm that social inequalities increased substantially among men, where the gap in life expectancy at 65 more than doubled from the 1981 census to the 2001 one. For women, no significant difference in life expectancy emerges in TLS data in all the census cohorts, suggesting that when the reference population encompasses the public sector too, longevity inequality among female workers vanishes.

Furthermore, we assessed the robustness of our life expectancy analysis by modifying the follow up duration, using more cohorts, and adopting a dynamic definition of income quartile. All these robustness tests have confirmed our main analysis showing that longevity inequalities are increasing in Italy (more details are available in [8]).

5 Conclusions

This work revealed that inequalities in life expectancy at 65 and mortality rates between income quartiles and occupational classes are widening among Italian workers.

These results have distributional implications for the pension system, too. As several studies have documented, life expectancy inequality translates into inequality of pension entitlements. In fact, individuals with a lower life expectancy spend less time in retirement and receive less than actuarially fair pension treatments. Hence, it is important for pension policy to establish compensating mechanisms that explicitly consider differential longevity. This is especially important in a pension system in which, as the Italian one, there is an automatic link of pension eligibility to the average life expectancy, an adjustment that in this moment applies also to social groups whose life expectancy is potentially stagnating.

The role of health conditions in the relationship between socio-economic status and well-being: the counterfactual approach in mediation models

Il ruolo delle condizioni di salute nella relazione fra stato socio–economico e benessere: l'approccio controfattuale nei modelli di mediazione

Sara Manzella and Margherita Silan

Abstract In this work, the relationship between the socioeconomic status and the well-being of older people has been explored by investigating the mediator role played by physical health. A counterfactual approach in mediation models is applied to SHARE data, considering five waves from 2004 to 2015. The three key concepts, socioeconomic status (SES), well-being and physical health, can be seen as latent concepts and measured through factor analysis. The use of Marginal Structural Models also allowed to consider a longitudinal approach, discovering that the mediation effect of the individual's health history in the relationship between SES and well-being has a far greater impact than the one only considering the cross-sectional role of health on well-being.

Abstract *In questo lavoro è stata esplorata la relazione tra lo status socio-economico e il benessere degli anziani, indagando il ruolo di mediatore giocato dalla salute fisica. E' stato utilizzato un approccio controfattuale con modelli di mediazione applicati ai dati SHARE, considerando cinque wave dal 2004 al 2015. I tre concetti chiave, status socio-economico (SES), benessere e salute fisica, sono considerati concetti latenti e misurati tramite analisi fattoriale. L'uso di modelli strutturali marginali permette di considerare anche un approccio longitudinale, scoprendo che il ruolo di mediatore della storia di salute dell'individuo nella relazione tra SES e benessere ha un impatto molto maggiore rispetto al ruolo trasversale della salute sul benessere.*

Introduction

The last decade has seen an increase in life expectancy in Italy and most European countries. This growth has also been accompanied by a significant increase in life expectancy in good perceived health and disability-free [1], therefore, a high proportion of older people are in good health. In this framework, the interest in analysing not only the general health of older people, but also their well-being has grown; questioning the extent of the direct and indirect impact through health, of the socioeconomic level on well-being.
Well-being is a very broad concept that encompasses different aspects of human beings characterising their quality of life in a society. It does not only include purely biological aspects, but it is important to be aware that, in reality it also combines psychological, mental, and social aspects of any individual's life.

In this work, the relationship between socioeconomic status and well-being of older people is explored by investigating the mediator role played by physical health. The method used is the counterfactual approach in mediation models [2].

Data

Data from the Survey of Health, Ageing and Retirement in Europe (SHARE), a multidisciplinary and multinational database that collects panel data on health, socioeconomic status, households, and lifestyles of respondents, are used to explore ageing at the European level. The target population of the survey is people aged 50+ living in 27 European countries and Israel. From the first interview in 2004 to the sixth in 2015, more than 120000 respondents were involved. After the first wave, in addition to the longitudinal sample, a refreshment sample was introduced to cope with the dropout and exit of some subjects from the survey. Nine countries participated in all surveys (Austria, Belgium, Denmark, France, Germany, Italy, Spain, Sweden, and Switzerland), allowing both a cross-sectional and a longitudinal analysis of the data, considering the evolution of the sample over the period of time from 2004 to 2015.

Socioeconomic status, well-being, and physical health

The three key concepts, socioeconomic status, well-being, and physical health, are seen as latent concepts and measured through factor analysis.

Socioeconomic status (SES) is measured by wealth and it is based on the following one-dimensional measures collected by the questionnaire: value of main residence, value of other possessions, bank accounts and bonds, shares, and mutual funds.

To represent the concept of well-being, two indicators have been used: CASP-12, a recognised measure to assess the well-being of individuals, together with EURO-D, which allows taking into consideration purely psychological aspects of the subjects' under analysis lives [3].

The third key concept is physical health. To define it, the limitations in activities of daily living and mobility-related difficulties reported by the respondents have been used. Even if physical health is a broader concept that involves many different dimension, in this work a simplification is needed to represent it with the available data.

The literature and an initial exploratory analysis of the correlations highlighted the expected relationships between the three key concepts: improved health and well-being as the socioeconomic status of the individuals increases and increased well-being as the physical condition of the subjects improves (Figure 1).

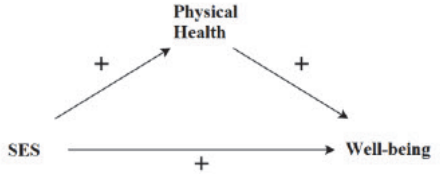

Figure 1: Graphical representation of the hypothesized relationships (and associations observed in the exploratory correlation analysis) between exposure (SES), mediator (physical health), and response variable (well being).

Methods

To trace the possible causal relationships between these variables, mediation models have been used following the counterfactual approach. This method allowed the decomposition of the total effect of socioeconomic status (treatment) on well-being (response variable) by assessing what portion of this effect is mediated by physical health (mediator).

In other words, it is hypothesized that well-being can change as a result of changes in socioeconomic status or physical health, but that physical health can also be influenced by socioeconomic status. In particular, four quantities are defined and estimated [2]:

- The Controlled Direct Effect (CDE), which quantifies whether there is a change on average in well-being if socioeconomic status varies but physical health does not change.
- The Natural Direct Effect (NDE), which expresses the average effect on well-being given a change in socioeconomic status, assuming that physical health is fixed at the value it would have been if the socioeconomic status

had not changed (i.e. the mediator does not change as a result of the change in socioeconomic status).

- The Natural Indirect Effect (NIE), which represents the average change in well-being assuming that socioeconomic status remains constant but physical health varies.
- The total effect (TE), which is simply the sum of NDE and NIE.

Several assumptions are needed to estimate these quantities [2] [4] [7] [8]. However, considering the longitudinal nature of the data coming from five waves of a panel, it is also possible to take into account time-varying exposure and mediators, despite the violation of some assumptions.

In order to handle these scenarios, Marginal Structural Models are combined with a system of weights, and the aforementioned assumptions may be adapted into a longitudinal framework [4]. Thus, it is possible to include in the analysis some important variables such as physical activity, whose inclusion would be otherwise tricky due to reverse causality. Estimation of the direct and indirect effect of physical health on well-being results from an adaptation of the VanderWeele and Tchetgen Tchetgen procedure [5]. Since in the longitudinal procedure exposition histories are considered, some weights may become particularly high due to less likely situations. Hence, the weights are trimmed in order to obtain more stable estimates [6].

Results

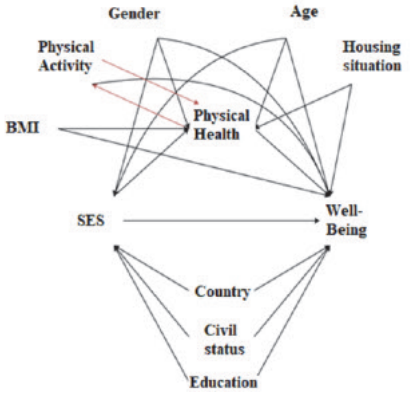
As a first step, the analysis was carried out without correcting for the presence of so-called confounding variables, estimating the necessary models to calculate the aforementioned effects without adding appropriate covariates.

This step of the analysis allows to estimate how much of the total effect is due to the mediating process of physical health. This percentage varies between 20% and 30% of the total effect, depending on the wave considered.

The effects estimated with the models without covariates cannot be interpreted as causal effects as some necessary assumptions are not respected; however, they represent a first confirmation of the mediating role played by physical health.

The term confounding refers to the bias and inaccuracy of association measures that occur when both the exposure of interest and the outcome are associated with a third variable. When conducting mediation analysis, identifying and cleaning effect estimates from this phenomenon is crucial. The method used to recognise confounding variables is called the change-in-estimate criterion, and it is based on the assessment of the proportion by which estimates of association measure change.

The relationships assumed in this second step of the analysis are considerably more complex and involve a larger number of variables (Figure 2).



Exposure Levels	TE	CDE ($m - mean\|min\|max$)	NDE	NIE
		0.0734 (0.06613: 0.08069)

		2.0566 (1.8428: 2.2704)		

Figure 2: Graphical representation of the hypothesised relationships between socioeconomic level (exposure factor), physical health (mediator), and well-being (outcome), considering possible confounders (on the left). Effects estimates corresponding to different levels of exposure and mediator (on the right).

A part of the results from the analysis on the sixth wave is provided below.

The outcome is well-being, a quantitative variable derived from factor analysis, standardised, and with a range of about 6. The CDE, that is, the effect of socioeconomic level (SES) on well-being for fixed values of health, is 3.3 when comparing the minimum and maximum levels of SES and setting the value of health at its minimum. Hence, the level of well-being doubles when moving SES from the minimum to the maximum, keeping health levels set at the minimum. For health levels set at the mean or maximum value, well-being increases by just over two points. That is, whenever health is at its worst, the role of SES is greater, and the gap between minimum and maximum SES increases. Similar results are obtained if the comparison is between the average and the maximum SES. If, on the other hand, the comparison is between average and minimum SES, the effect of SES on well-being is greatly reduced, regardless of the value of health. This shows that a large gap is generated between very high SES levels and low to medium levels. The NIE, that is the average change in the outcome (well-being) when the exposure (SES) is fixed and the mediator (health) takes on values corresponding to different levels of SES, can account for 10% to 20% of the total effect, depending on the wave. In absence of confounders, this share was on the order of 30%. The estimates of the indirect effects cannot be considered high and in some waves are not significant. This is particularly noticeable when comparing very different levels of SES. Complete results are available at [4].

Cross-sectional analyses were performed both in the complete sample and in the one including only subjects who participated in all survey waves (panel sample), observing the majority of differences in the significance of estimates rather then in the magnitude of the effects. Thus, a negligible selection bias is expected using this sample.

Nevertheless, these analyses do not consider the longitudinal nature of the data, excluding the possible confounding effect that the variables observed at different time instants may have on each other and on themselves. To carry out this analysis, only

the panel sample has been used (6707). The longitudinal approach assesses the cumulative influence of socio-economic status and health over time identifying a significant, positive effect of both on the well-being of individuals. The estimated total effect indicates that a change in exposure history of one standard deviation across all time periods is followed by a change in well-being of 3.18%. This analysis shows that about one third of the total effect of socioeconomic status on individual well-being is mediated by the effect of physical health. This is a far greater effect than the one emerged from the cross-sectional analyses.

Conclusions

People's history, the accumulation of risk factors, and adverse health conditions strongly influence well-being in old age. Overall, some important findings arise from the analysis: first of all, the strong impact of socioeconomic level on well-being and the strong differentials in well-being generated by comparing high and low socioeconomic levels. Furthermore, the mediation effect of the individual's health history in the relationship between socioeconomic level and well-being, accounting for 33% of the total effect, has a far greater impact than the one obtained considering the cross-sectional role of health on well-being (10-20%).

Excess economic burden of multimorbidity: a population-based study in Italy

Eccesso di costo economico della multimorbilità: uno studio di popolazione in Italia

Chiara Seghieri, Niccolò Borri, Gaia Bertarelli and Sabina Nuti

Abstract In Italy the increasing incidence of chronic disease and multimorbidity are major challenges for health systems. When a patient suffers from more than one chronic condition, the conditions can interact causing a significant increase in patients' care needs. Using healthcare administrative databases of Tuscany region to identify cohorts of chronic prevalent patients and their total direct healthcare expenses, in this paper we aim to study the economic burden of multiple chronic conditions and calculate the excess cost when comorbidities occur in order to assess how combinations of chronic conditions in adults affect total direct health expenditure.

Abstract *In Italia la multi morbidità è una sfida importante per i sistemi sanitari. Quando un paziente soffre di più di una condizione cronica, le condizioni possono interagire causando un aumento dei costi sanitari del paziente. Tuttavia, resta da determinare la misura in cui le co-morbidità influiscono sui costi. Utilizzando i database amministrativi sanitari della regione Toscana per identificare le coorti di pazienti prevalenti e le loro spese sanitarie dirette totali, in questo lavoro vogliamo studiare l'onere economico a carico del Sistema Sanitario Nazionale di molteplici condizioni croniche e calcolarne l'eccesso di costo quando si verificano co-morbidità al fine di valutare come le combinazioni di condizioni croniche negli adulti incidono sulla spesa sanitaria diretta totale.*

1 Introduction and background

The Italian National Health System is going through a period of strong criticality and reflection, with reference to its sustainability at an economic-financial level. This occurs for several reasons, including the gradual increase in subjects suffering from Noncommunicable diseases (NCDs) that require adequate continuum of care. NCDs, also known as chronic diseases, are recognised as the leading causes of death and disability worldwide. According to WHO, 70% of the deaths worldwide are due to NCDs. Multimorbidity, which is the presence of two or more chronic conditions in the person, is particularly relevant in Italy where more than 7 million people - 11.7% of the total population - are more than 75 years old and 42.3% of them have multiple chronic conditions (Istat, 2020). As consequence, the increasing of multimorbidity is a major health-related challenge for patients, health professionals, and society more broadly: it is associated with poor health outcomes, including increased mortality (Nunes et al., 2016), worse quality of life (Makovski et al., 2019), functional decline and increasing use of healthcare services (Ryan et al., 2018) thus imposing considerable economic burden on health systems (Wang et al., 2018). Nonetheless, many people with chronic conditions, and in particular those with multiple conditions, are still failing to receive appropriate care. Despite the guidelines that lead to suggesting bringing the patient to the center of the health care process (Starfield, 2009), health care systems are still organised around a single disease model with professionals working in a fragmented way, focusing on the intervention for the treatment of a specific disease rather than on the patient overall. Prevention and treatment services should shift from a single disease focus to a person-centred approach, so that morbidity gains match that of longevity; a health, rather than simply illness, approach to the prevention and care of patients is warranted to protect and promote maintenance of good health and to contribute to the sustainability of the health systems (Pearson-Studdard, 2019).
Knowing the absorption of resources related to the chronic population in charge by the Health System is very important and can help policy and decision makers in the health planning phase, in order to allocate adequate resources with respect to the entire path of diagnosis and treatment of these patients. In this sense, the present study aims at identifying, quantifying, and characterizing in terms of demographic characteristics and direct costs the combinations of chronic disease in a population of multimorbid patients in Tuscany Region (Italy). We will then estimate the economic burden of multiple chronic conditions by identifying selected conditions and calculating the excess costs of the specific condition when other conditions co-occur in order to know more about how combinations of chronic conditions in adults affect total direct health care expenditures and increase awareness among health profes-

sionals on how the healthcare delivery should move to a value-based health service, based on patient perspective and needs.

2 Data and Methods

We conducted a population-based study using administrative healthcare data of the Tuscany region at the individual level. This study utilizes a database consisting of all residents enrolled in the Tuscan health care system, aged 16 or more, alived in 2019 and who were classified as affected or not affected by one or more specific chronic diseases according to administrative data algorithms.
The Tuscany healthcare administrative databases contain information on all public and private accredited healthcare providers. The individual-level databases used in the present study include: (i) hospital inpatient data; (ii) emergency care data; (iii) outpatient care data; (iv) drug prescription data (v) exemption data; and (vi) registered person database which contains demographic information on all residents enrolled in the Tuscan health care system including, sex, date of birth and date of death. The different administrative databases were linked at the individual (patient) level through a unique identifier. Aggregate direct care costs of the year 2019 (1 January 2019 and 31 December 2019) were calculated for each selected chronic patient by considering cost information from the following administrative databases: inpatient care (DRG tariffs), drugs (net costs) and outpatient services (outpatient tariffs), emergency department care (tariffs).
In order to conduct our analysis, we selected six non-communicable diseases that contribute to the bulk of deaths, preventable disabilities and morbidity worldwide, namely heart disease, heart failure, stroke, cancer, diabetes, and chronic respiratory disease (World Health Organization, 2020).

Direct care costs for the selected prevalent population were estimated using Generalized Linear Models (GLMs) given the low number of zero costs (1.6%). Three different GMLs were tested, specifying several families (Gamma, Poisson, Inverse Gaussian) and a link log. To decide on the correct specification of the model, we employed the Modified Park test and Pregibon's Link test which indicated that the Poisson-Log link model was adequate compared to other types of distributions. More specifically, we run a log-poisson model separately for each of the six selected pathologies using as independent variables: gender, age classes (16-34, 35-54, 55-69, 70-84 and over 85), the 5 binary chronic disease variables and the interaction of each pathology with each of the other selected pathologies. Additionally, in order to control for the presence of a chronic condition outside of the list of the other 5 selected chronic conditions, we also added a variable for the number of any other chronic condition, and interaction between the number of other chronicities and each of the selected disease. The estimated excess costs of one condition when other co-occur were then estimated through the recycled predictions methods (Glick et al., 2014). The increase in healthcare expenditure attributable to each selected disease

was estimated by subtracting average predicted expenditure for sick people from average predicted expenditure for the individuals with the other disease variables set to 0 or 1 in case of comorbidity for a given disease. This allows us to analyzed the excess cost of chronic combinations using all the permutations for every possible couple of diseases. Therefore we were able to simulate the impact of a specific chronic condition on an already existing one among the six considered, and controlling for the presence of any other co-occurring chronic condition. With this method, as an example, we were able to estimate the excess cost attributable to diabetes in a cohort of patients with cancer and vice versa. All considered models were also run separately by gender to analyse potential gender differences in the excess costs for each combination of conditions.

3 Preliminary Results

Overall, in 2019, 1,257,413 (approx. 40%) of the 3,203,190 registered residents in Tuscany aged 16 years old or more, had one or more of the 36 chronic diseases identified by the algorithms and were included for analysis. Among these patients, 55% were female and 45% men; as expected, the percentage of patients with at least one chronic condition increased with increasing age (Table 1).
The economic burden of chronicity in 2019 was 30% of the total healthcare expenditures (23,5% only considering the selected six diseases) and, on average, the yearly direct costs per patient with at least one chronic condition were 2436€(SD 6913€). Multimorbidity affected about half of the chronic patients (39% of all Tuscan population aged 16 years or more having two or more chronic conditions) and the average number of conditions per person was equal to 1.97 (SD 1.28).
The six conditions identified for the study counted for 50.25% of the chronic cases (69% if excluding hypertension and hypercholesterolemia) and 77% of the healthcare expenditures of chronic patients. Of these identified diseases, heart disease accounted for the highest number of cases (21.1%) followed by cancer (15.7%), COPD (7.7%), heart failure (6.7%), diabetes (6.4%) and stroke (6.3%) (Table 2). Among these conditions, the most prevalent combinations, as expected, were heart disease with heart failure (5.1%) followed by diabetes with heart diseases (4.7%). Table 3 shows that for all the six selected conditions, healthcare expenditures increased with each additional chronic condition (each different morbidity counts one for this analysis), with, approximately an exponential trend, except for cancer which is likely to show a linear behaviour on costs as the number of chronic conditions increases.

4 Strengths, limitations and future analyzes

The proposed short paper present preliminary results of the analysis of costs of the healthcare system in multichronic patients for residents in Tuscany through adminis-

	N	%	Mean of chronicities	Std. Dev.
16-34	50884	4.05%	1.14	0.44
35-54	219942	17.49%	1.35	0.74
55-69	368943	29.34%	1.78	1.1
70-84	451184	35.88%	2.3	1.38
85+	166460	13.24%	2.6	1.5
Male	563629	44.8%	2.08	1.35
Female	693784	55.2%	1.88	1.2
1 condition	633066	50.35%		
2 conditions	297368	23.64%		
3 conditions	162302	12.91%		
4 conditions	87960	7.00%		
5 conditions	44077	3.51%		
6 + conditions	32640	2.59%		

Table 1 Number and percentages of patients with chronicities in patients group according to age, sex and number of chronicities. Percentages sum up to 100 since we considered the share of each class over the total number of chronic and multichronic patients in Tuscany, t-test for gender gives us a significant difference between the two group in the number of chronicities, a oneway ANOVA test is performed for the groups of age range giving again significant difference in the number of chronicities.

	Prevalence rate	Diabetes	Heart failure	Heart disease	Stroke	COPD
Diabetes	16.4%					
Heart failure	21.1%	4.7%				
Heart disease	6.7%	2.0%	5.1%			
Stroke	6.3%	1.5%	3.2%	1.1%		
COPD	7.7%	1.4%	2.8%	1.5%	0.9%	
Cancer	15.7%	2.1%	3.1%	1.0%	1.0%	1.3%

Table 2 Prevalence of the combination of the six selected index chronic conditions in the study population.

Index disease	One disease	Two diseases	Three diseases	Four diseases	Five diseases	Six or more diseases
Diabetes	995(±29)	1680(±33)	2615(±53)	4030(±90)	5757(±127)	9175(±165)
Heart failure	2434(±308)	2166(±148)	3472(±102)	4805(±126)	6361(±136)	9514(±167)
Heart disease	1254(±47)	2874(±105)	4283(±118)	5692(±141)	7344(±194)	9988(±199)
Stroke	3295(±305)	3763(±169)	4282(±218)	5068(±141)	6110(±168)	8941(±186)
COPD	1700(±59)	2408(±47)	3445(±48)	4744(±77)	6390(±102)	9326(±140)
Cancer	3918(±78)	4720(±88)	5607(±101)	6816(±167)	8159(±210)	10445(±435)

Table 3 Costs in euros for the six selected index chronic conditions according to the number of comorbidities. Each different morbidity counts one for this analysis.

trative data. Estimates of the excess costs of a specific chronic condition when other chronic conditions co-occur, also stratified by gender, are an ongoing research.
There are limitations to this study. It utilizes only administrative data sources, which although widely available at reasonable cost, refer to health problems for which people seek medical care, therefore they might not provide correct prevalence for specific diseases. Additionally, they do not provide information on the gravity of the diseases and socio-economic details of the patients. Moreover, the type of data only allows the identification and estimation of direct medical costs thus underrepresenting the economic burden of the care of multimorbidity. It is also important to underline that in our analysis only 6 chronic diseases are considered and they only concern the 23.5% of healthcare costs in Tuscany, even if they contribute to most of deaths and preventable disabilities (World Health Organization, 2020). As to the strengths, this is a population study covering a large and well-characterized population with chronic conditions, and to the best of our knowledge it is the first study that shows the extent to which combinations of selected conditions contribute to the excess cost burden associated with multicronicity in Italy.

Depression-free life expectancy among 50 and older Americans by gender, race/ethnicity and education: the effect of marital disruption

Aspettativa di vita libera dalla depressione tra gli americani over 50 per genere, etnia e istruzione: l'effetto della rottura del legame matrimoniale

Alessandro Feraldi and Cristina Giudici

Abstract Depression is a common mental health disorder, positively associated with mortality and morbidity, especially in the elderly. The study examines differences in Depression-Free Life Expectancy by gender, race/ethnicity, education and marital status between 2012 and 2018, using a cohort of 50 and older Americans of the Health and Retirement Study**.** On average, people not in union anymore could expect to live less years in total as well as less years free of depression than people in union. Women, who were also more likely to be not in union anymore, could expect to live more years with depressive symptoms in late life than men. Estimates of depression-free life expectancies are important as they may contribute to the definition of current and future social and medical service needs and policies.

Abstract *La depressione è un disturbo mentale comune, associato positivamente a mortalità e morbilità, soprattutto negli anziani. Lo studio esamina le differenze nell'aspettativa di vita libera da depressione per genere, etnia, istruzione e stato civile tra il 2012 e il 2018, utilizzando una coorte di americani over 50 intervistati attraverso l'indagine Health and Retirement Study. In media, gli individui non più coniugati possono aspettarsi di vivere meno anni in totale e meno anni liberi dalla depressione rispetto a quelli sposati. Le donne, le quali hanno maggiore probabilità di non essere più sposate, possono aspettarsi di vivere più anni con sintomi depressivi in tarda età rispetto agli uomini. Le stime dell'aspettativa di vita libera dalla depressione sono importanti in quanto possono contribuire alla definizione delle esigenze e delle politiche dei servizi sociali e medici attuali e futuri.*

Key words: depression-free life expectancy, multistate life tables, marital disruption, ethnic groups, educational differences, gender differences

1. Introduction

Depression is among the most common mental disorder worldwide that can adversely affect both mental and physical health [12]. In 2015, the prevalence of depression and the lifetime prevalence in the global population were 4.4% and 10.0%, respectively [12]. Additionally, it has been observed a positive associations of depression with mortality and morbidity [7, 12]. Although this increased mortality risk may be indirectly caused by chronic conditions and risky behaviours (e.g. excess in alcohol and drug abuse), depression is likely to be responsible for a proportion of the increase in mortality risk [7].

Important studies have shown a higher prevalence of depressive symptoms among women compared to men at various stages of the life-course in the U.S. In their meta-analysis of 24 studies on people aged 75 and older, Luppa and colleagues [10] found that the men-to-women depression prevalence ratio of was 1:1.4–2.2. Yet, several studies have shown that gender differences in life expectancy are partially explained by social and economic status which differ not only by gender but also by education, ethnicity and marital status [1, 10, 11]. For example, low educational attainment is associated with higher depressive symptom burden in older adults [11]. Other evidences in the U.S. suggested that Black older adults have higher depressive symptoms and psychological distress than White, whereas Hispanics have lower lifetime prevalence of major depressive episodes [2].

2. Marital disruption and depression

It is generally well recognised that marital status and transitions have important implications for health. On the one hand, marriage can be protective for health and reduce morbidity and mortality: compared to unmarried people, separated, divorced and widowed generally have greater social and financial support, overall healthier behavioural patterns. On the other hand, marital disruption, such as separation, divorce and widowhood, are stressful life events that have been associated with poor health and survival outcomes [5]. Although divorces that occur after age 50 (grey divorce) has doubled between 1990 and 2010, marital disruption in late life mostly occurs through spousal death. Recent marital disruption has been associated with increased alcohol intake and decreased body mass index in men, whereas it has been associated with higher risk of smoking initiation/relapse in women [5]. Some studies found that men are more likely to experience widowhood-related depression than women [8]. In a recent study on a sample of middle-aged and older Australian adults, after adjusting for socio-demographic characteristics, the authors found that people who recently divorced had much higher odds depression (OR = 2.9) and divorce had a much stronger impact on depression in men than women [5]. Finally**,** to date, there has been limited longitudinal research on how divorce/widowhood affects mental health expectancies

As shown, several studies have provided important estimates of the prevalence of depressive symptoms and major depressive symptoms among older adults in U.S. as well as the factors associated with this condition. However, little is known about the dynamics of length of life with and without depression among recent cohorts of U.S. older adults and the effect of marital disruption, particularly by gender, race/ethnicity, and educational attainment. Although early reports provided estimates of mental ill-health and depression-free life expectancies in the mid-to-late 1990s, studies on this field have slowdown.

The aim of this study is to estimate the life expectancy with depression (DepLE), the depression-free life expectancy (Dep-FLE) as well as the total life expectancy (TLE) by

gender in U.S. adults and examine differences in race/ethnicity and education over a 7-year period (2012–2018). Additionally, we investigate differences in Dep-FLE due to distinctive marital status: in union and not in union.

3. Data and methods

3.1 Sample

The study uses data from the RAND version of the Health and Retirement Study (HRS), an ongoing nationally representative longitudinal survey of health characteristics of U.S. men and women aged 50 and older, with oversampling of minority ethnic groups [4]. Participants have been interviewed approximately every two years from 1992 to 2018 and several other cohorts have been added at each wave. Data on vital status and month and year of death are obtained through the mortality register and exit interviews. RAND HRS version is a user-friendly longitudinal data file, which is cleaned and compiled by the RAND Corporation [4]. After excluding 533 HRS respondents aged 50 years or older in 2012 who were never married (2.7%), the analytic sample consisted of 19,315 individuals.

3.2 Measurements

Depressive symptoms were measured using the eight-item Center for Epidemiologic Studies Depression scale (CESD-8). The eight-item CESD is a commonly-used and validated depressive symptom measure in older adults and it is computed as the sum of eight indicators: depression, everything is an effort, sleep is restless, felt alone, felt sad, could not get going (negative indicators) and felt happy and enjoyed life (positive indicators). A cut-off score of three was used as suggested by previous validation studies to indicate clinically relevant depressive symptoms: in each survey wave, a participant was classified as having a depression if one scored three or above on the CESD-8 in that wave. Information on marital status and race/ethnicity and educational attainment were included in the analysis: marital status was categorized as currently in union (i.e. married/partnered), hear after “in union”, and not in union anymore (i.e. divorced, separated and widowed), hereafter “not in union”; ethnicity was categorized as “White” and “non-White” (Black, Hispanic and others); education was categorized as “lower educated” (less than high school degree, high school degree or General Education Development, GED) and “higher educated” (some college, and college or more).

3.3 Statistical analysis

In order to estimate the age-specific hazard rates of transitions to depression, recovery and death, multistate life tables approach (MSLTs) were used. MSLTs is a Markov modelling of stochastic processes that involves individuals moving between a finite number of states over time, including exit and re-entry into the same state [6]. It allows to incorporate covariates into the models to relate individual characteristics to intensity rates and probabilities to better

explain the heterogeneity in the changes of depression status over time. Additionally, MSLTs applies the estimated rates to a synthetic cohort and summarizes the age-specific transition rates into durations [6], in our case DepLE and Dep-FLE. To assess the effect of marital disruption on the Dep-FLE, we used the Interpolated Markov Chain (IMaCh) software [3, 9] version 0.99r19. This method partitions the time intervals between successive interviews into shorter steps and then models the resulting transition probabilities by multinomial logistic regression on age and covariates (in our case race/ethnicity and education). Afterwards, estimated transition probabilities are used as inputs in the multistate life table. Ethnicity and education were modelled as two dummy variables enabling calculation of Dep-FLE for four groups: White, higher educated; White, lower educated; Non-White, higher educated; Non-White, lower educated. To study the effect of marital disruption to the transition rates and length of life with and without depression, marital status was included and it was measured as a time-varying covariate reflecting the current marital status at the time of the survey. Finally, the analyses were performed separated for men and women.

4. Preliminary results

Total sample comprised 11,123 women (42.4%) with mean age of 67.8 years (SD = 11.2 years) and 8,192 men (57.6%) with mean age of 67.4 years (SD = 10.6 years). Between 2012 and 2018, more women than men were not in union: 51.4% and 26.4%, respectively ($p < .05$). Total years of life, years without depressive symptoms, and years with depressive symptoms at age 65 for people in union and not in union are shown in Table 1. Estimates are presented by gender, ethnicity and education. On average, women could expect to live more years with depressive symptoms in late life than men. White women aged 65, who were higher educated could expect to live around 3.7 years more than their men counterpart, 2.3 years were free of depression and around 1.4 with depression ($p < .05$). Non-White women and men, who were lower educated and not in union, showed the largest gender difference in Dep-FLE. In this group, women aged 65 could expect to live around 4.1 years more than men. Nevertheless, 36.9% of women's remaining life expectancy was with depression whereas in men it was only 24.8% ($p < .05$). Concerning education attainment, higher educated women and men could expect to live more years than lower educated (i.e. total life years). Additionally, compared to higher educated people aged 65 who were in union, their lowed educated counterpart could expect to live around 4.2 fewer years free of depression ($p < .05$) and almost one year more with depression (men: 0.6 years; women: 1.0 year).

Table 1. Total life expectancy (TLE), years free of depression (Dep-FLE), and years with depression (DepLE) at age 65, by gender, ethnicity, education and marital status (SEs in parentheses).

		Life expectancies (years)						Proportion (%)	
Women		**TLE**	**(SE)**	**Dep-FLE**	**(SE)**	**DepLE**	**(SE)**	**DepLE**	**Dep-FLE**
White, higher educated	In union	26.0	(0.7)	22.1	(0.6)	3.9	(0.2)	15.1	84.9
	Not in union	24.3	(0.6)	20.0	(0.5)	4.3	(0.2)	17.6	82.4
White, lower educated	In union	23.0	(0.5)	18.1	(0.5)	4.9	(0.2)	21.3	78.7
	Not in union	21.5	(0.4)	16.1	(0.4)	5.4	(0.2)	25.0	75.0
Non-White, higher educated	In union	24.9	(1.1)	19.3	(0.9)	5.6	(0.4)	22.6	77.4
	Not in union	23.4	(1.0)	17.2	(0.8)	6.2	(0.5)	26.4	73.6
Non-White, lower educated	In union	22.5	(0.9)	15.3	(0.7)	7.2	(0.5)	31.8	68.2
	Not in union	21.3	(0.8)	13.4	(0.7)	7.9	(0.5)	36.9	63.1
Men									
White, higher educated	In union	22.3	(0.5)	19.8	(0.5)	2.5	(0.2)	11.4	88.6
	Not in union	20.7	(0.7)	18.0	(0.6)	2.7	(0.2)	13.0	87.0
White, lower educated	In union	18.5	(0.4)	15.4	(0.4)	3.1	(0.2)	17.0	83.0
	Not in union	17.2	(0.6)	13.9	(0.5)	3.3	(0.2)	19.1	80.9
Non-White, higher educated	In union	21.9	(1.0)	18.5	(1.0)	3.4	(0.3)	15.6	84.4
	Not in union	20.5	(1.1)	16.9	(1.0)	3.6	(0.4)	17.5	82.5
Non-White, lower educated	In union	18.2	(0.9)	14.1	(0.8)	4.1	(0.4)	22.4	77.6
	Not in union	17.2	(0.9)	12.9	(0.8)	4.3	(0.4)	24.8	75.2

In contrast to education, the stronger effect of marital disruption was reflected in years with no depressive symptoms than for total life years. This resulted in large differences in the proportion of remaining life in depression between people who were in union and who were not in union. The study revealed the double burden of lower life expectancy and higher proportion of time spent with depression for people who had a marital disruption than people who were still in union, especially in non-White women who were lower educated.

Comparisons of differences in Dep-FLE, DepLE and total life expectancy over ages are shown in Figure 1. For the sake of brevity, results are presented only for lower educated White Americans, however estimates for both White and non-White differences were very similar by marital status. Differences in the length of life with depressive symptoms between people in union and not in union were not statistically significant. Yet the latter could expect to have less total years of life expectancy as well as lower life expectancy free of depression than people in union.

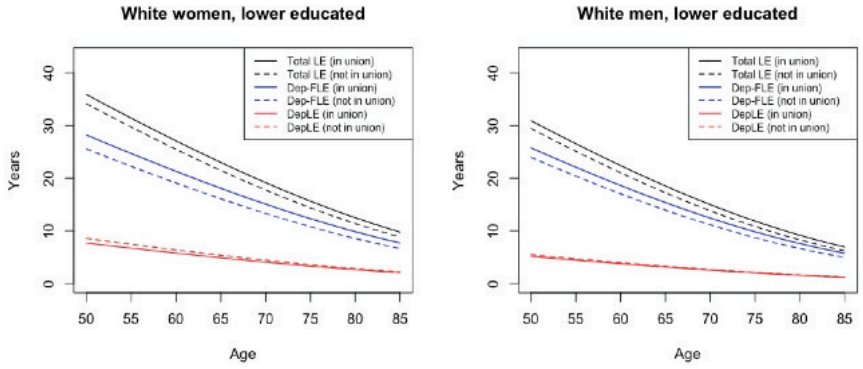

Figure 1. Total life expectancy (Total LE), years free of depression (Dep-FLE), and years with depression (DepLE) over ages, by gender and marital status.

5. Conclusion

This work gives a deeper insight of the Depression-Free Life Expectancy among older Americans, examining differences by gender, ethnicity and education. The study also aims at illustrating differences in Depression-Free Life Expectancy due to distinctive marital status (in union and not in union, i.e. marital disruption). The analysis revealed that, on average, people not in union could expect to live less years in total as well as less years free of depression. Additionally, women, who were less likely to be in union, could expect to live more years with depressive symptoms in late life than men. Our findings emphasize how estimates of depression-free life expectancies are helpful for researchers and policy makers as they may contribute to the definition of current and future social and medical service needs and policies. Furthermore, understanding the implications of marital disruption on health is relevant to the life of many around the world [5].

Disability-free grandparenthood in Italy. Trends and gender differences

Vita da nonni libera da disabilità in Italia. Tendenze e differenze di genere

Margherita Moretti, Elisa Cisotto, Alessandra De Rose [1]

Abstract Longer life expectancies potentially translate into more years of intergenerational overlap, but this effect can be counterbalanced by the delay in the timing of grandparenthood. Grandparents are older today that in the past and it is therefore crucial to study their health, since it could affect the quality of intergenerational exchange. Applying the Sullivan method on Italian data from 1998 to 2016, disability-free grandparenthood at age 65 (period life expectancy as a grandparent free from disability) by gender is estimated, as well as the contribution of changes in mortality and grandparenthood-disability prevalence on the evolution on disability-free grandparenthood.

Abstract *Speranze di vita più lunghe si traducono potenzialmente in più anni di coesistenza fra generazioni diverse, ma questo effetto può essere controbilanciato dalla posticipazione al momento in cui si diventa nonni. Oggi i nonni sono mediamente più anziani che in passato ed è quindi cruciale studiarne lo stato di salute, da cui dipende fortemente la qualità degli scambi intergenerazionali. Utilizzando il metodo Sullivan, viene stimata la speranza di vita da nonni senza disabilità a 65 anni per genere, e viene valutato l'effetto dei cambiamenti avvenuti nella mortalità e nella prevalenza della disabilità tra i nonni dal 1998 al 2016.*

Key words: Disability, Grandparenthood, Life expectancy, Ageing

1 Introduction and background

Increasing longevity and changes in fertility have been two key demographic features of European countries during the twentieth century. From the one side, longer life expectancies potentially translate into more years of intergenerational overlap than in the past. On the other side, fertility delay and reduction can counterbalance the effect of the longevity revolution on kin networks. One of the intergenerational relationships most affected by these processes is grandparenthood [1]–[3]. Italian grandparents are older today that in the past [4] and whether the years of life gained in later life are of good or bad quality is a major concern [5]–[8]. Indeed, the health status of grandparents can strongly affect the generational overlap with grandchildren, both in terms of duration [9]–[11] and of quality [12]. In particular, grandparents' health is a crucial issue in understanding the direction of intergenerational transfers, since it could impact whether grandparents are providers or recipients of care: on the one hand, when grandparents are healthy, they can eventually generate intergenerational transfers, so as caring for grandchildren, or supporting (financially, functionally, or emotionally) adult children; on the other hand, when grandparents are unhealthy, they are more likely to be recipients of care, turning intergenerational relations into a caring burden for adult children or grandchildren. This is particularly relevant if we also value the beneficial effect of the time spent together, for both grandparents [13] and grandchildren [14], and how informal grandparental care of grandchildren impacts on adult children's outcomes, including labour force participation [15], [16], and fertility decisions [17]. Moreover, Italy is clearly one of the countries in which grandparents constitute a fundamental resource for the provision of informal childcare [18], [19], and families remain the most tenacious and preferred sources of support for individuals [16], [20]. The dynamics of mortality, health and fertility differ between men and women in several regards: women generally marry at a younger age (with older men), have children (thus grandchildren) earlier, live longer but in poorer health [3], [21], [22]. This implies that women can expect to live more grandparent years than men; at the same time, older women live in worst health conditions than men, and this may lead to equal or shorter period as healthy grandparents. Within this context, our study has three main objectives: first, to shed light on the evolution of the disability-free grandparenthood (DFGP) (i.e. the length of time that one can expect to live as a grandparent free from disability) at age 65 between 1998 and 2016 in Italy; second, to disentangle the DFGP evolution according to changes due to longevity revolution and due to grandparenthood-disability prevalence; third, to analyse gender differences in DFGP in Italy and its evolution.

2 Data and methods

Data are drawn from two sources. First, we use two waves of the *Family and Social Subjects* (FSS) survey of the Italian National Institute of Statistics (Istat) for 1998 and 2016[1]. Our analytical sample considers all respondents aged 65 and over, living in Italy and reporting their grandparenthood and disability status (i.e., individuals reporting having severe disability or not, and either being grandparent or grandchild-less). The second data source are Italian life tables of 1998 and 2016, by age and gender, released by Istat. Our research builds on the healthy grandparenthood measure recently introduced by Margolis and Wright [12], as we apply the Sullivan method [23] to calculate the disability-free grandparenthood (DFGP) for older women and men living in Italy in the two target years. We first compute the prevalence of individuals in each status (disability-free grandparent, grandparent with disability, disability-free grandchild-less and grandchild-less with disability). Second, we apply the age-specific prevalence of the four statuses of interest to the age-specific person-years lived from the life tables. In this way, we specify the person-years lived in each status. Finally, we sum these quantities for the ages above 65 and divided them by the lifetable survivors at age 65, resulting in residual life expectancy in the four statuses. The sum of life expectancy at age 65 in each of the four statuses equals the total life expectancy at the same age. Thus, life expectancy is partitioned into years spent being (i) disability-free grandparent, (ii) grandparent with disability, (iii) disability-free grandchild-less and (iii) grandchild-less with disability. The key outcome is the DFGP estimate (i.e., the period life expectancy as disability-free grandparent), which measures the average number of years that a hypothetical cohort of individuals can expect to live as grandparents free from disability, if they experience the mortality, disability and grandparenthood conditions observed in the studied year. Finally, by implementing the Horiuchi decomposition method [24] we analyse the age-specific contribution that the changes in mortality and grandparenthood-disability prevalence have on the evolution of DFGP from 1998 to 2016.

3 Results

Figure 1 shows the partition of overall life expectancy at age 65 (represented by the overall length of the bars and noted in black next to them) into the different states of grandparenthood and health status, by gender, for 1998 and 2016. In 1998, at the age of 65, Italian men have approximately a life expectancy of 16 years and women of almost 20. Of these, the years spent as grandparent (purple and pink part of the bars) outweigh those as grandchild-less, and only half of life expectancy is of

[1] The data processing for the year 2016 was conducted at Istat's Laboratory for the Analysis of Elementary Data (ADELE) and in compliance with the regulations on the protection of statistical confidentiality and personal data protection. The results and opinions expressed are the sole responsibility of the author and do not constitute official statistics.

DFGP (almost 9 and 10 years for men and women, respectively). Women can expect to live more years as grandmothers than men as grandfathers, but the share of years lived as grandparents over total life expectancy is similar for both gender (more than 70%). However, although women having one year more of DFGP than men, the share of DFGP on total life expectancy and on overall years as grandparents, are higher for men (respectively, 55% and 78%) than for women (50% and 70%). In fact, Italian women aged 65 in 1998 have more years with disability than men and, particularly, of those to live as grandmothers. From 1998 to 2016, as life expectancy at age 65 increases (by more than 3 years for men and 2.5 for women), DFGP at the same age increases for both genders, reaching more than 10 years for men and more than 12 for women. Over the same years, the increase in DFGP of men (of around 2 years) is at a slower pace than that of life expectancy, while for women the rise (more than 2.5 years) is faster. As a result, despite the gender difference in life expectancy decreases between 1998 and 2016, the gender difference in DFGP increases and reaches almost 2 years in 2016. Interestingly, in 2016, women and men share the same portion of DFGP life expectancy (around the 56%). However, compared to men, women display a higher portion of life expectancy as grandmothers (almost 70% vs 65% for men), and a lower share of DFGP over the total grandparent years (80% vs 85% for men), implying that the health quality of grandmothers is poorer than that of grandfathers.

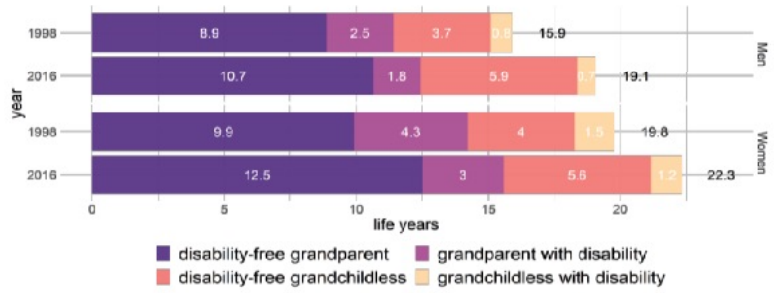

Figure 1: Life expectancy at age 65 by grandparent-disability status for Italian men and women in 1998 and 2016

Figure 2 displays the contribution of changing mortality rates and prevalence of disability-free grandparents to the change in DFGP between 1998 and 2016, by gender. For women, the contribution of mortality and prevalence of disability-free grandparents increase with ages (except for mortality contribution at age 85+). Up to the age 80, the contribution of the improved survival is more important in determining the evolution (increase) in DFGP, while for the oldest old women (aged 80+) there is a greater contribution of the prevalence of disability-free grandparents. Overall, from 1998 to 2016, there is an improvement in women's survival and an increase in the prevalence of healthy grandmothers for each age, which contributes to 2.6 years increase in DFGP. For men, mortality always contributes positively to the increase in DFGP, however, after the age of 70 its relevance decreases with age. In determining the evolution of DFGP, the prevalence of disability-free grandparents contributes less than mortality and, moreover, negatively between the ages of 65 and

74. Therefore, from 1998 to 2016, improvement in survival reduce its contribution to the change in DFGP as men gets older, while there is a reduction in the prevalence of disability-free grandparents for men, which lead to a decrease of 4 months (0.19 + 0.16 years) in the average number of years as DFGP. Knowing that overall population health improves from 1998 to 2016, this indicates that there is a noticeable reduction of the prevalence of grandparents during this period, resulting in a slowdown in the increase of DFGP, offsetting the positive effect of the reduction in disability and mortality along the observed period.

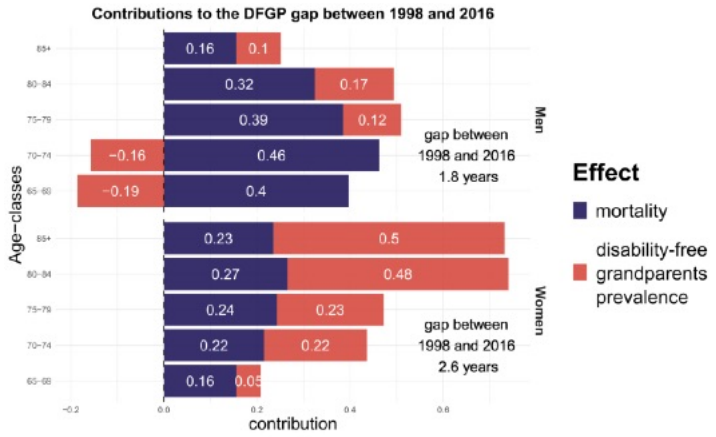

Figure 2: Mortality and disability-free grandparents prevalence contributions to the DFGP gap between 1998 and 2016 for Italian older men and women, by age classes

4 Conclusions

The average number of years individuals spend in DFGP is influenced by patterns of grandparenthood, disability, and mortality observed in the years under consideration. Because these rates and prevalence vary over time and across several dimensions, demographic methods such as Sullivan's can help to explain the effects of these changes on the quality and duration of intergenerational overlaps. Our study shows that, from 1998 to 2016, absolute DFGP and its share on the overall years spent as grandparents increases for both women and men. This reveals that, on average, Italian grandparents have more disability-free years of overlap with their grandchildren. Moreover, our results suggest that the speed of increase of DFGP is primarily led by the sharp improvement of health and survival conditions; hence, it has been slowed down by the postponement in the transition to grandparenthood. Overall, this study provides the first evidence on DFGP evolution in Italy and its gender differences. It also contributes to reflections on the roles of mortality, health, and family dynamics as measures to be considered simultaneously in a synthetic indicator, as life expectancy by disability and grandparenthood status.

Advances in regression models

Semiparametric M-quantile regression for modelling georeferenced housing price data

Regressione M-quantile semiparametrica per la modellizzazione di dati georeferenziati relativi ai prezzi delle abitazioni

Riccardo Borgoni, Antonella Carcagnì, Alessandra Michelangeli, Nicola Salvati, Francesco Schirripa Spagnolo

Abstract This paper applies the M-quantile regression approach to address the heterogeneity of the housing market of a modern European city, Milan (Italy). Our findings show that several housing attributes differ significantly across the response distribution suggesting that buyers of lower-priced properties behave differently from buyers of higher-priced properties.

Abstract *L'obiettivo di questo lavoro è quello di applicare l'approccio di regressione M-quantile per studiare l'eterogenità dei prezzi della abitazioni nella città di Milano, una moderna città europea. I risultati ottenuti, mostrano come alcune caratteristiche abbiano un effetto diverso sulla distribuzione condizionata dei prezzi, suggerendo che gli acquirenti delle proprietà a basso valore si comportano in modo diverso rispetto a quelli delle proprietà ad alto valore.*

Key words: Robust methods; Hedonic approach; Real Estate Observatory

1 Introduction

In this paper we use the M-quantile approach to model the distribution of housing prices conditional to housing attributes at different points of the housing price distribution. We focus on the Milan apartment market, characterized by a complex market dynamics reflecting the heterogeneity of such a big city in terms of neighbourhood, building and population features. Milan residential market has already

Riccardo Borgoni; Antonella Carcagnì; Alessandra Michelangeli
Dipartimento di Economia, Metodi Quantitativi e Strategia di Impresa Università degli Studi di Milano Bicocca, Via Bicocca degli Arcimboldi, 8, Milano, Italy, e-mail: riccardo.borgoni@unimib.it; antonella.carcagni@unimib.it;alessndra.michelangeli@unimib.it

been investigated in a number of quite recent studies [1, 2, 4, 8]. In particular, one of these studies, [1], uses the hedonic approach to estimate the effect of culture, public transport, education and environmental conditions on the housing market value in the city of Milan. In this paper, we maintain the hedonic framework and we propose an statistical model based on the M-quantile regression in order to obtain a more robust and efficient estimation of the hedonic price function accounting for the heterogeneities of the price market mentioned above.

For our purposes, we consider a semiparametric M-quantile regression, proposed by [10, 11] to account for potential non-linear effects of the predictors and for the spatial dependence in the response variable.

2 The Semiparametric M-quantile regression

M-quantile regression [5] is a 'quantile-like' generalization of regression based on influence functions (M-regression) able to grasp differential effect of a covariate at different levels of the conditional distribution of the response variable. Given $\boldsymbol{x}$, the linear M-quantile regression model is defined by $MQ_y(q \mid x, \psi)) = x'\beta$ where β represents a vector of unknown parameters and ψ_q denotes an asymmetric influence function. In our paper, the set $\boldsymbol{x}$ includes a range of variables representing housing-specific characteristics and urban amenities described in details in Section 3. Throughout the paper, the influence function is Huber proposal-2 influence function: $\psi(u) = uI(-c \leq u \leq c) + c\text{sgn}(u)I(|u| > c)$, with a tuning constant $c = 1.345$ that guarantees 95% of efficiency of the estimates under normality [6].

The semiparametric model for the conditional for M-quantile q considered in this paper assumes the following form:

$$MQ_Y(\mathbf{x}, t, \mathbf{s}_i; \psi) = \mathbf{x}^T\beta_q + f_{1q}(t) + f_{2q}(\mathbf{s}_i), \tag{1}$$

where $f_1(\cdot)$ and $f_2(\cdot)$ represents two unknown arbitrary smooth functions; $\mathbf{s}_i \in \mathbb{R}^2$ represents the geographical coordinates of unit i; t is the scalar covariate expected to impact on Y nonlinearly. In this paper $f_{1q}(\cdot)$ and $f_{2q}(\cdot)$ are represented by linear combination of thin plate spline basis functions.

The regression parameters of the semiparametric M-quantile model (S-MQ) are estimated via penalised least squares by solving the following estimation equations [11]:

$$\sum_{i=1}^{n} \psi_q(y_i - \mathbf{z}_i^T\eta_q)\mathbf{z}_i^T + \lambda_{1q}\mathbf{D}_1\eta_q + \lambda_{2q}\mathbf{D}_2\eta_q = \mathbf{0}, \tag{2}$$

where $\eta_q = (\beta_q^T, \theta_{1q}^T, \theta_{2q}^T)^T$, $\mathbf{z}_i^T = (\mathbf{x}_i, t_i, t_i^2, \mathbf{b}_{1i}, \mathbf{b}_{2i})$, $\mathbf{D}_1$ and $\mathbf{D}_2$ are two penalty matrices and λ_{1q} and λ_{2q} are the smoothing parameters estimated via external Generalised Cross Validation (GCV). In particular, the GCV to be minimised in order to

obtain $\Lambda_q = (\lambda_{1q}, \lambda_{2q})$ is $\text{GCV}(\Lambda_q) = \dfrac{||(\mathbf{I} - S_{\Lambda_q})\mathbf{y}||^2}{(1 - n^{-1}\delta \text{tr}(S_{\Lambda_q}))^2}$, where S_{Λ_q} is a smoother-type matrix associated with $MQ_Y(\mathbf{x}, t, \mathbf{s}_i; \psi)$ and and δ is a penalization term for the additional degrees of freedom given by the trace of the smoother matrix.

3 Modelling housing price in Milan using semiparametric M-quantile regression

The data come from different sources and are combined into a single data set. Housing market data are from the Real Estate Observatory (Osservatorio del Mercato Immobiliare). These data provide information about 4,000 individual housing transactions in Milan between 2004 and 2010. In addition to housing market values, the data set provides information and detailed description of housing-specific attributes of the sample units. Housing units in the sample are spatially identified by their civic address. Each civic address is geocoded by its UTM coordinates using a Java script that retrieves this information from Google Maps geographical databases. This allows us to add geocoded data about urban amenities to the housing transaction dataset. Urban amenity variables are taken from the open data portal of the municipality of Milan and the Regional Environmental Protection Agency (ARPA) of the Lombardy region. In particular, we consider the availability of public transport, education, air quality, cultural activities and related infrastructures. Finally, to control for the effect of the financial crisis of 2008 on the housing market, a binary variable that identifies all the transactions occurred before and after this year has been also defined. The list, description and definition of the variables used in the empirical analysis is given in Table 1.

Table 1 Variables description

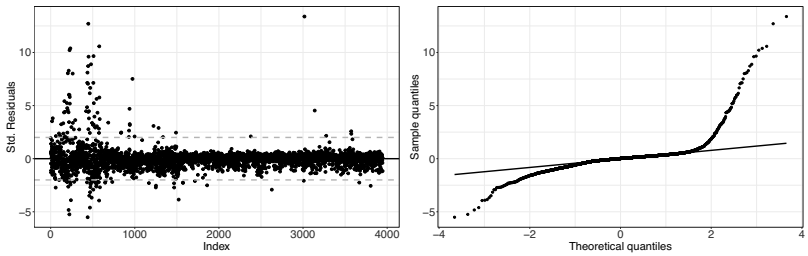
Variables	*Values*
Housing specific characteristics	
Annual market value	annual market value in Euro
Total floor area	coded on three levels < 63; (63,115]; (115,491]
Elevator	1: at least one elevator; 0 otherwise
Parking area	1: the house has a parking place or garage; 0 otherwise
Bathroom	1: two or more bathrooms; 0 otherwise
Floor	1: the house is located at the second floor or above; 0 otherwise
Heating system	1: autonomous heating system; 0 otherwise
Urban Amenities	
Cultural catalyst	Positive real values (rescaled in 0-1)
Metro	1: far from houses; 0 otherwise
University	1: far from houses ; 0 otherwise
Air quality index	1: bad air quality; 0 otherwise
Abandoned area	1 distance from houses $\leq$200; 0 otherwise
Year	1: sold in the post-crises sample period (2009-2010); 0 otherwise

To assess the need for using a robust approach a standard semiparametric linear model has been estimated:

$$\mathrm{E}(y|\mathbf{x},t,\mathbf{s}_i;\psi) = \mathbf{x}^T\beta_q + f_{1q}(t) + f_{2q}(\mathbf{s}_i), \tag{3}$$

In this paper, we include the univariate spline component, $f_{1q}(\cdot)$, to take into account the potential nonliner effect of the Cultural Catalyst (t) on the target variable (see [1]). This variable, is a composite indicator of cultural amenities available in our data set: theatres, museums, libraries and auditoria. Moreover, a bivariate spline component, $f_{2q}(\cdot)$, has been included to account for the spatial dependence. The nodes are located in the plane by the cluster separation method `clara` implemented in `R`. More in detail, $f_{2q}(\cdot)$ is a regular function in the spatial coordinates approximated by a bivariate spline while $f_{1q}(\cdot)$

We report in Fig. 1 the plot and the normal probability plot of standardized residuals. The plots indicate that the normality assumption adopted in standard semiparametric modelling does not hold and the presence of outliers. Therefore, the application of a robust model is justified.



(a) (b)

Table 2 reports the results of the SMQ model. The model has been fitted by using the tuning constant of the Huber influence function equal to 1.345 and $\delta = 3$.

This results, suggest that several variables tend to have a different effect at different points of the conditional distribution of the house market values and also the statistical significance tends to change. Regarding the housing-specific characteristics, "lift", "bathroom" and the two dummies of the floor area, have a positive and statistically significant effect at all M-quantiles, moreover, the magnitude of the effect is higher at the top of the distribution than it is elsewhere. "Parking area" is not statistically significant at $q = 0.10$, while "floor" and "heating system" tend to do not affect the price of houses in Milan. Focusing on amenities variables, no variable significantly different from zero across the entire conditional distribution. More in detail, "University" is significant at every M-quantile except the most extreme ($q = 0.9$) and it slightly increases as the price increases. As expected, the neighbouring degradation (variable "Abandoned area") contributes negatively to the

Table 2 Results of SPMQ ($q = 0.10, 0.25, 0.50, 0.75, 0.90$) estimated using 20 knots for f_{1q} and 40 knots for f_{2q} - $\delta = 3$†.

house price and in particular it affects most the the price of high valued houses while it is not significant for very low valued hoses ($q = 0.1$).

4 Conclusions

The aim of this paper has been to apply the M-quantile approach to examine how the effect of housing characteristics may vary across the conditional distribution of house prices in Milan. By employing a a semiparametric M-quantile regression, the findings suggest that several housing attributes differ significantly across the response distribution, suggesting the usefulness of estimating the conditional M-quantile functions in addition to the conditional mean.

Resampling-Based Inference for High-Dimensional Regression

Inferenza Tramite Ricampionamento per Regressioni ad Alta Dimensionalità

Anna Vesely and Jelle J. Goeman and Angela Andreella and Livio Finos

Abstract We propose a novel procedure for resampling-based multiple testing in high-dimensional regression. First, we construct permutation test statistics for each individual hypothesis by means of repeated random splits of the data. In each split, half of the observations is used to perform variable selection, and half to build test statistics for the selected variables. Then we define an asymptotically exact test for any subset of hypotheses by aggregating the individual statistics through a suitable function, e.g., maximum or weighted sums. The procedure is flexible, allowing different selection techniques and combining functions. It can be embedded into closed testing methods to make simultaneous confidence statements on the proportion of true discoveries (TDP) of all subsets, valid even under post-hoc selection.

Abstract *Si propone un metodo basato sul ricampionamento per test multipli in regressioni ad alta dimensionalità. Si definiscono statistiche test per ogni singola ipotesi tramite partizioni casuali dei dati, in cui metà delle osservazioni sono usate per selezionare le variabili, e metà per costruire statistiche per le variabili selezionate. Aggregando tali statistiche, ad es. con il massimo o somme pesate, si ottiene un test asintoticamente esatto per ogni sottoinsieme di ipotesi. La procedura è flessibile, poiché ammette diverse tecniche di selezione e diverse funzioni di combinazione. Può essere utilizzata all'interno di metodi di closed testing per ottenere*

limiti di confidenza per la proporzione di variabili attive (TDP), simultaneamente su tutti i sottoinsiemi di ipotesi.

Key words: high-dimensional regression, multiple testing, Multisplit, resampling-based test, true discovery proportion

1 Introduction

In linear regression, interest usually lies in discovering relevant predictor variables and assessing statistical significance; however, many challenges arise in high-dimensional settings. Researchers are often interested in studying subsets of variables with an exploratory approach, quantifying activation inside. Moreover, when they do not know a priori which subsets they are interested in, they may want to study many and make the selection post hoc.

We propose a multiple testing method for high-dimensional linear regression that defines a test for any subset of variables and ensures asymptotic error control. We use the permutation framework, which is often more powerful than the parametric approach, especially when considering multiple hypotheses [2]. The method relies on two building blocks: the Multisplit proposed by [4], that computes adjusted p-values for all variables using variable selection techniques and repeated splits of the data, and the sign-flipping test given in [3].

First, we construct permutation test statistics for all variables. Then we aggregate these individual statistics to define an asymptotically exact test for any subset of variables. Different combining functions are possible, including the maximum and weighted sums. As we can test any subset, the procedure can be embedded into closed testing methods that give simultaneous confidence sets for the true discovery proportion (TDP), such as [1] and [6]. This way we are able to provide confidence statements on the TDP of all subsets, valid even under post-hoc selection.

The structure of the paper is the following. We introduce the model and its assumptions in Sect. 2, then we define the method in Sect. 3. Finally, in Sect. 4 we compare the proposed method and the Multisplit through simulations.

2 High-Dimensional Linear Regression

We consider a linear regression framework with n observations and m variables, potentially high-dimensional ($n < m$). The model is

$$Y = X\beta + \varepsilon, \qquad \varepsilon \sim \mathcal{N}_n(0, \sigma^2 I) \tag{1}$$

where $\mathcal{N}_n$ denotes the multivariate normal distribution, and $I \in \mathbb{R}^{n\times n}$ is the identity matrix. Here $Y \in \mathbb{R}^n$ is the response vector, $X \in \mathbb{R}^{n\times m}$ is a fixed design matrix,

$\beta \in \mathbb{R}^m$ is the vector of coefficients and $\varepsilon \in \mathbb{R}^n$ is a random error vector. We assume that X has rank m, and $X^\top X/n$ converges to a finite positive semi-definite matrix as $n \to \infty$.

We are interested in exploring which variables in X are active, meaning that they have non-null coefficients. Let $M = \{1, \ldots, m\}$ be the set of variable indices, and $N = \{j \in M : \beta_j = 0\}$ the unknown subset corresponding to inactive variables. For any $j \in M$, we may define the null hypothesis $H_j : \beta_j = 0$, that is true when $j \in N$, regardless of the value of other variables' coefficients. We want to study more variables taken together, i.e., test intersection hypotheses of the form

$$H_S = \bigcap_{j \in S} H_j : \beta_j = 0 \text{ for all } j \in S \qquad (S \subseteq M,\ S \neq \emptyset)$$

with significance level $\alpha \in [0, 1)$. H_S is true if all variables in S are inactive ($S \subseteq N$).

To test any H_S, we will rely on a variable selection procedure that estimates the set of active variables with $A \subseteq M$. As in [4], we assume the following properties.

Sparsity $\quad |A| \leq n/2$.
Screening property $\quad \lim_{n\to\infty} P(M \setminus N \subseteq A) = 1$.

The ideal selection procedure, for which the screening property always holds, is an oracle method that selects all truly active variables, plus eventually some others. Even though this is not available in practice, it can be used in simulations to show the performance of the proposed method when the assumptions are ensured. When studying real data, we suggest using the Lasso [5] with a suitable calibration of the λ parameter, so that it selects enough variables for the screening property to be likely. If m_1 is an estimate of the expected number of active variables, we recommend choosing λ so that the Lasso selects $\min(2m_1, n/2)$ variables.

3 Resampling-Based Multisplit

We propose an asymptotically exact test for any intersection hypothesis H_S corresponding to a non-empty set $S = \{j_1, \ldots, j_s\} \subseteq M$. The method will efficiently construct permutation test statistics for H_S by combining statistics for the individual hypotheses H_j with $j \in S$. We take as combining function any $g : \mathbb{R}^s \longrightarrow \mathbb{R}$ which is increasing in each argument, such as the maximum or (weighted) sums.

To define permutation test statistics for all individual hypotheses H_j, we use Q random splits of the data and B random sign-flipping transformations. The values of Q and B do not need to grow with m; larger values of B tend to give more power, but to have non-zero power we only need $B \geq 1/\alpha$ [2]. Hence fix B diagonal sign-flipping matrices $F_1, \ldots, F_B \in \mathbb{R}^{n\times n}$, where $F_1 = I$ is the identity, while the diagonal elements of the other matrices are independently and uniformly drawn from $\{-1, 1\}$. As in [4], for each split q we randomly partition observations into two equally-sized subsets $\mathscr{D}_0^q$ and $\mathscr{D}^q$, and we use $\mathscr{D}_0^q$ to estimate the set of active vari-

ables with $A^q \subseteq M$. Then we use $\mathscr{D}^q$ and A^q to compute test statistics similarly to [3], as follows.

For each split q, we restrict the design matrix X to observations in $\mathscr{D}^q$ and variables in A^q, obtaining $X^q = X_{\mathscr{D}^q, A^q}$. For each selected variable $j \in A^q$, we define X^q_{-j} as X^q without the j-th column, then we construct the split's residual maker matrix

$$R^q_{-j} = 0 \in \mathbb{R}^{n\times n} \qquad \text{except} \qquad R^q_{-j;\mathscr{D}^q,\mathscr{D}^q} = I - X^q_{-j}(X^{q\top}_{-j}X_{-j})^{-1}X^{q\top}_{-j}$$

where all elements are zero except those corresponding to observations in $\mathscr{D}^q$.

We give statistics for all variables by aggregating information over the Q splits:

$$C_{j,b} = \sum_{q:\, j\in A^q} R^q_{-j} F_b R^q_{-j} \in \mathbb{R}^{n\times n}$$

$$T^b_j = \begin{cases} 0 \text{ if } \|X_j^\top C_{j,b}\| = 0 \\ \|X_j^\top C_{j,b}\|^{-1} |X_j^\top C_{j,b} Y| \text{ otherwise} \end{cases} \qquad (j \in M,\, b \in \{1,\dots,B\})$$

where X_j is the j-th column of X.

To test H_S, it is sufficient to combine the individual statistics T^b_j as

$$T^b_S = g\left(T^b_{j_1}, \dots, T^b_{j_s}\right) \qquad (b \in \{1,\dots,B\}).$$

As a critical value we take $T_S^{(\lceil (1-\alpha)B \rceil)}$, where $T_S^{(1)} \le \dots \le T_S^{(B)}$ are the sorted statistics, and $\lceil \cdot \rceil$ denotes the ceiling function.

Theorem 1. *The test that rejects H_S when $T^1_S > T_S^{(\lceil (1-\alpha)B \rceil)}$ is asymptotically an α-level test.*

Proof. Assume that H_S is true, and consider any couple of variables $j,h \in S$, any transformation b, and any split q. Suppose that the variable selection procedure selects all active variables; by the screening property, this is true at least asymptotically, so this assumption does not affect asymptotic results. As H_j is true and A^q contains all active variables, we can write

$$Y_{\mathscr{D}^q} = X_{-j;\mathscr{D}^q,A^q}\beta_{-j;A^q} + \varepsilon_{\mathscr{D}^q}, \qquad \varepsilon_{\mathscr{D}^q} \sim \mathscr{N}_{n/2}(0, \sigma^2 I).$$

For any selected variable $j \in A^q$, the matrix R^q_{-j} has non-null elements only corresponding to observations in $\mathscr{D}^q$, and so the effective score for this model is

$$V^{qb}_j = \frac{1}{\sqrt{n}} X_j^\top R^q_{-j} F_b R^q_{-j} Y = V^{*qb}_j + o_P(1), \qquad V^{*qb}_j = \frac{1}{\sqrt{n}} X_j^\top R^q_{-j} F_b \varepsilon$$

(see Theorem 2 in [3]). Hence the sB-dimensional vectors

$$\mathbf{V}_S = (V^1_{j_1}, \dots, V^B_{j_1}, \dots, V^1_{j_s}, \dots, V^B_{j_s})^\top, \qquad V^b_j = \sum_{q:\, j\in A^q} V^{qb}_j$$

$$\mathbf{V}^*_S = (V^{*1}_{j_1}, \dots, V^{*B}_{j_1}, \dots, V^{*1}_{j_s}, \dots, V^{*B}_{j_s})^\top, \qquad V^{*b}_j = \sum_{q:\, j\in A^q} V^{*qb}_j$$

are asymptotically equivalent. Notice that T_j^b is the standardization of $|V_j^b|$. Since

$$\mathbf{V}_S^* \xrightarrow[n\to\infty]{\mathrm{d}} Z \sim \mathcal{N}_{sB}(0, \Xi \otimes I)$$

$$I \in \mathbb{R}^{B\times B}, \qquad \Xi = (\xi_{k\ell}) \in \mathbb{R}^{s\times s}, \qquad \xi_{k\ell} = \sigma^2 \lim_{n\to\infty} \frac{1}{n} X_{j_k}^\top C_{j_k,1} C_{j_\ell,1} X_{j_\ell}$$

the B vectors $(V_{j_1}^1,\ldots,V_{j_s}^1),\ldots,(V_{j_1}^B,\ldots,V_{j_s}^B)$ converge to i.i.d. random vectors, and so do the vectors $(T_{j_1}^1,\ldots,T_{j_s}^1),\ldots,(T_{j_1}^B,\ldots,T_{j_s}^B)$. Therefore the combinations of their elements $T_S^1,\ldots,T_S^B$ converge to i.i.d. random variables. Moreover, high values of T_S^1 correspond to evidence against H_S. From Lemma 1 in [3],

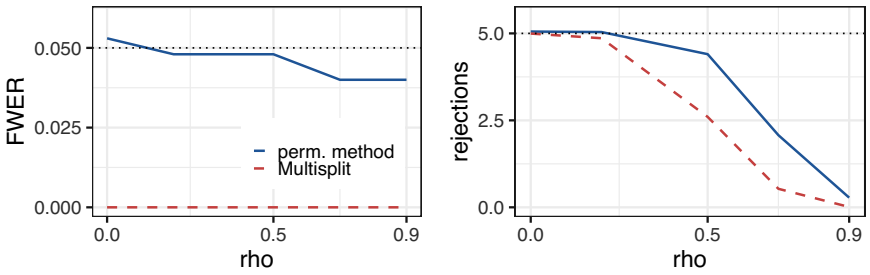
$$\lim_{n\to\infty} P\left(T_S^1 > T_S^{(\lceil(1-\alpha)B\rceil)}\right) = \frac{\lfloor \alpha B \rfloor}{B} \leq \alpha.$$

□

To summarize, we have constructed permutation test statistics for all variables in high-dimensional regression, that are sufficient to define an asymptotically exact test for any intersection hypothesis H_S. The test is obtained combining the statistics for variables in S through any function g that is increasing in each argument.

4 Simulations

We compare the proposed method with the Multisplit, using simulation settings similar to those in [4], with $n = m = 100$. We simulate X from a centered multivariate normal distribution with $\mathrm{cov}(X_j, X_h) = \rho^{|j-h|}$ for $j,h \in M$, taking $\rho \in \{0, 0.2, 0.5, 0.7, 0.9\}$. We compute Y as in (1), where $\beta = (1,\ldots,1,0,\ldots,0)$ has 5 non-null elements, and σ is such that the signal-to-noise ratio is 4. We take $\alpha = 0.05$,



(a) FWER. The dotted line corresponds to the significance level α.

(b) Number of rejections. The dotted line denotes the number of active variables.

Fig. 1: Results by covariance parameter ρ.

$Q = 50$, $B = 200$, and an oracle selection that returns 10 variables. We simulate data 1000 times and study the set of all variables. For the proposed method, we correct for multiplicity with the maxT-method [8], corresponding to $g = \max$.

Results are shown in Fig. 1. Both methods control the FWER, computed as the proportion of simulations where at least one true null hypothesis is rejected. In terms of rejections, the proposed method is equivalent to the Multisplit when the covariance parameter ρ is small, and more powerful in all the other scenarios.

5 Discussion

We have considered the problem of testing multiple hypotheses in high-dimensional linear regression. Our proposed approach provides asymptotically valid resampling-based tests for any subset of hypotheses, which can be employed within closed testing procedures to make confidence statements on the number of active predictor variables (TDP) within any set. These confidence statements are valid even when the subsets of interest are chosen post hoc, after seeing the data.

First, we have provided a procedure that repeatedly splits the data into two random subsets, using the first to select variables and the second to build permutation test statistics for each variable. Then we have shown that statistics for any intersection hypothesis can be defined by aggregating individual statistics with any function which is increasing in each argument, including the maximum and weighted sums. Our method is extremely flexible, allowing different selection procedures and combining functions. Preliminary simulations show a considerable increase in power over the Multisplit [4]. An implementation of the procedure is available in [7].

Quantile regression coefficient modeling for counts to evaluate the productivity of university students

Modellazione dei coefficienti di regressione quantile per dati di conteggio per valutare la produttività degli studenti universitari

Viviana Carcaiso and Leonardo Grilli

Abstract The extension of quantile regression to count data raises several issues. In this research we compare a solution which exploits jittering to obtain a continuous working variable to a more recent approach, in which the coefficients of quantile regression are modeled by parametric functions. Both methods are applied for evaluating the effect of remote teaching on university students' productivity. In this context, the latter approach is found to be advantageous.

Abstract *L'estensione della regressione quantile ai dati di conteggio provoca diversi problemi. In questa ricerca confrontiamo una soluzione che sfrutta il jittering per ottenere una variabile continua con cui lavorare con un approccio più recente, in cui i coefficienti di regressione quantile sono modellati da funzioni parametriche. Entrambi i metodi sono applicati per valutare l'effetto della didattica a distanza sulla produttività degli studenti universitari. In questo contesto, l'approccio più recente risulta vantaggioso.*

Key words: COVID-19, jittering, parametric modeling, quantiles, university credits

1 Introduction

Quantile regression has the main advantage of being completely distribution-free and avoiding some of the restrictive assumptions of conventional regression: it does not require homoscedasticity or a specific type of distribution for the response and it

Viviana Carcaiso
Department of Statistical Sciences, University of Padova, Padova, Italy. e-mail: viviana.carcaiso@phd.unipd.it

Leonardo Grilli
Department of Statistics, Computer Science, Applications "G. Parenti", University of Florence, Florence, Italy. e-mail: leonardo.grilli@unifi.it

is very flexible since regression equations at different quantiles are fitted separately. Most of its theoretical developments and empirical applications concern continuous outcomes. Indeed, the response variable is generally assumed to be sampled from an absolutely continuous population, which is not true if the outcome is a count. The extension of quantile regression to count data raises several issues, mainly related to the fact that the conditional quantile function of a discrete random variable cannot be a continuous function of the regression parameters [6]. The solution suggested by Machado and Santos Silva (2005) [6] is to generate an artificial continuous variable by adding a uniform random variable to the original counts, a procedure referred to as jittering. This allows to obtain a continuous working variable whose quantiles have a one-to-one relation with those of the response (see [4] for an application to the productivity of university students). A recent alternative approach considered in this research is the one by Frumento and Salvati (2021) [3], who suggest applying the quantile regression coefficients modeling (QRCM) paradigm described in [2] to model a discrete response. As Machado and Santos Silva, they want to impose some degree of smoothing to the assumed distribution, without altering the response itself. Their solution permits to avoid jittering and was shown to provide numerous advantages, including parsimony, efficiency and simplicity in terms of interpretation. Here, we apply both methods to evaluate the effect of remote teaching due to COVID-19 pandemic on university students' productivity of freshmen from the academic year 2019/2020 of the University of Florence. The rest of the paper is organised as follows. Section 2 outlines the theory of the two methods, Section 3 illustrates the case study and the applied statistical models, and in Section 4 we discuss the obtained results.

2 Methods

In 2005, Machado and Santos Silva [6] proposed analyzing count data using quantile regression, which permits avoiding strong parametric assumptions and enables investigating every aspect of the conditional distribution of the response variable, not just its mean. However, there are some complications, related to the non-smoothness of the objective function combined with the discreteness of the response variable. The solution of Machado and Santos Silva [6], that will be referred to as QRCJ (Quantile Regression for Counts based on Jittering), is based on the artificial smoothing of the data using jittering.

More specifically, after defining $Z = Y + U$, where U is a uniform random variable independent of Y and $\boldsymbol{x}$, and noting that $Q_Z(p|\boldsymbol{x})$ is bounded from below by p, the authors specified a model of the form $Q_Z(p|\boldsymbol{x}) = p + \exp(\boldsymbol{x}'\boldsymbol{\beta}(p))$. In other words, they propose to use a monotone transformation of the conditional quantile function of Z, namely $T(Z;p) = \log(Z-p)I(Z > p) + \log(\zeta)I(Z \leq p)$, where ζ is an arbitrary small positive number, and then $\boldsymbol{\beta}(p)$ can be estimated by running a linear quantile regression of $T(Z;p)$ on $\boldsymbol{x}$. The value of $\hat{\boldsymbol{\beta}}(p)$ depends not only on the sample information but also on the specific realization of U, thus the authors

propose to generate m "jittered" samples and to average the estimates (they call this procedure "average-jittering"). The average jittering estimator is proved to be more efficient than the one based on a single sample and, under mild conditions on the covariates, to be consistent and asymptotically normal, therefore standard asymptotic theory can be used to perform inference. The simulation study in [6] shows that the proposed estimator has good properties in finite samples of size $n = 500$.

The fact that quantiles are estimated one at a time and that no parametric structure is assigned to the coefficient functions has relevant drawbacks [3]. The quantile regression coefficients modeling (QRCM) approach, first developed by [2], and then applied to count data by [3], consists in describing the regression coefficients by smooth parametric functions with closed-form mathematical expressions and should provide a gain in terms of efficiency and simplicity of interpretation. In the general QRCM framework presented by [2] the q regression parameters are defined as $\boldsymbol{\beta}(p|\boldsymbol{\theta}) = \boldsymbol{\theta}\boldsymbol{b}(p)$, where $\boldsymbol{b}$ is a vector of k known functions of p that are assumed to be continuous and differentiable, and $\boldsymbol{\theta}$ is a $q \times k$ matrix. In the specific case of quantile regression for count data, the model proposed by Frumento and Salvati is driven by the empirical evidence that the estimators obtained by applying QRCM to the jittered response, $Z = Y + U$, and directly to $Y^{\circ} = Y + E[U]$ are almost identical, due to imposed parametric structure [3]. Therefore, after assuming, without loss of generality, $E[U] = 0.5$, the model is applied to a transformation $T(\cdot)$ of $Y^{\circ} = Y + 0.5$, that is

$$Q_{T(Y^{\circ})}(p|\boldsymbol{x}, \boldsymbol{\theta}) = \boldsymbol{x}'\boldsymbol{\beta}(p|\boldsymbol{\theta}) = \boldsymbol{x}'\boldsymbol{\theta}\boldsymbol{b}(p).$$

The estimation is carried out by minimizing the integrated objective function, which is the integral, with respect to the order of the quantile, of the loss function of standard quantile regression. This estimation approach allows to estimate the entire quantile process instead of a discrete set of quantiles. Furthermore, the integrated loss function is a smooth function of its arguments, and this allows to carry out minimization using standard algorithms, like Newton–Raphson or gradient search, and to apply the standard theory of M-estimators to investigate the asymptotic behaviour of the estimator. Fitting linear quantiles is the most common practice because of the simplicity of the interpretation [2], but in [3] it is also proposed a logarithmic transformation.

The idea is that the imposed parametric structure should yield some gain in terms of efficiency, as shown by the simulation results reported by the authors in [3]. However, specifying a "good" parametric model for a quantile function it is not easy, since there are many different possible specifications. The model is determined by the choice of $\boldsymbol{b}(p)$, which must be defined in advance, and by the restrictions that are imposed on $\boldsymbol{\theta}$. In practice, the most common choices are polynomials, splines, piecewise linear functions, roots, logarithms, trigonometric functions, quantile functions of known distribution (e.g., that of a Normal, Beta or Gamma distribution), and combinations of the above. In many situations, some of the quantile regression coefficients can be assumed to be linear functions of p, or not to depend on p at all. [2] propose a goodness-of-fit test procedure that is based on the idea of assessing the

model fit by comparing the distribution of $F(y_i|\boldsymbol{x}_i,\boldsymbol{\theta})$, $i = 1,\ldots,n$, with a $U(0, 1)$ distribution, but it just represents an approximation in the framework of count data.

3 Application

The evaluation of the impact of the change to remote teaching on university students' careers represents an interesting application of quantile regression for count data. The data were collected in the administrative records and concern first-year students who enrolled in the Bachelor's degree courses of Psychological Sciences and Industrial Design in the academic years 2018/2019 and 2019/2020 at the University of Florence. Two different degree courses are selected to have an insight in different fields of study. The idea is to compare the productivity of freshmen in the second semester of 2019/2020, which is the one affected by online teaching, to that of first-year students in the second semester of 2018/2019, who received the usual frontal lectures. Both cohorts attended regular lectures in the first semester, but were exposed to different forms of teaching in the second one. In both academic years of interest the study plan remained the same. After excluding students who got no credits in the first semester, the data set consist of 946 first-year students, whose characteristics are displayed in Table 1. We can notice that within each degree course the two cohorts have similar characteristics.

Table 1 Summary of background characteristics of freshmen by degree course and year of enrollment (2018 or 2019), University of Florence.

	Psychological Sciences			Industrial Design		
	2018	2019	Total	2018	2019	Total

Std. error	10.9	11.1	11.00	10.1	11.1	10.79

Students' productivity is measured by the number of gained credits (ECTS). According to the study plan, students should obtain approximately 30 credits per semester. Since the number of credits is always a multiple of 3, the response variable used in the models, denoted by Y, is defined as the number of credits gained in the second semester divided by 3. Since Y presents an irregular distribution in

both degree courses, quantile regression represents an appealing methodology. The covariates included in the models are:

- X_1: number of credits obtained during the first semester, centred around 15.
- X_2: dummy variable for cohort 2019 vs 2018.
- X_3: dummy variable for male vs female.
- X_4: high school grade, centred around 80.
- $X_5, ..., X_{10}$: dummy variables for the types of high school (except for the baseline category "Scientific").

The analysis is performed separately for each bachelor's degree course and the effect of interest is represented by the estimate of the coefficient of X_2, since this is the variable that distinguishes the students whose second semester was affected by remote teaching (cohort 2019) from the others (cohort 2018). Both the QRCJ and QRCM approaches are exploited and, more specifically, the applied models are

$$\text{QRCJ}: \quad Q_Z(p|\boldsymbol{x}) = p + \boldsymbol{x}'\boldsymbol{\beta}(p) = p + \beta_0(p) + \sum_{i=1}^{10} \beta_i(p) x_i,$$

$$\text{QRCM}: \quad Q_{Y^\circ}(p|\boldsymbol{x}, \boldsymbol{\theta}) = \boldsymbol{x}'\boldsymbol{\beta}(p|\boldsymbol{\theta}) = \beta_0(p|\boldsymbol{\theta}) + \sum_{i=1}^{10} \beta_i(p|\boldsymbol{\theta}) x_i.$$

In both of them the transformation of the working variable is the identity function: in the QRCJ approach the logarithmic function is not applied, in order to ease the comparison with QRCM. The methods were computationally implemented by using the function `rq` of the R package `quantreg` [5] for QRCJ, and the function `iqr` of the `qrcm` package [1] for QRCM.

For both degree programs, a variety of parametric models were applied to the conditional quantile function of $Y^\circ = Y + 0.5$ and they were compared based on the number of free model parameters, the integrated loss function, the p-values of the Kolmogorov–Smirnov (KS) test for goodness-of-fit and the similarity of the estimates of the constant and $\beta_2(p|\boldsymbol{\theta})$ to the ones obtained from QRCJ. In both cases, in the selected model the intercept and the coefficient which represents the effect of interest, $\beta_2(p|\boldsymbol{\theta})$, are modelled in a more complicated and flexible way. In particular, they are formulated as combinations of shifted Legendre polynomials and logarithmic functions. The other coefficients are instead approximated by constant (for the ones related to the type of high school) and linear functions.

4 Discussion and final remarks

Quantile regression represents an appealing methodology for dealing with an outcome variable characterized by an irregular distribution, as in the case of the number of credits gained by university students. In this research two different methods for applying quantile regression to count data were employed: the jittering approach

of [6] and the parametric modelling one of [3]. The obtained results show that they lead to similar estimates of regression coefficients, especially for the variables which were modelled through flexible parametric functions (combinations of polynomial and logarithmic functions) in the QRCM setting. The QRCM approach in most cases entails a gain in efficiency, especially in the tails of the distribution of the response. This gain is generally more substantial for the control variables that are approximated by constant functions, whereas is lower or not present for the coefficients described by more flexible parametrizations. The parametric modeling approach has the advantage of providing estimates of the regression coefficients that are smooth functions of p, and makes the interpretation more straightforward. Moreover, it allows to estimate multiple quantiles at the same time, resulting in a much faster computation. However, model selection is not easy and requires time and expertise. The suggested goodness-of-fit procedure is not completely appropriate in the case of count data, and the integrated loss function is not very useful since it depends on the number of parameters. In our case study, the number of possible models was reduced by the fact that there is a specific coefficient of interest, but it was still quite large. A combination of QRCJ and QRCM was found to be a good method for model selection. Indeed, the estimates obtained with the jittering method can be used as a benchmark when choosing among a set of parametric specifications, in order to derive a satisfactory functional form for some specific covariates, keeping always under control the value of the loss function and the goodness of fit.

As far as the interpretation is concerned, the effect of remote teaching on Psychological Sciences freshmen is negative, but small, at most quantiles. It is stronger on the tails, namely for students with low or high productivity (but not for the ones with the greatest performance), however all the estimates are not significantly different from 0 (at a level of 5%). For freshmen in Industrial Design the effect is instead positive, but again small, and stronger for the group of the most productive students. Indeed, the QRCM estimates do not reach statistical significance at 5% except at a few quantiles around 0.95. In both courses the data size does not seem large enough for identifying such small effects.

Adaptive smoothing spline using non-convex penalties

Spline con smoothing adattivo utilizzando penalizzazioni non convesse

Daniele Cuntrera, Vito M.R. Muggeo

Abstract We propose a new adaptive penalty for smoothing via penalized splines. The new form of adaptive penalization is based on penalizing the differences of the coefficients of adjacent bases, using non-convex penalties. This makes possible to estimate curves with varying amounts of smoothness. Comparisons with respect to some competitors are presented.

Abstract *Proponiamo una nuova penalizzazione adattiva per le spline lisciate. La nuova forma di penalizzazione adattiva si basa sulla penalizzazione delle differenze dei coefficienti delle basi adiacenti, utilizzando forme non convesse di penalizzazione. Questo rende possibile la stima di curve il cui grado di lisciatura è determinato in modo adattivo. In questo lavoro vengono presentati alcuni confronti.*

1 Introduction

The use of splines in statistical modelling has undergone a significant increase in the analyses conducted: in just five years, the number of packages using splines has tripled (Perperoglou et al., 2019). The success lies in their flexibility in different settings, such as modelling non-linear effects in regression models and estimating baseline risk in survival models). However, when the underlying relationship to be estimated shows particular and somewhat complex shapes, the amount of smoothing

e-mail: vito.muggeo@unipa.it

should not be kept constant. The resulting non-constant or varying smoothing is referred as adaptive smoothing. To date, there exist just few packages dealing with adaptive smoothing. This contribution is organized as follows: in the second section, we briefly present the rationale of B-splines and P-splines, and then we present our proposal in some detail. Some simulations and conclusions are reported in the last section.

2 Splines, B-splines and P-splines

Roughly speaking, a spline is a function consisting of a set of polynomials joined together, which interpolate a set of points called nodes. The function is continuous at least up to the specified order of derivatives depending on the degree of the piecewise polynomials. A set of properly defined spline functions represent the *B*-spline (Eilers and Marx, 1996, 2010), namely $B(x) = [B_1(x), B_2(x), \ldots, B_K(x)]$ where K is the number of bases depending on degree polynomial and number knots.

Any unspecified but smooth function $f(x)$ can be expressed via the B-spline basis. For the generic value x_i we write

$$f(x_i) = \sum_{k=1}^{K} b_k B_k(x_i) = B(x_i)^T b. \tag{1}$$

where the coefficients b_ks have to be estimated by data. For the response values $\{y_i\}_{1,\ldots,n}$ the objective to be minimized is the well known least square $S(b) = \sum_i (y_i - B(x_i)^T b)^2$ which yields K regression coefficient estimates. To by pass the issues related to the selection of the basis dimension K, namely in turn the number and location of knots, a generous basis with several knots is built up and a penalty is set on the dth coefficient differences $\Delta^d b$; for instance if $d = 2$ is chosen $\Delta^2 b_k = (b_k - b_{k-1}) - (b_{k-1} - b_{k-2})$. This leads to so-called penalized splines or simply *P*-splines [ref].

Therefore, the penalized least square to be optimized is

$$S_\lambda(b) = \sum_{i=1}^{n} (y_i - B(x_i)^T b)^2 + \lambda \sum_k (\Delta^2 b_k)^2, \tag{2}$$

where λ is the tuning parameter determining how the curve has to be penalized. The larger λ, the smoother the fitted curve, and the optimal value is usually selected by cross-validation. However, regardless of its value, a unique and constant λ implies that the amount of smoothing does not change across the covariate range. Unfortunately, in some particular cases, such *constant* smoothing leads to undesirable fits as illustrated in Figure 3 where the grey line portrays fitted curve corresponding to the unique λ selected by minimizing the BIC.

3 The proposal: using non-convex penalties

The idea proposed in this paper is to adopt non-convex penalties for P-Spline estimation adaptively and thus to have a λ that varies along the x-domain. In this way, it is possible to obtain a curve that modifies the jaggedness according to the dispersion of the points of x, allowing to have a more or less smooth curve according to the needs dictated by the data. In our context, we penalize for the differences between the coefficients estimated for each base for orders of difference greater than or equal to 2. So the minimize function becomes

$$S = \sum_{i=1}^{n} (y_i - B(x_i)^T b)^2 + \sum_k \lambda_k \, p_\lambda(|\Delta_k^d b|). \tag{3}$$

The term Δ_k^d denotes the j-th difference of order d that is penalized. The term $p_\lambda(\cdot)$ thus indicates one of the two non-convex penalties taken into account, namely SCAD (Fan and Li, 2001) and MCP (Zhang, 2010). These are defined as

$$p_{\lambda_{SCAD}}(|\Delta_k^d|) = \begin{cases} \lambda|\Delta^d| & \text{if } |\Delta^d| \leq \lambda, \\ \frac{2\gamma\lambda|\Delta^d| - \Delta^{D^2} - \lambda^2}{2(\gamma-1)} & \text{if } \lambda < |\Delta^d| < \lambda\gamma, \\ \frac{\lambda^2(\gamma+1)}{2} & \text{otherwise} \end{cases}$$

$$p_{\lambda_{MCP}}(|\Delta_k^d|) = \begin{cases} \lambda|\Delta^d| - \frac{\Delta^{D^2}}{2\gamma} & \text{if } |\Delta^d| \leq \lambda\gamma, \\ \frac{1}{2}\gamma\lambda & \text{otherwise} \end{cases}$$

where γ is the threshold that defines the shape of SCAD and MCP penalties. We will set $\gamma = 3.7$. The advantage of using these penalties is that the estimated parameters are less biased than lasso. In fact, for both, after the threshold value $\lambda\gamma$, the penalty does not increase, unlike the lasso. On the other hand, these penalties have unavoidable estimation difficulties due to their non-concave form for the parameters. This leads to substantial difficulties in maximizing the penalized likelihood function. Fan and Li (2001) propose a local quadratic approximation, which allows to write the penalty function as

$$p_\lambda(|\Delta_k^d|) \approx p_\lambda(|\Delta_k^{d,(0)}|) + \frac{p'_\lambda(|\Delta_k^{d,(0)}|)}{2|\Delta_k^{d,(0)}|}(\Delta_k^{d^2} - \Delta_k^{d,(0)^2}) \tag{4}$$

where $\Delta^{d,(0)}$ is the point in which the linear quadratic approximation is centred. The same linear quadratic approximation will also be used for the MCP penalty.

The definition of λ_k takes advantage of the lower bias of SCAD and MCP for coefficients with high estimates. We then decompose λ_k as λw_k, where

$$w_k = p'_\lambda(|\Delta_k^d|; \lambda, \gamma). \tag{5}$$

High coefficient differences will have a smaller penalty, so the estimated curve will be less smoothed and will be able to follow the data in a better way; on the other hand, similar coefficients will be penalized more, so a smoother part of the curve will be obtained. In this way, we allow the penalty to adjust according to the dispersion of the data. Defined the number of bases, the degree of polynomials, the order of differences, and the penalty to be used (SCAD or MCP), the estimate is made as follow:

1. Estimation of the non-penalized model, to initialize the algorithm
2. Calculation of d-order differences and weights
3. Construction of augmented matrices and estimation of the penalized model
4. Update of estimated b_j
5. Repeat steps 2 to 4 till convergence

For the optimal λ search, we proceed with a grid search to minimize the BIC.

4 Simulation study

In this section we show the simulation study conducted to assess the performance of our proposals empirically. These will be compared with B-splines, P-splines and spatially-adaptive P-splines (SOP) (Rodríguez-Álvarez et al., 2019). We present two different analyses: in the first one we consider as signal the Doppler function $\mu = \sqrt{x(1-x)}\sin\frac{2\pi(1+2^{(9-4*6)/5})}{x+2^{(9-4*6)/5}}$, while in the second one we define the signal as $\mu = cos(x) + cos(\pi x)$.

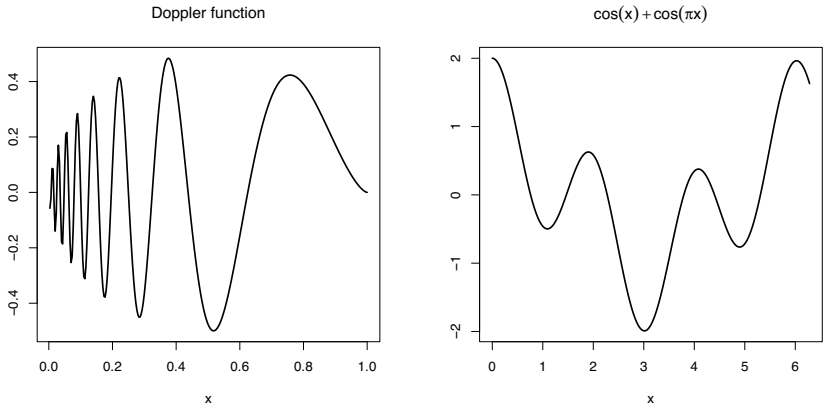

Fig. 1 The two signals used for simulation study

The Doppler signal is a typical example in the literature on adaptive smoothing. In contrast, the second signal is useful for assessing whether, in a context that does not require adaptive smoothing, the method has advantages over b-spline and p-spline. Once the signals have been determined, we then define

$$y_i = \mu_i + \sigma_j \varepsilon_i \quad , \quad i = 1,...,n; \quad j = 1,...,4$$

where x were equally spaced on [0,1], $\varepsilon_i \sim N(0,1)$, $n = 300$. We also consider different values for σ_j to assess how performance varies as noise increases. For all setting, we carried out 500 simulations. To measure the behaviour of the five methods tested, we define the measure $MISE = \sum_{i=1}^{n}(\mu(x_i) - \hat{\mu}(x_i))^2$.

For all 5 methods, 50 bases were used, with polynomials of order 3 and penalizing differences of order 3.

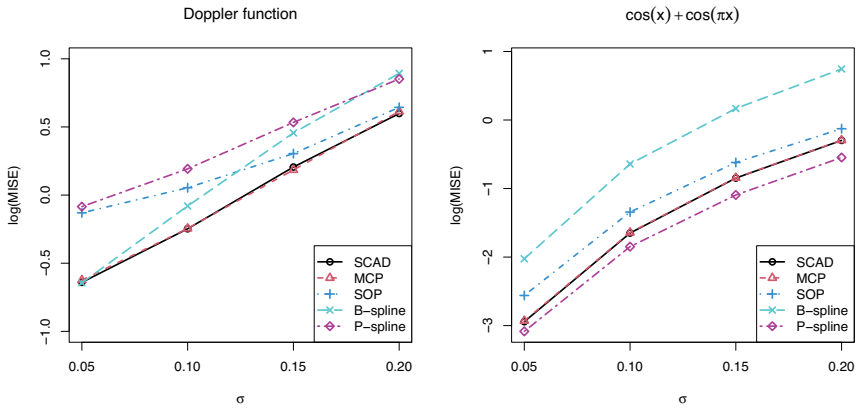

Fig. 2 log(MISE) for different method and σ

Figure 2 shows the results of the simulations, considering the log(MISE) (for graphical purpose). In the scenario using the Doppler function, it is observed that, for the proposed method, there is no substantial difference in the use between the SCAD or MCP penalties. Compared to the other methods, better performance is observed for all the σ values used. Compared to the SOP (the only adaptive alternative), better results are observed, which tend to converge for higher σ values. The scenario changes in the second simulation setting: when an adapting λ is not required from the signal, the best results are obtained using P-splines. The adaptive penalizations with SCAD and MCP return almost equal results, always better than those obtained with SOP.

Figure 3 shows a generic curve estimated by adaptive (SCAD) and non-adaptive method. From the graph, it is possible to observe how the adaptive method estimates a curve much closer to the true signal, since the adaptivity of λ makes it possible to obtain a smoother curve on the right-hand less smooth on the left-hand side.

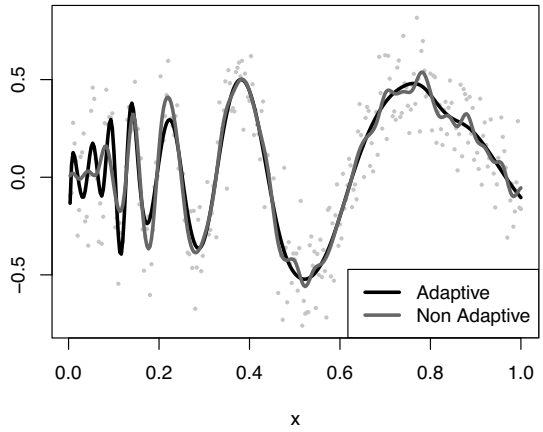

Fig. 3 Adaptive (SCAD) and non-adaptive estimated curve, using a Doppler signal with σ=0.15

This paper presents a new proposal to fit adaptive P-spline using the SCAD and MCP-based penalties. In the presented simulation experiments, the proposed method had good performance with respect to the traditional, constant smoothing, and the adaptive SOP competitor.

Conditional tests for generalized linear models

Test condizionali per modelli lineari generalizzati

Riccardo De Santis, Jelle J. Goeman, Anna Vesely, Livio Finos

Abstract The relevance of any possibly significant covariate when using a generalized linear model should be further investigate by means of an appropriate statistical test. The most known parametric approach might fail when some assumptions are missing, losing the control of type I error. Permutation tests can often be useful in these situations, requiring fewer assumptions, and we will apply them in this general framework.

Abstract *Nell'ambito dei modelli lineari generalizzati, la rilevanza di qualsiasi covariata potenzialmente significativa deve essere confermata da una valida statistica test. Il più usato approccio parametrico può fallire quando alcune assunzioni vengono meno, causando una perdita del controllo dell'errore di I tipo. I test di permutazione offrono una valida alternativa in queste situazioni, richiedendo meno assunzioni, e li applicheremo in questo contesto.*

1 Introduction

Generalized linear models (GLMs) are a flexible tool which permits to relate one dependent variable with some potentially significant covariates. They allow to model non-linear functions of the mean and require the dependent variable to belong to the exponential distribution family, which encompasses many of the most common distributions. However, this complexity leads to some drawbacks. It comes harder to properly check the reliability of the assumptions made and it becomes more difficult to build robust testing procedures.

In the ambit of hypothesis testing, permutation methods offer an alternative which requires fewer assumptions than the standard parametric approach. Permutations are encompassed in the general definition of groups of transformations, which might be also rotations or sign flipping contributions [6]. However, these methods are generally limited in the ambit of GLMs since they require the observations to be exchangeable, which prevent us to use a naive permutation approach.

In order to overcome this limit [3] proposed the effective flip score test. This test based on flipping score contributions defines a valid approach to the problem and results to be robust against some forms of overdispersion. Furthermore, the simulation study shows some promising results against generic variance misspecification. However, this method is not fully satisfactory. A slightly anti-conservative behavior remains for small-sample sizes which demands to look for a further step. In this work we answer this open question by proposing an improvement – called Standardized Score test. We will see that the proposed test turns out to provide a better type I Error control.

In Section 2 we will present some notation about generalized linear models, Section 3 includes a discussion of statistical tests available while Section 4 contains a simulation study. Finally, the conclusions are in Section 5.

2 Generalized Linear Models

Assume that we observe n independent observations $Y = \{y_1, \dots, y_n\}$ drawn from a particular distribution which belongs to the exponential dispersion family, whose i-th element has density of the form [1]

$$f(y_i; \theta_i, \phi_i) = \exp\left\{ \frac{y_i\theta_i - b(\theta_i)}{a(\phi_i)} + c(y_i, \phi_i) \right\},$$

where θ_i and ϕ_i are respectively the canonical and the dispersion parameter.

According to the usual literature of GLMs [1] we have

$$\mu_i = E[y_i] = b'(\theta_i) \qquad v(\mu_i) = b''(\theta) = \frac{Var(y_i)}{a(\phi_i)}$$

which are respectively the mean and the variance function. We assume that the mean of y_i depends on some observed covariates $(x_i, \mathbf{z}_i)$ through a non-linear relation

$$g(\mu) = \eta = X\beta + \mathbf{Z}\gamma \tag{1}$$

where $g(\cdot)$ is the link function, $(X, \mathbf{Z})$ is the design matrix with $dim(X) = n \times 1$ and $dim(\mathbf{Z}) = n \times q$.

Let $l(\beta)$ denote the log-likelihood function, from which we can derive the score function with respect to β

$$\frac{\partial l(\beta)}{\partial \beta} = l_*(\beta) = X^T D V^{-1}(y - \mu),$$

where, in a compact matrix form, we have

$$D := diag\left\{\frac{\partial \mu_i}{\partial \eta_i}\right\} \qquad V := diag\{Var(y_i)\}.$$

Furthermore, deriving the score function we can obtain the expected Fisher information

$$E\left[\frac{\partial^2 l(\beta)}{\partial \beta^2}\right] = J(\beta) = X^T W X$$

where $W := DV^{-1}D$. The maximum likelihood estimator does not have a closed form, but it is estimated through a Fisher scoring algorithm, which is an iterative method based on the second-order approximation of the log-likelihood function.

We will focus on univariate hypothesis testing of the form

$$H_0 : \beta = \beta_0 \qquad vs \qquad H_1 : \beta \neq \beta_0 \tag{2}$$

or, equivalently, to one-sided hypothesis testing, while the other parameters γ are treated as nuisance parameters. The difficulties of deriving a valid hypothesis testing are described in the following section.

3 Conditional resampling in GLMs

Type I error control is a crucial property of a statistical test in the ambit of hypothesis testing in order to ensure an adequate analysis. An exact control of the type I error is therefore a desiderable property for any test. Linear models with normal responses admit exact control within the well-known parametric approach. However, in the more general case of GLMs, this property is rarely met, even if the parametric approach to hypothesis testing still ensures accurate control. Indeed, it is based on a second-order Taylor approximation, and hence it focuses on the first and second moment of the distribution of the test statistic. This, together with the Central Limit Theorem, ensures a quick convergence to a common normal distribution, towards an

exact control of the type I error, whose rate of convergence is specific of any particular model. Nevertheless, this parametric approach relies on stringent assumptions, that are usually difficult to be checked properly.

Conditional tests have been developed to answer a general demand of less stringent assumptions. A general structure can be described as follows. Let $\mathbb{F}$ be a group of transformations. Conditional approaches rely on applying this group of transformations (or an appropriate sub-group [2]) to the observed data. For a given test statistic T, the conditional distribution of the test statistic under the null hypothesis is defined by the set $\{T \circ F; \forall F \in \mathbb{F}\}$ (the observed test statistic is usually defined by $F = \mathbf{I}$ – with $\mathbf{I}$ identity matrix). Depending on the way T and $\mathbb{F}$ are defined, the resulting test will reach different inferential properties. In order to have a valid test, the requirement is that they all share the same conditional distribution, *i.e.*, $T \circ F \overset{d}{=} T \circ \mathbf{I}\ \forall F \in \mathbb{F}$. This property is usually met only in linear model [6, 4] or in GLMs with simple experimental designs. However, a general approach is still lacking, and only some *ad hoc* solutions can be found in the literature [5]. The *second-order exactness* provided by GLMs – and mentioned above – has its conditional equivalent in the *second-moment null-invariance* property, that is, the test statistics have mean and variance independent of the flip: $S \circ F \overset{2M}{=} S \circ \mathbf{I}\ , \forall F \in \mathbb{F}$. Under this condition, the test statistics do not have the same distribution, but they have the first two moments in common, providing almost exact control for practical purposes.

Inference in the GLM framework can be made by the use of flipping score contributions. Unfortunately, the use of basic scores is unfeasible in presence of unknown nuisance parameters. Their estimation makes the basic scores no longer exchangeable, since they are no longer sharing the same expected value. This property is retrieved by [3] in an asymptotic framework by proposing the use of contributions based on the effective scores. The flipping score contributions are introduced in form of a diagonal matrix F of dimension equal to n, whose elements are independent random variables which can take values on $\{-1;+1\}$. Consequently we define the effective flipped score for any F as

$$S(F) = n^{-1/2} X^T W^{1/2} (I - H) V^{-1/2} F (y - \hat{\mu}) \tag{3}$$

where $\hat{\mu}$ are the fitted values under the null model, while

$$H := W^{1/2} X (X^T W X)^{-1} X^T W^{1/2}. \tag{4}$$

is a particular matrix, which recovers the concept of a projection matrix in the GLM framework. It is symmetric and idempotent, and it is a proper projection matrix for studentized units as shown by the following relation [1]

$$V^{-1/2}(\hat{\mu} - \mu) = H V^{-1/2}(y - \mu)(1 + o_{\mathbb{P}}(1)) \tag{5}$$

where there is an asymptotically negligible error term.

It is trivial to show that all the flipped effective scores share the same expected value, while it is not true for the variances, which using the results above are equal to

$$Var[S(F)] = n^{-1}X^T W^{1/2}(I-H)F(I-H)F(I-H)W^{1/2}X + o_{\mathbb{P}}(1). \quad (6)$$

As proven in [3] the exactness of the test based on the flipped effective scores is only asymptotic. It turns out to be a weaker version of *second-moment null-invariance*, *i.e.*, an asymptotic one. The relevance of this result is related to the general derivation for any kind of GLMs. The quality of this control is often good-enough, but it has poor results for small sample sizes and demands for a further improvement.

In this work we propose a straightforward but efficient way to get finite *second-moment null-invariance*, that is, finite second-moment exactness. We have called it Standardized Score test where the standardized score is defined as

$$S_S(F) = S(F)/\sqrt{Var(S(F))}, \quad (7)$$

whose advantadges can be easily exploited:

Theorem 3.1 (Standardized Flip Score test) *Standardized Flip Score as defined in (7) is finite second-moment null-invariant. The test is exact in case of normal response with identity link and asymptotically exact in all other cases.*

The result is quite trivial. The expected value is left unchanged from that of the effective score, while the variance of each flipped statistic is somehow standardized and made equal to one. Hence the independence of the first two moments from any fixed flip F.

4 Simulation study

In this simulation we compare the parametric test with the two permutation tests when estimating a logistic regression model. The model is set as in (1) with $dim(\gamma) = 3$, $\gamma = c(1,1,1)$, $\beta = 0$, correlation of the non-relevant variable with the others equal to $(0.5, 0.1, 0.1)$. We carried on 5000 simulations testing (2), setting the sample size equal to 40.

In Figure 1 on the left is reported the type I error control for the most interesting values of α, *i.e.* $\alpha \in (0, 0.10)$. We observe a conservative behavior of the parametric test, while as expected the effective score test is anti-conservative. The standardized score test gives a more satisfying control, which is nearly exact. This simulation shows a clear preference of the new test over that based on the effective score, while it is surprisingly performing better than the parametric approach.

To complete the analysis we perform a comparison of the power of the tests, shown in the right plot of Figure 1. We set $\gamma = (1,1,0), \beta = 1.5$, again with 5000 simulations and sample size equal to 40. The standardized test is still satisfying, having slightly more power than the parametric counterpart for low values of α.

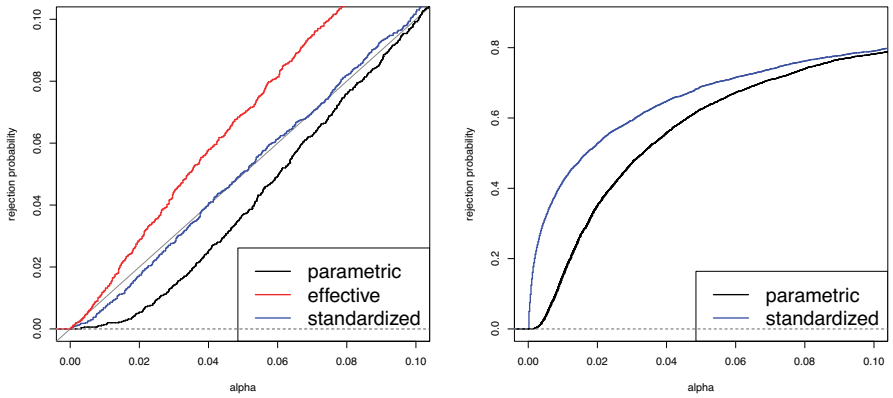

Fig. 1 Left: Type I error control for a logistic regression model. **Right:** Power comparison for a logistic regression model for the two tests with a non anticonservative control of type I error

5 Conclusion

We have seen that permutation testing is a valid alternative to the wide-spread standard parametric approach when conducting statistical tests in the ambit of GLMs. We propose an almost exact test which turns out to be satisfying for small sample sizes and inherits some properties of the effective score test, being competitive to the parametric testing in a well-specified logistic regression model. Further research is needed in order to exploit general robustness with respect to the usual assumptions (as general heteroscedasticity) and regarding the extension to a multivariate setting, following the way introduced by [3].

Methods and applications in economics and finance

Mixed models for anomaly detection in anti-money laundering aggregate reports

Modelli lineari misti per l'individuazione di anomalie nelle Segnalazioni Anti-Riciclaggio Aggregate (S.AR.A.)

Stefano Iezzi[1] and Marianna Siino[2]

Abstract Banks and other financial intermediaries operating in Italy are mandated to report monthly to Italy's Financial Intelligence Unit (UIF) all transactions after aggregating them by branch, customer sector and type of transaction. These non-nominal reports, the so-called Anti-money Laundering Aggregate Reports (S.AR.A.), are then analysed to the end of identifying money laundering- or terrorist financing-related phenomena. For the detection of anomalies in international financial flows we propose to apply linear mixed models on cross-border wire transactions between Italy and three counterpart countries in 2019 following a high-performance statistical procedure to deal with high-dimensional data. Several model specifications are compared and an in-sample validation through perturbation of data is performed providing satisfactory results.

Abstract *In base alla normativa antiriciclaggio, le banche e gli altri intermediari finanziari operanti in Italia inviano mensilmente all'Unità di Informazione Finanziaria per l'Italia (UIF) le cosiddette Segnalazioni Antiriciclaggio Aggregate (S.AR.A.), relative alle operazioni effettuate dalla propria clientela. Tali dati vengono analizzati al fine di individuare potenziali fattispecie di riciclaggio e finanziamento del terrorismo. In questo lavoro proponiamo una metodologia per la rilevazione delle anomalie nei dati S.AR.A. mediante l'utilizzo di modelli lineari misti focalizzando l'analisi sui bonifici esteri del 2019 tra l'Italia e tre paesi esteri, adottando una procedura che tenga conto dell'alta dimensionalità dei dati. Diverse modelli sono stati stimati e opportunamente confrontati, ed è stata effettuata una verifica in-sample che ha fornito risultati soddisfacenti.*

Key words: anti-money laundering, illicit financial flows, cross-border wire transactions, anomaly detection, linear mixed model, high-dimensional data.

1 Introduction and data description[1]

Money laundering (ML) is a complex phenomenon encompassing all the techniques deployed by criminals to deceptively introduce money, earned by illegitimate sources, into the financial system. In spite of the strict international standards enforced in most countries for the purpose of fighting it, criminal organisations and terrorists actively engage in attempting to use financial institutions as vehicles for ML, which presents the latter with challenges such as regulatory compliance, maintaining financial security, preserving goodwill and reputation, and avoiding operational risks like liquidity crunch and lawsuits. With its connections to organized crime as well as terrorist financing, ML has become a serious issue worldwide and has been receiving considerable attention from national governments and international bodies.

Under the Italian anti-money laundering (AML) law[2], banks and other financial intermediaries in addition to filing suspicious transaction reports (STRs) to Italy's central anti-money laundering authority, the so-called Financial Intelligence Unit (FIU), are also mandated to produce the Anti-Money Laundering Aggregate Reports (S.AR.A., from the Italian acronym) on a monthly basis. These are threshold-based reports referring to all transactions for 15,000 euros or more[3]. For each reporting intermediary, transactions are aggregated according to several information related to the type of transaction, some of the customer's features and, with reference to wire transfers, the counterpart's country of residence and that of his/her intermediary. The data are non-nominal as no personal information is provided on the customer or the counterpart thereof; hence massive data mining and statistical analysis can be performed with no confidentiality-related issues, as opposed to analyses using STRs which contain sensitive data.

The view taken in our analysis is that of AML/CFT authorities: the approach described here may support FIUs in discharging their institutional task to identify money laundering related trends and patterns at a national scale. The relevance of the threats that illicit international financial flows pose to the stability of national financial systems and countries can never be understated, so much that fighting them is included within the United Nations Sustainable Development Goals[4]. Cross border transfers may thus represent a crucial vulnerability for a country financial integrity and need to be systematically and efficiently monitored.

In order to achieve this goal, we offer a contribution to the class of techniques for anomaly detection [1,2,4,6,10] by proposing the application of linear mixed-effect models to the Italian data on monthly cross-border wire transfers coming from the SARA. In particular, the models are estimated on 2019 data of cross-border wire

[1] The views and the opinions expressed in this paper are those of the authors and do not necessarily represent those of the institution they are affiliated with.

[2] Legislative Decree no. 231/2007

[3] Since 2021 the threshold has been lowered to 5,000 euros.

[4] Target 16.4 of the Sustainable Development Goals (SDGs) calls to "*by 2030, significantly reduce illicit financial flows and arms flow, strengthen the recovery and return of stolen assets and combat all forms of organised crime*."

transactions between Italy and three foreign countries with different volumes of records and amounts.

2 Model specification

The presence of multiple levels and repeated measurements on S.AR.A. data implies the presence of a complex source of random variability and correlation patterns. The class of linear mixed models [8,12] provides a flexible framework for modelling this type of data. The basic specification of our model is:

$$y_{ijkpq\bar{p}\bar{q}t} = \alpha + \gamma_t + \beta Sector + \mu_j + \delta_k + \vartheta_{i|jk} + \\ + \eta_p^{ITA} CL\_ITA + \eta_q^{FR} CL\_FR + \varphi_{\bar{p}}^{ITA} CT\_ITA + \varphi_{\bar{q}}^{FR} CT\_FR + \varepsilon_{ijkpqt}$$

where $y_{ijkpq\bar{p}\bar{q}t}$ is the amount of wire transfers recorded in month t in branch i of municipality j and bank k, ordered by clients resident in municipality p or foreign country q vis-à-vis counterparts resident in municipality $\bar{p}$ or foreign country $\bar{q}$. Parameter α is the intercept, γ_t is a time component, and $\varepsilon_{ijkmpqt}$ is the error term.

We have a set of pure random effects μ_j, δ_k and $\vartheta_{i|jk}$ which represent, respectively, the effect of the bank level, the effect of the branch's municipality, and the effect of the branch level, that is nested in the combination of the two previous levels. Then we have a random coefficient part: CL_ITA is the dummy for clients resident in Italy and CL_FR is the dummy for clients resident in foreign countries; η_p^{ITA} and η_q^{FR} are the corresponding random coefficients across municipalities and across countries respectively. A mirror random coefficient part is defined for counterparts by dummies CT_ITA and CT_FR, and random coefficients $\varphi_{\bar{p}}^{ITA}$ and $\varphi_{\bar{q}}^{FR}$. Finally, we have a fixed effect part made by the variable Sector, which defines the economic sector of the clients, and its fixed effect coefficient β. Furthermore, we adopt four alternative specifications for the time component: a quadratic parametric trend, a cubic parametric trend, monthly dummy variables and monthly dummy variables interacted with the economic sector of the clients, meaning that for each sector we estimate a time dynamic.

In this multilevel model structure we may wish to know at what level(s) and with respect to which explanatory variable(s) a particular transaction is outlying, as more than one level of analysis might be of interest [9]. On the one hand, model residuals are used to detect individual outlier transactions [7]: accordingly, a record is identified as anomalous when its Studentized residual is higher than the 1 per cent right tail critical value of the standard-normal distribution. On the other hand, group outliers can be identified by analysing the random part of a mixed effect model. The realized values of random effects, that are estimated by the Best Linear Unbiased Prediction (BLUP) procedure [11,12], can be interpreted as group residuals since they reflect

how much the level of a particular random effect factor deviates from the overall fit across the groups. The application of a proper inferential test allows the identification of potential group anomalies.

3 Main results

The proposed methodology is applied to 2019 S.AR.A. data of monthly wire transfers between Italy and three countries for which we have different amounts of records in our dataset (large, average and small amount).[1] Results are shown only for the country with a medium size amount of observations.

Before estimating the models the response variable is properly transformed with the Box-Cox method [3,5] in order to adjust for positive skewness. The transformed response variable is the dependent variable of seven alternative specifications. Overall, the model that has a complete structure with monthly dummies for the temporal components seems to be the best choice among all specifications since it performs well for all the countries and directions of flows.

In Table 1 and Table 2 the main results of the identified individual anomalies (in terms of percentage of records and total amount) and group anomalies (in terms of percentage of random effects for each aggregation variable) are shown, respectively. For instance, for the inward transactions 0.42 % of records are identified as anomalous, corresponding to 15.64% of total amounts. In addition, for group anomalies, 3.47% of branches are identified as anomalous.

Table 1 – Number of transactions and amount in millions of euros for the outward and inward wire-transactions between Italy and the selected country in 2019. The percentage of identified anomalous transactions and the corresponding percentage of total amounts are reported.

	Outward		**Inward**	
	N	% of anomalies	N	% of anomalies
Number of transactions	101,721	0.47	192,040	0.42
Amounts in millions of euros	79,272	13.35	85,024	15.69

Table 2 – Descriptive results of the group anomalies identified for the selected country considering the test statistics on the estimated random parameters with a p-value less than 0.0001. The number of significant random effect (n) and their percentage (%) with respect to the total number of effect for the specific group are shown.

			Outward		**Inward**	
Variable description		**Model parameters**	**n**	**%**	**n**	**%**
Financial intermediary	identification code	δ_k	3	0.76	1	0.24
	municipality of the branch	μ_j	2	0.07	1	0.03

[1] The names of the countries under analysis are not disclosed for confidentiality reasons.

	branch identification code	$\vartheta_{i\|jk}$	235	1.87	509	3.47
Customer	country of residence	η_q^{FR}	13	12.50	13	11.82
	municipality of residence	η_p^{ITA}	178	4.89	224	4.95
Counterpart	country of residence	$\varphi_{\bar{q}}^{FR}$	1	1.23	7	6.93
	municipality of residence	$\varphi_{\bar{p}}^{ITA}$	-	-	1	1.11

4 In-sample performance validation

In order to assess the capacity of the models to detect anomalies, we implement an in-sample validation through perturbation of the data by inserting artificial anomalies. Despite such anomalies do not replicate real anomalies we simulate them to the best of our capabilities as follows:

1. the number of records of each k-combination of the aggregate variables, including the month, are computed where k = 1,…, M+1, and M+1 are the number of aggregate variables plus the month;
2. the combinations with less than 10 records are discarded;
3. we randomly select one combination;
4. within the selected combination, a record is randomly selected;
5. the selected record is perturbed by assigning a random value in the range of $[V_1, V_2]$

$$V_1 = Q_3 + C \cdot IQR$$
$$V_2 = Q_3 + 2C \cdot IQR$$

where Q_3 and IQR are the third quartile and the interquartile range of the records within the selected combination, and $C > 1$ is a predefined constant, determining the degree of anomaly.

We generate four perturbed datasets for inward cross-border wire transfers by using a degree of anomaly c equal to 1.5, 2, 2.5 and 3 and injecting r={100, 1000} anomalous data points.

The performance of the anomaly indicator based on the Student residual is assessed in terms of sensitivity and specificity by changing the number of injected points (r) and the degree of anomaly (c) in the simulation design. According to the simulation results in Table 3, after increasing the degree of anomaly, both the sensitivity and specificity increase. Moving from 100 to 1,000 injected points in the dataset, the two statistics slightly decrease. Furthermore, the ROC curves computed by changing the threshold value used to define the indicator are overall satisfactory.

Table 3 – Sensitivity and specificity for the anomaly indexes based on the Student residual. The c value indicates the degree of anomaly.

r	Sensitivity				Specificity			
	c				c			
	1.5	2.0	2.5	3.0	1.5	2.0	2.5	3.0
100	0.680	0.750	0.810	0.840	0.996	0.996	0.996	0.997
1,000	0.600	0.700	0.775	0.808	0.997	0.998	0.998	0.999

5 Final remarks

The proposed approach can play a fundamental role in the strategic analysis of cross-border wire flows carried out by FIUs. Although the analysis focuses on the cross-border wire transactions, the proposed methodology, which takes properly into account the complex multi-level structure of S.AR.A. data, can have a more general purpose for transaction monitoring and detection of other types of potential anomalies, such as the cash usage, and for banking AML supervision. Furthermore, the outcome of this type of analysis can give an overview of specific dynamics and trends that can be share to the national investigative bodies and competent judicial authorities for AML/CTF purposes.

Moreover, the large amount of records (about 100 million per year) which banks and other financial intermediaries deliver in compliance with the Italian anti-money laundering law is a challenge for the Italian FIU in terms of analytical techniques and computational tools, and the proposed procedure is a step forward in this direction.

On the drivers of Greenwashing risk: evidence from Eurostoxx600

Le determinanti del Greenwashing: evidenze empiriche dall'Eurostoxx600

Yana Kostiuk, Costanza Bosone, Paola Cerchiello

Abstract The aim of this article is analysing both the external and internal drivers of greenwashing, relying on FinScience[1] company's well-established methodology and on rigorous statistical methods. We will shed light on ESG components, carefully identifying all the indicators which may potentially impact on a company sustainable performance. As crucial insights, we will show that the companies' tendency to "greenwash" seems correlated to (I) the industry in which they operate (II) the level of female presence in the company itself and (III) the size of the Board. Similar results, although with different variables, are in line with the existing literature (e.g. Chen et al., 2018; Lenard et al., 2014; Romero et al., 2019; Wilson & Altanlar, 2009; Yu et al., 2020).

Abstract *Questo articolo mira ad analizzare le determinanti interne ed esterne del "greenwashing". Utilizzeremo la solida metodologia della società di Fintech "FinScience" e specifici metodi statistici. Studieremo nel dettaglio le componenti degli ESG e le modalità in cui ogni componente può potenzialmente influenzare la per-*

[1] FinScience is a data-driven fintech company founded in 2017 by Google's former senior managers and Alternative Data experts. The company originates from the merger of the world of Finance and the world of Data Science through Augmented Analytics solutions applied to Investing activities (FinScience, n.d.).

formance di un'impresa in termini di sostenibilità. Come osservazioni fondamentali proveremo che la tendenza di un'impresa ad ingaggiare in pratiche di "greenwashing" sembra correlata (I) al settore in cui l'impresa stessa opera (II) al livello di donne assunte dall'impresa ed (III) al numero di membri del Consiglio. Simili risultati, pur con variabili differenti, sono in linea con la letteratura precedente (e.g. Chen et al., 2018; Lenard et al., 2014; Romero et al., 2019; Wilson & Altanlar, 2009; Yu et al., 2020).

Key words: ESG; Sustainable Finance; Greenwashing; Risk Management, AI

1 Introduction

The implementation of ESG criteria in the investment decision-making process of a company is defined as "sustainable finance" (Forstater & Zhang, 2016) and it has been gaining importance ever since the 2008's Great Recession, which brought about a positive shift in capital markets perception towards corporate sustainability (Escrig-Olmedo et al., 2019).

Despite a similar growth, ESG criteria have experienced little or no regularisation in terms of common guidelines for their definition or interpretation (Escrig-Olmedo et al., 2019; Mooney, 2021; Strobel, 2020), with the most significant achievement being the "EU taxonomy" as defined by the Technical Experts Group (TEG) (2019; 2020).

In a similar context, the interpretation of ESG scores, as provided by major financial platforms such as Refinitiv or Bloomberg, becomes challenging and sometimes, deceiving. Indeed, more and more firms engage in "greenwashing" behaviours, thus misleading stakeholders about their environmental performance and impact (Delmas & Burbano, 2011; Furlow, 2010).

The aim of this article is to shed light on the drivers of greenwashing, furtherly expanding the literature on the topic.

2 Methodology

We will shed light on ESG components, carefully identifying all the indicators potentially impacting on a company's sustainable performance. With regard to our scientific approach, we will rely on FinScience company's well-established methodology and on rigorous statistical methods, which will be explained more in details in the following paragraphs.

As for FinScience methodology, we opted for Eurostoxx600 as a sample of data. Since the EU seems more sensible to sustainability problems than other institutions (i.d. TEG, 2019; 2020), this choice is consistent with the aim of conducting an analysis on ESG. Time span of extraction ranges from 2020 to 2021. The sustainability

performance of a company is based both on self-disclosed data (internal score), external data (external score) and a combination of the two (overall score). Such scores range from 0 to 100. The Internal sources include: Sustainability/CSR Reports, Corporate Websites, Sustainability Memberships/Affiliations, Certifications, Sustainability Rankings, Controversies and Reviews. External sources include: ONG, Vertical Website and mainstream NEWS. We can state that internal scores are company-generated, whereas external scores are stakeholder-generated.

By combining together such two scores, we can produce an indicator of greenwashing risk. More in details, we consider the difference between internal and external scores - hereafter referred as *delta* - and used it as a proxy for greenwashing. In absolute terms, a higher *delta* implies a higher risk of greenwashing, as a company's internal perception drifts away from its stakeholders' external one. On the contrary, low values of *delta* refer to a better perception from the external stakeholders' point of view relative to the declared internal status.

We widen the Eurostoxx600 dataset by downloading the following variables from Refinitiv: total assets, Revenue per Share, ROA, ROE (all used as control variables); a variable accounting for the size of the Board, another accounting for the number of women employed in a company (%) and finally, a variable accounting for the presence of the CSR Sustainability Committee (dummy variable). In addition, we included the country where the headquarter of each firm is located as provided by Refinitiv (Austria, Belgium, Denmark, Finland, France, Germany, Ireland, Italy, Luxembourg, Netherlands, Norway, Poland, Portugal, Spain, Sweden, UK) and clustered firms into 9 main operating sectors, according to the Global Industry Classification Standard (GICS) (MSCI, 2018): Communication services & Info, Consumer discretionary, Consumer Staple, Energy, Financials & Real Estate, Healtcare, Industrial, Materials, Utilities.

In line with those studies claiming that a company tendency to greenwash can be mitigated by influential public interests via a less corrupted country system (e.g. Yu et al., 2020), we included a variable accounting for the level of corruption in a country, namely: the Corruption Perception Index (CPI) as computed by the Transparency International Agency (2020). In the end, we obtained a dataset of roughly 8000 observations.

Tab. 1 provides a summary of statistics for all the continuous variables included in our dataset.

Variable	**Mean**	**Std.Dev.**	**Min**	**Max**
Delta	-46.41	13.34	-48	38
Board size	11.29	3.5	4	23
Total Assets	$1.20e^{11}$	$3.23e^{11}$	$0.4e^{11}$	$2.99e^{12}$
Women Employees	0.37	0.15	0.11	0.76
Revenue Per Share	59.04	191.29	0.06	3229.74

Return on Equity	0.14	0.26	-3.29	1.37

Table 1 Summary Statistics of continuous variables (not standardized).Source: Authors' Elaboration based on Finscience Data and Refinitiv, 2020-21

3 Empirical Findings

We standardized the dataset and performed a standard linear regression model and a stepwise linear regression model, using delta as dependent variable. **Tab.2** reports results for the stepwise model.

The following crucial insights can be retained: (I) the presence of women in a company (Women Employees) is negatively and significantly correlated to *delta*, thus implying that higher female presence favours lower risks of greenwashing. This is line with current literature (e.g. Chen et al., 2018; Lenard et al., 2014).

(II) The risk of greenwashing depends on the industry in which the company operates; companies in Energy, Consumer Staples and Discretionary, Healthcare and Materials seem to suffer from higher risks of greenwashing than others. This is fairly in line with the literature enquiring the correlation between environmental sensibility and different operating sectors (e.g. Romero et al., 2019).

(III) The size of the Board impacts on the probability of greenwashing. Though this result is in line with the literature, it usually goes in the opposite direction (e.g. Yu et al.,2020). As an explanation, we argue that our sample only focuses on the biggest companies in Europe which are likely to present similarly-sized Boards, thus reducing the impact of the variable.

The presence of a Corporate Social-Responsibility Committee (CSR Sustainability Committee) shows a positive and significant correlation, which may sound counter-intuitive to some extent. In reality, CSR committees are designed to fight corruption, protect stakeholders and reduce a company's exposure to failures in contexts where management becomes more complicated (Gennari & Salvioni, 2019), hence companies are more likely to set up such Committees when facing some distresses as a way of conquering or maintaining investors' trust. This explains the positive correlations between the presence of a CSR committee and the probability of greenwashing.

The corruption CPI index does not make its appearance in the model as it is not statistically significant. As a reasonable explanation, European countries do not greatly differ in terms of perceived levels of corruption (Transparency International, 2020).

4 Conclusions

In conclusion, by relying on FinScience internal and external score for sustainability, we obtain a *delta* score, which is used as a proxy for greenwashing. Firms with a higher number of female employees are less likely to engage in greenwashing behaviours. Vice versa, firms operating in Retail, Transports, Energy & Utility and Healthcare & Chemical face a higher risk of greenwashing. On its part, the size of the Board impacts as well on the probability to greenwash.

All these results are in line with the existing literature (e.g. Chen et al., 2018; Lenard et al., 2014; Romero et al., 2019; Wilson & Altanlar, 2009; Yu et al., 2020).

	Estimate	Std.Error	T value	Pr $> \|t\|$

Further analysis are needed. Given the considerable variation across non-European countries in terms of sustainability and "green-actions", enlarging the dataset beyond the Eurostoxx600 horizon -by means of inclusion of American and Asian companies- will lead to a more complete analysis on the drivers of greenwashing. Moreover, it is worth considering a deeper analysis of the two components of the 'delta' score indicator.

Modelling Financial Returns with Finite Mixtures of GED

Modellazione dei Rendimenti Finanziari con Misture Finite di GED

Pierdomenico Duttilo and Stefano Antonio Gattone

Abstract As widely identified by the empirical evidence, daily returns on financial assets are not Normally distributed, because they are characterized by excess kurtosis and different degrees of skewness. Finite mixtures of distributions have been proposed in literature to capture these features. In this work a finite mixture of two Generalized Error Distributions (GED) is applied to fit the distribution of the daily returns on the Dow Jones Industrial Average (DJIA) index for the period from January 4, 2016 to January 31, 2022. Moreover, in order to highlight the flexibility of the shape parameter over time, the entire analysis period was divided in three different sub-periods and for each one the mixture of GED was estimated.

Abstract *Come ampiamente identificato dall'evidenza empirica, i rendimenti giornalieri delle attività finanziarie non sono distribuiti normalmente, poiché sono caratterizzati da curtosi eccessiva e diversi gradi di asimmetria. Per catturare queste caratteristiche, in letteratura sono state proposte misture finite di distribuzioni. In questo lavoro viene applicata una mistura finita di due distribuzioni GED (Generalized Error Distribution) per stimare la distribuzione dei rendimenti giornalieri dell'indice Dow Jones Industrial Average (DJIA) per il periodo dal 4 gennaio 2016 al 31 gennaio 2022. Inoltre, al fine di evidenziare la flessibilità del parametro di forma nel tempo, l'intero periodo di analisi è stato suddiviso in tre diversi sottoperiodi e per ciascuno è stata stimata la mistura di GED.*

Key words: daily financial returns, excess kurtosis, skewness, finite mixtures of GED

1 Introduction

Commonly, financial time series such as daily returns on stocks, indices, currencies, cryptocurrencies and many others financial assets do not follow a Gaussian distribution because they are characterized by excess kurtosis and different degrees of skewness. Finite mixtures of distributions have been proposed in literature to capture these features.
Finite mixture of Normal distributions known also as mixtures of Gaussians are widely used in this field, for instance Kon (1984) [5] proposed a discrete mixture of Normal distributions to approximate the excess kurtosis and positive or negative skewness of daily returns distribution of common stocks and indices. More recent studies [1, 2, 4] argued that finite mixtures of Gaussians (with two or three components) are a good tool to fit the empirical distribution of financial returns. However, these mixtures impose a priori specific constraints on the form of the returns distribution since the components are Gaussians. The finite mixture of GED, known also as the finite mixture of generalized normal distribution can overcome this critical issue thanks to the flexibility provided by the additional shape parameter ν_k.
In this framework, the recent contribution of Wen et al. [8] (2020) is remarkable. They studied a univariate mixture of GED and proposed an expectation conditional maximization (ECM) algorithm for parameter estimation. Additionally, using data sets of the S&P 500 and Shanghai Stock Exchange Composite Index (SSEC), it was found that the mixture of GED better describes the excess kurtosis and skewness of daily returns compared to mixtures of Gaussians.
This work aims to enrich the existing literature on the use of mixtures of GED in finance by applying a finite mixture of two generalized error distributions to fit the distribution of the daily returns on the Dow Jones Industrial Average (DJIA) index. Besides, the likelihood-ratio test (LR Test) and information criteria were applied to compare the goodness of fit performance among the mixture of two GED, the mixture of two Gaussian distributions and the mixture of a Gaussian and a Laplace distribution [3].
Moreover, the entire analysis period was divided in three different sub-periods and for each one the mixture of GED was estimated in order to highlight the flexibility of the shape parameter over time.
The rest of the paper was organized as follows. Section 2 illustrates the methodological framework. Section 3 illustrates the empirical application. Finally, Section 4 provides the results discussion and some conclusions.

2 Methodological Framework

2.1 Generalized Error Distribution

A random variable X is said to have the generalized error distribution with parameters μ (location), σ (scale) and ν (shape) if its *probability density function* (p.d.f.) is given by

$$f(x|\mu,\sigma,\nu) = \frac{\nu}{2\sigma\Gamma(1/\nu)} \exp\left\{ -\left| \frac{x-\mu}{\sigma} \right|^{\nu} \right\}, \tag{1}$$

with $\Gamma(1/\nu) = \int_0^{\infty} t^{1/\nu-1} \exp^{-t} dt$, $-\infty < x < \infty$, $-\infty < \mu < \infty$, $\sigma > 0$, $\nu > 0$. Thanks to the shape parameter, the GED distribution is a flexible tool to capture a large class of statistical distributions [7, 8], for example with $\nu = 1$ and $\nu = 2$ GED becomes a Normal and Laplace distribution, respectively.

2.2 Finite Mixtures of GED

A finite mixture of GED with K components is given by the marginal distribution of the random variable X

$$\begin{aligned} f(x|\mu_k,\sigma_k,\nu_k) &= \sum_{k=1}^{K} \pi_k p(x|\mu_k,\sigma_k,\nu_k), \\ &\sum_{k=1}^{K} \pi_k \frac{\nu_k}{2\sigma_k\Gamma(1/\nu_k)} \exp\left\{ -\left| \frac{x-\mu_k}{\sigma_k} \right|^{\nu_k} \right\}, \end{aligned} \tag{2}$$

where $\nu_k > 0$, $\sigma_k > 0$, $\mu_k \in \mathrm{R}$, $0 < \pi_k < 1$ and $\sum_{k=1}^{K} \pi_k = 1$. With $K = 2$ the mixture of two GED is given by:

$$\begin{aligned} f(x|\theta) &= \sum_{k=1}^{2} \pi_k p(x|\mu_k,\sigma_k,\nu_k), \\ &= \frac{\pi_1\nu_1}{2\sigma_1\Gamma(1/\nu_1)} \exp\left\{ -\left| \frac{x-\mu_1}{\sigma_1} \right|^{\nu_1} \right\} + \frac{\pi_2\nu_2}{2\sigma_2\Gamma(1/\nu_2)} \exp\left\{ -\left| \frac{x-\mu_2}{\sigma_2} \right|^{\nu_2} \right\}, \end{aligned} \tag{3}$$

where $\theta = (\pi_1,\pi_2,\mu_1,\mu_2,\sigma_1,\sigma_2,\nu_1,\nu_2)$. The mixture of two GED can be estimated via the ECM algorithm [8]. As shown by Wen et al. (2020) [8], this model has important properties because it nests several distributions as its sub-models. Especially, depending on the value of the shape parameter (ν_k), the mixture of two GED reduces to:

- the mixture of two Gaussians when $\nu_1 = \nu_2 = 2$;
- the mixture of two Laplace distributions when $\nu_1 = \nu_2 = 1$;
- the mixture of a Gaussian and a Laplace distribution when $\nu_1 = 2$ and $\nu_2 = 1$;
- the mixture of a Gaussian and a GED distribution when $\nu_1 = 2$ and $\nu_2 > 0$;
- the mixture of a Laplace and a GED distribution when $\nu_1 = 1$ and $\nu_2 > 0$.

As a result the mixture of GED does not impose a priori specific constraint on the shape of each component of the mixture [6].

3 Empirical Application

The daily closing prices of the DJIA index between January 4, 2016 to January 31, 2022 were collected for the analysis from https://finance.yahoo.com. Next, the daily return r_t in period t is defined as $r_t = (\ln P_t - \ln P_{t-1})100$ where P_t and P_{t-1} are the closing prices at time t and $t-1$, respectively. Panel (a) of Figure 1 shows the daily returns on the DJIA index.
Estimation results of the mixtures of distributions with two components for the daily returns on the DJIA index are summarized in Table 1. According to the LR Test and information criteria the mixture of two GED (Figure 1, panel b) is preferred over the mixture of two Gaussians and the mixture of a Gaussian and a Laplace distribution. Furthermore, the estimated shape parameters show that the first component has heavier tails than a Laplace distribution ($0.53 < 1$), while tail weights of the second component intermediate between the Gaussian and the Laplace distribution ($1 < 1.12 < 2$). These results are in line with those found by Wen et al. (2020) [8] who estimated the two-component mixture of GED on the daily returns of the S&P500 identifying a mixture component that allows a more extreme tail behaviour compared to the other.

In order to highlight the flexibility of the shape parameter over time, the entire analysis period was divided in three different sub-periods and for each one the two-component mixture of GED was estimated. As showed in panel (a) of Figure 1 each sub-period reflects different volatility levels: low (2016-2017), intermediate (2018-2019) and high (2020-2022). In addition, the latter two sub-periods are characterized by a higher number of large negative returns, i.e. negative skewness. Finally, Table 2 suggests that the third sub-period has a two-component mixture of GED with heavy tails compared to the other sub-periods.

It is important to note that the current version of the mixture model proposed in this work can be cast in the framework of unconditional (with respect to time) estimation which suggests a poor predictive ability. Indeed, previous studies [1, 2, 4, 5, 8] do not apply mixtures of distributions to make predictions. Nonetheless, this work provides an out-of-sample application of the Value at Risk (VaR) estimation. The first two sub-periods are taken as "in-sample" observations and the third sub-period as the "out-of-sample" observations. The estimated $\widehat{\text{VaR}}_{\alpha=0.01}$ in the "in-sample" observations is -2.736, -2.482 and -2.364 for the mixture of GED, mixture of Gaussians, and mixture of a Gaussian-Laplace, respectively. The empirical $\text{VaR}_{\alpha=0.01}$ of

the third sub-period (out-of-sample) is -5.702. The evidence suggests that the third sub-period is characterised by an extreme $\text{VaR}_{\alpha=0.01}$ value (due to the COVID-19 crisis) and the estimated $\widehat{\text{VaR}}_{\alpha=0.01}$ of the two-component mixture of GED is the closest compared to the other two-component mixtures.

4 Conclusion

It has been shown that the mixture of GED is a powerful and flexible tool to fit the empirical distribution of financial returns. Considering the results of the empirical application in Section 3 at least two interesting considerations arise. Firstly, the mixture of GED with two components can model the behaviour of daily returns more appropriately and steadily compared to benchmark models, i.e. the mixture of two Gaussians and the mixture of a Gaussian and a Laplace distribution. Secondly, the estimated shape parameters change over time, they are not constant. Thus, the shape parameter changes according to the behaviour of daily returns i.e. market conditions. Consequently, the overall volatility estimated by the mixture in each sub-period (0.63, 0.97, 1.73) reflects the corresponding volatility level showed by Figure 1 (low, intermediate and high).

Risk Parity strategy for portfolio construction: a kurtosis-based approach

Risk Parity strategy per la costruzione di un portafoglio: un approccio basato sulla curtosi

Maria Debora Braga, Consuelo Rubina Nava and Maria Grazia Zoia

Abstract Investors interested in the homogeneous distribution of responsibility for the dispersion of portfolio returns can pursue not only the equal constituents' contribution to portfolio volatility as, alternatively, they can focus on portfolio's extreme outcomes (either positive or negative). This leads to the proposal of a kurtosis-based risk parity strategy (KRP) that is a new risk parity strategy based on portfolio kurtosis as reference measure. In this paper, the portfolio weights, obtained with the KRP strategy. are compared with those estimated following the traditional standard deviation-based risk parity strategy. An analysis of KRP strategy performance is carried out through an out-of-sample study which takes advantage of real data from a global equity investment universe.

Abstract *Gli investitori, interessati a una distribuzione omogenea del rischio tra i vari asset di portafoglio, possono concentrarsi non solo sull'equa contribuzione dei costituenti alla volatilità di portafoglio poiché, in alternativa, essi si possono focalizzare sui risultati estremi di portafoglio (sia positivi che negativi) prendendo in considerazione la curtosi di portafoglio. In questo contesto, si sviluppa una strategia di parità di rischio basata sulla curtosi (strategia KRP) di portafoglio quale misura di rischio anziché sulla sua volatilità. I pesi per la costruzione del portafoglio ottenuti con la strategia KRP sono messi a confrontati con quelli ottenuti con la tradizionale strategia di parità di rischio basata sulla volatilità. Le performance della strategia KRP sono studiate con un approccio out-of-sample basato su dati reali di un universo di investimento azionario globale.*

Key words: Kurtosis, Risk parity, Risk diversification, Asset allocation

1 Introduction

Since 2008, in finance, a new strategy for portfolio construction, known as risk parity (RP), has appeared [4]. Its main feature is the wealth allocation (accordingly to a suitable defined risk-measure) among asset classes in such a way that each asset contributes in the same manner to the selected portfolio risk-measure. Thus, risk contribution forms the basis for the development of the RP strategy [3]. So far, portfolio volatility has been the most used reference risk-measure.

Here we develop the new version of the RP strategy where portfolio volatility is replaced by the portfolio kurtosis as the reference risk-measure. The existing literature has already dealt with other risk measures but never with the kurtosis. This is also due to the absence of a close form expression of the portfolio kurtosis. This is also due to difficulty of deriving closed form expressions for the marginal risk contribution of each asset and, consequently, the set-up of the optimization problem, necessary to identify optimal portfolio weights.

In this paper, a risk parity strategy based on portfolio kurtosis as reference measure (KRP – kurtosis-based risk parity) is investigated, applied, and its performance is compared with the traditional standard deviation-based risk parity (SRP). In such a way a novel strategy able to better accommodate the needs of investors interested in the homogeneous distribution of responsibility for portfolio returns' huge dispersion, as that measured by portfolio kurtosis, is developed. A novel and effective expression for portfolio kurtosis is proposed, which integrates the results proposed in [1]. The proposed methodology is applied on real data and compared with the classical RP allocation strategy based on volatility in order to explore its peculiar features.

The paper is organized as follow. Section 2 proposes an original formula for portfolio kurtosis. Section 3 describes the dataset used for the empirical application and provides main results. Section 4 concludes the paper.

2 Methodology

Let consider a portfolio composed by N assets with returns $\boldsymbol{R} = [R_i]$ and associated weights $\boldsymbol{w} = [w_i]$ with $i = 1, \ldots, N$. The weights w_i are the percentage of asset class i in the portfolio and satisfy the following normalizing constraint $\sum_{i=1}^{N} w_i = 1$. Let $\boldsymbol{\mu}$ and $\boldsymbol{\sigma}$ be the $N \times 1$ vectors of the expected returns and standard deviations for the selected asset classes in the investment universe: μ_i is the expected return of asset class i while σ_i is its risk. Furthermore, let $\boldsymbol{C} = [\rho_{ij}]$ and $\boldsymbol{\Sigma} = [\sigma_{ij}]$ be the $N \times N$ correlation matrix and covariance matrix. Accordingly, the expected return of the portfolio P and its variance are:

$$\mu_P = \boldsymbol{w}'\boldsymbol{\mu},\ \sigma_P^2 = \boldsymbol{w}'\boldsymbol{\Sigma}\boldsymbol{w}.$$

Let's now recall for the purpose of this contribution some results concerning the kurtosis of two generic random variables R_i and R_j

$$K_i = K(R_i) = \mathbb{E}\left[\left(\frac{R_i-\mu_i}{\sigma_i}\right)^4\right] = \frac{\mathbb{E}[(R_i-\mu_i)]^4}{[\mathbb{E}[(R_i-\mu_i)]^2]^2} = \frac{\mu_{i,4}}{\sigma_i^4}$$

with $\frac{R_i-\mu_i}{\sigma_i}$ representing the standardized returns. Thus,

$$K(w_iR_i) = \mathbb{E}\left[\left(\frac{w_iR_i-w_i\mu_i}{w_i\sigma_i}\right)^4\right] = \frac{\mu_{i,4}}{\sigma_i^4} = K(R_i)$$

$$K(R_i+R_j) = \frac{\sum_{k_1+k_2=4}\frac{4!}{k_1!k_2!}\sigma_1^{k_1}\sigma_2^{k_2}coK(R.,R.,R.,R.)}{(\sigma_i^2+\sigma_j^2+2cov(R_i,R_j))^2}$$

where the cokurtosis (coK) is defined as follows

$$coK(R_i,R_i,R_i,R_j) = \frac{\mathbb{E}[(R_i-\mu_i)^3(R_j-\mu_j)]}{\sigma_i^3\sigma_j};$$
$$coK(R_i,R_i,R_j,R_j) = \frac{\mathbb{E}[(R_i-\mu_i)^2(R_j-\mu_j)^2]}{\sigma_i^2\sigma_j^2}.$$

The cokurtosis is invariant over linear transformation, i.e. $coK(w_iR_i,w_iR_i,w_jR_j,w_jR_j) = coK(R_i,R_i,R_j,R_j)$. Moreover, the particular case of $coK(R_i,R_i,R_i,R_i)$ reduces to the kurtosis of R_i, i.e. $coK(R_i,R_i,R_i,R_i) = K(R_i)$, still invariant over linear transformation. However, it is worth noting that $K(w_iR_i+w_jR_j) \neq K(R_i+R_j)$.

The previous results can be extended to obtain a portfolio kurtosis including N asset, which can be expressed as follows

$$\begin{aligned} K_P = K\left(\sum_{i=1}^N w_iR_i\right) &= \frac{\mathbb{E}\left[\sum_{i=1}^N w_iR_i - \sum_{i=1}^N w_i\mu_i\right]^4}{\left(\mathbb{E}\left[\sum_{i=1}^N w_iR_i - \sum_{i=1}^N w_i\mu_i\right]^2\right)^2} \\ &= \frac{\sum_{\sum_{i=1}^N k_i=4}\frac{4!}{k_1!\cdots k_N!}coK(R.,R.,R.,R.)\prod_{i=1}^N w_i^{k_i}\sigma_i^{k_i}}{\left(\sum_{\sum_{i=1}^N k_i=2}\frac{2!}{k_1!\cdots k_N!}cov(R.,R.)\prod_{i=1}^N w_i^{k_i}\right)^2} \end{aligned} \tag{1}$$

where $k_i = 0,1,2,3,4\ \forall i = 1,\ldots,N$, $cov(R.,R.)$ is the covariance between two assets while $coK(R.,R.,R.,R.)$ is the cokurtosis.

Thus, based on this portfolio kurtosis formula, which can be also written in a closed form for using matrix notation [1], the portfolio kurtosis gradient, needed for

the determination of the marginal risk contributions of the asset classes to portfolio kurtosis, can be computed.

In this connection, it is worth noting that the RP approach is based on the idea that portfolio risk must be equally distributed among asset classes, a goal that can be pursued for any risk measure RM, provided it is homogeneous of degree one in the weights. This is also the case of the portfolio kurtosis. All methodological details are reported in [1] while in the next section we show the effect of selecting a KRP strategy compared with a SRP one.

3 Data and Results

The empirical application is based on seven equity indices from January 2001 to December 2020, provided by Morgan Stanley Capital International. In particular, the selected indexes are MSCI EMU, MSCI UK, MSCI USA, MSCI CANADA, MSCI JAPAN, MSCI PACIFIC EX-JAPAN, MSCI EMERGING MARKETS (expressed in euros). Here weekly returns are considered. Further empirical results considering also monthly data can be found in [1].

Main summary statistics, together with the Jarque-Bera test, are displayed in Table 1. Looking at it, we see that the indexes show negative skewness and positive excess kurtosis. The Jarque-Bera test is always significantly rejected.

Table 1 Summary statistics of the standardized returns assets of the investment universe

Asset	Mean	Volatitily	Skewness	Kurtosis	JB test (p-value)
MSCI EMU	0,0010	0,0291	-0,8840	9,4767	0
MSCI UK	0,0006	0,0273	-0,7391	12,7522	0
MSCI USA	0,0015	0,0261	-0,4513	6,7135	0
MSCI CANADA	0,0014	0,0291	-0,7728	10,1454	0
MSCI JAPAN	0,0008	0,0264	-0,1579	5,4569	0
MSCI PACIFIC EX JP F	0,0017	0,0271	-0,8073	10,4945	0
MSCI EM	0,0019	0,0284	-0,1937	8,4607	0

The test bed for our methodological proposal takes advantage of a rolling sample approach [2], considering different estimation window lengths and applying alternative portfolio rebalancing frequencies to determine the portfolio weights with the KRP and SRP strategies. In particular, here we consider an estimation window that covers 5 years (260 weeks) over which we have calculated portfolios with quarterly (i.e. every 12 weeks) and semi-annual (i.e. every 24 weeks) rebalancing windows. Figure 1 presents the results for the selected estimation window, together with the alternative rebalancing frequencies considered.

It emerges that the KRP strategy turns out to lead to a much more unbalanced and erratic portfolio structure compared with the one of the SRP. The Shannon Entropy measure also shows a different behavior for the two risk parity strategies (Figure 2).

According to Figure 2, the Shannon index is close to 2 when the SRP strategy is adopted, while it shows a very unstable and oscillating behavior when the KRP strategy is adopted. It is worth noting that exposures to asset classes within the KRP-based portfolios are inversely linked to their contribution to the portfolio kurtosis.

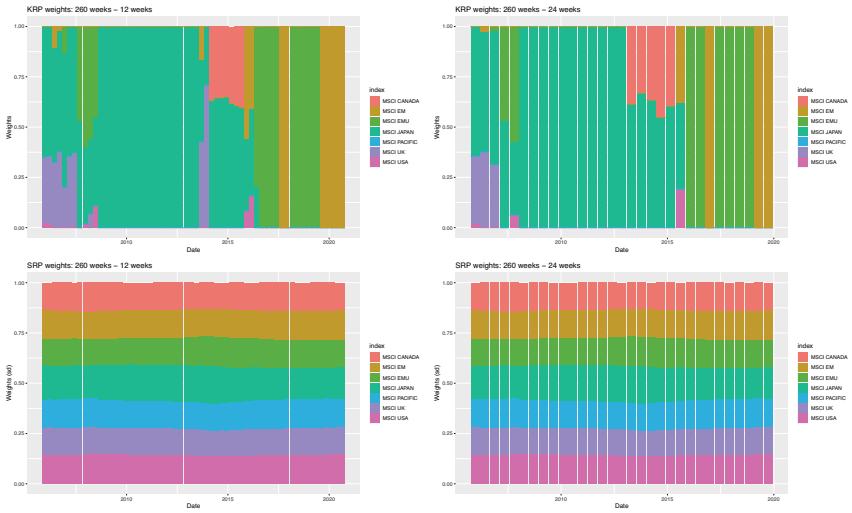

Fig. 1 Bar-charts representing the weights worked out using the KRP (top panels) and the SRP strategy (bottom panels). The estimation windows is 260 weeks long. The left panels refer to a rebalancing frequency of 12 week, while the right ones to 24 weeks.

The relevant characteristics of the out-of-sample returns provided by the two risk parity strategies have been also investigated. The KRP strategy systematically implies a lower kurtosis of out-of-sample returns. Finally, the risk-adjusted performance of the competing risk parity strategies, using the Sharpe ratio, the Sortino ratio and the Omega ratio have been evaluated. From Table 2, it results that KRP strategy provides persistently better reward per unit of risk taken.

Table 2 Sharpe, Omega and Sortino ratios obtained with the KRP and SRP strategies by using different rebalancing frequencies

Estimation window	Rebalancing frequency	Risk Parity strategy	Sharpe ratio	Omega ratio	Sortino ratio
260	12	KRP	0,380	1,159	0,520
		SRP	0,144	1,052	0,199
260	24	KRP	0,245	1,102	0,325
		SRP	0,126	1,046	0,171

Fig. 2 Shannon entropy using KRP and SRP strategies. The estimation windows is 260 weeks long. The top panel refer to a rebalancing frequency of 12 week, while the bottom one to 24 weeks.

4 Conclusions

Our empirical results reveal that a kurtosis-based risk parity strategy, compared to the classic risk parity, produces asset allocation solutions characterized by extremely unbalanced portfolio weights.

in addition we note that the "democratization" of kurtosis also helps its mitigation at least in comparison with the SRP strategy.

The methodological proposal of the paper, even if requires a more complex procedure for its implementation and leads to portfolio weights with a more unstable behavior, allows a better risk-return profile than SRP.

Fully reconciled probabilistic *GDP* forecasts from Income and Expenditure sides

Riconciliazione completa delle previsioni probabilistiche del PIL dal lato del reddito e della spesa

Tommaso Di Fonzo and Daniele Girolimetto

Abstract We propose a complete reconciliation procedure of probabilistic *GDP* forecasts, resulting in *GDP* forecasts coherent with both Income and Expenditure sides' forecasted series, and evaluate its performance on the Australian quarterly *GDP* series, as compared to the original proposal by Athanasopoulos *et al.* (2020).
Abstract *In questo lavoro viene proposta una procedura di riconciliazione delle previsioni probabilistiche del PIL e delle sue componenti tanto dal lato del Reddito quanto da quello della Spesa, volta a produrre previsioni coerenti rispetto ad entrambi i lati. Tale procedura, applicata alle serie trimestrali del PIL australiano, viene posta a confronto con la proposta originale di Athanasopoulos et al. (2020).*

Key words: probabilistic forecast reconciliation, linearly constrained multiple time series, GDP, Income, Expenditure

1 Introduction and summary

Probabilistic forecasting has become relevant and widely used in many fields in recent years (Gneiting and Katzfuss, 2014). Panagiotelis *et al.* (2020) propose an effective definition of reconciled (coherent) probabilistic forecasts in the case of genuine[1] hierarchical/grouped time series, that has been further worked out by Wickramasuriya (2021) in a Gaussian framework.

The reconciliation of point and probabilistic forecasts of Australian *GDP* from Income and Expenditure sides, each one distinctly dealt with, was originally considered by Athanasopoulos *et al.* (2020) in order to perform aligned decision making and to improve forecast accuracy. In their empirical study they consider 95 Australian Quarterly National Accounts time series, describing the Gross Domestic Product (*GDP*) at current prices from Income and Expenditure sides, interpreted as two distinct hierarchical structures. In the former case (Income), *GDP* is on the top of 15 lower level aggregates, while in the latter (Expenditure), *GDP* is the top level aggregate of a hierarchy of 79 time series (for details, see Athanasopoulos *et al.*, 2020, and Bisaglia *et al.*, 2020).

T. Di Fonzo (e-mail: tommaso.difonzo@unipd.it); D. Girolimetto (e-mail: daniele.girolimetto@phd.unipd.it); Department of Statistical Sciences, University of Padova.

[1] In a genuine hierarchical/grouped time series, the link between the top-level and $n_b > 1$ bottom variables is uniquely defined (Di Fonzo and Girolimetto, 2021).

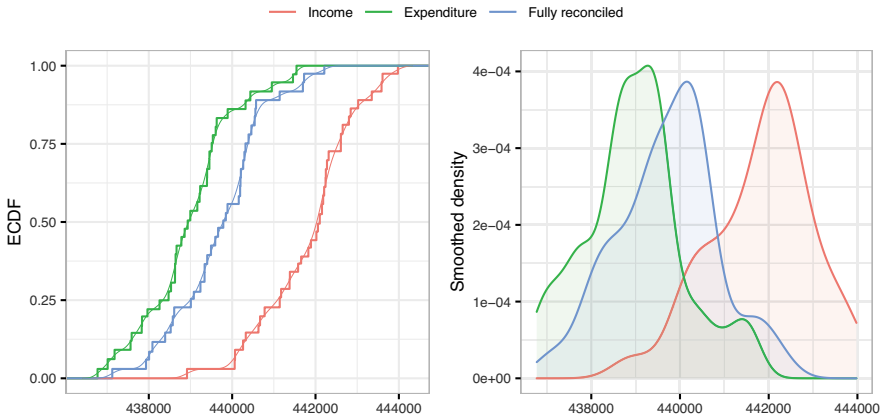

Fig. 1 *GDP* empirical 1-step-ahead forecast distributions for 2018:Q1, MinT-shr reconciliation approach. Empirical Cumulative Distribution Function (left), and Smoothed density (right).

In this paper, the results shown in Bisaglia *et al.* (2020) as for the reconciliation of point macroeconomic forecasts, are extended to a probabilistic forecasting framework. We re-consider the results of Athanasopoulos *et al.* (2020), where the probabilistic forecasts of the Australian quarterly *GDP* aggregates are separately reconciled from Income ($\widetilde{GDP}^{I}$) and Expenditure ($\widetilde{GDP}^{E}$) sides. This means that the empirical forecast distributions $\widetilde{GDP}^{I}$ and $\widetilde{GDP}^{E}$ are each coherent (according to Theorem 3.5 in Panagiotelis *et al.*, 2020) within its own pertaining side with the other empirical forecast distributions, but in general $\widetilde{GDP}^{I} \neq \widetilde{GDP}^{E}$ at any forecast horizon. This circumstance could confuse the user, mostly when the difference between the empirical forecast distributions is not negligible, as shown in Figure 1, where the *GDP* empirical forecast distributions from Income and Expenditure sides for 2018:Q1 are presented along with their fully reconciled counterparts through the MinT-shr approach (Athanasopoulos *et al.*, 2020). Bisaglia *et al.* (2020) propose a complete reconciliation strategy, able to produce a 'one number point forecast' of the *GDP* figure. However, a similar result is still missing for the probabilistic reconciliation setting. We fill this gap, showing how (incoherent) base probabilistic forecasts for general linearly constrained multiple time series (i.e., not necessarily genuine hierarchical/grouped time series) may be coherently reconciled[2].

2 Coherent probabilistic forecast reconciliation

We consider a linearly constrained n-dimensional multiple time series $\{\mathbf{y}_t\}_{t=1}^{T}$, with constraints expressed in homogeneous form as $\mathbf{U}'\mathbf{y}_t = \mathbf{0}_{r\times 1}$, where $\mathbf{U}'$ is a $(r \times n)$ matrix of known coefficients. For a genuine hierarchical/grouped time series, setting $n_a = r$, the standard structural representation (Hyndman *et al.*, 2011) holds:

[2] Note that the naive practice of averaging *GDP* forecasts from different sides yields a single forecast, that is though inconsistent with the component variables from both sides.

$$\mathbf{y}_t = \mathbf{S}\mathbf{b}_t, \quad t = 1, \ldots, T, \tag{1}$$

where $\mathbf{S} = \begin{bmatrix}\mathbf{C}' & \mathbf{I}_{n_b}\end{bmatrix}'$ is the summing matrix mapping the n_b bottom time series $\mathbf{b}_t$ into the complete vector $\mathbf{y}_t = \begin{bmatrix}\mathbf{a}_t' & \mathbf{b}_t'\end{bmatrix}'$. The $(n_a \times 1)$ vector $\mathbf{a}_t$ contains the aggregated (upper) time series, $\mathbf{C} \in \{0,1\}^{n_a \times n_b}$ is the contemporaneous aggregation matrix (Di Fonzo and Girolimetto, 2021), $\mathbf{a}_t = \mathbf{C}\mathbf{b}_t$, and $\mathbf{U}' = \begin{bmatrix}\mathbf{I}_{n_a} & -\mathbf{C}\end{bmatrix}$.

To exploit definitions and results of Panagiotelis *et al.* (2020), valid for genuine hierarchical/grouped time series expressed as in (1), we need to find out a relationship like expression (1) for a general linearly constrained multiple time series as well. In general, for example when the number of constraints makes manual handling of the problem difficult, this can be done in the following steps:

1. compute $\mathbf{R}'$, the $(n_v \times n_f)$ reduced row echelon form (*rref*, Strang, 2019) of matrix $\mathbf{U}'$, where possible $r - n_v$ zero rows are not considered;
2. find out a $(n \times n)$ permutation matrix $\bar{\mathbf{P}}$, such that $\bar{\mathbf{U}}' = \mathbf{R}'\bar{\mathbf{P}}'$ has the form $\bar{\mathbf{U}}' = \begin{bmatrix}\mathbf{I}_{n_v} & -\bar{\mathbf{C}}\end{bmatrix}$, where $\bar{\mathbf{C}}$ is a $(n_v \times n_f)$ matrix of known coefficients (differently from matrix $\mathbf{C}$, the items of matrix $\bar{\mathbf{C}}$ are not necessarily equal to either 0 or 1, and may be negative);
3. define the matrix $\bar{\mathbf{S}} = \begin{bmatrix}\bar{\mathbf{C}}' & \mathbf{I}_{n_f}\end{bmatrix}'$ (analogous of the summing matrix $\mathbf{S}$), and $\bar{\mathbf{y}}_t = \bar{\mathbf{P}}\mathbf{y}_t = \begin{bmatrix}\mathbf{v}_t' & \mathbf{f}_t'\end{bmatrix}'$, where $\mathbf{f}_t$ is a $(n_f \times 1)$ vector of 'free' variables, and $\mathbf{v}_t$ is a $(n_v \times 1)$ vector of 'basic' variables, such that $\mathbf{v}_t = \bar{\mathbf{C}}\mathbf{f}_t$, $t = 1, \ldots, T$;
4. define the 'structural' representation of a general linearly constrained multiple time series as
$$\bar{\mathbf{y}}_t = \bar{\mathbf{S}}\mathbf{f}_t, \quad t = 1, \ldots, T; \tag{2}$$
5. consider the general optimal combination reconciliation formula according to the projection approach (Di Fonzo and Girolimetto, 2021), $\tilde{\mathbf{y}}_h = \mathbf{M}\hat{\mathbf{y}}_h$, where $\mathbf{M} = \mathbf{I}_n - \mathbf{W}_h\mathbf{U}\left(\mathbf{U}'\mathbf{W}_h\mathbf{U}\right)^{-1}\mathbf{U}'$, with $\mathbf{W}_h$ $(n \times n)$ p.d. matrix, and express the same result as:
$$\bar{\mathbf{P}}\tilde{\bar{\mathbf{y}}}_h = \bar{\mathbf{S}}\bar{\mathbf{G}}\bar{\mathbf{P}}\hat{\bar{\mathbf{y}}}_h, \tag{3}$$
where $\bar{\mathbf{G}} = \left(\bar{\mathbf{S}}'\bar{\mathbf{P}}'\mathbf{W}_h^{-1}\bar{\mathbf{P}}\bar{\mathbf{S}}\right)^{-1}\bar{\mathbf{S}}'\bar{\mathbf{P}}'\mathbf{W}_h^{-1}$;
6. given n_f (and $n_v = n - n_f$), $\tilde{\mathbf{y}}_h$ is uniquely determined and does not depend on a particular choice of the free variables. This point is formally clarified in the extended version of the paper.

We consider 3 cases for the approximation of the covariance matrix $\mathbf{W}_h$:

- ols: $\mathbf{W}_h = \sigma^2\mathbf{I}_n$ (Hyndman *et al.*, 2011),
- wls: $\mathbf{W}_h = \widehat{\mathbf{W}}_D = \operatorname{diag}\widehat{\mathbf{W}}_1$ (Hyndman *et al.*, 2016),
- shr: $\mathbf{W}_h = \widehat{\mathbf{W}}_{shr} = \lambda\widehat{\mathbf{W}}_D + (1-\lambda)\widehat{\mathbf{W}}_1$ (Wickramasuriya *et al.*, 2019),

where $\widehat{\mathbf{W}}_1$ is the $(n \times n)$ covariance matrix of the in-sample one-step-ahead base forecasts errors, and $\widehat{\mathbf{W}}_{shr}$ is its shrinked version (Wickramasuriya *et al.*, 2019).

Representation (2) means that $\bar{\mathbf{y}}_t$ lies in an n-dimensional subspace of $\mathbb{R}^n$ spanned by the columns of $\bar{\mathbf{S}}$, called "coherent subspace" and denoted by $\mathscr{S}$ (Panagiotelis *et al.*, 2020). Now, let $\mathscr{F}_{\mathbb{R}^{n_f}}$ be the Borel σ-algebra on $\mathbb{R}^{n_f}$, $\left(\mathbb{R}^{n_f}, \mathscr{F}_{\mathbb{R}^{n_f}}, \nu\right)$ a probability space for the free variables, and $\bar{s}: \mathbb{R}^{n_f} \to \mathbb{R}^n$ a continuous mapping matrix. Then a σ-algebra $\mathscr{F}_{\mathscr{S}}$ can be constructed from the collection of sets $\bar{s}(\mathscr{B})$ for all $\mathscr{B} \in \mathscr{F}_{\mathbb{R}^n}$.

Definition 1. (*Coherent probabilistic forecast for a linearly constrained multiple time series*) Given the triple $\left(\mathbb{R}^{n_f}, \mathscr{F}_{\mathbb{R}^{n_f}}, \nu\right)$, we define a coherent probability triple $\left(\overline{\mathscr{S}}, \mathscr{F}_{\overline{\mathscr{S}}}, \check{\nu}\right)$ such that $\check{\nu}(\overline{s}(\mathscr{B})) = \nu(\mathscr{B})$, $\forall \mathscr{B} \in \mathscr{F}_{\mathbb{R}^{n_f}}$.

In order to extend forecast reconciliation to the probabilistic setting, let $(\mathbb{R}^n, \mathscr{F}_{\mathbb{R}^n}, \hat{\nu})$ be a probability triple characterizing base (incoherent) probabilistic forecasts for all n series, and let $\psi : \mathbb{R}^{n_f} \to \mathbb{R}^n$ be a continuous mapping function defined by Panagiotelis *et al.* (2020) as the composition of two transformations, $\overline{s} \circ \overline{g}$, where $\overline{g} : \mathbb{R}^n \to \mathbb{R}^{n_f}$ is a continuous function corresponding to matrix $\overline{\mathbf{G}}$ in equation (3).

Definition 2. (*Probabilistic forecast reconciliation for a linearly constrained multiple time series*). The reconciled probability measure of $\hat{\nu}$ with respect to ψ is a probability measure $\tilde{\nu}$ on $\overline{\mathscr{S}}$ with σ-algebra $\mathscr{F}_{\overline{\mathscr{S}}}$ such that

$$\tilde{\nu}(\mathscr{A}) = \hat{\nu}\left(\psi^{-1}(\mathscr{A})\right), \quad \forall \mathscr{A} \in \mathscr{F}_{\overline{\mathscr{S}}}, \tag{4}$$

where $\psi^{-1}(\mathscr{A}) = \{x \in \mathbb{R}^n : \psi(x) \in \mathscr{A}\}$ is the pre-image of $\mathscr{A}$.

3 Joint bootstrap-based probabilistic forecast reconciliation

Since an analytical expression of the forecast distribution is either unavailable, or relies on unrealistic parametric assumptions, the empirical evaluation of the results will be grounded on reconciled samples obtained according to Theorem 3.5 in Panagiotelis *et al.* (2020)[3]:

Theorem 1. *(Reconciled samples). Suppose that* $\left(\hat{\mathbf{y}}^{[1]}, \ldots, \hat{\mathbf{y}}^{[L]}\right)$ *is a sample drawn from an incoherent probability measure* $\hat{\nu}$*. Then* $\left(\tilde{\mathbf{y}}^{[1]}, \ldots, \tilde{\mathbf{y}}^{[L]}\right)$*, where* $\tilde{\mathbf{y}}^{[\ell]} := \psi\left(\hat{\mathbf{y}}^{[\ell]}\right)$ *for* $\ell = 1, \ldots, L$*, is a sample drawn from the reconciled probability measure* $\tilde{\nu}$ *as defined in (4).*

According to this theorem, reconciling each member of a sample obtained from an incoherent distribution yields a sample from the reconciled distribution. As a consequence, coherent probabilistic forecasts may be developed through a post-forecasting mechanism analogous to the point forecast reconciliation setting. For this purpose, the bootstrap procedure by Gamakumara *et al.* (2018) is applied:

1. appropriate univariate models M_i for each series in the system are fitted based on the training data $\{y_{i,t}\}_{t=1}^{T}$, $i = 1, ..., n$, and the one-step-ahead in-sample forecast errors are stacked in an $(n \times T)$ matrix, $\widehat{\mathbf{E}} = \{\hat{e}_{i,t}\}$;
2. $\hat{\mathbf{y}}_{i,h}^{[l]} = f_i\left(M_i, \hat{e}_{i,h}^{[l]}\right)$ is computed for $h = 1, ..., H$ and $l = 1, ..., L$, where $f(\cdot)$ is a function of the fitted univariate model and associated error, $\hat{\mathbf{y}}_{i,h}^{[l]}$ is a sample path simulated for the $i-$th series, and $\hat{e}_{i,h}^{[l]}$ is the $(i,h)-$th element of an $(n \times H)$ block bootstrap matrix containing H consecutive columns randomly drawn from $\hat{\mathbf{E}}$;
3. the optimal combination reconciliation formula (3) is performed for each $\hat{\mathbf{y}}_{h}^{[l]}$.

[3] Extension to a linearly constrained multiple time series for the Gaussian case (Wickramasuriya, 2021) is currently under study, and will be presented in the extended version of the paper.

The accuracy of the probabilistic forecasts is evaluated using the Cumulative Rank Probability Score (CRPS, Gneiting and Katzfuss, 2014, Panagiotelis *et al.*, 2020). In addition, we employ the Energy Score (ES), that is the CRPS extension to the multivariate case, to evaluate the forecasting accuracy for the whole system (Gamakumara *et al.*, 2018).

4 Reconciled probabilistic forecasts of the Australian *GDP*

For the complete Australian *GDP* accounts from both Income and Expenditure sides, it is $n = 95$ ($n_f = 62$ and $n_v = 33$), and the homogeneous constraints are described by matrix $\mathbf{U}'$ shown in Bisaglia *et al.* (2020). In addition, the available time series span over the period 1984:Q4 - 2018:Q1.

Athanasopoulos *et al.* (2020) produced base forecasts for each time series using univariate ARIMA models (with the `auto.arima` function of the R-package). Our reconciliation proposal is applied within the same forecasting experiment, that considers forecasts from $h = 1$ quarter ahead up to $h = 4$ quarters ahead, using an *expanding* window, where the first training sample is set from 1984:Q4 to 1994:Q3. The base forecasts are reconciled using the `htsrec` function of the R-package `FoReco` (Girolimetto and Di Fonzo, 2022).

Figure 2 shows the *skill scores* of CRPS for the *GDP* reconciled forecasts (top panel), and of ES for Income and Expenditure sides, and the whole system (bottom panel), that is the percentage changes registered by these indices for the considered reconciliation procedures, computed such that positive values signal an improvement in forecasting accuracy over the base forecasts. 'Income' and 'Expenditure' panels, respectively, refer to the results found by Athanasopoulos *et al.* (2020), while the 'Fully reconciled' panel shows the *skill scores* of the fully reconciled probabilistic forecasts. From the bottom panel of Figure 2, it appears that the reconciliation improves on the base forecasts' accuracy, shr and wls offering almost always the best performance. For *GDP*, ols outperforms both wls and shr, whatever side is considered. In general, the simultaneously reconciled probabilistic forecasts give results as good as those of Athanasopoulos *et al.* (2020). In addition, the newly proposed approach produces forecasts that are fully coherent with all economic constraints coming from National Accounts relationships.

Latent Class models

Latent thresholds model in classification tasks

Modello delle soglie latenti nei compiti di classificazione

Giuseppe Mignemi, Andrea Spoto, Antonio Calcagnì

Abstract Categorical rating scale with two, three or more ordered categories are widely used in many contexts such as screening and diagnostic assessment, quality control, sport refereeing or emergency. The present research aims to model classification tasks in which raters can evaluate the belonging of an item to a certain category according to several ordered levels. It is supposed that each rater has his/her own thresholds (i.e., a reference point) to perform the classification task. The classification outcomes have been described as a function of two independent latent sources of uncertainty, one related to the item, the other one related to the rater. Model parameters have been estimated using an ABC-based algorithm. Finally, the characteristics of the proposed method have been discussed by means of a real case study.

Abstract *Valutazioni categoriali con due, tre o più categorie ordinate sono ampiamente utilizzate in molti contesti come lo screening e la valutazione diagnostica, il controllo della qualita, l'arbitraggio sportivo o situazioni d'emergenza. Il modello proposto mira a descrivere le attività di classificazione in cui rater differenti possono valutare il grado d'appartenenza di un oggetto ad una determinata categoria secondo diversi livelli ordinati. Si suppone che ogni valutatore abbia le proprie soglie per svolgere il compito di classificazione. I risultati della classificazione sono stati descritti in funzione di due fonti di incertezza latenti indipendenti, una relativa all'item, l'altra relativa al valutatore. I parametri del modello sono stati stimati utilizzando un algoritmo ABC-based. Infine, le caratteristiche del metodo proposto sono state discusse attraverso un caso studio reale*

Key words: Classification process, Conditional model, Approximate bayesian computation

1 Introduction

Categorical rating scales with two, three or more ordered categories are widely used in many contexts such as screening and diagnostic assessment [9], sport refereeing [10] or emergency department [4]. Consensus is expected among raters when they classify the same items. It is deemed that raters' agreement is evidence of an accurate and reliable classification, although their opinion may differ, resulting in a controversial classification. For instance, several research works in biostatistics have been moving toward the modelling of this systematic individual variability using GLMM (e.g., [6, 9, 8]). The following contribute aims to model classification tasks in which raters can evaluate the belonging of an item to a certain category according to several ordered levels. It is supposed that each rater has his/her own levels thresholds (i.e., a reference point) to make this kind of classification. Examples of such a situation include the case of a physician who has to classify a patient's disease severity or an emergency operator who has to classify the urgency of intervention.

2 Model specification

Consider the case where a rater $i \in \{1,...,I\}$ has to classify one item $j \in \{1,...,J\}$ according to an ordered set of disjoint categories $\mathscr{C} \doteq \{1,...,C\} \subset \mathbb{N}$. For each item, we observe I different unit vectors $\mathbf{w}_{ij} = [w_{ij1},...,w_{ijC}] \in \{0,1\}^C$, one for each rater, in which the element $w_{ijc} = 1$ indicates that the rater i classifies the item j into the c-*th* category. The observed data are modeled as a function of two independent latent processes, the first of which is related to specific characteristics of the item, whereas the other is related to rater-specific characteristics. As for other psychometric models,the item-specific component is represented by the latent variable $\eta_j \in (0,1)$, whereas the rater-specific component is represented by a vector of independent latent variables, $\boldsymbol{\xi}_i = [\xi_{i1},...,\xi_{iC}] \in \mathbb{R}^C_+$. The vector of observed values $\mathbf{w}_{ij}$ is function of η_j and $\boldsymbol{\xi}_i$ so that the complete sample space is $\mathscr{Y} : (0,1)^J \times \mathbb{R}^C \times \{0,1\}^{J\times I\times C}$. We propose the following model specification for the aforementioned process. For a generic pair (i,j), the model is specified as follows:

$$\eta_j \sim Beta(\eta_j;\alpha_j,\beta_j), \tag{1}$$

$$\xi_{ic} \sim logNormal(\xi_{ic};\mu_c,\sigma_c), \quad \xi_{ic} \in \boldsymbol{\xi}_i \tag{2}$$

$$\pi_{ijc} = \mathscr{P}(w_{ijc} = 1;\boldsymbol{\theta}) = \int_{t(\boldsymbol{\xi}_i,c-1)}^{t(\boldsymbol{\xi}_i,c)} Beta(\eta_j;\alpha_j,\beta_j)\,d\eta, \quad \pi_{ijc} \in \boldsymbol{\pi}_{ij}, \tag{3}$$

$$\mathbf{W}_{ij}|\eta_j,\boldsymbol{\xi}_i \sim Multinomial(\mathbf{W}_{ij};n=1,m=C,\pi=\boldsymbol{\pi}_{ij}), \tag{4}$$

where $\theta=[\alpha_{\eta_j},\beta_{\eta_j},\mu_1,\ldots,\mu_C,\sigma_1,\ldots,\sigma_C]$ with parameter space $\Theta:\{\alpha_{\eta_j},\beta_{\eta_j},\mu_1,\ldots,\mu_C,\sigma_1,\ldots,\sigma_C\in\mathbb{R}_+\}$. The function $t:\mathbb{R}_+^C\times\mathscr{C}\rightarrow(0,1)$ is applied to $\boldsymbol{\xi}_i$ so that

$$t(\boldsymbol{\xi}_i,c)=\frac{\sum_{c=1}^{c}\xi_{ic}}{\sum_{c=1}^{C}\xi_{ic}}\ .$$

The following properties are assumed: $\eta_{ij}\perp\!\!\!\perp\boldsymbol{\xi}_i$, $\xi_{ic}\perp\!\!\!\perp\xi_{ic+1}$ and the $t(\boldsymbol{\xi}_i,c)=0$ if $c=1$ and $t(\boldsymbol{\xi}_i,c)=1$ if $c=C$.
The joint density function is

$$p(\boldsymbol{\eta},\boldsymbol{\xi},\mathbf{w};\boldsymbol{\theta})=\prod_{i=1}^{I}\prod_{j=1}^{J}\left(\prod_{c=1}^{C}\pi_{ijc}^{w_{ijc}}\right)B(\alpha_j,\beta_j)^{-1}\eta_j^{\alpha_j-1}(1-\eta_j)^{\beta_j-1}\times$$
$$\times\prod_{c=1}^{C}\frac{1}{\sqrt{2\pi^C|\boldsymbol{\Sigma}|}}exp\{-\frac{1}{2}\left[\log(\xi_{ic})-\mu_c\right]^T\boldsymbol{\Sigma}^{-1}\left[\log(\xi_{ic})-\mu_c\right]\} \tag{5}$$

2.1 Parameter estimation

Because of the incomplete nature of observed data, the likelihood function implied by the data generating process is computational prohibitive, it requires integrating the joint likelihood function over all the complete sample space [12, 14, 1]. Therefore a *likelihood-free* approach might be applied to circumventing these problems. The *Approximate Bayesian computation* (ABC) methods bypass the direct numerical evaluation of the likelihood function by using a measure of distance d (e.g., Euclidean distance, Mahalanobis distance) between an observed summary statistics based on the actual data $S(y_{obs})$ and the one obtained by the simulated data $S(y_b)$, $b=1,...,B$, where B is the number of the simulations. If the distance $d(S(y_b),S(y_{obs}))$ is less than a fixed threshold (i.e., tolerance acceptance condition) the related parameter value θ_b is accepted. The set of the accepted parameter values $\pi_{ABC}(\theta|y_{obs})$ represents a sample from the approximated posterior distribution $\tilde{\pi}(\theta|y_obs)$. Several techniques have been developed to improve this approximation, including regression adjustments [2], strategies to choose $S(y_{obs})$ [11], or sampling procedures [13, 15, 7].

3 Application

We analyzed a data set from the retail context. We consider a convenience sample of $N_r=203$ consumers, who were administered with a survey in which they were asked to classify each of $N_i=10$ different products of the same brand according to $C=3$ mutually exclusive categories (i.e.,*"Bad"*,*"Neutral"*,*"Good"*). Their choices have been converted into boolean variables (e.g.,*"Bad"*:$=[1,0,0]$, *"Neutral"*:$=[0,1,0]$)

resulting in an array-structured data set. As required by the ABC approach a collection of summary statistics was computed. The $N_i \times C$ integer matrix containing the marginal counts of the categories chosen for each product (i.e., how many times a product was classified into each of the three categories) was used as summary statistics.

Two parameters per product and two parameters per category had to be estimated, resulting in a vector of $N_i \times 2 + C \times 2 = 26$ parameters. We tested two different set of priors to fit our model. Within the former, all the priors were uniform distributed as follows: $\alpha_j \sim Unif(0.1,5), \beta_j \sim Unif(0.1,5), j = 1,..,J$; $\kappa_1 \sim Unif(0.1,20), \kappa_2 \sim Unif(0.1,30), \kappa_3 \sim Unif(0.1,50), \sigma_c \sim Unif(0.1,1), c = 1,..,C$. For the second one, the priors were specified as follows: $\alpha_j \sim LN(0.5,0.09), \beta_j \sim LN(0.5,0.09), j = 1,..,J$; $\kappa_c \sim LN(3,0.5), \sigma_c \sim Unif(0.1,1), c = 1,..,C$.

The *R* package *Easy-ABC* [5] was used to get the simulated summary statistics based on both the specified priors and the observed summary statistic. The ABC-MCMC algorithms proposed by Marjoram [7] with Wegmann's [15] improvements was used to explore the parameter space. The approximate posterior distributions were estimated through the ABC method applying a regression adjustment accounting for *heteroscedasticity* (i.e., neural networks) using of the *R* package *abc* [3]. In the case of uniform priors, we chose a logit transformation of the parameters before regression adjustment as guarantee that the parameter values lie in the range of the prior.

The two sets of priors were compared by means of the Bayes factors and the posterior model probabilities computed using a logistic regression-based variant of ABC with neural network [1, 2]. The model fitted with uniform priors showed a Bayes factor of 12796.3817 and a posterior model probability of .99. Furthermore, a Principal Component Analysis performed using the a priori simulated summary statistics showed the better fit of the model with uniform priors. Thus, the parameters inference was based on the model with uniform priors. The accuracy of the estimation was assessed through a leave-one-out cross validation; the mean prediction error along all the parameters was 0.61. The features of the approximate posterior distributions of the parameters are shown in Table 1. Figure 1 shows an example the prior and the posterior (with and without regression-based correction) densities of the parameter κ_1, the euclidean distance as function of the parameter values and Q-Q plot of the regression's residuals.

4 Conclusion

We have developed a novel approach to the statistical modeling of raters classification process. Raters' classification outcomes have been described as function of two independent latent sources of uncertainty. One related to the item, the other one related to the rater. However, as for any statistical models, further improvements might be implemented. For instance, covariates might be specified in equations (1,2). The assumption of conditional independence between the elements of $\boldsymbol{\eta}$ may be relaxed

Adaptive filters for time-varying correlation parameters

Filtri adattivi per parametri di correlazione che variano nel tempo

Michele Lambardi di San Miniato, Ruggero Bellio, Luca Grassetti, Paolo Vidoni

Abstract Adaptive filters from control theory are recursive estimators for time-varying parameters. We propose an adaptive filter targeting spatial and temporal correlation parameters, that we conjecture to be more stable in the case of regime shifts. This proposal should be suitable for online environmental monitoring tasks. We illustrate an application to sensor data with a spatio-temporal conditional autoregressive model.

Abstract *I filtri adattivi, afferenti alla teoria del controllo, sono stimatori ricorsivi per parametri variabili nel tempo. Proponiamo un filtro adattivo per parametri di correlazione spaziale e temporale, che congetturiamo essere più stabile di fronte a cambi di regime. Questa proposta pare adatta per applicazioni di monitoraggio ambientale in tempo reale. Un'applicazione a dati provenienti da sensori illustra la metodologia, mediante un modello condizionale autoregressivo spazio-temporale.*

1 Adaptive filtering approach

Environmental monitoring often requires to collect physical data by means of sensors and to provide predictions in real time. A suitable model can be highly nonlinear, complicated, and even time-varying. One may wait and collect a long training set, then estimate a complicated model. Here, we opt for an adaptive filtering approach [2], where even a simple model can be made flexible by assuming a time-varying parameter vector and then tracking it via recursive estimators.

An adaptive filter provides a *current* estimate $\hat{\theta}_n$ for a real-valued parameter vector θ at step n and updates into $\hat{\theta}_{n+1}$ upon observing a new data chunk y_{n+1}, possibly without parsing older data $y_n, y_{n-1}, \ldots$ again. The update steers towards parameter values that are more supported in the light of y_{n+1}, while compromising with $\hat{\theta}_n$. A hyperparameter $\lambda \in]0,1[$ is involved, called learning rate, which weighs y_{n+1} relative to $\hat{\theta}_n$. Following [2], the update can be formulated as

$$\hat{\theta}_{n+1} = \hat{\theta}_n + \lambda\, C_{n+1}^{-1}\, g_{n+1}\,,$$

where $g_{n+1} = g(\hat{\theta}_n; y_{n+1})$ and $g(\cdot; y)$ is the gradient with respect to θ of some objective function $G(\theta; y)$; C_n is a positive-definite condition matrix that tunes the efficiency aspects of the filter. In a likelihood framework, it is sound to define $G(\cdot; y)$ as the log-likelihood function conditional on the past observations, $g(\cdot; y)$ as the score function, and then set

$$C_{n+1} = (1-\lambda) C_n + \lambda\, g_{n+1}\, g_{n+1}^{\top}\,, \tag{1}$$

which emulates the Fisher information matrix: we refer to this as *Type 1 conditioning*. We also propose the following *Type 2 conditioning*:

$$C_n = \mathrm{diag}(\sqrt{v_n})\,, \quad \text{where} \quad v_{n+1} = (1-\lambda) v_n + \lambda\, g_{n+1} \circ g_{n+1}\,, \tag{2}$$

where $\circ$ is the Hadamard product, thus $v \circ v$ is just the vector v with squared components, while $\mathrm{diag}(v)$ is a diagonal matrix with vector v as its main diagonal. Thus, C_n retains only the diagonal square-rooted entries of the information matrix.

This Type 2 formulation is less efficient, but also less memory- and compute-intensive. It is numerically stable as there is virtually no risk of C_n becoming near-singular. Type 2 filters may also be better than Type 1 at discounting initial conditions and thus coping with regime shifts; this is only a conjecture, based on the resemblance with AdaGrad stochastic gradient descent [5], and supported to some extent by the numerical example provided in the following.

Here we apply Type 1 and 2 filters for a spatio-temporal conditional autoregressive model (STCAR) [4] and then compare the two estimates on a data stream, based on the Intel Lab Data, available in the public domain [1].

2 Spatio-temporal model

Let $(y_{st})_{s,t}$ be a spatio-temporal data matrix, where $s \in \mathscr{S} = \{1,2,\ldots,S\}$ is the space index and $t \in \mathscr{T} = \{1,2,\ldots,T\}$ is the time index. We assume the data are available on a grid, that is, for all pairs $(s,t) \in \mathscr{S} \times \mathscr{T}$, or can be projected onto such a grid.

Let the data be modeled by a random matrix $(Y_{st})_{s,t}$. Define $X_{st} = Y_{st} - \mu$, where $\mu \in \mathrm{R}$ is a constant mean parameter. Let $Y_t = (Y_{st})_s$ and $X_t = (X_{st})_s$ be column vectors, for all $t \in \mathscr{T}$. Let W be a $S \times S$ matrix of known weights with generic s-th row $w_s = (w_{s1},\ldots,w_{sS})^\top$, such that $w_{ss} = 0$ and $\bar{X}_{st} = w_s^\top X_t$ represents a spatial prediction for X_{st}. Following [4], the STCAR model is defined as

$$(\mathrm{Id} - \rho W)(1 - \phi L^{\Delta})(Y_t - \mu) = \varepsilon_t \,.$$

Here, Id is the $S \times S$ identity matrix and

- ρ and ϕ are the spatial and temporal dependence parameters, respectively;
- L is a temporal lag operator, so $L^{\Delta} a_{st} = a_{s(t-\Delta)}$ for all st-indexed quantities a_{st};
- $\Delta \in \{1,2,\ldots\}$ is a temporal lag hyperparameter;
- $\varepsilon_t = (\varepsilon_{st})_s$, and ε_{st} are Gaussian white noise with constant variance σ^2.

As in adaptive filtering approach, we treat the parameter vector $\theta = (\mu, \sigma, \rho, \phi)^\top$ as time-varying. Upon observing $y_{n+1} = y_{st}$, the current estimate $\hat{\theta}_n = (\hat{\mu}_n, \hat{\sigma}_n, \hat{\rho}_n, \hat{\phi}_n)^\top$ is updated suitably. Exponential smoothing is used to update $\hat{\mu}_n$ and $\hat{\sigma}_n$ into

$$\hat{\mu}_{n+1} = (1-\lambda)\hat{\mu}_n + \lambda Y_{st} \,, \quad \hat{\sigma}^2_{n+1} = (1-\lambda)\hat{\sigma}^2_n + \lambda \hat{\varepsilon}^2_{st} \,,$$

where $\hat{\varepsilon}_{st} = X_{st} - \hat{\rho}_n \bar{X}_{st} - \hat{\phi}_n (X_{s(t-\Delta)} - \hat{\rho}_n \bar{X}_{s(t-\Delta)})$ and $X_{st} = Y_{st} - \hat{\mu}_n$. In estimating the correlation parameter $\psi = (\rho, \phi)^\top$, the filter $\hat{\psi}_{n+1} = \hat{\psi}_n + \lambda\, C^{-1}_{n+1}\, g_{n+1}$ can be based on the pseudo score function, after replacing μ and σ with their current estimates. Thus, we set for use in (1) and (2)

$$g_{n+1} = \hat{\varepsilon}_{st} \cdot (\bar{X}_{st} - \hat{\phi}_n \bar{X}_{s(t-\Delta)} \,,\, X_{s(t-\Delta)} - \hat{\rho}_n \bar{X}_{s(t-\Delta)})^\top / \hat{\sigma}^2_n \,.$$

3 Data analysis

The Intel Lab Data were collected by means of a mesh network with 54 sensors in the Intel Berkeley Research Lab between February 28 and April 5, 2004 [1]. The sensors were numbered and located in the building as in Figure 1. The sensors collected data asynchronously, roughly every 30 seconds, often with slight delays due to routing. We project the data onto a grid layout: upon observing the generic Y_{st}, we define $Y_{s'(t-k+1)}$ as the k-th most recent observation from sensor s'. This is a pragmatic approximation for the case when it is not perfectly known whether all sensors will be able to provide readings on time as requested.

The original data include nearly 2.3 million rows. Room temperature in Celsius degrees (°C) is recorded. We dropped all observations taken by sensors whose bat-

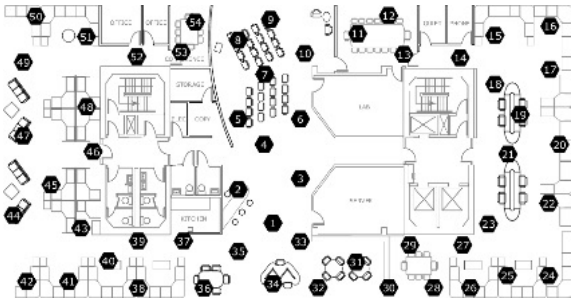

Fig. 1 Map of the Intel Berkeley Research lab. Sensors are numbered from 1 to 54. The image is modified from [1].

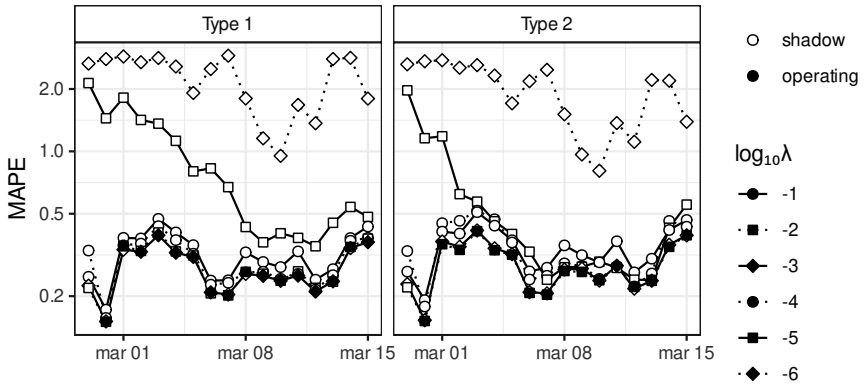

Fig. 2: Daily MAPE depending on λ and filter type. Operating sensors are selected at the end of each day, so there is no operating sensor on the first day.

tery voltage was less than or equal to $2.4V$, since this condition was not nominal. Then, we dropped all the observations after March 15, as too few sensors were still in working order. We thus kept 1.36 million data rows.

The Intel Lab Data are accompanied by connectivity data, which consist of the fractions of successful pings among sensors. We use these data as an automatic proximity measure [3]. We then define W such that $\bar{X}_{st}$ represents a k-nearest-neighbors prediction; for simplicity, we set $k = 1$, since choosing $k > 1$ was seen leading to no significantly different results.

We restrict the domain of the hyperparameter λ and consider the case when it takes values in $\Lambda = \{10^{-i} : i = 1,\dots,6\}$. Multiple configurations of λ are compared based on some performance metric, such as the mean absolute prediction error (MAPE). We predict $Y_{s(t+\Delta)}$ via $\hat{Y}_{s(t+\Delta)} = (1-\hat{\phi}_n)\hat{\mu}_n + \hat{\phi}_n Y_{st}$, where Δ is the lag hyperparameter of the model. We assume $\Delta = 20 \approx 10$ minutes, as this value turns out to provide the best balance between spatial and temporal effects on the predictions.

In Figure 2, the daily MAPE is reported, for all configurations of λ and for both Type 1 and 2 filters. We assume that all the filters run in parallel and are evaluated

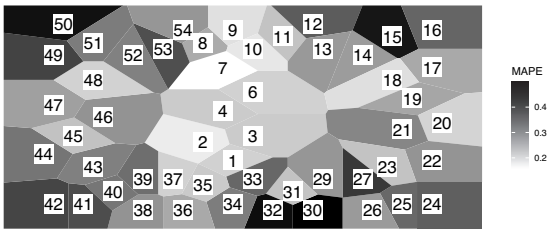

Fig. 3 MAPE, per location, based on the Type 2 filter with $\lambda = 10^{-3}$. Sensor numbers are in line with Figure 1. There were no data for sensors 5 and 28.

at the end of each day, so the best filter insofar is selected as the "operating" one, providing the official predictions of the system for the subsequent day, while the others are hence "shadow" filters acting as a backup. As a by-product of selection, λ is tuned automatically. Both Type 1 and 2 filters seem to harness the intermediate values of λ. The six instances of the Type 2 filter are only slightly less efficient than Type 1, but they are more stable when dealing with more extreme values of λ. The "operating" filter, performs near-optimally on the subsequent day, independently of the filter type. Type 1 operating filters only slightly outperform their Type 2 operating counterparts, whose MAPE is at most 0.03°C higher on March 14 and 0.01°C lower on March 7.

Now, we illustrate the Type 2 filter with $\lambda = 10^{-3}$, which is near-optimal over the whole observation period, as in Figure 2. In Figure 3, the MAPE is reported for each location. The STCAR covariance structure partly explains heteroscedasticity; net of this factor, prediction would look poor only in the table area (bottom center) and the enclosed office rooms (top).

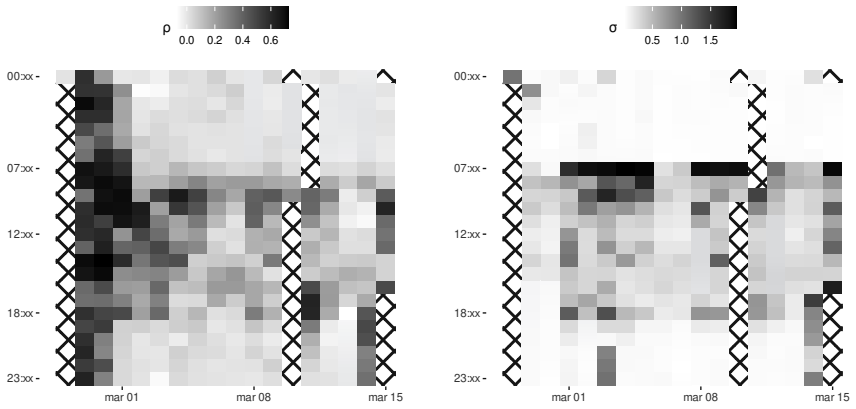

Fig. 4: Hourly averaged parameters, based on the Type 2 filter with $\lambda = 10^{-3}$. Crosshatch pattern in tiles stands for missing or insufficient data.

In Figure 4 the hourly averages of $\hat{\rho}_n$ (left) and $\hat{\sigma}_n$ (right) are reported. Estimates for ϕ are very often close to one, so we do not show them. Also μ is uninteresting, office hours being warmer while nights are colder, in a predictable fashion. In Figure 4, both ρ and σ look substantially time-varying. Nights and weekends are eventless, with little spatial correlation, except for the first few days and Sunday 14 in the evening. As to σ, shocks can be seen early in the morning as the office opens.

4 Final remarks

Adaptive filtering is a natural alternative to time-constant models when the obsolescence of estimates is suspected. In our example, the approach was even more useful as the parameters were seen to vary *within* days. Instead of resorting to complicated models, it may be advisable to keep things simple, as the complexities of both estimation and prediction are affected. Computational easiness also leaves room for self-tuning of systems with limited computing capabilities.

While we call for adaptive filters, their good behavior should not be taken for granted, though. Stability, both numerical and with respect to initial conditions, can be an appealing property to look for in filters. It may be worth considering multiple filter types and instances at least as a backup, or during warm-up, in the light of their complementary advantages.

Bayesian structural learning for Latent Class Model with an application to Record Linkage.

Un approccio Bayesiano al problema di structural learning in Modelli a Classi Latenti con un'applicazione al Record Linkage.

Davide Di Cecco

Abstract We consider an extended family of Latent Class models which relaxes the local independence assumption by modeling additional dependencies via graphical models. We propose a Bayesian model averaging procedure to avoid the difficulties of model selection within this family and learn the dependence structure from the data. We show that, by focusing on decomposable dependence graphs, we can design two Gibbs–based MCMC algorithms to sample over the space of eligible models. The procedure is applied on real data on probabilistic Record Linkage.
Abstract *In questo lavoro consideriamo una famiglia estesa di modelli a Classi Latenti che ammette una struttura di dipendenza più ricca dell'ipotesi classica di indipendenza condizionata. Per stimare le dipendenze aggiuntive proponiamo un model averaging Bayesiano e mostriamo come, focalizzandoci sui modelli caratterizzati da grafi delle dipendenze decomponibili, sia possibile costruire due algoritmi MCMC di tipo Gibbs sampling per lo scopo. Presentiamo un'applicazione della procedura a dati sul Record Linkage probabilistico.*

Key words: Latent Class Models. Bayesian Model Averaging. Record Linkage.

1 Introduction

Latent class models (LCM) constitutes a popular family of models utilized for multiple categorical data in many different areas. The classic conditional independence assumption (CIA) implies the independence of all observed variables conditionally on the latent variable. If we do not question that assumption, model selection within this family is necessarily limited to the identification of the number of latent classes (or components) and, in the recent literature, there has been various contributions

Davide Di Cecco
Università di Roma La Sapienza e-mail: davide.dicecco@uniroma1.it

focusing on Bayesian model selection and model averaging techniques, with several important developments (e.g., [4], [10], [13], [3]).

In the present work we consider a different setting, where the number of latent classes is fixed. If in many applications the latent classes are not given a particular meaning and are used to improve the goodness of fit, there are situations where the different components have a specific interpretations, and their number is fixed in the hypothesis of the model. An example is in the Fellegi–Sunter approach to probabilistic Record Linkage ([5], [6], [7]) where we fix two latent classes: one representing pairs of records that constitute matches, and one for non–matches.

In these cases, relaxing the CIA is of particular importance since we cannot tune the model fitting by changing the number of latent classes. There are various proposals in literature to detect violation of the CIA ([9]), and to overcome its limitation. The latter have also been explored in the context of record linkage: for example, random effects ([1]). We focus on the approach including additional dependencies by modeling them as interaction parameters in a graphical model.

Even if the number of latent classes is fixed, selecting the appropriate model in this extended family is still a difficult task in many cases, especially because estimating all possible models can be computationally demanding. As pointed out by many authors even in the context of Record Linkage (see [12], [1]), ignoring existing violation of the CIA can have disastrous consequences on the estimates. However, at the same time, an ill–defined dependence structure can lead to worse linkage results than the simple CIA model ([14]). Here we propose Bayesian model averaging (BMA) as a natural way to overcome this difficulty. In fact, through a BMA procedure we consider several possible models at once, which appears a suitable strategy to address the structural learning problem.

We show that, by focusing on decomposable models, it is possible to design a simple Gibbs–based MCMC algorithm visiting all eligible alternatives. The restriction to decomposable models, in fact, guarantees a tremendous computational advantage as we can exploit analytical results for the posterior probability of each model, and develop a simple Gibbs sampler to generate values over all selected models. At the same time, this restriction does not appear to limit the usability of the procedure.

The applications on probabilistic Record Linkage typically involves considerable quantity of (possible pairs of) records. As a consequence, in some applications the algorithm occasionally remains stuck over a single model. To avoid this, we present a second algorithm based on a Collapsed Gibbs sampler to enhance the mixing properties of the MCMC.

2 The model

The Fellegi-Sunter model consists of a LCM with k manifest binary variables $\mathbf{Y} = (Y_1, \ldots, Y_k)$ representing the agreement/disagreement on each field, and a binary latent variable X representing the true link status. The model assumes the CIA:

$$P(\mathbf{Y}=\mathbf{y}) = p_{\mathbf{y}} = \sum_{x=0}^{1} p_x \prod_{i=1}^{k} p_{y_i|x}, \tag{1}$$

where $p_{y_i|x}$ indicates the conditional probability $P(Y_i = y_i|X = x)$. The dependence graph of this model is a star–shaped graph, where the node representing X is connected to all other nodes, like the one in Figure 1 on the left. Any additional interaction term, (i.e., any additional arc in the graph), constitutes a relaxation of the CIA.

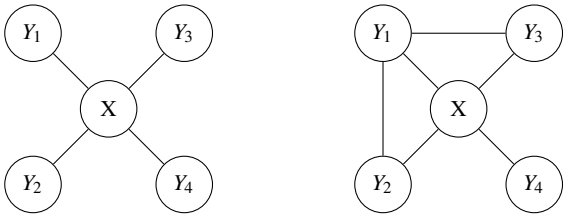

Fig. 1 Two examples of dependence graphs with 4 manifest variables and a latent variable.

Denote the number of observed units presenting profile $\mathbf{y} = (y_1, ..., y_k) \in \{0,1\}^k$ of the manifest variables as $n_{\mathbf{y}}$, and let $\{n_{\mathbf{y}}\}$ represent the whole set of profile counts observed in our data. Let $n_{x,\mathbf{y}}$ be the latent number of units having that profile which belong to latent class x, so that $\sum_x n_{x,\mathbf{y}} = n_{\mathbf{y}}$. Let $N_{x,\mathbf{y}}$ be the random variable associated to $n_{x,\mathbf{y}}$, M be the random variable associated to the model, and Θ_M the set of parameters associated to model M.

2.1 Decomposable models

A model is said decomposable if its dependency graph G is chordal, i.e., if any cycle of G of four or more nodes has an edge connecting two non–adjacent nodes. Let $\{\mathscr{C}_1, \ldots, \mathscr{C}_g\}$ be the maximal cliques of G. Then, it has been proved (see e.g., [2]) that in a decomposable model we have an ordering $\{\mathscr{C}_{\sigma(1)}, \ldots, \mathscr{C}_{\sigma(g)}\}$ of the set, such that, having defined the set of separators $(\mathscr{S}_2, \ldots, \mathscr{S}_g)$ as

$$\mathscr{S}_i = \mathscr{C}_{\sigma(i)} \cap \bigcup_{j=1}^{i-1} \mathscr{C}_{\sigma(j)} \qquad i = 2, \ldots, g,$$

the joint distribution can be written as a product of conditional distributions in the following way:

$$p_G = \prod_{i=1}^{g} p_{\mathscr{C}_i} \left(\prod_{j=2}^{g} p_{\mathscr{S}_j} \right)^{-1} = p_{\mathscr{C}_1} \prod_{i=2}^{g} p_{\mathscr{C}_i|\mathscr{S}_i}, \tag{2}$$

where p over a (sub)graph is to be intended as the (marginal) probability distribution over the variables included in the (sub)graph. [8] utilized a class of priors over the parameters of each decomposable model based on Hyper Dirichlet distribution (see [2]). Such a choice allowed them to give an analytical formula for the posterior probability of each possible decomposable model given the data.

In our models X is latent, so decomposability refers to the augmented dependence graph. However, we can utilize the same analytical formula for the quantity

$$P(\{n_{x,\mathbf{y}}\} \mid M) = \int P(\{n_{x,\mathbf{y}}\} \mid \Theta_M, M)\pi(\Theta_M)\, d(\Theta_M), \tag{3}$$

which can be considered as the marginal augmented likelihood of the model. The integral results in a product of Gamma functions (see [8]).

2.2 Limiting the space of eligible models

Let $\mathscr{M}$ denote the set of eligible models for our BMA. We focus on decomposable models to exploit an analytical formula for the posterior probability of each model in $\mathscr{M}$ at each step of a MCMC algorithm. Obviously, the choice of a prior over the set of models $\mathscr{M}$, as on any other r.v., is subjectively arbitrary. However, we usually just want to exclude some cases, and give a uniform prior on all remaining cases. As a first criterion to exclude some models, we rule out all unidentifiable models. For the case of a binary latent variable, [11] gives a necessary and sufficient condition for the identifiability of any graphical model.

In practice, to utilize the proposed methodology, we have to list out all possible models for a given number of variables. That is, all LCM represented by decomposable graphs containing the star–shaped graph relative to the CIA. Consider the case $k = 4$: in Figure 2.2 we show all possible decomposable identifiable graphs grouped by isomorphism. When $k = 5$ the number of identifiable decomposable models goes up to 445, and when $k = 6$ it goes up to 12830.

Of course, we can restrict $\mathscr{M}$ a priori excluding models that we deem too complex. For example, we can rule out those with too many parameters, or those including interactions of higher order. Higher order interactions in fact, are more difficult to interpret, and, in our experience, lead to instability/slower convergence of the algorithm. As an example, if we exclude all models with 4-cliques, we are left with 285 cases when $k = 5$ and 2925 when $k = 6$.

3 The Gibbs sampler

The t–th iteration of our Gibbs sampler consists of the following steps:

1) sample $n^{(t)}_{x,\mathbf{y}}$ from $\pi(N_{x,\mathbf{y}} \mid M, \Theta_M, N_{\mathbf{y}})$, for all $\mathbf{y}$,

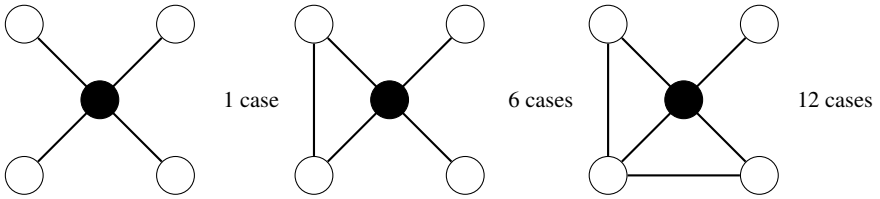

Fig. 2 Identifiable decomposable graph models with 4 manifests (empty nodes) and a latent (black node) grouped by classes of isomorphism

$$N_{x,\mathbf{y}}^{(t)} \sim Mult\left(n_{\mathbf{y}}, \{p_{x|\mathbf{y}}^{(t)}\}_{x=1,\ldots,m}\right) \quad \text{where} \quad p_{x|\mathbf{y}} = \frac{p_{x,\mathbf{y}}}{\sum_x p_{x,\mathbf{y}}},$$

and where the $p_{x,\mathbf{y}}$ are calculated according to the current value of M and Θ_M;

2) sample from $\pi(M, \Theta_M \mid N_{x,\mathbf{y}}) = \pi(\Theta_M \mid M, N_{x,\mathbf{y}})\, \pi(M \mid N_{x,\mathbf{y}})$. That is,

- calculate the posterior probability of each eligible decomposable model in $\mathscr{M}$ conditional on the current value of X, by calculating the quantity

$$\int P(\{n_{x,\mathbf{y}}\} \mid \Theta_M, M)\pi(\Theta_M \mid M)\, d(\Theta_M),$$

  for each model and then normalizing over $\mathscr{M}$. Then sample $M^{(t)}$ from $\pi(M \mid n_{x,\mathbf{y}})$.

- sample all parameters $\Theta_M^{(t)}$ from their posterior conditional distribution $\pi(\Theta_M | N_{x,\mathbf{y}}, M)$, which is a product of Dirichlet distributions.

The algorithm can be used for model selection by simply inspecting the generated values of M, as the relative frequency of each model constitutes an estimate of its posterior probability. Or, it can be used for BMA, by evaluating the posterior distribution of some quantity of interest averaged across the various models. For example, the number of links for each linkage profile $\mathbf{y} \in \{0,1\}^k$.

We also propose a Collapsed Gibbs Sampler (CGS) (see also [13]) which at each iteration sample a model M and a latent configuration $\{n_{x,y}\}$ integrating out the models parameter, to enhance the mixing properties of the MCMC, so to avoid the algorithm being stuck in certain subregions of the posterior distribution.

As we have seen, we can calculate analytically the quantity (3) for any model M and any configuration $\{n_{x,y}\}$ consistent with the observed $\{n_y\}$. Then, we can propose a candidate new configuration $\{n_{x,y}\}^*$, and accept or reject it in a Metropolis-Hastings step.

4 Application

We applied our procedure to a dataset reported in [14] of linked records from patient registries of two hospitals. According to the chosen blocking scheme, the dataset has 590000 record pairs. The number of correct links for each observed linkage profile have been obtained by manual review and are reported in the cited paper. The proposed algorithms took about a minute to run 2 millions of iterations. We do not show here the detailed results for space limitation. However, we considered the posterior averaged distribution of the number of links by profile, and, in all cases, the correct number were included in the 95% credibility intervals. Our results confirmed those obtained in [14] in assessing the inadequacy of the CIA model, and detecting a relevant interaction between (agreement on) telephone number and zip code as linkage variable, as all models with the highest posterior probability included that additional interaction.

Multilevel Latent Class modelling to advise students in self-learning platforms: an application in the context of learning Statistics

Modello multilivello a classi latenti per fornire raccomandazioni agli studenti sulle piattaforme di auto-apprendimento: un'applicazione nell'ambito dell'apprendimento della Statistica

Fabbricatore R., Bakk Z., Di Mari R., de Rooij M., Palumbo F.

Abstract The growing interest in using technology in education has brought new challenges for data analysis, especially when the main aim is providing students with an appropriate feedback on their latent ability level. Any *recommender system* should be able to properly account for the multidimensional nature of such latent trait, while correctly modelling the relationships between variables and individuals at possibly different levels. In this perspective, we focus on a non-standard application of multilevel latent class analysis in the context of learning Statistics. The goal is to detect homogeneous groups of students according to their level of ability, concurrently accounting for the hierarchical structure of the data.

Abstract *Il crescente interesse per l'uso della tecnologia nell'istruzione ha generato nuove sfide per l'analisi dei dati, soprattutto quando il principale obiettivo è fornire agli studenti un feedback appropriato sul proprio livello di abilità latente. Ogni sistema di raccomandazioni dovrebbe essere in grado di considerare la natura multidimensionale di questo tratto latente, identificando al contempo le relazioni tra variabili e individui a possibili differenti livelli. In tal senso, il presente contributo si propone di illustrare l'applicazione di un modello multilivello a classi latenti nell'ambito dell'apprendimento della statistica. L'obiettivo consiste nel rilevare gruppi omogenei di studenti in base al livello di abilità tenendo conto contemporaneamente della struttura gerarchica dei dati.*

1 Introduction

In recent years, there has been a growing interest in using technology to ensure large-scale learning achievements [6]. Self-learning platforms, for example, constitute a very flexible learning environment, which enhances support to students by means of a constant feedback on their ability level [2]. Two main issues emerged concerning (1) how to evaluate learners' proficiency, and (2) the role of psychometric theories and statistical models in analyzing responses - and profiling students accordingly.

Regarding the first issue, a challenging task consists of assessing students' competencies in a multidimensional way, accounting for their intrinsic complexity. In this vein, the Dublin descriptors [4] represent meaningful dimensions used to assess the ability levels a student has achieved with respect to one or more specific topics. More specifically, they define five learning objectives: knowledge and understanding, knowledge application, judgement (critical) ability, and communications and learning skills. Given our focus on learning achievement via technological platforms, only the first three descriptors will be taken into account - i.e., Knowledge (K), Application (A), and Judgement (J).

From a practical point of view, learners' proficiency evaluation is typically based on responses to a set of questions, such as multiple-choice tests, with a different level of difficulty. These questions represent manifest indicators referring to several unobservable abilities (multidimensional latent construct). Notably, moving to the second issue, latent variable models [7] have a key role in the assessment of students' ability, and the detection of homogeneous groups based on their ability level. As such, they are an ideal tool for developing tailored recommendations/remedies from self-learning platforms.

The present work is motivated by an empirical application in the context of learning Statistics. The data include answers to questions (items) covering different Statistic–related topics from students of an introductory course in Statistics. Item-responses are gathered by means of the Moodle survey platform during the course, and will be analysed exploiting the features of multilevel latent class analysis [8].

The remainder of the contribution is structured as follows: Section 2 provides details about the data and the survey procedure, Section 3 describes the central details of the multilevel LC model, Section 4 presents the main results, and Section 5 reports some conclusions, along with possible future developments.

2 Data and procedure

The study involved $N = 202$ Italian students, enrolled in the first year of the psychology course at the University of Naples Federico II, attending the introductory Statistics course. Concerning general descriptive characteristics, attendees were predominantly female (83.6%), and their ages ranged between 18 and 43 (mean = 19.7, sd = 2.77).

Data collection consisted of three waves, each focusing on different statistical topics: descriptive statistics, graphs, tables, and Gaussian distribution (Time 1), probability and random variables (Time 2), hypothesis testing and bivariate statistics (Time 3). For each wave, students were asked to respond to 30 multiple-choice questions, equally divided into K, A, and J, which had four answer options and three different response scores: totally correct answers received two credits, and were scored as 2; partially correct answers received one credit, and were scored as 1; wrong answers received no credit, and were scored as 0. Blank responses were considered missing values.

During data collection, some students dropped out. More specifically, $n = 166$ students remained at Time 2, and $n = 126$ at Time 3.

3 Statistical analysis: Multilevel Latent Class model

The multilevel latent class model is part of the most general multilevel latent variable modeling framework, which allows managing hierarchical data structures with either discrete or continuous latent variables at each level [8]. Herein, we defined a two-level data structure: time–points (low–level/Level 1) clustered within individuals (high–level/Level 2). In particular, at Level 1, three discrete latent variables (K, A, J), conditional on Level 2 class membership, are measured by ordinal indicators with categories $j = 0, 1, 2$; at higher level, another discrete latent variable clusters students based on their likelihood to be in one of the lower–level groups for each Dublin descriptor. Following previous analyses on the same data set, the number of latent classes was set to 3 for both Level 1 and Level 2 discrete latent variables. Moreover, to model potential students' ability change over time (namely for different statistical topics), we added time dummies at level 1.

Formally, let Y_{sdk} denotes the response of student s on item k measuring the dimension d (with $k = 1, \ldots, K$ and $d = 1, \ldots, D$). Whereby X_{sd} indicates the d-th latent class variable at Level 1, i is an index of latent class membership, with I being the total number of latent classes. Similarly, let W_s be the discrete latent variable at Level 2, taking value $m = \{1, \ldots, M\}$.

In the specification we focus on, the manifest distribution of the entire response vector $\mathbf{Y}_{sd} = (Y_{sd1}, Y_{sd2}, \ldots, Y_{sdK})$ with realisation $\mathbf{y}_{sd}$ can be expressed, for each dimension, as:

$$P(\mathbf{Y}_{sd} = \mathbf{y}_{sd}) = \sum_{i=1}^{I} P(X_{sd} = i) P(\mathbf{Y}_{sd} = \mathbf{y}_{sd} | X_{sd} = i), \tag{1}$$

where $\sum_{i=1}^{I} P(X_{sd} = i) = 1$, and $P(\mathbf{Y}_{sd} = \mathbf{y}_{sd} | X_{sd} = i) = \prod_{k=1}^{K} P(Y_{sdk} = j | X_{sd} = i)$ due to the *local independence* assumption. We parametrise the response probabilities by means of the following continuation–logit logistic regressions:

$$P(Y_{sdk} = j|X_{sd} = i) = \frac{\exp\sum_{l=1}^{j}(\beta_{li}^{k})}{\sum_{r=0}^{q}\exp\sum_{l=1}^{r}(\beta_{li}^{k})}, \text{ with } j = 1,2. \tag{2}$$

It is worth noting that response probabilities are assumed to be independent of Level 2 latent variable, and covariates.

On the other hand, lower–level class membership probabilities depend on both high-level class membership (i.e., W_s latent variable), and time. Thus, let $\mathbf{Z}_s$ be the vector of covariates, including the time dummies. Multinomial logistic regressions can be used to parametrise conditional class membership X_{sd} as follows:

$$P(X_{sd} = i|W_s = m, \mathbf{Z}_s) = \frac{\exp(\gamma_{0im} + \boldsymbol{\gamma}_{im}\mathbf{Z}_s)}{\sum_{r=1}^{I}\exp(\gamma_{0rm} + \boldsymbol{\gamma}_{im}\mathbf{Z}_s)}, \tag{3}$$

where $\boldsymbol{\gamma}_{im}$ is the vector of regression coefficients, with $i = 2,\ldots,I$ and $m = 1,\ldots,M$. The full model specification can be visually represented as in Figure 1.

The estimation process was performed through Latent GOLD 6.0 [9] that exploits an Expectation-Maximization (EM) algorithm to obtain maximum likelihood (ML) parameter estimates [8].

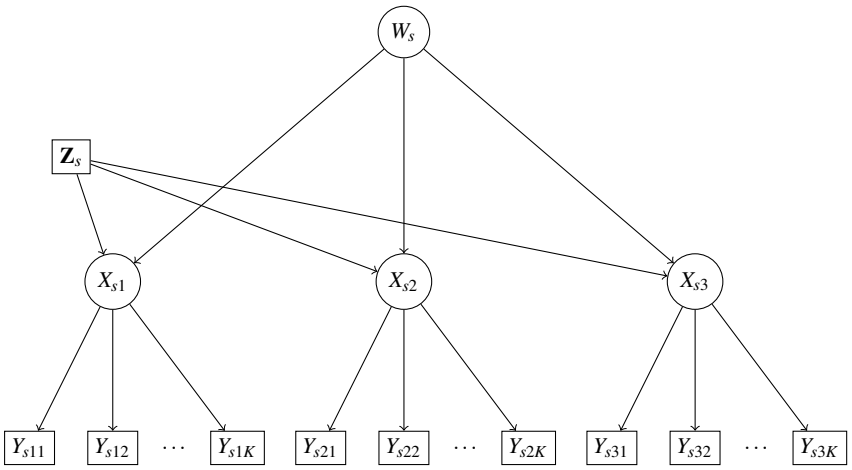

Fig. 1 Multilevel Latent Class model specification for the current application. Note that X_{s1}, X_{s2}, and X_{s3} correspond to the Level 1 latent variables Knowledge, Application, and Judgement, respectively. Each of them was measured by $K = 30$ indicators ($Y_{sd1},\ldots,Y_{sdK}$), 10 for each time point. The Time variable was considered as nominal and was added as a covariate ($\mathbf{Z}_s$) affecting Level 1 class membership probabilities. Finally, Level 2 latent variable $\mathbf{W}_s$ defined groups of students based on their likelihood to be in one of the Level 1 latent classes for each Dublin descriptor (K, A, J).

4 Results

Overall model's summary statistics show no general estimation problems. The entropy-based R^2 reveals a high separation between latent classes for all the discrete latent variables: $R^2_{ENTR} = 0.86$ for Level 2 group variable, $R^2_{ENTR} = 0.77$ for Knowledge, $R^2_{ENTR} = 0.75$ for Application, and $R^2_{ENTR} = 0.74$ for Judgement latent variables at Level 1.

Item conditional response probabilities can be used to characterise the classes of the discrete latent variables at Level 1. Low-, medium-, and high-level ability classes were found for each Dublin descriptor. Regarding Application, the largest class (Class 2) was constituted by high performers, and comprised 37% of the students, followed by Class 3 with a medium level of ability - with 34% of the sample. Conversely, for Judgement, the largest class (Class 1) was that with low performers (49%), followed by the high-performer class - i.e. Class 2, embracing the 36% of the students. Instead, the Knowledge dimension presented more balanced groups, with percentages equal to 34% (Class 1), 35% (Class 3), and 31% (Class 2) for low-, medium-, and high-performance classes, respectively.

Concerning the effect of the Level 2 latent variable, Table 1 shows parameter estimates for the low-level class proportion, conditional on higher-level class membership. We observe (Table 1) that the discrete latent variable at Level 2 detected two well-defined groups of high- (Group 1) and low- (Group 2) performer students in all the Dublin descriptor domains, as well as a third group (Group 3) with moderate ability level in Knowledge and Application but a greater uncertainty related to the Judgement dimension. Specifically, for the latter class, we report almost equal proportions for medium and low levels of ability.

Table 1 Low-level class proportion conditioned to the higher-level class membership. The weight of latent classes at Level 1 and Level 2 was also added.

	Knowledge			**Application**			**Judgement**			
Level 2 class	*1*	*2*	*3*	*1*	*2*	*3*	*1*	*2*	*3*	*Weight*
1	0.01	0.71	0.28	0.05	0.84	0.11	0.16	0.82	0.02	*0.43*
2	0.95	0.01	0.04	0.82	0.01	0.17	0.97	0.01	0.02	*0.30*
3	0.21	0.01	0.78	0.09	0.01	0.90	0.47	0.02	0.51	*0.27*
Weight	*0.34*	*0.31*	*0.35*	*0.29*	*0.37*	*0.34*	*0.49*	*0.36*	*0.15*	

Finally, the analysis revealed a significant effect of time on Knowledge ($p = 0.01$), and Judgement ($p < 0.01$), but a non-significant one on Application ($p = 0.24$). More specifically, students' performance in Knowledge was higher in Time 2 and Time 3 with respect to Time 1; wheres students' critical ability in Statistics increased in Time 2 and decreased in Time 3. All in all, the results highlighted a great difficulty of students in gathering and evaluating information to exert appropriate judgement in hypothesis testing and bivariate statistics. In addition, we report significant inaccuracies and vagueness in the acquisition of theoretical concepts related to descriptive statistics, graphs, tables, and normal distribution.

5 Conclusion

In order to analyse data from self-learning platforms, the present contribution proposes a novel classification strategy exploiting non-parametric multilevel latent variable models. On a practical level, the students' clustering can be straightforwardly used to develop tailored recommendations, and remediations for each group. Moreover, model parameters can also be employed for prediction of class membership of new individuals according to their response vector.

Although we have shown the merit of multilevel latent class analysis in our motivating empirical problem, their potential usefulness is much broader. Further extensions might be conceived, with the goal of bringing the latent underlying structure of data into light. For instance, adding a level in the model to define K, A, and J as continuous latent variables allows to define item response probabilities according to the Item Response Theory framework [5]. Subsequently, a comprehensive evaluation of the effect of item characteristics on students' response probabilities could be performed.

Moreover, it could also be interesting to investigate the effect of demographic and psychological variables (e.g., statistical anxiety or attitude towards statistics) on class membership probabilities. In this respect, several studies (see for example [1, 3]) reported that psychological factors assume a relevant role in students' achievement in Statistics, especially for those enrolled in non-STEM degree courses (where STEM is the abbreviation for Science, Technology, Engineering, and Mathematics). Future works might also address these issues.

Latent Markov models with associated mixed responses

Modelli Markoviani latenti con risposte associate e di natura mista.

Alfonso Russo and Alessio Farcomeni

Abstract We derive a multivariate latent Markov model to analyse associate responses of mixed nature, including individual covariates in the manifest distribution by suitable link functions. The residual dependency structure in simultaneous outcomes is captured by a Gaussian copula. Outcomes can be any mix of continuous, discrete, ordinal variables. The framework introduced allows for the possibility of modeling multivariate panel data, with separate and distinct margins, without requiring independence assumptions. Inference is conducted by means of an EM algorithm.

Abstract *In questo articolo, si propone un modello Markoviano latente per l'analisi di variabili risposta correlate e di natura mista. E' possibile includere covariate individuali per mezzo di appropriate funzioni link. La struttura di dipendenza nelle osservazioni è gestita con una copula Gaussiana. La procedura inferenziale è condotta tramite un algoritmo EM.*

Key words: Copula; Mixed responses; Panel data

1 Introduction

Latent Markov (LM) models for panel data provide a flexible framework to analyse univariate and multivariate responses. They can be seen as mixed models where random effects are discrete and their evolution over time is Markovian ([9],[3]). They are based on a latent discrete random variable U_{it} that captures the dynamic

unobserved heterogeneity and is assumed to follow a first-order Markov chain with $k \in \mathcal{N}$ latent masses. Response variables are modelled with assumptions of *local independence*, i.e. each outcome is independent of its history and other outcomes conditionally on covariates and the latent process. Several extensions have already been proposed in the literature, see [4] for a general review and for details on the inclusion of individual covariates. Some contributions have dealt with the issue of residual dependency structures for the observations, particularly [1] formulate a class of LM models where categorical response variables are affected by contemporary dependence. The case of mixed outcomes is cumbersome, and to the best of our knowledge the only viable approach at this time involves independence assumptions (e.g., [2]).

In this paper, we develop an extension to the classical LM formulation that aims at relaxing the assumption of local independence in the presence of outcomes that can be a mix of continuous, categorical, binary, and ordinal variables. Specifically, the dependency structure is captured by copula functions.

2 Background

We start by formalizing copulas, following [8] as a general reference. A d-dimensional copula, $\mathscr{C} : [0,1]^d \to [0,1]$, is a cumulative distribution function with uniform marginals $u_1, \ldots, u_d$. We write $\mathscr{C}(\boldsymbol{u}) = \mathscr{C}(u_1, \ldots, u_d)$. Consider a random vector $\boldsymbol{X} = (X_1, \ldots, X_d)$ with continuous and increasing marginals $F_{X_1}, \ldots, F_{X_d}$. We can specify the joint distribution of $F_{X_1}(X_1 \mid \boldsymbol{\theta_1}), \ldots, F_{X_d}(X_d \mid \boldsymbol{\theta_d})$ as a copula $\mathscr{C}_{\boldsymbol{X}}$ of the form:

$$\begin{aligned} \mathscr{C}_{\boldsymbol{X}}(u_1, \ldots, u_d) &= \mathbb{P}\left[F_{X_1}(X_1 \mid \boldsymbol{\theta_1}) \leq u_1, \ldots, F_{X_d}(X_d \mid \boldsymbol{\theta_d}) \leq u_d\right] \\ &= F_{\boldsymbol{X}}\left[F_{X_1}^{-1}(u_1 \mid \boldsymbol{\theta_1}), \ldots, F_{X_d}^{-1}(u_d \mid \boldsymbol{\theta_d})\right] \end{aligned} \tag{1}$$

from which, according to Sklar's Theorem, follows immediately that

$$F(x_1, \ldots, x_d) = \mathscr{C}_{\boldsymbol{x}}[F_1(x_1 \mid \boldsymbol{\theta_1}), \ldots, F_d(x_d \mid \boldsymbol{\theta_d})] \tag{2}$$

for all $x_i \in [-\infty, +\infty]$, $i = 1, \ldots, d$. Its density takes the usual form:

$$c_{\boldsymbol{X}}(u_1, \ldots, u_d) = \frac{\partial^d \mathscr{C}_{\boldsymbol{X}}(u_1, \ldots, u_d)}{\partial u_1, \ldots, u_d} \cdot f_{X_1}(x_1 \mid \boldsymbol{\theta_1}), \cdot \ldots \cdot f_{X_d}(x_d \mid \boldsymbol{\theta_d}) \tag{3}$$

where $u_i = F_{X_i}(x_i \mid \boldsymbol{\theta_i}). \forall\, i = 1, \ldots, d$
Among several parametric alternatives (t, Gumbel, Clayton), we choose Gaussian copulas to model the response variables, as usually there are very few of them. Following [6], in this work we make use of *mid*-distribution functions, a modification of the standard CDF that plays an important role when discrete quantiles are at stake. Unlike quantiles, mid-quantiles have good theoretical properties even in the

presence of ties ([7]). For a generic random variable Y with CDF $F_Y(y)$, the function

$$G_Y(y) \equiv \mathbb{P}(Y \leq y) - \frac{1}{2}\mathbb{P}(Y = y)$$

is the mid-CDF of Y. If Y is discrete, $G_Y(y)$ is a step function, a downward-shifted version of $F_Y(y)$. If Y is instead continuous, $G_Y(y)$ reduces simply to $F_Y(y)$ since $\mathbb{P}(Y = y) = 0$.

3 The model

Let Y_{itr} denote the r-th endpoint of interest, measured for the i-th subject at time t; with $r = 1,\ldots,d$, $t = 1,\ldots,T_i$, and $i = 1,\ldots,n$. We also assume there exists a discrete unidimensional latent variable U_{it} with support in $\{1,\ldots,k\}$, where k is known. The latent variable is assumed to evolve over time according to a homogeneous first-order Markov chain, with initial probabilities $\Pr(U_{i1} = u) = \pi_u$, collected in a vector $\boldsymbol{\pi}$ and transition probabilities $\Pr(U_{it} = v|U_{i,t-1} = u) = \pi_{uv}$, collected in a transition matrix $\boldsymbol{\Pi}$. For the marginal distributions, conditionally on U_{it}, we assume a natural exponential family

$$p(Y_{itr}|U_{it} = u, \boldsymbol{\eta}, \psi_r) = \exp\{(Y_{itr}\eta_{utr} - c(\eta_{utr}))/(a(\psi_r) - b(Y_{itr}, \psi_r))\}, \quad (4)$$

where $p(\cdot)$ can either be a PDF or PMF. Functions $a(\cdot)$, $b(\cdot)$, and $c(\cdot)$ are known. The parameter of interest is η_{utr}, while ψ_r is a nuisance parameter. Homogeneity assumptions on ψ_r can easily be relaxed. The regression model will usually be specified after reparameterization through a known link function $g(\cdot)$ as

$$h(\eta_{utr}) = \alpha_{ru} + \boldsymbol{\beta}_r' X_{itr}, \quad (5)$$

where X_{itr} is a vector of time-subject-outcome specific covariates. In (5) only the intercept depends on U_{it}, as customary with latent Markov models. Also this assumption can be easily relaxed. Usually, a conditional independence assumption is put forward so that Y_{itr} is independent of Y_{itq} for all $q \neq r$, conditionally on U_{it}. We relax this assumption through a Gaussian copula model, which requires an unstructured correlation matrix $\boldsymbol{\Sigma}$ as additional parameter. Let $\Phi^{-1}(\cdot)$ denote the quantile function of a univariate standard Gaussian distribution. We assume that $\boldsymbol{Y}_{it}$ has density, conditionally on $U_{it} = u$,

$$\boldsymbol{c}(\boldsymbol{Y}_{it} \mid U_{it} = u) = \frac{\phi_{\boldsymbol{\Sigma}}(\Phi^{-1}(m_{it1u}), \Phi^{-1}(m_{it2u}), \ldots, \Phi^{-1}(m_{itdu}))}{\prod_{r=1}^{d} \phi(\Phi^{-1}(m_{itru}))} \prod_{r=1}^{d} g_r(Y_{itr} \mid U_{it} = u, \boldsymbol{\eta}, \psi_r),$$

with $\phi(\cdot)$ being the density function of a univariate standard normal, and $\phi_{\boldsymbol{\Sigma}}$ the density of a multivariate zero-centered Gaussian with correlation matrix $\boldsymbol{\Sigma}$; $m_{itru} = G_Y(Y_{itr} \mid U_{it} = u, \boldsymbol{\eta}, \psi_r)$ and $g_r(\cdot)$ being the corresponding marginal density/mass

functions governed, together with $G_Y(\cdot)$, by state-specific parameters. Part of the conditional independence assumption still holds as we assume $\boldsymbol{Y}_{it}$ to be independent of $\boldsymbol{Y}_{is}$, for $s < t$, conditionally on U_{it}. Clearly, also Y_{itr} is assumed to be independent of Y_{jsh} for $i \neq j$ as usual.

4 Inference

4.1 Observed likelihood

The observed likelihood can not be conveniently computed directly, as it would involve a telescopic sum over all possible $k^{\max T_i}$ configurations of the latent variables. We adapt, as customary in the latent Markov literature, a simple forward recursion. The computational complexity is linear in $\sum_i T_i$, and the recursion allows to exactly evaluate the observed likelihood. Define $a_{it}(u) = f(\boldsymbol{Y}_{i1}, \ldots, \boldsymbol{Y}_{it}, U_{it} = u)$. Let, by definition,

$$a_{i1}(u) = \pi_u \mathscr{C}(\boldsymbol{Y}_{it} \mid U_{it} = u).$$

It is possible to show with some algebra that if $T_i > 1$, for $t = 2, \ldots, T_i$,

$$a_{it}(u) = \mathscr{C}(\boldsymbol{Y}_{it} \mid U_{it} = u) \sum_{h=1}^{k} a_{i,t-1}(h)\pi_{hu}.$$

The recursion shall be repeated for $i = 1, \ldots, n$. By definition of $a_{it}(u)$, the observed log-likelihood at the parameter $\boldsymbol{\theta}$ is

$$l(\theta) = \sum_{i=1}^{n} \log\{L_i(\theta)\} = \sum_{i=1}^{n} \log\left(\sum_{u=1}^{k} a_{iT_i}(u)\right).$$

A backward recursion is also implemented to obtain the posterior distributions of each latent states and pairs of consecutive ones. Define $s_{it}(u) = f(\boldsymbol{Y}_{i,t+1}, \ldots, \boldsymbol{Y}_{i,T_i} | U_{it} = u)$. This recursion is initialised with

$$s_{iT_i}(u) = 1 \qquad \forall i$$

and then is based on the following steps

$$s_{it}(u) = \sum_{v=1}^{k} \pi_{uv}\, s_{i,t+1}(v)\, \mathscr{C}(\boldsymbol{Y}_{it} \mid U_{it} = u)$$

to be performed for $t = T_i - 1, \ldots, 1$. For the maximisation of $l(\boldsymbol{\theta})$ an EM algorithm is implemented. We need therefore to introduce the log-likelihood of the complete data, which takes form

$$l^*(\boldsymbol{\theta}) = \sum_{i=1}^{n}\sum_{u=1}^{k} w_{i1u}\log(\pi_u) + \sum_{i=1}^{n}\sum_{t=2}^{T_i}\sum_{u=1}^{k}\sum_{v=1}^{k} z_{ituv}\log(\pi_{uv}) + \sum_{i=1}^{n}\sum_{t=1}^{T_i}\sum_{u=1}^{k} w_{itu}\log\left[\mathscr{C}(\boldsymbol{Y}_{it} \mid U_{it}=u)\right]$$

where w_{itu} is equal to 1 if subject i is in state u at time t and 0 otherwise; while z_{ituv} takes value 1 if subject i at time t moves to state v from u and 0 otherwise.
The EM algorithm iterates the following two steps until convergence.

(a) The *E-step* amounts to computing the conditional expectation of $l^*(\boldsymbol{\theta})$ given the observations and the current value of the parameters. This is actually equivalent to compute the conditional expected value of the variables w_{itu} and z_{ituv} as follows:

$$\mathbb{E}\left[w_{itu}\right] = \frac{a_{it}(u)s_{it}(u)}{\sum_{u=1}^{k} a_{iT_i}(u)}$$

$$\mathbb{E}\left[z_{ituv}\right] = \pi_{uv}\frac{a_{it}(u)s_{i,t+1}(v)}{\sum_{u=1}^{k} a_{it}(u)s_{it}(u)} \times \mathscr{C}(\boldsymbol{Y}_{i,t+1} \mid U_{it}=v)$$

(b) In the *M-step*, the parameters are updated by maximisation of the expected value of $l^*(\boldsymbol{\theta})$ calculated in the previous step. This is performed as follows:

$$\hat{\pi}_u = \frac{\sum_{i=1}^{n}\mathbb{E}\left[w_{i1u}\right]}{\sum_{i=1}^{n}\sum_{h=1}^{k}\mathbb{E}\left[w_{i1h}\right]}$$

$$\hat{\pi}_{uv} = \frac{\sum_{i=1}^{n}\sum_{t=1}^{T_i-1}\mathbb{E}\left[z_{ituv}\right]}{\sum_{i=1}^{n}\sum_{t=1}^{T_i-1}\sum_{v=1}^{k}\mathbb{E}\left[z_{ituv}\right]}$$

The parameters modulating the Gaussian copula are updated separately. First, the matrix $\boldsymbol{\Sigma}$ could in principle be updated by weighted versions of traditional measures like Spearman's rho or Kandall's tau. However, [**?**] prove that, when marginals are not continuous, this strategy might lead to bias. Once the model is fully specified, margin-specific correction factors can be derived to correct these estimators. One step of a Newton-Raphson algorithm is finally implemented to update the remaining free parameters.

5 Conclusions

We have proposed a model for dealing with multivariate outcomes of mixed nature in panel data, when the local independence assumption shall be relaxed. In further work we will apply the described methodology to an original data set about living conditions, poverty, and employment, for selected European countries.

Methods for health studies

Beyond the fragility index

Oltre l'indice di fragilità

Piero Quatto and Enrico Ripamonti

Abstract Results of randomized clinical trials (RCTs) can be evaluated through the Fragility Index (FI). Information provided via FI may supplement *p*-values. However, the FI presents with intrinsic weaknesses and shortcomings, which limit its application in biomedicine. Based on the general principles of the analysis of fragility, we propose a new index of strength (SI) of an RCT. This can be obtained in case of either a significant or a non-significant result. SI is straightforward to be calculated, presents with compelling advantages as compared to FI, and solves some of its inherent problems and weaknesses. SI can be obtained as a normalized index, and a threshold for its application can be provided.

Abstract *I risultati degli studi clinici randomizzati (RCT) possono essere valutati attraverso l'indice di fragilità (FI). Le informazioni fornite da FI possono integrare quelle fornite dal p-value. Tuttavia, FI presenta debolezze e carenze intrinseche, che ne limitano l'applicazione nel contesto biomedico. Sulla base dei principi generali dell'analisi della fragilità, proponiamo un nuovo indice di forza (SI) di un RCT. Questo può essere ottenuto in caso di risultato significativo o non significativo. SI è semplice da calcolare, presenta vantaggi convincenti rispetto a FI e risolve alcuni dei suoi problemi e punti deboli intrinseci. SI può essere ottenuto come indice normalizzato e viene suggerita una soglia per la sua applicazione pratica.*

1. Introduction

The analysis of the fragility of a randomized clinical trial (RCT) is a very controversial issue in the literature. To operationalize the concept of "fragility", Feinstein introduced in the literature the concept of Fragility Index (FI) [1]. The FI has been revised by Walsh et al. in case of a significant result [2]. Since then, its use in the applied medical literature has increased. A relative version of FI has also been proposed, known as Fragility Quotient (FQ) [3]. FI or FQ can also be adopted in case of a non-significant result [4]. Today, there are many applications of FI in several fields of biomedical research [5,6]. The FI has objective weaknesses, and it has been strongly criticized [7]. However, the index is in agreement with one of the recent statements of the American Statistical Association, namely "scientific conclusions and business or policy decisions should be not based only on whether a *p*-value passes a specific threshold" [8]. Thus, it is worth re-considering the analysis of fragility setting it in a broader framework than the current one, so that it could supplement the *p*-value and provide reliable information to researchers.

2. A new index of strength of a randomized clinical trial

2.1 The Fragility Index

In the context of an RCT, the FI can be defined as the minimal number of outcomes that must change their status from "non-event" to "event" to transform a significant result into a non-significant one [2]. The FI is calculated by virtually adding events to the group that contains less events, until the *p*-value p exceeds the threshold α with the use of Fisher's exact test. In case of a non-significant result, the adopted procedure is to subtract events from the group that contains a smaller number of events, until $p \leq \alpha$ is reached. In this case, the FI is generally known as Reverse Fragility Index (RFI). The FQ is obtained as a transformation of FI, namely by dividing FI by the total sample size.

The FI has some objective weaknesses, which can be summarized as follows: (i) it can only be calculated for dichotomous data; (ii) it does not present a threshold above which the result can be considered robust, according to a common terminology in the literature; (iii) it grows as the sample size grows, virtually suggesting that experiments with greater sample size may be less fragile than others; (iv) it is negatively correlated with the *p*-value, therefore large *p*-values are considered fragile and small *p*-values are considered robust.

2.1 Beyond the Fragility Index

Let us consider a general setting of comparison of $\theta_1$and θ_2, indicating the unknown proportions of events in the treatment groups T_1 and T_2, respectively:

$$H_0\colon \theta_1 = \theta_2 \ vs.\ H_1\colon \theta_1 \neq \theta_2. \tag{1}$$

Let us indicate with $\frac{x_1}{n_1}$ and $\frac{x_2}{n_2}$ the proportions of events verified in T_1 and T_2, respectively.
Without losing generality, we assume $\frac{x_1}{n_1} \leq \frac{x_2}{n_2}$ so that $\hat{\theta} = \frac{x_2}{n_2} - \frac{x_1}{n_1}$ is an estimate of $\theta = |\theta_1 - \theta_2|$ and

$$\hat{\sigma}^2 = \frac{x_1}{n_1^2}\left(1 - \frac{x_1}{n_1}\right) + \frac{x_2}{n_2^2}\left(1 - \frac{x_2}{n_2}\right) \tag{2}$$

is a suitable estimate of its variance. We suppose that the difference of proportions can be approximated by a Normal r.v..
We consider the quantity Q satisfying the Equation:

$$2\Phi\left(-\frac{\left|\frac{x_1}{n_1} - \frac{x_2}{n_2} + Q\right|}{\hat{\sigma}}\right) = \alpha \tag{3}$$

where Φ is the distribution function of a Normal r.v. That is to say that, to make the *p*-value equal to the threshold α, it is sufficient to add to x_1 (approximately) Qn_1 events, or, equivalently, to subtract from x_2 (approximately) Qn_2 events, according to the equalities:

$$\frac{x_1}{n_1} - \frac{x_2}{n_2} + Q = \frac{x_1 + Qn_1}{n_1} - \frac{x_2}{n_2} = \frac{x_1}{n_1} - \frac{x_2 - Qn_2}{n_2}.$$

Expression (3) is equivalent to

$$\left|\frac{x_1}{n_1} - \frac{x_2}{n_2} + Q\right| = \hat{\sigma} z_{1-\alpha/2}$$

where $z_{1-\alpha/2}$ is the percentile of order 1 -$\alpha/2$ of the standardized Normal r.v. Z. In particular, for Q we propose the explicit formula

$$Q = \frac{x_2}{n_2} - \frac{x_1}{n_1} - \hat{\sigma} z_{1-\frac{\alpha}{2}} = \left(z_{1-p/2} - z_{1-\alpha/2}\right)\hat{\sigma} \tag{4}$$

where $z_{1-p/2} = \frac{\frac{x_2}{n_2} - \frac{x_1}{n_1}}{\hat{\sigma}} = \frac{\hat{\theta}}{\hat{\sigma}}$ and $p = 2\Phi\left(-\frac{\hat{\theta}}{\hat{\sigma}}\right)$ is the two-sided *p*-value for the null hypothesis (1).
If the experiment led to a significant result, Expression (4) takes a positive value, while it takes a negative value in case of non-significant result. More precisely, from

(4) it follows $Q \leq \frac{x_2}{n_2} - \frac{x_1}{n_1}$ in case of significance and $-\hat{\sigma} z_{1-\frac{\alpha}{2}} \leq Q \leq 0$ in case of non-significance.

In light of these results, we can introduce the normalized index SI given by

$$SI = \begin{cases} \dfrac{Q}{\frac{x_2}{n_2} - \frac{x_1}{n_1}} = 1 - \dfrac{\hat{\sigma} z_{1-\frac{\alpha}{2}}}{\frac{x_2}{n_2} - \frac{x_1}{n_1}} = 1 - \dfrac{z_{1-\frac{\alpha}{2}}}{z_{1-p/2}} & : p \leq \alpha \\ \dfrac{Q}{-\hat{\sigma} z_{1-\alpha/2}} = \dfrac{\frac{x_2}{n_2} - \frac{x_1}{n_1}}{-\hat{\sigma} z_{1-\alpha/2}} + 1 = 1 - \dfrac{z_{1-\frac{p}{2}}}{z_{1-\frac{\alpha}{2}}} & : p > \alpha \end{cases} \quad (5)$$

In general, for a fixed p-value, Q decreases as sample sizes grow and, if $p \leq \alpha$,

$$SI \geq 1 - \frac{1}{\sqrt{2}} \Leftrightarrow \frac{\frac{x_2}{n_2} - \frac{x_1}{n_1}}{\hat{\sigma}} \geq \sqrt{2} z_{1-\frac{\alpha}{2}} \Leftrightarrow p \leq 2\Phi\left(\sqrt{2} z_{\frac{\alpha}{2}}\right)$$

according to [9]. Details for $p > \alpha$, further discussion, and examples are in Quatto et al. [10].

3. Conclusion

The FI can be considered as a measure of robustness of an inferential procedure, in the sense that small variations in the data can subvert the *p*-value, modifying it from significant ($p < 0.05$) to non-significant or vice versa. The FI has raised a lot of criticism, although it continues to be used in the applied literature.

The index (5) is a normalized index of strength of RCT, which varies as a function of the *p*-value and for which a threshold can be provided [10], contrary to FI, as highlighted in observation (ii). In its formulation, the index solves many shortcomings of the FI, and can also be extended to the case of unidirectional hypotheses.

Evaluation of the diagnostic-therapeutic paths for schizophrenic patients through state sequences analysis

Analisi dei percorsi diagnostico-terapeutici dei pazienti schizofrenici tramite tecniche di analisi delle sequenze

Laura Savaré[1,2,3], Giovanni Corrao[3,4], Francesca Ieva[1,2,3]

Abstract To date, there are still few attempts to monitor the quality of mental health care through tools that are easily accessible from databases used for health care. The aim of this work is to analyze the diagnostic-therapeutic pathways, provided to patients diagnosed with schizophrenia, through the analysis of the sequences. This methodology, not yet used in the field of mental health, consists in considering the patient's therapeutic path as a conceptual unit, i.e. a sequence, composed by a succession of different states, which in this case represent the weekly coverage of different treatments. This technique seems to be a valid support for describing complex scenarios, such as the heterogeneity of the paths followed and grouping patients with more similar paths. Therefore, it stands as a precious tool for informing decision making and supporting the definitions of new guidelines in a real-world evidence prespective.

Abstract *Ad oggi, sono ancora pochi i tentativi di monitorare la qualità dell'assistenza sanitaria, in ambito di salute mentale, attraverso strumenti facilmente fruibili dai dati disponibili. Lo scopo del presente lavoro è analizzare i percorsi diagnostico-terapeutici, seguiti dai pazienti schizofrenici, tramite l'analisi delle sequenze. Questa metodologia, non ancora usata in questo contesto, consiste nel considerare il percorso terapeutico del paziente come un'unità concettuale, ovvero una sequenza, composta dalla successione di diversi stati, che in questo caso rappresentano la copertura su base settimanale dei diversi trattamenti. Questa tecnica sembra essere un valido sostengno nel descrivere scenari complessi, come l'eterogeneità dei percorsi seguiti e raggruppare i pazienti con percorsi più simili. Pertanto, rappre-*

senta uno strumento prezioso per supportare il processo decisionale e supportare le definizioni di nuove linee guida in una prospettiva di evidenza del mondo reale.

Key words: analysis of sequences, diagnostic-therapeutic pathways, mental health

1 Introduction

Currently, the vast majority of people with schizophrenia around the world are not receiving mental health care. Schizophrenia is a chronic brain disorder that affects approximately 24 million people or 1 in 300 people (0.32%) worldwide[1]. When schizophrenia is active, symptoms can include delusions, hallucinations, disorganized speech, trouble with thinking and lack of motivation. However, with treatment, most symptoms of schizophrenia will greatly improve and the likelihood of a relapse can be reduced. At least one third of people with schizophrenia experiences complete remission of symptoms [2]. Some people with schizophrenia experience worsening and remission of symptoms periodically throughout their lives, others a gradual worsening of symptoms over time. Most resources for mental health services are inefficiently spent on care within mental hospitals. In Italy, the transition from a hospital to a community-based system started in 1978, with a reform that led to the gradual closing of psychiatric hospitals [3]. The aim of the work is to develop methods to allow the governance to monitor over time, asses the quality and optimize the diagnostic-therapeutic pathways, provided to patients newly taken-into-care for schizophrenic disorders by the National Health Service (NHS) of the Lombardy Region. In particular, there is the need to describe the treatment paths to then evaluate its association with the incidence of negative outcomes.

2 Data

The data used for this study were retrieved from the healthcare utilization databases on the residents of Lombardy, a Region of Italy that accounts for about 16% (10 million) of its population. The Italian population is covered by the National Health Service that provides hospitalization, major diagnostic procedures, and so-called life-saving drugs to all citizens free or almost free of charge. In addition, a specific automated system concerning psychiatric care gathers data from regional Departments of Mental Health (DMHs) accredited by the NHS. This system provides demographic information and diagnostic codes for patients receiving specialist mental healthcare [4].
The target population of this work consisted of all NHS beneficiaries resident in Lombardy, aged 18-40 years, who during the recruitment period (2015-2018) had at least one contact with a mental health service and had a diagnosis of schizophrenia. We then excluded prevalent patients and those with less than 1 year of follow-up.

The patients included into the final cohort were followed for 1 year after the the onset of schizophrenia (i.e, without experiencing death, emigration or hospitalization during the fist year after diagnosis of schizophrenia). During the first year we have collected all psychiatric visits, psycho-social interventions and anti-psychotic dispensed drugs delivered to each patient. The combination of these three interventions make up the optimal treatment path (OTP).

3 Methods

In order to analyze the specific pathways of each patient, intended as a sequence of treatments received, we used the analysis of the *state sequences*.

A sequence is defined as an ordered list of elements, where an element can be a certain status (e.g., employment, health status or coverage of a treatment), a physical object (e.g. base pair of DNA, protein, or enzyme), or an event (e.g. an hospitalization). The positions of the elements are fixed, ordered by elapsed time and they refer to a relative, not absolute, time point (Figure 1). The addressed methods are for sets of sequences each of which are considered as a whole; i.e., as a conceptual unit [5] .

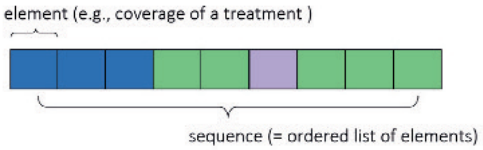

Fig. 1 Sample sequence

In particular, in our case-study, we defined the states of the sequence of each patient on a weekly basis. Based on the OTP, we classified each state (i.e. every week) into four adherence categories, based on how many of the three treatments (i.e, psychiatric visits, psycho-social interventions and anti-psychotic) were dispensed to the patients:

- *Not treated (0 out of 3)*, if in that given week the patient is not covered by any of the three treatments;
- *Low intensity of treatment (1 out of 3)*, if covered by only one treatment;
- *Medium intensity of treatment (2 out of 3)*, if covered by two treatments out of three;
- *High intensity of treatment (3 out of 3)*, if covered by all three treatments.

In particular, we considered for each psychiatric visits a coverage of 2-4 weeks, depending on who provided the visit, for each psycho-social interventions a coverage of 2 weeks and for the anti-psychotic drugs the defined daily dose.

The primary objective of sequence methods is to extract simplified workable information from sequential datasets; that is, to efficiently summarize the data identifying typical patterns and categorizing them into a limited number of groups. This is essentially an exploratory task that consists of computing summary indicators, as well as sorting, comparing and grouping sequences. The resulting groups and real-value indicators may then be submitted to classical inferential methods and serve, for instance, as response variables or explanatory factors for regression-like models.

For the comparison step, we had to determine how sequences should be compared and how the difference between two sequences should be measured. Dissimilarity measures can be classified into measures based on the (minimal) cost of transforming one sequence into the other and those defined as the count of matching attributes. Another interesting distinction is between those that make position-wise comparisons; i.e., that do not allow shifting a sequence or part of it, and those accounting for similar shifted patterns. We decided to build our definition of dissimilarities on counts of common attributes. Let $A(x,y)$ be a count of common attributes between sequences x and y. It is a proximity measure since the higher the counts, the closer the sequences. We derive a dissimilarity measure from it through the following general formula

$$d(x,y) = A(x,x) + A(y,y) - 2A(x,y)$$

where $d(x,y)$ is the distance between objects x and y. The dissimilarity is maximal when $A(x,y) = 0$; i.e., when the two sequences have no common attribute. It is zero when the sequences are identical, in which case we have $A(x,y) = A(x,x) = A(y,y)$. One of the implemented metric is based on the length of $A_S(x,y)$ of Longest Common Subsequence (LCS) [8], which extracts the elements within a group of sequences that occur in the same order, while allowing gaps in between elements, as shown in the Figure 2

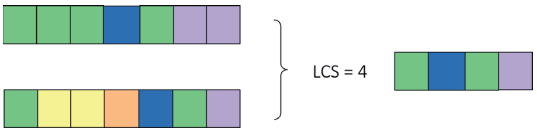

Fig. 2 The Longest Common Subsequence between two sequences

When compared with metrics based on position-wise, the LCS metric reduces distances by accounting for non-aligned matches; i.e., position-shifted similarities. Note that this methodology has a purely sequential and do not take into account any temporal dimensions.

Given the notion of (dis)similaruty, a clustering procedure may be adopted. We used a hierarchical clustering and through the elbow method and silhouette analysis or score techniques we found the optimal number of clusters.

4 Results

Out of the 8'566 patients aged 18-40 years and assisted by the NHS for schizophrenia in the years 2015-2018, 2'739 were incident users. Among these, only 2'329 patients had at least 1 years of observation and were included in the final cohort.
It was observed that during the first year, on average, they were not covered by any treatment for about 5 months, they were covered by 1 or 2 treatments for about 3 months, and for one month they resulted fully covered by all the OTP's treatments. The most stable state is the state in which no treatment is received, i.e. *0 out of 3*, as the probability of remaining in this state, for those who are already there, is 95%. On the other hand, for the other 3 states, the probability of remaining in the same state is 81%, 83% and 87%, respectively. Furthermore, the highest transition rate is from *2 out of 3* to *1 out of 3* and from *3 out of 3* to *2 out of 3* state, that is equal to 0.12. The calculation of the distance through the LCS metric and the study of the optimal number of groups to be considered, as above mentioned in the methods session, allowed us to cluster our patients into 3 groups (as shown in Figure 3):

- 953 patients with *very low intensity* of treatment [1];
- 932 patients with *medium-low intensity* of treatment [2];
- 444 patients with *medium-high intensity* of treatment [3].

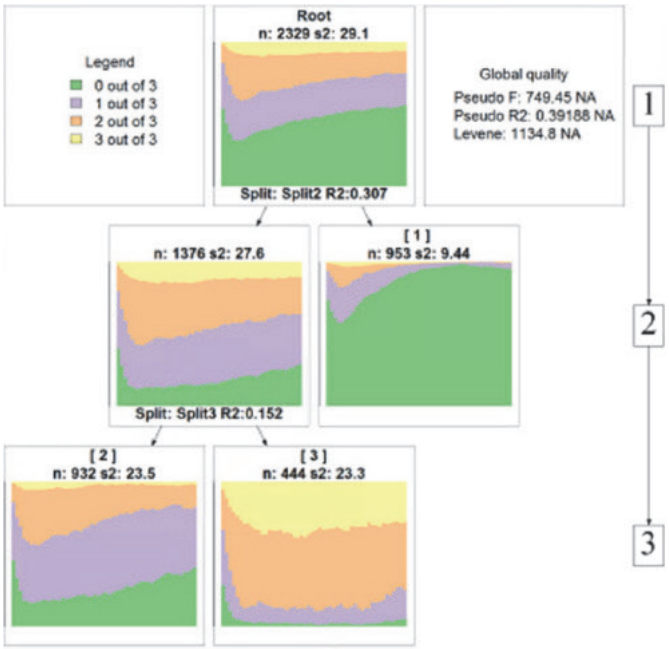

Fig. 3 Hierarchical clustering dendrogram. For each group it is represented the state distribution for each week

5 Conclusions

The analysis of state sequences is useful and effective in this field because it offers a descriptive gain by being able to identify typical patterns. Furthermore, via the inclusion of covariates, it could establish why certain sequence patterns exist and allow the researcher to establish what the effects of a given sequential pattern have on other outcomes. Further developments in these directions will lead to profile the groups according the healthcare rationale through a post-hoc analysis and to capture the potential predictive effect that a specific treatment path has on future negative outcomes. Therefore, sequences analysis could be an intuitive tool supporting providers to assess the quality and effectiveness of the diagnostic-therapeutic pathways provided to these patients and to monitor them over time. Further research could study different definition of the states of the sequences and different metrics used for the distances.

Optimal timing of bone-marrow transplant in myelodysplastic syndromes through multi-state modeling and microsimulation

Tempo ottimale per il trapianto di midollo osseo nelle sindromi mielodisplastiche attraverso un modello multi stato e di microsimulazione

Caterina Gregorio[1,2], Marta Spreafico[1,3], Francesca Ieva[1,4]

Abstract In myelodysplastic syndromes tailoring the timing of bone-marrow transplant according to patient's genomic profile and characteristics is fundamental since it represents the only curative treatment available in this disease and it can be performed only once. In this work we present a method based on a multi-state model to analytically optimize the timing of the transplant. This method can be used as an alternative to the microsimulation approach based on Monte Carlo. As objective function for the optimization, the Restricted Mean Survival Time was considered together with its first derivative. This decision analysis is the basis for a novel quantitative tool to assist clinicians in their decision process for the treatment of patients affected by this condition.

Abstract *Nelle sindromi mielodispastiche è fondamentare personalizzare il tempo al trapianto di midollo osseo sulla base del profilo genetico del paziente e sulle sue caratteristiche individuali poiché questo è l'unico trattamento curativo attualmente a disposizione e non può essere ripetuto. In questo lavoro presentiamo un approccio basato su un modello multi stato per ottimizare il tempo al trapianto per via analitica. Questo metodo è un'alternativa all'approccio della microsimulazione basato su stima Monte Carlo. Come funzione obiettivo per l'ottimizzazione è stato considerato il Restricted Mean Survival Time e la sua derivata prima. Questa analisi decisionale rappresenta il primo passo per lo sviluppo di un nuovo strumento quantitativo che può assistere i medici nel processo decisionale legato al trattamento dei pazienti affetti da questa patologia.*

1 Introduction

The myelodysplastic syndromes (MDS) are a group of tumors affecting haematopoietic stem cells characterized by cytopenia, dysplasia, ineffective haematopoiesis and increased risk of developing acute myeloid leukemia[1]. Nowadays diagnosis and treatments are guided by clinical parameters and biomarkers. However, in the last few years much research has been focused on studying the role of genetic mutations in the progression and prognosis of this disease since it may play a role in therapeutic programs in the future[2]. The only available curative treatment for patients with MDS is allogeneic haematopoietic stem-cell transplantation (HSCT). HSCT can be performed only once and it comes with significance probability of failure because of toxicity and disease relapse. HSCT's success and survival after transplant it is also believed to depend of patients' characteristics as well as their genomic profile. With this in mind, it becomes essential to tailor the timing of HSCT in eligible patients according to individual characteristics and genomics at MDS diagnosis in order to maximize the survival probability in patients. From a statistical point of view, the problem consists in balancing individual pre-HSCT survival probability and post-HSCT in order to maximize patient's overall life-expectancy. The aims of this work are to (1) provide a statistical method to quantitatively assess the individual risk of death before and after the transplant according to different transplant policies with regards to the timing and (2) optimize the HSCT timing by considering the Restricted Mean Survival Time (RMST) and its first derivative.

2 Data

Data comes from a retrospective international cohort study which enrolled patients diagnosed with primary MDS according to 2016 WHO criteria. The data contains demographics, clinical and genomic information at the time of the diagnosis. Moreover, events in the follow-up such as the timing of HSCT (for patients who were transplanted) and the time of death were recorded. 2476 patients were considered in this analysis including 558 who underwent HSCT at some time during the follow-up. Genomic information was summarized using a genomic classification recently proposed for MDS patients[3] which allows to identify patients with a similar mutations profile.

3 Methods

As a first step, we specified a suitable model to describe the clinical problem under study. Using this model, we were then able to tackle the optimization of the HSCT timing following two different methods: one based on microsimulation and one based on an analytic formula hereby proposed.

3.1 Multi-state model

A multi-state model as the one represented in Figure 1 was considered . Let $M(t)$ be the state occupied at time t and let x_i be the vector of baseline covariate information observed for subject i.

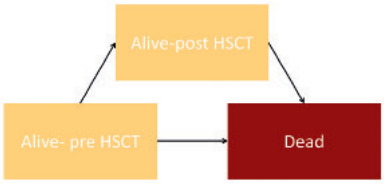

Fig. 1 Multi-state model representation

The model has two "Alive" states corresponding to pre-HSCT and post-HSCT and one absorbing state representing "Dead" status. Specifically, the model corresponds to a standard illness-death model and it is assumed to be semi-markov. The transition from state "pre-HSCT" to death is used to study the natural history of the disease conditionally on baseline covariates relating to disease progression. On the other hand, the transition from "post-HSCT" to death relates to post-transplant survival probability and it depends on the probability of HSCT's success.

3.2 Microsimulation

Similarly to a multi-state model, in a microsimulation model[4, 5] individuals can transit in one state at the time from a sets of mutually exclusive states. We consider now the time to be discrete and finite: $c = \{1, \ldots, c^*\}$ where each time corresponds to a cycle of the model and c^* is the time horizon. For our problem we considered a time cycle of 1 months. The set of possible states at cycle c is denoted by $M(c)$ and $A(c)$ is the set of possible actions available at state $m \in M$ for an individual i. The microsimulation algorithm at each cycle c consists of the following steps:

1. the individual current state at cycle c is recorded;
2. the decision maker chooses an action a;
3. the individual transitions to the next cycle $c+1$ according to a transition probability $P_c(m'|m,a,x_i)$.
4. the individual receives a reward $r_c(m,a)$;

The reward, $r_c(m,a)$, is a real valued function, whereas $P_c(m'|m,a)$ denotes the probability that the individual is in state $m' \in M_{c+1}$, conditionally on state m occupied at time c, the vector of baseline covariates and the action taken at time c. A

policy, $\pi = \{a_1, ..., a_c, ..., a_{c^*}\}$, is defined as the sequence of actions taken, where an action taken is mapping from states to actions, so that $a_c(m) \in A_m$. In our case, the states of the microsimulation correspond to the states of model defined in Section 3.1. The policies that we aimed to compare were π_h: perform HSCT at time $c^h \in \{1, ..., 12\}$ months. Therefore, the policy "perform HSCT at time c^h" induces a probability of transition to state "post-HSCT" at time c^h equal to one minus the probability of dying in c^h for subjects still alive at time c^{h-1} and equal to 0 otherwise. The probabilities of dying at each time c, conditionally on covariates, required for the complete definition of $P_c(m'|m, a, x_i)$ were obtained by the multi-state model. For each policy, performing a simulation based on the previous algorithm for a set of M individuals with covariates x_i allows us to obtain a Monte Carlo estimate of the total reward for the subgroup of patients with characteristics x_i. A reward of 1 was considered if the patient was alive at the end of the cycle and 0 otherwise. As a consequence, the total reward corresponds to an estimate of the RMST over a time horizon of c^* months:

$$\mu^{c^*|x_i} = \sum_{c=0}^{c^*} S(c|x_i) \tag{1}$$

3.3 Analytic Formula

Since our aim is to model the survival probability as a function of the HSCT time, conditionally of baseline covariates, we decompose it using the law of total probability:

$$\begin{aligned} S(t|x_i) &= Pr(T_i > t|x_i) = \\ &= Pr(T_i > t|T > t^h, x_i) Pr(T_i > t^h|x_i) + Pr(T_i > t|T \leq t^h|x_i) Pr(T_i \leq t^h|x_i) \end{aligned}$$

where t^h corresponds to the transplant time. We can now study this formula considering the two possible cases: either time t is before of equal to t^h or is greater than t^h. In the former case we can work on the formula using the definition of conditional probability, whereas in the latter we observe that the probability of surviving at least until t, given that death has occurred before t^h, is 0. We therefore obtain:

$$S(t|x_i) = \begin{cases} Pr(T > t^h|x_i) + Pr(t < T \leq t^h|x_i) = Pr(T > t|x_i) & \text{if } t \leq t^h \\ Pr(T > t|T > t^h, x_i) Pr(T > t^h|x_i) & \text{if } t > t^h \end{cases} \tag{2}$$

Therefore, the RMST becomes:

$$\begin{aligned}\mu^{t^*|x_i} &= \int_0^{t^*} S(u|x_i)du = \\ &= \int_0^{t^h} S(u|x_i)du + \int_{t^h}^{t^*} S(u|x_i)du = \\ &= \int_0^{t^h} Pr(T > u|x_i)du + \int_{t^h}^{t^*} Pr(T > u|T > t^h, x_i)Pr(T > t^h|x_i)du\end{aligned}$$

The RMST can be estimated directly from the model described in Section 3.1 since the probabilities correspond to the multi-state model predicted probabilities of transition.

4 Results

The analysis was stratified according to the genomic group i.e. a separate model was fitted for each genomic group while age and gender were considered as covariates. A Cox type multi-state model was fitted using the `mstate` [7] and `survival` [6] R packages. We applied the methods explained in Section 3.2 and 3.3 in order to obtain the RMST according to different treatment policies. As time horizon for the RMST we considered 36 months. As an example, we reported the results for 57 years old male patients in different genomic groups (Fig.2). Since the microsimulation and the analytic formula leads to the same results, we reported the ones obtained from the analytic formula which has the computational advantage not to require any simulation. Interestingly, it can be observed how most of the variability in the estimated RMST is mostly captured by the patient's genomic profile. To better study the variability related to the timing of HSCT, curves were smoothed using cubic b-splines in order to obtain the first derivative of RMST. It can be observed how latter timing for HSCT seem to be preferred for genomic group A, B, C and D, while the RMST start decreasing after 6 months in genomic group E.

5 Conclusions

Optimizing the time of HSCT in a personalized manner is a non-trivial statistical problem. In this work we presented an analytic formula based on a multi-state model which can be used for the maximization of the RMST. The formula is equivalent to using a microsimulation approach but has a significant advantage in terms of computational effort. Further developments in this direction can lead to a new decision tool for the treatment of patients affected by MDS. Further research could study uncertainty assessment of this method. Moreover, it could be of clinical interest to include biomarkers information in the optimization problem.

A fully Bayesian approach for sample size determination of Poisson clinical trials.

Approccio completamente Bayesiano per la scelta della dimensione campionaria di studi clinici basati su dati di conteggio.

Susanna Gentile and Valeria Sambucini

Abstract In this paper, we exploit a fully Bayesian approach to determine the optimal exact sample size of a single-arm trial based on count data. The idea is to select the sample size by controlling the *Predictive Bayesian Power*, i.e. the predictive probability of obtaining a Bayesian significant result, under the assumption that the treatment is actually effective. An essential element of the procedure is the specification of two different prior distributions and some suggestions about their choice are provided.

Abstract *In questo articolo si sfrutta un approccio completamente bayesiano per la scelta della numerosità campionaria esatta per uno studio a braccio singolo basato su dati di conteggio. L'idea è di selezionare la dimensione del campione controllando la Potenza Bayesiana Predittiva, ovvero la probabilità predittiva di ottenere un risultato statisticamente significativo secondo un ottica Bayesiana, assumendo che il trattamento sia effettivamente efficace. Un elemento essenziale della procedura è l'introduzione di due diverse distribuzioni a priori sulla scelta delle quali vengono forniti alcuni suggerimenti.*

1 Introduction

The choice of the sample size is a key element of any study design, especially in the field of clinical trials. In this context, Bayesian methods for sample size calculation are particularly attractive because of their flexibility and capability of modelling uncertainty. In this paper, we adopt a "fully Bayesian approach", also called a "proper Bayesian approach", that does not mix frequentist and Bayesian tools, but uses only Bayesian concepts both at the analysis and at the design stage of the trial. As a consequence, the method requires the specification of two different prior distributions, which pursue different purposes: the *analysis* and the *design* priors (see [1], [3] and [7]).

Let us focus on hypothesis testing and consider the null hypothesis $H_0 : \theta \in \Theta_0$ versus the alternative $H_1 : \theta \in \Theta_1$, where θ denotes the parameter of interest that measures the effect of the experimental treatment. The hypothesis H_1 defines the condition about the parameter that corresponds to a treatment considered sufficiently effective. In a Bayesian setup, we elicit the analysis prior distribution, $\pi^A(\theta)$, that expresses the pre-experimental knowledge, as well as the possible absence of information, about the unknown parameter θ. It is used to compute the posterior distribution, $\pi^A(\theta|y_n)$, where y_n denotes the observed experimental result based on a sample of size n. At the planning stage of the trial, we have not collected the trial data yet and the experimental result is a random quantity, Y_n. Following Spiegelhalter et al. [6], this random result can be considered statistically significant under a Bayesian perspective if it yields a large posterior probability that θ belongs to the alternative hypothesis. In other words, the definition of the *Bayesian significance* provides the condition to obtain a successful experiment that leads to the rejection of the null hypothesis. The sample size determination criterion is based on the computation of the so-called *Predictive Bayesian Power*, $PBP(n)$, that is the predictive probability of obtaining a Bayesian significant result, when the true θ actually belongs to the alternative hypothesis. This latter optimistic assumption is realized by introducing a design prior distribution, $\pi^D(\theta)$, that assigns negligible probability values to the sub-space under H_0 and that is used to compute the prior predictive distribution of Y_n. In general terms, the criterion selects the minimum n that ensures a sufficiently large value for the Predictive Bayesian Power.

In this paper, we apply the fully Bayesian procedure described above for exact sample size calculation in single-arm trials based on count data. As a consequence of using exact methods, we obtain that $PBP(n)$ is not a monotonically increasing function of n, but tends to increase following a saw-toothed behaviour that typically occurs when dealing with discrete distributions of Y_n (see [2]). To take into account this behaviour, in line with Sambucini [5], we suggest to select the optimal sample size as

$$n^{PBP} = \min\{n^* \in \mathbb{N} : PBP(n) > \gamma, \forall n \geq n^*\}, \tag{1}$$

where γ is a fixed threshold. In practice, this more conservative criterion takes into account the behaviour of $PBP(n)$ by imposing that the condition of interest is satisfied for all the sample size values greater than or equal to the optimal one.

The outline of the article is as follows. In Section 2, we illustrate the Bayesian formulation of the problem when a single-arm study with Poisson data is performed and describe the sample size determination criterion based on $PBP(n)$. In Section 3 we show some numerical results and provide some suggestions about the choice of the analysis and the design priors. Finally, Section 4 contains some concluding remarks.

2 Sample size determination based on $PBP(n)$ for Poisson data

Let $(X_1, X_2, ..., X_n)$ be a random sample of count data. We assume that, for $i = 1, ..., n$, X_i represents the number of negative events occurred over a period of time for the i-th patient enrolled in a single-arm study aimed at establishing the efficacy of a new experimental treatment. Each X_i follows a Poisson distribution of rate $\theta > 0$, so that the sampling distribution of the sufficient statistic $S_n = \sum_{i=1}^{n} X_i$ is $f(s_n|\theta) = \text{pois}(s_n; n\theta)$, for $s_n = 0, 1, 2, \cdots$. The experimental treatment can be considered sufficiently effective if the event rate is below a target value θ_0 and, therefore, the interest is focused on the hypotheses $H_0 : \theta \geq \theta_0$ and $H_1 : \theta < \theta_0$.

Under a Bayesian framework, we exploit standard conjugate results and introduce a *gamma analysis prior distribution* to account for pre-experimental information on θ, $\pi^A(\theta) = \text{gamma}\left(\theta; \alpha^A, \beta^A\right)$, with $\alpha^A, \beta^A > 0$. The corresponding posterior distribution is $\pi^A(\theta|s_n) = \text{gamma}\left(\theta; \alpha^A + s_n, \beta^A + n\right)$. At the planning stage of the trial, the *Bayesian significance* of the random result S_n is provided by the condition

$$\mathbb{P}_{\pi^A(\cdot|S_n)}(\theta < \theta_0) = \text{Gamma}(\theta_0; \alpha^A + S_n, \beta^A + n) > \lambda, \tag{2}$$

where λ is a fixed probability threshold, $\mathbb{P}_{\pi^A(\cdot|S_n)}$ denotes the probability measure associated with the posterior distribution of θ and $\text{Gamma}(\cdot; a, b)$ denotes the c.d.f. of a gamma distribution of parameters a and b. The posterior probability in (2) is a decreasing function of S_n and, due to the discreteness of the random result, it is possible to find a non-negative integer k such that

$$\mathbb{P}_{\pi^A(\cdot|k)}(\theta < \theta_0) > \lambda \qquad \text{and} \qquad \mathbb{P}_{\pi^A(\cdot|k+1)}(\theta < \theta_0) \leq \lambda.$$

As a consequence, we can say that the random result S_n is significant under a Bayesian perspective if $S_n \leq k$, where

$$k = \max\left\{u \in \{0, 1, \cdots\} : \text{Gamma}\left(\theta_0; \alpha^A + u, \beta^A + n\right) > \lambda\right\}.$$

In order to derive the Predictive Bayesian Power, we introduce a *gamma design prior distribution*, $\pi^D(\theta) = \text{gamma}\left(\theta; \alpha^D, \beta^D\right)$, with $\alpha^D, \beta^D > 0$, used to

formalize the optimistic design expectations about the efficacy of the experimental treatment. By exploiting this prior density, we obtain the following Negative-Binomial prior predictive distribution of S_n

$$m^D(s_n) = \text{Nb}\left(s_n; \alpha^D, \frac{\beta^D}{\beta^D + n}\right), \quad \text{for } s_n = 0, 1, 2, \cdots.$$

Then, the Predictive Bayesian Power can be obtained as

$$\begin{aligned} PBP(n) &= \mathbb{P}_{m^D(\cdot)}(S_n \leq k) \\ &= \sum_{s_n=0}^{k} \text{Nb}\left(s_n; \alpha^D, \frac{\beta^D}{\beta^D + n}\right), \end{aligned}$$

where $\mathbb{P}_{m^D(\cdot)}$ denotes the probability measure associated with the prior predictive distribution of S_n. In practice, it is given by the sum of the predictive probabilities of all the possible Bayesian significant results, obtained under the assumption that the experimental treatment is actually effective. Given the discrete nature of the Negative-Binomial distribution, we propose to use the conservative criterion in (1) to select the optimal value of n.

3 Numerical results

In this Section, we analyse the impact of the different design parameters on the optimal sample size. Let us assume that $\theta_0 = 1.9$. To elicit the gamma design prior, we find it useful to follow a procedure commonly used for the beta prior densities in the presence of binary data, that consists in expressing the hyperparameters in terms of prior mode and prior sample size (see [4]). In our case, we obtain that by setting

$$\alpha^D = n^D \theta^D + 1 \qquad \text{and} \qquad \beta^D = n^D,$$

$\pi^D(\theta)$ is centred on θ^D and its concentration can be regulated by varying the prior sample size n^D. Since we use this distribution to assume that θ belongs to the alternative hypothesis, it is reasonable to fix θ^D smaller than θ_0 and to set n^D so that the prior probability assigned to the null hypothesis is negligible. In particular, we consider two possible strategies to select n^D: (i) we set $n^D = \infty$, obtaining that $\pi^D(\theta)$ assigns all the probability mass to θ^D and (ii) we select n^D as the smallest value such that $P(\theta < \theta_0) \simeq 0.999$. Note that, in the first case, no uncertainty is introduced at the planning stage and the Predictive Bayesian Power equals the so-called *Conditional Bayesian Power* (see [1] and [5]). For the analysis prior, we similarly ensure that the prior mode is θ^A, but we set the prior sample size n^A equal to 1, in order to represent weak prior information that lets the data be predominant in the posterior analysis.

In Figure 1, we show the behaviour of $PBP(n)$, when $\theta^D = 1.5$, $\theta^A = 1.9$ and $\lambda = 0.95$. Because of the saw-toothed shape, we fix $\gamma = 0.8$ and select the optimal

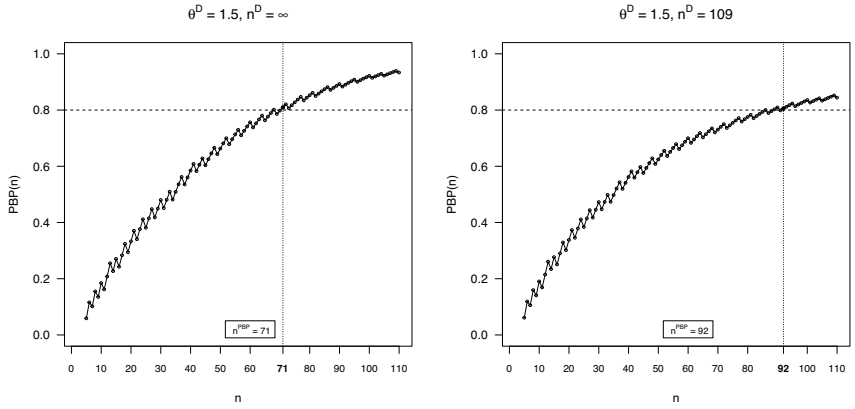

Fig. 1 Behaviour of $PBP(n)$, when $\theta_0 = 1.9$, $\theta^A = 1.9$, $n^A = 1$ and $\lambda = 0.95$. The optimal sample size is selected according to the criterion in (1) for $\gamma = 0.8$.

sample size according to the criterion in (1). We can note that, when $n^D = \infty$ and no uncertainty is accounted for through the design prior, the Bayesian power increases faster and the corresponding n^{PBP} is smaller. The same behaviour can be observed in Table 1, which reports the optimal sample sizes for $\gamma = 0.8$ for different values of θ^A, θ^D, λ and n^D. More specifically, the gap between the two sample sizes increases as θ^D gets closer to θ_0. Regardless of n^D, the selection of θ^D especially impacts the optimal sample sizes because we are considering three completely different scenarios under H_1. In particular, the closer θ^D and θ_0 are, the larger n^{PBP} is. The sample size also increases with λ because we require stronger evidence to consider the result statistically significant. Finally, even though the analysis priors are weakly informative, the optimal sample size increases with the degree of prior scepticism towards the new treatment expressed by $\pi^A(\theta)$. In this case, given the hypothesis system at interest, a larger θ^A expresses stronger scepticism.

4 Conclusion

In the present paper, we address the problem of sample size determination for single-arm studies based on Poisson data. More specifically, we adopt a fully Bayesian approach by exploiting the concept of Predictive Bayesian Power. The proposed strategy has two important advantages in that (i) it allows the introduction of possible pre-experimental knowledge about θ through the specification of an analysis prior distribution and (ii) it models uncertainty on θ at the planning stage with the design prior distribution, avoiding local optimality. Moreover, instead of using normal approximations, we resort to exact methods based on discrete

Table 1 Optimal sample sizes for different values of θ^D, n^D, θ^A and λ, when $\theta_0 = 1.9$, $n^A = 1$ and $\gamma = 0.8$.

		$\lambda = 0.9$			$\lambda = 0.95$			$\lambda = 0.99$		
		θ^A			θ^A			θ^A		
θ^D	n^D	0.9	1.9	2.9	0.9	1.9	2.9	0.9	1.9	2.9
1.5	∞	48	52	57	66	71	75	109	113	118
	109	58	66	71	84	92	97	143	151	156
1.6	∞	86	95	101	121	126	132	196	205	210
	195	107	117	123	152	162	168	260	270	279
1.7	∞	200	212	219	280	287	298	453	464	475
	444	249	262	270	353	366	374	600	612	625

distributions of the data and a conservative criterion is necessary to account for the not monotonic behaviour of $PBP(n)$.

Finally, let us notice that, without loss in generality, we have considered the count of "negative" events, that represent a not-desired outcome for patients. The proposed Bayesian criteria can be similarly derived when the hypotheses are reversed because a "positive" event is considered.

Compartmental models in epidemiology: Application on Smoking Habits in Tuscany

Modelli compartimentali in epidemiologia: Applicazione sull'abitudine al fumo in Toscana

Alessio Lachi, Cecilia Viscardi, Maria Chiara Malevolti, Giulia Carreras, and Michela Baccini

Abstract We developed a compartmental model to describe the smoking habits evolution in Tuscany, relying on flexible modelling of age and sex-dependent smoking transition rates. Calibrating on observed data, we estimated the prevalence of current, former and never smokers in the population, and quantified the fraction of deaths attributable to smoking from 1994 to 2033. The model results indicate that smokers prevalence is decreasing over time. We speculate that this reduction could be related to health policies implemented up to now. Results highlight also that smoking habits are different among males and females.

Abstract *Abbiamo sviluppato un modello compartimentale che descrive l'evoluzione delle abitudini al fumo in Toscana, modellando in modo flessibile i tassi di fumo, età e sesso dipendenti. Calibrando su dati osservati, abbiamo stimato la prevalenza di fumatori, ex fumatori e non fumatori nella popolazione e abbiamo quantificato la frazione di decessi attribuibili al fumo dal 1994 al 2033. I risultati del modello indicano che la prevalenza dei fumatori sta diminuendo nel tempo. Tale riduzione potrebbe essere dovuta alle politiche sanitarie sinora attuate. I risultati mostrano inoltre che le dinamiche di abitudine al fumo sono diverse tra uomini e donne.*

Key words: Compartmental Model, Smoke, Tobacco control, Prevalence, Population attributable fraction.

1 Introduction

Smoking is a major risk factor for many common chronic diseases. In particular, over 85% of lung cancers are attributable to smoking. Also, smoking reduces length and quality of life [13].

The World Health Organization Framework Convention on Tobacco Control (WHO FCTC) considers the implementation of tobacco control policies (TCP) as the primary prevention strategy to reduce the prevalence of smokers in the population and the burden of mortality and morbidity attributable to smoking.

Aggregate or compartmental models allow to describe the dynamics of smoking habits in time and to compare the effectiveness of TCPs. They start from an initial population, divided into non overlapping compartments according to observed smoking prevalence, and reproduce the evolution of their sizes through a system of continuous-time dynamic equations [11, 9]. The mechanistic nature of such models results in the easiness of simulation of the system evolution.

This study aims to develop a compartmental model that describes the evolution of smoking habits from 1994 to 2033 in Tuscany, a region of central Italy, estimating the rates of starting, quitting, and relapsing smoking, and forecasts the prevalence of actual, former, and never smokers over time, allowing the evaluation of the impact of previous TCPs.

2 Methods

2.1 Model specification

We considered a compartmental smoking model (CSM) in which people, classified by gender (g) and age (a), are grouped into non overlapping compartments based on their smoking status: Current (C), Never (N), Former (F) smokers, and the related deaths compartments. The compartments C and F are further divided into subgroups denoted by C_i and $F_{i,c}$ for $i \in \{l,m,h\}$ and $c \in \{0,...,15\}$. Subscripts l, m and h stand for smoke intensity: low (cig/day$<$10), medium (10$\leq$cig/day$\leq$19), and high (cig/day$>$19). Subscript c denotes the time from smoking cessation in years.

Transitions of the individuals from a given compartment to another one determine flows that generate changes in the size of the compartment. Such transitions occur with probabilities governed by the annual rate of starting (γ), quitting (ε) and relapsing (η_c) smoking, and by the mortality rates (δ_{C_i}, δ_N, and $\delta_{F_{i,c}}$).

The assumptions underlying the model are: 1) the population is closed to immigration and emigration but opened to newborns, (birth rates from the Italian Institute of Statistics (ISTAT) database of 2011); 2) people start smoking in age $\in \{14,...,24\}$ ($\gamma(a) = 0$ for $a \in \{0,...,13\} \cup \{25,...,100\}$; 3) people are allowed becoming former smokers in age $\in \{25,...,100\}$ ($\varepsilon(a) = 0$ for $a \in \{0,...,24\}$); 4) the probability of starting, quitting, and relapsing smoking are independent from mortality.

Accordingly, the dynamic of the system is described by the following differential equations defined for each cohort [1] (y), and gender (g):

$$\begin{cases} \frac{dN^y(t)}{dt} = & N^y(t)\Big(1-\delta_N(t-y)\Big)\Big(1-\gamma(t-y)\Big) \\ \frac{dC_i^y(t)}{dt} = & C_i^y(t)\Big(1-\delta_{C_i}(t-y)\Big)\Big(1-\varepsilon(t-y)\Big)+N^y(t)\Big(1-\delta_N(t-y)\Big)\gamma(t-y)\pi_{C_i}(t-y)\mathbb{1}_{14\leq(t-y)\leq 24}+ \\ & \sum_{c=1}^{15+}F_{i,c-1}^y(t)\Big(1-\delta_{F_c}(t-y)\Big)\eta_c\mathbb{1}_{(t-y)>24} \\ \frac{dF_i^y(t)}{dt} = & \sum_{c=1}^{15+}F_{i,c-1}^y(t)\Big(1-\delta_{F_c}(t-y)\Big)\Big(1-\eta_c\Big)+C_i^y(t)\Big(1-\delta_{C_i}(t-y)\Big)\varepsilon(t-y) \\ \frac{dDN^y(t)}{dt} = & N^y(t)\delta_N(t-y) \\ \frac{dDC_i^y(t)}{dt} = & C_i^y(t)\delta_{C_i}(t-y) \\ \frac{dDF_i^y(t)}{dt} = & \sum_{i\in\{l,m,h\}}\sum_{c=1}^{15+}F_{i,c-1}^y(t)\delta_{F_c}(t-y). \end{cases} \tag{1}$$

Note that in Eq. (1) a can be viewed as $t-y$ and π_{C_i} represents the percentage of current smokers for each level of intensity $i\in\{l,m,h\}$.

We considered γ, ε, and η_c as unknown parameters to be estimated. In particular, we define γ and ε as natural cubic regression splines of a with 4 and 3 degrees of freedom:

$$\gamma(a)=s(a;\psi_0,\psi_1,\psi_2,\psi_3);\quad \varepsilon(a)=s(a;\phi_0,\phi_1,\phi_2).$$

The relapsing smoke rate, η_c is modelled as a negative exponential function of time from smoking cessation c:

$$\eta(c)=\alpha\beta e^{-12c\beta}$$

where β governs how fast the relapse rate declines over time from smoking cessation, and α governs the lifetime probability of no relapse [7].

The parameters π_{C_i} are fixed to values taken from ISTAT surveys [8].

The mortality rates δ_N, δ_{C_i} and $\delta_{F_{i,c}}$ are assumed gender-specific and constant over time. For each age we computed the mortality rates as follows:

$$\delta_N(a)=\delta_{Pop}(a);\ \ \delta_{C_i}(a)\approx RR_{C_i}\times\delta_{Pop}(a);\ \ \delta_{F_{i,c}}(a)\approx RR_{F_{i,c}}\times\delta_{Pop}(a).$$

We relied on the Relative Risks (RR) estimated in [12] and the mortality $\delta_{Pop}(a)$ rate taken from ISTAT database of 2011.

[1] People born in the same year

2.2 Model calibration and uncertainty quantification

Let us denote by $\theta = (\psi_0, \psi_1, \psi_2, \psi_3, \phi_0, \phi_1, \phi_2, \alpha, \beta)$ the vector of the parameters to be estimated and by $p^{\theta}(t,a) = \left(p_C^{\theta}(t,a), p_N^{\theta}(t,a), p_F^{\theta}(t,a)\right)$ the vector of prevalence computed from the sizes of compartments at time t for the age a [2], given a specific value of θ. A calibration procedure consists of searching the vector θ leading to $p^{\theta}(t,a)$ as closed as possible to $p^{obs}(t,a) = \left(p_C^{obs}(t,a), p_N^{obs}(t,a), p_F^{obs}(t,a)\right)$, the vector of the observed prevalence.

We calibrated our model on the prevalence estimates derived from the multipurpose household surveys data "Aspect of daily life" (AVQ) [8] carried out by ISTAT. Since 1993 the multipurpose surveys AVQ collect fundamental information related to the daily life of individuals and families. In particular, we considered $t \in \{1994, ..., 2019\}$ and we simulated the evolution of the system up to 2033. The model was calibrated separately by gender.

To compare observed and simulated trajectories we considered the following objective function where $H(\cdot,\cdot)$ denotes the Hellinger distance [6]:

$$min\left[\frac{1}{t \times a}\sum_{t,a} H\left(p^{\theta}(t,a), p^{obs}(t,a)\right)\right] = \frac{1}{t \times a \times \sqrt{2}}\sum_{t,a}\sqrt{\sum_{i \in \{C,F,N\}}\left(\sqrt{p_i^{\theta}(t,a)} - \sqrt{p_i^{obs}(t,a)}\right)^2}. \quad (2)$$

We performed a constrained optimization procedure resorting to the R package `nloptr` [14]. To take into account the sampling variability and quantify the uncertainty around point estimates we used a parametric bootstrap procedure [4]. Following an approach similar to [3], we estimated percentile bootstrap confidence intervals assuming that each prevalence followed a Dirichlet distribution, $p^{\theta}(t,a) \sim Dirichlet\left(C^{\hat{\theta}}(t,a), N^{\hat{\theta}}(t,a), F^{\hat{\theta}}(t,a)\right)$ where $C^{\hat{\theta}}$, $F^{\hat{\theta}}$, and $N^{\hat{\theta}}$ represent the size of the compartments corresponding to the best estimate $\hat{\theta}$ derived by minimizing Eq. 2. The sampling procedure was repeated n=1000 times to obtain bootstrap replicates of the unknown parameters used to compute confidence intervals.

We also computed population attributable fraction (PAF) for all cause of death as defined in [5] with never smokers as counterfactual level. These PAFs measure the proportion of deaths that would be avoided if the smoking risk factor in the population were eliminated.

3 Results and discussion

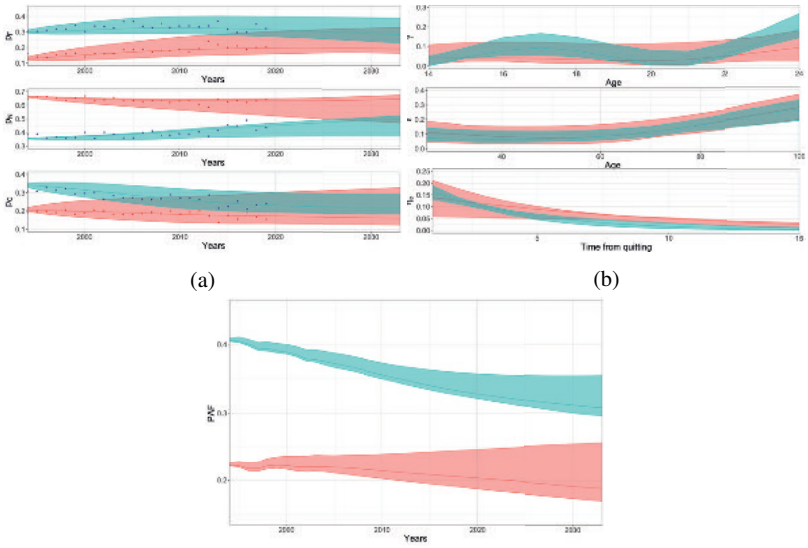
Fig. 1 panel a) shows the estimated prevalence from 1994 to 2033 for each gender. Looking at the observed data (blue and red dots), we observe an adequate model

[2] We considered the age classes 14-17, 18-19, 20-24, 25-34, 35-44, 45-54, 55-59, 60-64, 65-74, 75+

fit. Our forecasts suggest that the smoking prevalence will decrease in the next 15 years. This reduction may be due to the health policies so far implemented.

Panel b) shows the estimates of the rate of starting, quitting and relapsing smoking. From the comparison between rates of starting among males and females, we can see that males are more likely to start smoking than females. Moreover, the female rate exhibits an almost linear behaviour over time while the male rate shows a peak at seventeen. As regards the two rates of quitting, the two groups have the same behaviour, while the relapse rate among females becomes greater than among males after 5 years from quitting.

Panel c) represents PAFs. Our model predicts a reduction of PAF in the next years, due to the reduction of smoking prevalence. Males have a higher PAF than females, due to the higher prevalence of smoking among males.



(a) (b)

(c)

Fig. 1: Figure shows the prevalence estimates (a), the estimates of $\gamma - \varepsilon$ and η_c (b), and PAF (c) along with their 90% confidence bands by gender (males in blue and female in pink).

Several compartmental models have been developed to forecast future smoking rates and assess the impact of TCP [10, 9, 1, 2]. The Simsmoke model developed by Levy [10] has been largely used and applied to several countries, including Italy [9]. The model developed by Carreras et al [1, 2] extended the Simsmoke model by considering time from cessation in former smokers and by taking into account relapsing smoking. Our model adds further elements of novelty to this last model by considering also smoking intensity as a factor affecting mortality. Moreover, we introduced in the compartmental model cubic splines for estimating starting and

quitting smoking rates, thus obtaining more realistic trajectories. Finally, we evaluated parameter variability by estimating confidence intervals based on a parametric bootstrap procedure.

The model has several limitations. In particular, we assume the closeness of the population to immigration and emigration as well as constant mortality, birth rates, and, more in general, constant transition rates. Future work should include multivariate splines to model the dependence of the rates from calendar years. We should also consider second-hand smoking and other risk factors such as environmental pollution.

Covid-19 Assessment and Evaluation 2

We are in the same storm but not in the same boat: Impact of COVID-19 on UK households

Ognuno sta solo sul cuor della terra: Impatto del COVID-19 sulle famiglie del Regno Unito

Demetrio Panarello and Giorgio Tassinari[1]

Abstract The United Kingdom introduced a national lockdown in March 2020, as a means to curb the rising pace of COVID-19 infections in the country. Since then, the various restrictions imposed on citizens have caused enormous social and economic consequences on the UK population. However, full awareness of the mid- and long-term impacts of such measures is still lacking. In this paper, by making use of longitudinal data from the Understanding Society COVID-19 study, consisting of nine survey waves administered to a representative sample of UK citizens from April 2020 to September 2021, we analyse the potential determinants of employment losses and provision of financial assistance, particularly emphasising the differential effects related to individuals' socio-demographic characteristics.

Abstract *Il Regno Unito ha introdotto un lockdown nazionale nel marzo 2020, allo scopo di frenare il ritmo crescente di contagi da COVID-19 nel Paese. Da allora, le varie restrizioni hanno causato enormi conseguenze di tipo sociale ed economico sulla popolazione britannica. Tuttavia, manca ancora una piena consapevolezza degli impatti a medio e lungo termine di tali misure. In questo lavoro, facendo uso di dati longitudinali dell'Understanding Society COVID-19 study, consistente in nove ondate di questionari somministrati a un campione rappresentativo di cittadini britannici da aprile 2020 a settembre 2021, analizziamo le potenziali determinanti della perdita del lavoro e del supporto economico, sottolineando in particolare gli effetti differenziali legati alle caratteristiche socio-demografiche degli individui.*

1 Introduction

It has already been over two years since the introduction of the first national lockdown in the United Kingdom (March 23, 2020), carried out as a response to the rapid spread of COVID-19 cases in the country. Since then, the price of the implemented restrictions has been incredibly high, with strong consequences on the population as a whole and, in particular, on its most vulnerable segments, in terms of mass unemployment, isolation of the people, and widespread financial difficulties. Indeed, among European countries, the United Kingdom was one of the hardest hit by the pandemic. As of April 15, 2022, the national number of deaths due to COVID-19 amounts to about 171,000 (number of people who died within 28 days of being identified as a COVID-19 case by a positive test) and three lockdowns have been implemented in the country so far. The economic consequences at the aggregate level have been extremely strong. In 2020, GDP decreased by 9.7% compared to the previous year, followed by a growth of 6.9% in 2021 [7]; the unemployment rate in 2020 has increased by only 1.5%, mostly as a result of government support, while in 2021, despite the strong recovery in the economic activity level, a further increase of 1.8% is expected, until reaching a level of 7.1% [6]. Moreover, households' consumption fell by 22.4% in the second quarter of 2020, compared with the previous quarter [1]. Recent evidence has shown that the COVID-19 pandemic and the related social and economic interventions, such as physical distancing and closure of production activities, have had different impacts on the various social groups. For instance, in the UK, females and parents are among those who have experienced the largest reduction in subjective well-being [2,9]. Black, Asian and minority ethnic groups (BAME) exhibited a higher COVID-19-related mortality rate than the White population [8] and suffered harsher economic consequences [3]. The available evidence identifies the existence of immediate effects, but our understanding of the mid- and long-term impacts of COVID-19 and related measures remains incomplete. To this end, we analyse a representative sample of the UK population, the UK Household Longitudinal Study (UKHLS), making use of data from the Understanding Society COVID-19 Study [4,5].

Through this study, we aim at contributing to the comprehension of the effects of COVID-19 by focusing on two outcome variables: job loss and receiving financial support. In this regard, it should be mentioned that government interventions to support families and businesses accounted for 5.5% of GDP in 2020 [6]. As regards households, the Coronavirus Job Retention Scheme took shape. It guaranteed transfers to companies to pay 80% of furloughed workers' wages up to a maximum of 2,500 British pounds. In addition, self-employed workers received a taxable subsidy equal to 80% of the average income of the previous three years. Furthermore, the government temporarily increased the unemployment benefits.

In what follows, we will be highlighting the differential effects on the two outcome variables, related to the structural characteristics of individuals and households – such as gender, age, ethnic group, and family size. The next Section illustrates the data and techniques put to use to reach our aims, while the main findings are presented in Section 3. Then, some final remarks are given in Section 4.

2 Data and Methods

The Understanding Society COVID-19 study is a longitudinal survey aimed at capturing the experiences of UK individuals to the COVID-19 pandemic, covering the changing impact of the pandemic on the welfare of the UK population [4,5]. It is part of the UK Household Longitudinal Study (UKHLS) and includes all members of the main Understanding Society sample who participated in waves 8 or 9 (2017-2018), selected through a probability sampling of postal addresses in the UK. The COVID-19 survey was conducted during the first lockdown (April, May, June 2020), in its immediate aftermath (July, September 2020), during the last two lockdowns (November 2020, January 2021, March 2021), and finally in September 2021, for a total of nine survey waves so far.

For our analyses, we estimate panel logit models of two outcome variables: lost employment (Model 1) and financial support received (Model 2). Both models include several regressors related to the socio-demographic characteristics of the individuals and incorporate wave fixed effects. Descriptive statistics, computed for the sample that is not missing for any of the variables, are presented in Table 1.

Table 1: Descriptive statistics of the variables employed in the models.

Variable	*Obs.*	*Min*	*Median*	*Max*	*Mean*	*Std. Dev.*
Lost employment	39574	0	0	1		
Financial support	39574	0	0	1		
White	39574	0	1	1		
Age	39574	16	49	88	47.80	12.18
Male	39574	0	0	1		
Household size	39574	1	3	11	2.809	1.260
Living with a partner	39574	0	1	1		
Long-term health condition	39574	0	0	1		
Feeling lonely (1: Hardly ever or never; 2: Some of the time; 3: Often)	39574	1	1	3		
Payments (1: Up to date with all bills; 2: Behind with some bills; 3: Behind with all bills)	39574	1	1	3		
Currently employed	39574	0	1	1		
Type of employment in the previous wave (1: Employed; 2: Self-employed; 3: Both)	39574	1	1	3		
Current household income amount	39574	0	3000	250001	6665.11	16187.24

3 Main results

Table 2 shows the results from the first model, in which the outcome is a dichotomic variable taking value 1 if the respondent was working in January/February 2020 and has lost his or her job since, and 0 if he or she is still employed.

White people, compared to Black, Asian and minority ethnic groups, have a lower probability of losing their job. The same applies to males, compared to females, to those who are living with a partner, and to those who declared to be both employed and self-employed during the previous survey wave.

Older individuals have a higher probability of losing their job, as well as those with a long-term health condition, those who are experiencing loneliness, and those with higher incomes. Indeed, job loss is positively associated with difficulties in making ends meet, proxied by being behind with bills' payment.

Finally, it becomes more likely to report a job loss since June 2020, which corresponds to the third wave of the Understanding Society COVID-19 study, compared to the responses collected during the second wave (May 2020).

Table 2: Results from Model 1 – Panel logit regression of lost employment.

Variable	***Coefficient***	***Std. Error***
White	-0.284*	0.147
Age	0.035***	0.004
Male	-0.158*	0.094
Household size	-0.015	0.044
Living with a partner	-0.302***	0.114
Long-term health condition	0.250***	0.093
Feeling lonely: Some of the time	0.027	0.099
Feeling lonely: Often	0.468***	0.179
Payments: Behind with some bills	0.583***	0.196
Payments: Behind with all bills	1.780***	0.652
Self-employed in the previous wave	0.027	0.133
Employed and self-employed in the previous wave	-0.776**	0.302
Current household income amount	4.94e-06**	2.27e-06
Wave 3	0.839***	0.183
Wave 4	0.569***	0.193
Wave 5	1.513***	0.178
Wave 6	1.077***	0.191
Wave 7	1.161***	0.194
Wave 8	0.367	0.224
Wave 9	1.702***	0.182
Intercept	-7.036***	0.394
Observations	*39574*	
Log-likelihood	*-3310*	
Wald Chi-Square	*261.16***	

Note: * p < 0.1, ** p < 0.05, *** p < 0.01.

Table 3 shows the results from the second model, in which the outcome is a binary variable taking value 1 if the respondent states to be receiving financial support and 0 otherwise.

White people, compared to BAME, have a lower probability of receiving financial assistance. This is in line with the results of the previous model (see Table 2), in which White respondents were shown to have a lower probability of losing their job. A negative association with receiving financial support can also be pointed out for the older people in the sample, male respondents, and those living with a partner. Moreover, as expected, higher incomes are negatively associated with the likelihood of receiving financial support.

Conversely, individuals from larger households are more likely to receive financial support during the pandemic. The same applies to those declaring to be affected by a long-term health condition, to those who are experiencing loneliness, and to those who are behind with payments. Those who declared to be self-employed during the previous wave of the survey also show a higher likelihood of obtaining financial support, which is in line with the provisions of the Coronavirus Job Retention Scheme.

Finally, financial support looks to be unevenly distributed across the analysed survey waves, proving that policy measures aimed at financially supporting the citizens during the pandemic have seen various adjustments over time.

Table 3: Results from Model 2 – Panel logit regression of financial support received.

Variable	***Coefficient***	***Std. Error***
White	-0.551***	0.178
Age	-0.039***	0.005
Male	-0.402***	0.126
Household size	0.174***	0.046
Living with a partner	-0.605***	0.130
Long-term health condition	0.432***	0.118
Feeling lonely: Some of the time	0.216**	0.090
Feeling lonely: Often	0.517***	0.168
Payments: Behind with some bills	1.235***	0.169
Payments: Behind with all bills	2.475***	0.677
Currently employed	-0.017	0.252
Self-employed in the previous wave	6.109***	0.166
Employed and self-employed in the previous wave	3.279***	0.222
Current household income amount	-1.44e-05***	2.79e-06
Wave 3	-2.298***	0.132
Wave 4	-0.039	0.102
Wave 5	-1.895***	0.135
Wave 6	0.420***	0.106
Wave 7	-2.811***	0.163
Wave 8	-0.379***	0.116
Wave 9	0.347***	0.110
Intercept	-3.924***	0.426
Observations	*39574*	
Log-likelihood	*-6458*	
Wald Chi-Square	*1873.47***	

Note: * p < 0.1, ** p < 0.05, *** p < 0.01.

4 Conclusions

In this study, we analysed the consequences of the pandemic on the UK population, analysing data from the Understanding Society COVID-19 Study [4,5]. We estimated two panel logit regression models, focusing on two outcome variables: job loss and provision of financial aid. Our models considered several socio-demographic characteristics and controlled for the effect of time, as policy measures and their impact on the population have greatly changed throughout the pandemic.

Among other things, our outcomes highlight the vulnerability of some social groups. It appears that the ethnic component plays a key role in determining the probability of employment loss: Black, Asian and minority ethnic groups result to be more at risk of losing their jobs. However, such citizens are also more likely to receive financial assistance compared to Whites, proving that the policy measures put in place to help the individuals in need have performed well. The same can be pointed out for women, compared to men. Nevertheless, older adults are more likely to lose their jobs than younger individuals but less likely to get financial support: this is probably due to a higher monetary wealth that they might be able to tap into, making them more capable than younger individuals to absorb income shocks. However, this may not be true for all, and policymakers should ensure that older individuals who got financially affected by the pandemic are adequately assisted.

We also show that, as time goes by, it becomes increasingly likely for citizens to lose their jobs, although financial support does not seem to be constant over time.

As this pandemic keeps spreading and uncertainty increases, understanding how people react is crucial with a view to helping those in need. By doing so, we will be able to build back better in a post-COVID-19 world.

A network approach to investigate learning experiences and social support in higher education

Un approccio di rete per esplorare le esperienze di apprendimento e il supporto sociale degli studenti universitari

Ilaria Primerano, Maria Carmela Catone, Giuseppe Giordano, Maria Prosperina Vitale

Abstract The shift to distance learning during the Covid-19 pandemic generated a wide use of online services and platforms. The present contribution - based on a survey of students enrolled in an undergraduate degree course - aims at exploring the impact of online education on students' learning experiences and habits. Using a network analysis approach, we investigated students' learning perceptions, the types of social support, the collaborative behaviours students' learning perceptions and the interconnection of these aspects with the individual performance.

Abstract *Il passaggio alla didattica a distanza durante la pandemia da Covid-19 ha generato un ampio utilizzo di servizi e piattaforme online. Questo contributo – basato sulla realizzazione di un'indagine rivolta agli studenti iscritti ad un corso di laurea triennale - è finalizzato a esplorare l'impatto della didattica online sulle abitudini e sulle modalità di apprendimento degli studenti. Utilizzando un approccio di network analysis è stato possibile indagare le percezioni di apprendimento degli studenti, le tipologie di supporto sociale, i comportamenti collaborativi che emergono negli ambienti virtuali e l'interconnessione di tali aspetti con le performance individuali.*

1 Introduction

The Covid-19 pandemic has affected the education system forcing universities to adopt emergency forms of teaching by using online digital platforms [1] [2] [3]. Since the first phase of the pandemic, university students experienced different modalities of online teaching, from full distance to blended teaching, showing their resilience in dealing with different situations imposed by the health emergency. The dematerialization of teaching and learning processes have produced several effects on students experience in terms of spaces, times, tools, methods, contents and social relationships.

Several studies investigated the factors affecting university life during pandemic. Some authors explored the expectations underpinning the distance learning processes supported by digital tools and resources [4]. The technological, pedagogical, financial, and social issues were also studied [5] [6]. Furthermore, students' perceptions have been investigated by considering the role of prior digital skills [7], the effects on individual performance [8], the satisfaction for the online teaching and services [9], as well as the kinds of collaborative behaviours and social support among individuals [10].

Moving from this theoretical framework, we aim to address the following research questions: *i) How do prior individual digital skills affect students' abilities during distance learning? ii) Which kind of social support and collaborative behaviours are developed among students during pandemic? iii) How do students perceive and define the online learning experience?*

Based upon these questions, a pilot study is carried out on students enrolled in an undergraduate program to investigate how these aspects are related to individual performances. Different network data arises in terms of adjectival networks and social support networks.

The contribution is structured as follows. Section 2 presents questionnaire design, data collection and methods to deal with network data structures. Preliminary findings and some concluding remarks are reported in section 3.

2 Data collection and methods

This contribution aims at studying the effects of digital learning and digitalization process on university students' experiences and collaborative behaviours.

A pilot study has been designed in order to investigate different aspects, regarding the prior digital skills to support learning, the use of online platforms, the university life experience with its emotional connotation, the kinds of social support arising in virtual environments, the students' learning abilities and their performance. The research instrument designed to collect primary data is an online questionnaire structured in several sections, as described in Table 1.

Specifically, different network structures can be derived by the *perception* and *social support* sections. As regards students' perceptions of distance learning expe-

rience, semantic differential scales give raise to the definition of networks of adjectives [11, 12]. Twelve pairs of opposite adjectives have been chosen, describing the different aspects related to *distance learning activities*, *use of digital platform*, *online interactions*, and *self-study attitude*. Thus, the semantic differential scores are used to define valued networks characterizing the emotional meaning of the investigated concepts.

In the social support section, a 7-points Likert scale has been considered to measure students' agreement about *affiliative*, *informational*, *emotional*, and *instrumental* support items [13]. Moreover, a role relation approach [14] has been adopted to study the tangible and intangible relationships. As result, it is obtained a description of roles played by those figures (colleagues, friends, parents, etc.) who were involved in the students' support networks, helping them during pandemic.

Table 1: Questionnaire sections and descriptions

Section	Description
National and international mobility	Student's choice to move in another university within the national territory or to participate in the Erasmus+ international mobility programme
Use of digital tools	Kinds of device to access online platforms, ease and frequency in the use of interactive tools, and activities carried out together with other students and teachers
Prior digital skills	Skills measured according to the key components developed by the European Digital Competence Framework for Citizens (EU DigComp 2.1)
Perception	Students' perception of distance learning defined by opposite pairs of adjectives included in Semantic Differential scale
Social support	Students' collaborative behaviours emerging in virtual environments and the different kind of support to face with specific issues
Satisfaction	Students' opinions on distance learning experience related to platform's functionality, learning capabilities, organization of activities, effectiveness of distance learning, quality of the relationship between peers and teachers
Services evaluation	Students' assessment on usability of distance learning technological solutions, effectiveness of online teaching methods, and overall satisfaction
Performance	Students' exams grade, number of exams passed, and career progression

3 Preliminary results

The first results about the social support section and the network approach are reported. Specifically, as regards the analysis of perceived social support scales, Fig.1

shows students agreement about the twelve items used to measure the four considered dimensions: affiliative (*I1-I3*), informational (*I4-I6*), emotional (*I7-I9*), and instrumental (*I10-I12*). The seven-points Likert scale ranges from ”fully disagree” to ”fully agree” with a neutral option at the midpoint. In the stacked bar chart in Fig.1 each item corresponds to a bar centred on the neutral value (score 4) located in correspondence of the *O%* value on the horizontal axis. This value splits the disagreement responses (scores 1 to 3, on the left) from the agreement ones (scores 5 to 7, on the right). The responses with neutral score has been equally divided between agreement and disagreement.

Notice that, we combine in the same scale ten positively formulated items and four reversed ones (i.e., *I2*, *I4*, *I7*, and *I9*). Our findings show that respondents feel confident about their perceived social support circle, as they positively rated almost all items. This is particularly evident for the items related to the instrumental support: students are aware that among their acquaintances there is somebody ready to help them if they were dealing with a problematic event. Students also feel integrated in their community of friends with whom spent their time and share their personal affairs. They think to be able to maintain friendship relations and that there is certainly someone who is proud of their achievement.

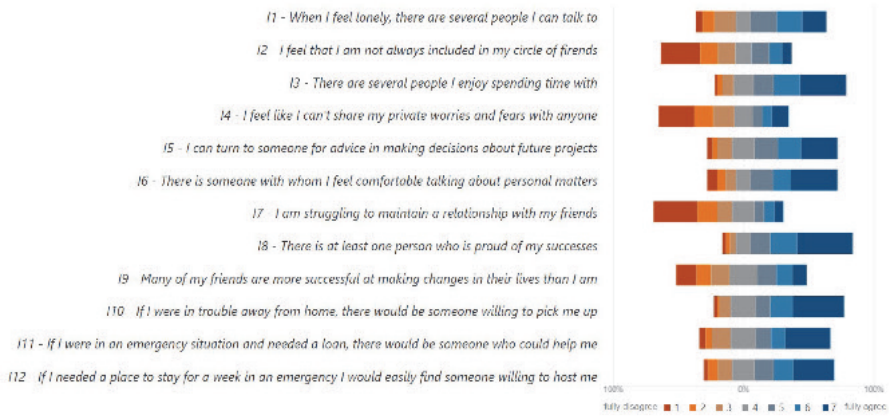

Fig. 1: Stacked bar chart of the perceived social support dimensions: affiliative (*I1-I3*), informational (*I4-I6*), emotional (*I7-I9*), and instrumental (*I10-I12*).

To outline the person profiles to whom students turn for social support, we asked to identify the three profiles they have addressed or would address to deal with specific circumstances. Fig.2 represents the bipartite graphs of the two-mode networks derived from both hypothetical and concrete social support dimensions, where links are defined only between nodes belonging to the two different sets (i.e., students and person profiles). Nodes are shaped and coloured according to the set they belong to and the type of support. Red square is used for person profiles, dots represent

students requiring concrete (black), and hypothetical (grey) support. The network is analysed by looking at the role played by the most relevant person profiles. In general, family of origin members, friends, and students enrolled in the same undergraduate program are the most central profiles in terms of network centrality degree. At the same time, the network representation allows to enhance the joint presence of different person profiles chosen by the same student. For instance, in Fig.2b on the top right, we notice a student pointing out to counseling, student association and professor when asking for emotional support. Specifically, as regards the *instrumental support* (Fig. 2a) some differences can be seen when comparing the relationships established for concrete and hypothetical support. In the first case, students mainly refer to peers and extended family members, while in the second one presence of family of origin (mother and father, brother and sister) is prominent. Furthermore, for *emotional support* (Fig.2b) students address, above all to their family of origin, then in the *informational support* network (Fig. 2c) the importance of peer relationships clearly emerges due to the relevance of both students enrolled in the same university program and friends.

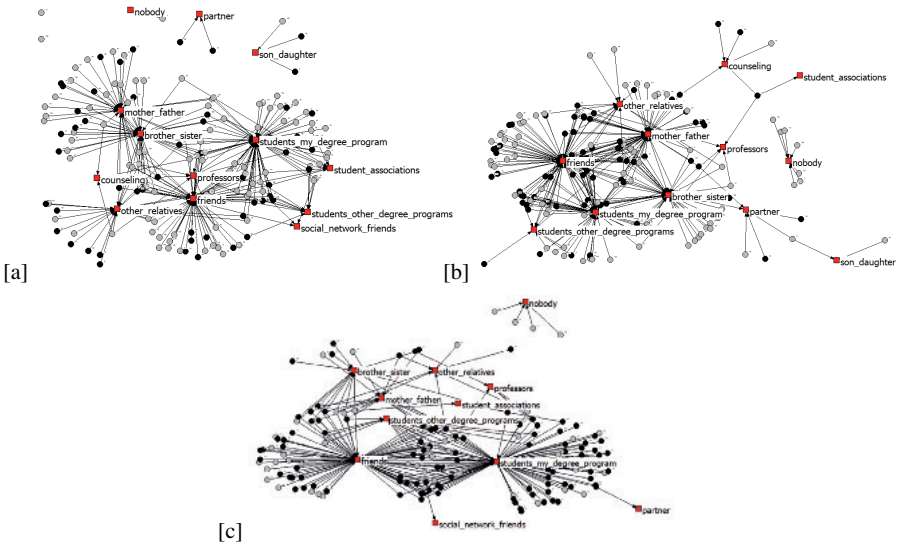

Fig. 2: Bipartite graph visualization of two-mode networks *students*-by-*support person profiles*: a) instrumental support; b) emotional support; c) informational support. Node color: hypothetical support (grey), concrete support (black), types of support person profiles (red)

Furthermore, the survey provides a detailed picture of students experience by highlighting levels of awareness and socialization towards digital tools. The interconnection between technological and social components characterizing the distance learning process is considered. In addition, the effect of relationships, defining

the university social life experience, are evaluated in explaining students' academic performance by controlling for individual covariates.

Physical and cultural activity, internet use and anxiety of Italian university students during the pandemic

Attività fisiche e culturali, uso di internet e ansia degli studenti universitari italiani durante la pandemia

Giovanni Busetta, Maria Gabriella Campolo and Demetrio Panarello

Abstract

The lockdown tends to produce an increase in mental distress such as anxiety through physical and psychological channels, which are correlated with daily life habits such as disturbed eating and sleeping behaviors, as well as variations in physical and cultural activity and internet use. The aim of this paper is to measure the impact of physical, cultural and internet-related activities on anxiety. Specifically, we focused on the differences in this relationship between the pre-pandemic and pandemic periods. To do so, we administered two questionnaires to several university students from three different universities belonging to the South, Center and North of Italy, at the beginning of the pandemic and at one year's distance. The survey also included a psychological test, the STAI-Y, which measures state and trait anxiety.

Abstract

Il lockdown tende a produrre un incremento del disagio mentale come l'ansia, che sono correlati alle abitudini della vita quotidiana. Tali variazioni possono riguardare disturbi nel mangiare e nel dormire, nonché variazioni nell'attività fisica e culturale e nell'uso di Internet. Lo scopo di questo lavoro è misurare l'impatto dell'attività fisiche, culturale e l'utilizzo di Internet, sull'ansia. Nello specifico, ci siamo concentrati sulle differenze in questa relazione tra il periodo pre-pandemia e quello pandemico. Per farlo abbiamo somministrato due questionari agli studenti universitari di tre diversi atenei del Sud, Centro e Nord Italia, all'inizio della pandemia e a distanza di un anno. L'indagine utilizza un test psicologico, lo STAI-Y, che misura l'ansia di stato e di tratto.

Key words: STAI test; Coronavirus outbreak; Pandemic; Mental health; Physical activity; Internet use; State and Trait Anxiety.

1 Introduction

Physical activity (from now on PA) is defined as "any bodily movement produced by skeletal muscles that results in energy expenditures… Exercise is a subset of physical activity that is planned, structured, and repetitive and has as a final or an intermediate objective the improvement or maintenance of physical fitness" (Caspersen et al., 1985). 150 min of moderate or 75 min of vigorous PA activity per week is considered to be protective against factors such as depression (Schuch et al., 2018) and anxiety (Schuch et al., 2019), according to the International PA guidelines (WHO, 2018).

Several studies detected a decrease in PA in multiple countries (Bauer et al., 2020; Schuch et al., 2020; Mattioli et al., 2020) during the current pandemic.

Also, the relationship between internet use and anxiety is considered controversial by the main literature. On the one side, internet-use disorders are generally caused by depression, anxiety, and loneliness (Longstreet et al., 2019). On the other side, gambling, online gaming, and social media use may produce states of anxiety and depression (Brand et al., 2019).

Considering specifically the current COVID-19 pandemic, the connected period of quarantine and the consequent reduction of social contacts acted as stressors on anxiety, negative emotions (Al-Kamdari and Al Sejard, 2020; Gao et al., 2020) and economic difficulties. The association between anxiety and internet use has been specifically studied and identified for the current pandemic (Planchuelo-Gomez et al., 2020; van der Velden et al., 2020).

According to several scholars, being male and/or young increases the risk of internet overuse. Some authors (Elhai et al., 2019; Yang et al., 2020) showed a significant correlation between problematic use of smartphones and mental health symptoms such as depression and anxiety. Finally, the increase in internet use could also be connected to the uncertain future, because of the need to escape from reality (Biolcati et al., 2017), and this increase is usually more pronounced for individuals presenting higher levels of anxiety (see Masaeli and Farhadi, 2021 for a review).

The aim of this paper is to measure the impact of physical, cultural and internet-related activities on anxiety. Specifically, we focused on the differences in this relationship between the pre-pandemic and pandemic periods. To do so, we administered two questionnaires to several university students from three different universities belonging to the South, Center and North of Italy, at the beginning of the pandemic and at one year's distance. The survey also included a particular psychological test, the STAI-Y, which measures state and trait anxiety.

Most previous studies with a similar research question are at risk of being affected by sample self-selection, due to the delicate nature of the topic. In our study, we overcome this problem by observing anxiety levels of the same individuals at different points in time (pre-pandemic, at the beginning of the pandemic and at one year's distance).

2 Data and Methods

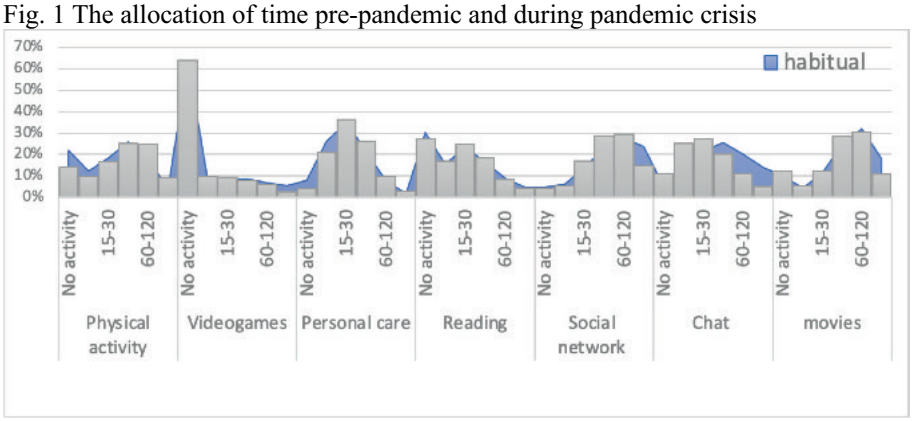
We collected data from an ad hoc questionnaire, administered to the students of three Italian universities located in Messina, Udine, and the Marche Polytechnic University one year after the lockdown, when Italy has been divided into three "colored" zones (red, orange, yellow), characterized by different restrictive measures on the basis of the severity of the spread of COVID-19 at the regional level (Panarello and Tassinari, 2021). The survey collected information on a total sample of 3,580 students.

In addition to gathering demographic information, the survey addresses the following topics: economic, labor, context-based, on-line teaching, time use, and psychological well-being features. About the last topic, to evaluate the level of anxiety we administered the State-Trait Anxiety Inventory (STAI-Y) composed of 40 items rated on a 4-point Likert scale. The first 20 items refer to the respondents' feelings "at this moment" (State), while the last 20 items evaluate the "usual" frequency of feelings (Trait). The score of each subtest ranges between 20 and 80. While the mean value of the State score is 54.85 (Std. Dev. 12.015); the Trait score one is 46.34 (Std. Dev. 10.940).

We collected information about the allocation of time considering two different moments, pre-pandemic and during the pandemic in the following activities: physical activity, videogames, personal care, reading, social network, chat and watching movies.

In the following graph (Fig. 1) we show the time (minutes per day) dedicated to different activities. For each activity we considered the following scale: No activitiy; less than 15 minutes; between 15 and 30 minutes; between 30 and 60 minutes; between 60 and 120 minutes and finally more than 120 minutes. In blue we show the distribution of the time devoted to the activities pre-pandemic and in grey the time spent during the pandemic.

Fig. 1 The allocation of time pre-pandemic and during pandemic crisis



Students who declare they did not exercise before the pandemic were 22% versus 14% during the pandemic, and the percentage of those who perform more than one hour of physical activity increases from 22% (15% 60-120 minutes; 4% over 120 minutes) to 34% (25% and 9%, respectively). More than 60% of students said they did not play video games, while the percentage of those who played more than an hour in the pre-pandemic period was 13% (6% during the pandemic). The percentage of those who did not dedicate time to read decreased, and the percentage of students who spent at least half an hour on this activity during the pandemic increased. Finally, concerning the time dedicated to watch movies, we can see no relevant differences in the trend of the two distributions.

3 Methods and Results

We separately estimate state anxiety and trait anxiety to evaluate the different impact of PA, internet use and cultural activities on habitual (Trait score) and current (State score) level of anxiety. While trait anxiety is defined as "an individual's predisposition to respond and state anxiety as a transitory emotion characterized by physiological arousal and consciously perceived feelings of apprehension, dread, and tension" we use the two typologies of anxiety to measure pandemic and pre-pandemic mental distress.

In the following table we report the results of our models. First, in terms of gender inequalities, being a woman produces an increase in anxiety, both habitual and current. High levels of trait anxiety are correlated with higher increases in anxiety during pandemic. Studying at Università Politecnica delle Marche is correlated with higher levels of anxiety compared to University of Messina and Udine. Furthermore, being more than 26 years old is correlated with higher both pandemic and pre-pandemic levels of anxiety.

PA is always correlated with lower levels of anxiety and this relationship is more pronounced for anxiety during pandemic, with respect to what happened previously. Videogaming increases trait anxiety when it overcome 30 minutes a day, but it has not any statistically significant effect on state anxiety. Social media increases both trait and state anxiety, but this relationship hold only for high levels of its use. The act of reading is negative correlated with both the categories of anxiety. Watching movies is correlated with higher levels of both trait and state anxiety, but this relationship appears only if more than two hours a day are devoted to this activity. Time devoted to personal care is negatively correlated with both pandemic and pre-pandemic anxiety. Not using chat at all is correlated with lower levels of trait anxiety, while using chat more than two hours a day produces an increase in state anxiety.

The digital divide in Italy before and during the pandemic phase

Il divario digitale in Italia prima e durante la fase pandemica

Laura Zannella

This study uses microdata from the Community Survey on ICT use by households and individuals to examine the digital divide in Italy on the basis of two dimensions: access to the internet (frequency of use of the network), levels of digital skills. The interest is focused on the analysis of the changes occurred in the digital divide before and during the pandemic phase (2019-2021) with reference both to the overall Italian population aged 16-74 years and to its particular segments. By logistic regression models will be analyzed the changes between the years and their interaction with a set of socio-demographic and territorial variables on both the frequency of Internet use and levels of digital competence

Questo studio utilizza i microdati dell'indagine comunitaria sull'uso delle ICT da parte delle famiglie e dagli individui per esaminare il digital divide in Italia sulla base di due dimensioni: accesso ad internet (frequenza di utilizzo della rete), i livelli delle competenze digitali. L'interesse è concentrato sull'analisi dei cambiamenti intercorsi nel digital divide prima e durante la fase pandemica (2019-2021) con riferimento sia al complesso della popolazione italiana in età 16-74 anni che a suoi particolari segmenti. Mediante modelli di regressione logistica verranno analizzate le variazioni tra gli anni e la loro interazione con un set di variabili socio-demografiche e territoriali sia sulla frequenza di utilizzo d'Internet che sui livelli di competenza digitale.

Key words: digital skill, digital divide, ICT

Introduzione

La pandemia di Covid-19 ha accelerato l'utilizzo delle tecnologie digitali nei diversi ambiti della vita quotidiana evidenziando il potenziale delle ICT (information and communication technology) per consentire l'esercizio dei diritti fondamentali come quelli legati all'istruzione e alla salute, ma ha anche messo in luce come i divari digitali condizionano l'inclusione sociale. Il 19 marzo 2021 la Commissione europea ha proposto una visione per la trasformazione digitale dell'Europa entro il 2030, che si sviluppa intorno a quattro cardini: competenze digitali, infrastrutture, trasformazione digitale delle imprese, digitalizzazione dei servizi pubblici. Nel settembre 2021 la Commissione ha introdotto un quadro di governance per raggiungere gli obiettivi digitali sotto forma di un percorso per il decennio digitale. Successivamente, il 26 gennaio 2022, la Commissione ha proposto al Parlamento europeo e al Consiglio di sottoscrivere una dichiarazione sui diritti e i principi che guideranno la trasformazione digitale nell'UE. Il progetto di dichiarazione riguarda diritti e principi fondamentali per la trasformazione digitale, quali porre al suo centro le persone e i loro diritti, sostenere l'inclusione, promuovere la partecipazione allo spazio pubblico digitale, aumentare la sicurezza, l'autonomia e la responsabilità delle persone e promuovere la sostenibilità del futuro digitale.

L'Istat attraverso l'indagine comunitaria "Uso delle tecnologie dell'informazione e della comunicazione da parte delle famiglie e degli individui" produce annualmente indicatori condivisi a livello europeo per valutare, monitorare e reindirizzare le politiche attuate dal governo in materia di ICT.

Il principale obiettivo di questo lavoro è quello di analizzare l'andamento del divario digitale nel nostro Paese. Mediante l'analisi dei micro-dati dell'indagine Istat si intende rispondere alle seguenti domande di ricerca: tra il 2019 e il 2021 è aumentato il ricorso all'utilizzo di internet? I divari digitali tra i diversi segmenti della popolazione sono aumentati o diminuiti? Ad una maggiore utilizzo della rete ha corrisposto un miglioramento delle competenze digitali?

1.1 Dati e metodi

Questo studio, si basa sui micro dati dell'indagine comunitaria sull'uso delle tecnologie della comunicazione e dell'informazione, condotta annualmente dall'Istat su un campione probabilistico di circa 24.000 famiglie e 54.000 individui. Con l'indagine ICT vengono rilevate informazioni sulle caratteristiche socio-demografiche degli individui (sesso, età, livello d'istruzione, occupazione, risorse economiche, territorio di residenza, etc.) e informazioni dettagliate sull'uso di internet: (tipo di connessione, frequenza di utilizzo, attività svolte, competenze digitali, etc.).

Il concetto di divario digitale viene reso operativo facendo riferimento a due dimensioni: l'accesso e le competenze digitali. Per quanto riguarda l'accesso (divario digitale di primo livello) viene analizzata l'a frequenza con cui ci si

connette ad internet. Sulla base della frequenza sono state individuate tre tipologie di utente: assiduo, è una persona che ha utilizzato internet tutti i giorni nei tre mesi precedenti l'intervista; utente settimanale, che si è collegato ad internet qualche volta a settimana ma non tutti i giorni, l'utente e sporadico che ha utilizzato internet qualche volta al mese nei 3 mesi precedenti l'intervista.

Ad ognuna delle tre definizioni corrisponde una variabile dummy che assume il valore 1 se la persona presenta quella caratteristica e il valore 0 altrimenti. Per analizzare i cambiamenti intervenuti tra il 2019 e il 2021 sono stati utilizzati tre modelli logistici, uno per ciascuna delle seguenti variabili dipendenti: P_1 = probabilità di essere un utente assiduo, P_2 = probabilità di essere un utente settimanale, P_3= probabilità di essere un utente sporadico. Sono state considerate le seguenti variabili esplicative categoriche: Y=Year (2019,2021), X_1= Gender (men, women), X_2= Age group (16-24, 25-34, 35-44, 45-54, 55-64, 65-74), X_3= Education level (high, medium, low), X_4= Occupational level (high, medium, low, unemployed), X_5= Geographic area of residence (north-west, north-est, centre, south, islands), X_6=Type of municipaljty (metropolitan area, over 50.000 inhab, 10,000-50.000 inhab, until 10.000 inhab), X_7=Family economic resource (very googd, good, bad, very bad).

Poiché l'obiettivo dell'analisi è quello di valutare i cambiamenti intercorsi tra i due anni, viene utilizzato un modello logistico comprendente tutti gli effetti semplici e gli effetti interattivi di Year con le variabili esplicative. Indicando con P la variabile dipendente, con m il numero di variabili esplicative, con X_r la r-ma variabile esplicativa e con h_r il numero delle sue modalità, per ciascun individuo i del campione il modello logistico può essere scritto come segue:

$$\text{logit}\left(P_i\right) = \log\left(\frac{P_i}{1-P_i}\right) = \alpha + \sum_{j=1}^{2}\beta_j Y_{ji} + \sum_{r=1}^{m}\sum_{s=1}^{h_r}\gamma_{rsi}X_{ri} + \sum_{j=1}^{2}\sum_{r=1}^{m}\sum_{s=1}^{h_r}\lambda_{jr}Y_{ji}X_{ri} + \varepsilon_i$$

$$i = 1,2,\ldots,n$$

I parametri del modello vengono stimati con il metodo della massima verosimiglianza, utilizzando la procedura proc logistic del Sas. La procedura fornisce le stime dei parametri e i corrispondenti errori standard, calcola i test relativi alla significatività complessiva del modello e delle singole variabili esplicative, consente di effettuare i confronti tra le diverse modalità di ciascuna variabile esplicativa. I confronti tra coppie di modalità sono basati sull'odds ratio, ossia sul rapporto tra gli odds delle due modalità. L'ipotesi nulla di uguaglianza dei due odds viene testata mediante il test di Wald basato sul rapporto tra le funzioni di verosimiglianza.

Successivamente, l'analisi si concentra sui divari digitali di secondo livello legati alle competenze digitali. Per la misurazione delle competenze digitali è stato adottato il quadro concettuale definito dalla Commissione europea in collaborazione con gli istituti nazionali di statistica. Le persone che hanno utilizzato internet negli ultimi 3 mesi vengono classificate sulla base delle attività svolte in quattro domini di competenza digitale: information, comunication, content-creation, problem-solving. Per ciascun dominio sono previsti tre livelli di competenza (below basic, basic, above basic), attribuiti sulla base del numero di attività svolte. A seconda del

dominio di competenza il numero di attività varia da un minimo di quattro a un massimo di nove. Le persone che non hanno utilizzato internet nei tre mesi precedenti l'intervista sono classificate come "without digital skills". I valori dei quattro indicatori di dominio vengono utilizzati per elaborare un indicatore complessivo dei digital skill con quattro modalità:

- above basic. competenze superiori a quelle di base in tutti e quattro i domini.
- basic, competenze di base (o superiori) nei quattro domini
- belowe basic. competenze inferiori a quelle di base in almeno un domini
- none digital skill, nessuna competenza in tutti e quattro i domini

L'analisi delle variazioni dei livelli dei digital skill nella popolazione italiana in età compresa tra i 16 e i 74 anni tra il 2019 e il 2021 è stata condotta applicando un modello logistico lineare analogo al precedente, nel quale la probabilità che un individuo disponga di competenze digitali di base o superiori è messa in relazione con l'anno di riferimento dell'indgine e il set di variabili socio-demografiche e territoriali

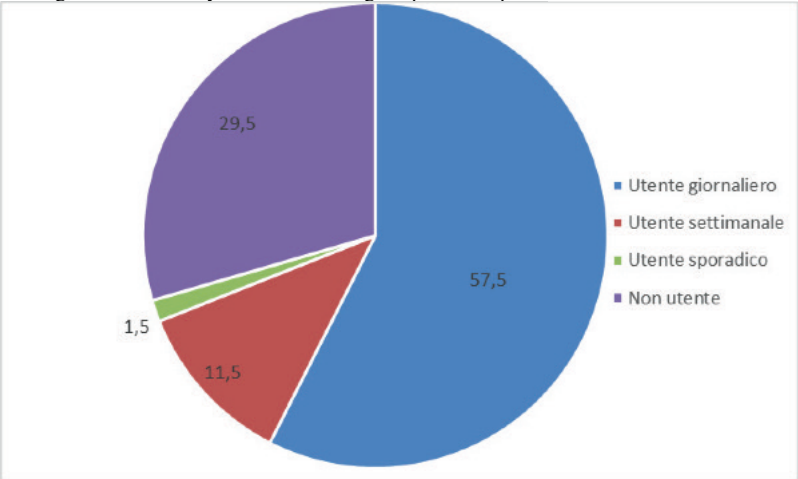
1.2 Risultati preliminari [1]

I risultati descrittivi forniscono una prima evidenza empirica delle relazioni esistenti tra i tassi di utilizzo di Internet e alcune delle caratteristiche "strutturali" della popolazione come il sesso, l'età, il livello di istruzione, status professionale, posizione nella professione, frequenza d'uso di Internet. Come mostrato nella figura1 nel 2020 la distribuzione della popolazione italiana di 6 anni e più genera tre gruppi principali: gli utenti giornalieri 57,5%; i non utenti, circa il 29,5% e le persone che si rapportano a Internet in modo poco intenso. Nel 2020 oltre l'80% dei ragazzi in età 15-24 anni è un utente giornaliero mentre tra i 60-64-enni la quota di internauti assidui scende al 50,1% e arriva al 30% tra le persone di 65-74 anni.

Tra il 2019 e il 2020 si registra un incremento degli utenti di internet. Ad aumentare è la quota di unteti giornalieri (+4 punti percentuali), mentre tra gli utenti settimanali o sporadici non si registrano variazioni significative. Sono soprattutto i ragazzi di 6-14 anni a far registrare gli incrementi maggiori +11,5, incrementi sensibili si registrano anche tra la popolazione anziana di 60-64 anni +6,3. Per quanto riguarda le competenze digitali nel 2019 il 35,8% degli utenti di internet giornalieri di 16-74 anni ha competenze digitali basse, il 27,9% ha competenze di base e solo il 34,6% ha competenze elevate.

Figura1 *Persone di 6 anni e più per frequenza d'uso d'Interne*t .Anno 2020

[1] Le elaborazioni sono limitate al 2020 in quanto i micro dati dell'indagini Istat del 2021 saranno disponibili a breve.



L'età resta un fattore importante ma non decisivo: i giovani di 20-34 anni hanno livelli avanzati di competenze (Figura 2a). Se si analizzano separatamente le quattro dimensioni in base alle quali è calcolato l'indicatore composito emerge che gli internauti hanno competenze digitali più avanzate per e-skill legati al dominio della comunicazione (78,8%) e dell'informazione (68,3%) rispetto a quelli collegati alla capacità di risolvere problemi (57,1%) e di utilizzare software per trattare/veicolare contenuti digitali (48,9%) (Figura 3b).

Covid-19 and financial professional advice

Consulenza finanziaria professionale e Covid-19

Marianna Brunetti and Rocco Ciciretti

Abstract This paper empirically investigates the use of financial professional advice by households and the effects on it of the outbreak of Covid-19 pandemic. Based on a new panel dataset provided by Consob, we estimate that the households suffering an income reduction induced by the lockdown due to the Covid-19 outbreak reacted resorting to professional financial advice more than their counterparts having a stable income during the same period. Dissecting the results, we show that this effect is driven by the more financially sophisticated households. These results survive to a variety of robustness checks and support the hypothesis that financial literacy might act as a complement of, rather than a substitute to, financial professional advice.
Abstract *Il lavoro analizza empiricamente la decisione di avvalersi di un consulente finanziario durante la pandemia da Covid-19, sulla base di un dataset appositamente predisposto in collaborazione con Consob. Le stime ottenute mostrano come le famiglie che hanno subìto una riduzione di reddito a causa delle misure restrittive volte ad arginare la diffusione del Covid-19 abbiano reagito rivolgendosi a consulenti finanziari professionali con maggiore probabilità rispetto a famiglie comparabili ma che durante lo stesso periodo non hanno subito riduzioni di reddito. Analisi di eterogeneità mostrano come questo risultato sia guidato dalle famiglie con maggior grado di fiducia nella figura del consulente finanziario e da quelle con maggiori conoscenze finanziarie, supportando l'ipotesi che sofisticazione finanziaria e consulenza professionale siano complementi piuttosto che sostituti.*

Key words: financial professional advice, financial literacy, covid-19, household finance, trust

1 Introduction

The outbreak of Covid-19 pandemic in the early months of 2020 has subverted the lives and projects of households under many aspects, albeit the economic consequences of the imposed closures and lockdown have been heterogeneous, depending e.g. on the employment status and the type of occupation (see e.g. Guiso and Terlizzese, 2020). In this paper we empirically investigate the effect it had on the use of financial professional advice. The first key strength of our empirical strategy is that the Covid-19 break we exploit was largely unexpected, thus providing an ideal quasi-natural experiment, which we exploit using a difference-in-differences methodology to compare propensities of a treated group (the households working in the private sector that underwent a sensible reduction of their income due to the Covid-19 first outbreak) with a control group of households (those working in the public sector and those in the private sector having not experienced an income reduction). Hence, we are plausibly able to identify a causal relationship between the reduction in the income, and the hike in financial advice search among the households economically affected by the Covid-19 restrictions and closure implemented to face the first outbreak of the pandemic. Another strength of this study is that the empirical analysis relies on a new and representative household panel survey dataset, provided by the Consob, the public authority responsible for regulating the Italian financial market, which allows us to control for a significant set of household characteristics, not only including the classical demographic and socio-economic controls, but also measures of trust and a pretty thorough measure of financial literacy.

2 Methodology

The dataset is obtained based on a survey administered every year since 2017 by GFK to around 3,000 randomly selected households, half of whom are rotating panel units, producing a final dataset that is population-representative. We use the panel component of the last three waves, referring to 2019, 2020 and 2021. The questionnaire comprises about a hundred questions, ranging from the demographic and socio-economic characteristics of the household, to investment preferences and choices, saving habits, financial knowledge and the consultation of a professional financial advisor, which we use as outcome variable. In the 2020 wave we also have information about whether the household experienced income reduction in the light of the restrictions imposed during the first months of 2020, when the pandemic firstly hit Italy. We use this information, along with the occupational condition of the financial respondent, to identify two groups. One, representing our control group, includes retirees and public employees, who overall have not experienced income reduction and, in many cases, have even increased their savings. The other one, representing our treatment group, includes self-employed, who by construction have to deal with an uncertain income, as well as private employees who declared a

reduction in their income in the verge of the lockdown, having them faced an unprecedented and definitely unexpected shock to their labour income, often having to draw down their savings, if any.

We then estimate the following regression:

$$FA_{it} = \alpha_0 + \alpha_1 \boldsymbol{Treated}_{it} + \alpha_2 \boldsymbol{Post}_t + \alpha_3 (\boldsymbol{Treated}_{it} \times \boldsymbol{Post}_t) + \mathbf{X}_{it}\boldsymbol{\theta} + \varepsilon_{it}$$

where FA_{it} takes value 1 if household *i* at year *t* declared having had contacts with a financial professional advisor in the previous 12 months, and 0 otherwise; $\boldsymbol{Treated}_{it}$ is defined as treatment above $\boldsymbol{Post}_t$ is a binary variable taking the value of 1 if the survey refers to the period after the Covid-19 outbreak, i.e. starting from 2020, and 0 otherwise. Finally, $\mathbf{X}_{it}$ is a vector of control variables, and ε_{it} is the error term

In line with the literature, the vector of controls includes a wide set of socio-economic and demographic characteristics that may affect the households' economic decisions (see, e.g., Guiso and Sodini, 2012), namely area of residence, income and net wealth, household size, and homeownership as well as age, gender, marital status, education employment status of the financial respondent. Moreover, we also control for the level of financial knowledge, assessed based on a set of 5 questions covering notions like the risk-return relationship, real interest rates, compound interest rate, diversification and mortgages.

We are interested in the coefficient α_3, which we estimate via OLS, as it measures the differential effect of the change induced by the pandemic across the households that underwent an income shock (treated) and those that did not (control). The common trend assumption, crucial in any DiD specification, is verified both graphically and statistically.

3 Main Results

Results reported in Table 3, column (1) prove that household experiencing an income reduction due to the Covdi-19 lockdown are 16,6 percentage points more likely to appeal to financial advice after the pandemic than a comparable household in the control group. Moreover, dissecting by level of financial literacy, in Columns (2) and (3), and by level of trust in the financial advisor, Columns (4) to (7), proves that the results are driven by households with a higher financial literacy and those that actually trust these professional figures. Two conclusions can be drawn: first, financial literacy does not act as a substitute to professional financial advice, it rather acts as a complement to it. This result is in line with what reported e.g. in Kim et al (2021). Second, trust in professional advisors is a key element, thus calling for interventions aimed at further increasing the credibility of these figures.

Table 1: Use of financial advisory before and after the pandemic

Estimates	(1)	(2)	(3)	(4)	(5)	(6)	(7)

Bayesian functional mixed effects model for sports data

Modelli funzionali Bayesiani a effetti misti per dati sportivi

Patric Dolmeta, Raffaele Argiento and Silvia Montagna

Abstract The use of statistical methods in sport analytics is common practice nowadays. In this work, we propose a hierarchical Bayesian model for describing and predicting the evolution of performance over time for shot put athletes. We address seasonality and heterogeneity in results by means of a linear mixed effects model with heteroskedastic errors. The model provides an accurate description of the performance trajectories and allows for prediction of athletes' performance in future seasons. We apply our method to an extensive real world data set on performance data of professional shot put athletes recorded at elite competitions.

Abstract *L'impiego di metodi statistici per lo studio dello Sport è ormai largamente diffuso. In questo lavoro, proponiamo un modello Bayesiano gerarchico per la descrizione e la previsione di risultati nel tempo per lanciatori del peso. Grazie a un modello lineare ad effetti misti con errori eteroschedastici, affrontiamo stagionalità e eterogeneità nei risultati. Applichiamo il metodo ad un dataset reale di grandi dimensioni contenente i risultati del lancio del peso in un gran numero di competizioni internazionali e osserviamo una soddisfacente descrizione dei dati e la possibilità di quantificare l'incertezza nelle previsioni di performance future.*

1 Introduction

Shot put is a track and field event involving throwing ("putting") the shot as far as possible. Shot put events range over the whole year, with indoor competitions held during Winter months and major tournaments during the Summer. So, results display some sort of seasonality, as it is common to all sportive competitions. We underline that here the term "seasonality" is not used to indicate a cyclical behaviour of observations over time, as in the literature of time series but, rather, a time dependent gathering of observations. On one hand competitions are traditionally concentrated in some months of the year, and on the other hand weather and environmental conditions may affect the performances or even the practicability of the sport itself. In shot put, it is reasonable to say that seasons coincides with calendar years and that taking seasonality effects into account is necessary to provide an accurate representation of the data.
In this work, we are interested in describing the evolution of performances of professional shot put athletes throughout their careers. We describe results of each athlete as error prone measurements of seasonal means trough a Bayesian mixed effects model, that describes the seasonal mean for each athlete as a deviation from a grand mean.

2 The World Athletics shot put data set

The data was obtained from an open results database (www.tilastopaja.eu) following institutional ethical approval (Prop_72_2017_18). The dataset comprises 41,000 measurements of World Athletics (the world governing body for track and field athletic sports) recognized elite shot put competitions for 653 athletes from 1996 to 2016. For each athlete, the data set reports the date of the event, the shot distance in meters, an indication of doping violation and some demographic information.
The outcome of interest is the shot distance. Data are collected over time: hereafter we will denote as t_{ij} the time at which the j-th observation for athlete i is recorded. t_{ij} corresponds to the time elapsed from January 1st of each athlete's career starting year to the date of the competition. Having described seasons as calendar years, athletes will compete in a different number of seasons according to their career length. Figure 1 shows the number of athletes per season as well as boxplots of the distribution of their mean performances across the various seasons. A general increasing trend in performance can be observed as a function of career length (right panel in Figure 1).

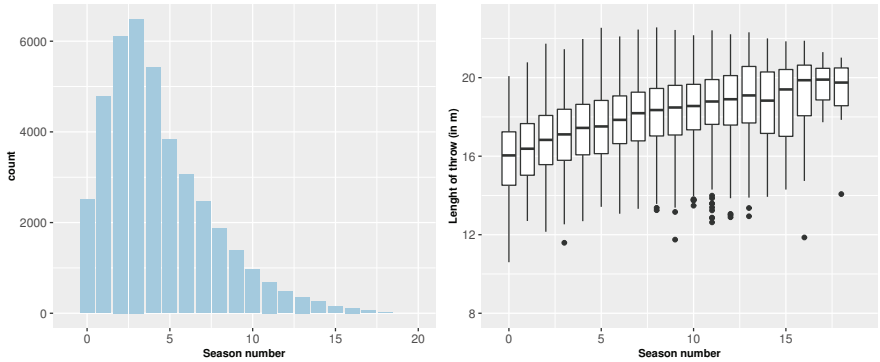

Fig. 1 Left: total number of athletes per season. Right: each boxplot shows the distribution of the athletes' mean performances within each season.

3 The model

Let n be the total number of athletes in the study. Shot put performances for athlete i collected over time represent temporal grouped data that we expect to be correlated when associated to the same individual and season. Hence, we propose a mixed-effects model for the shot put performances for athlete i at time point t_{ij} (y_{ij}), inducing a hierarchical structure in the error variance. Accordingly, y_{ij} are deviations from a seasonal mean function $\mu_i(\cdot)$ that takes constant value μ_{is} for any time point in a given season s:

$$y_{ij} = \mu_{is} + \varepsilon_{ij} \tag{1}$$

with $\varepsilon_{ij} \overset{iid}{\sim} N(0, \psi^2)$ independent errors recorded at time t_{ij}, for $j = 1, \ldots, n_i$ and n_i is the total number of measurements available on athlete i. We further regard the seasonal- and unit-specific random intercept μ_{is} as the latent effect that quantifies the extent to which performances in season s responds above or below the overall mean m:

$$\mu_{is} = m + \zeta_{i,s}, \quad \text{with} \quad \zeta_{i,s} \overset{iid}{\sim} N(0, h_{i,s}) \tag{2}$$

Again, residuals at this higher level of hierarchy are assumed to be normally distributed, uncorrelated with lower-level residuals, but not uncorrelated among themselves. Indeed, the assumption of homogeneity of variance is inadequate here. Early graphical displays, straightforward exploratory analysis and initial modeling choices suggest a significant variability of the average response and its variance across seasons. In particular, suppose the variance of some athlete's performances during a specific time interval is known, then it will provide insight on future variability. Even further, a history of volatility in results provides information about an athlete's potential more than a background of constant, close to the average, performances. Hence, we consider a random intercept model with Normal Generalized Autoregressive Conditional Heteroskedastic (GARCH) errors [1]. Specifically,

$$\mu_{is} \mid m, h_{is} = m + \zeta_{is} \overset{iid}{\sim} N(m, h_{is}) \tag{3}$$

$$h_{is} = \alpha_0 + \alpha_1 \zeta_{is-1}^2 + \varpi h_{is-1} \tag{4}$$

where $\alpha_0 > 0, \alpha_1 \geq 0$ and $\varpi \geq 0$ to ensure a positive conditional variance, and $\zeta_{is} = \mu_{is} - m$ with $h_{i0} = \zeta_{i0} := 0$ for convenience. The additional assumption of wide-sense stationarity with

$$E(\zeta_t) = 0 \tag{5}$$

$$Var(\zeta_t) = \alpha_0 (1 - \alpha_1 - \varpi)^{-1} \tag{6}$$

$$Cov(\zeta_t, \zeta_s) = 0 \text{ for } t \neq s \tag{7}$$

is guaranteed by requiring $\alpha_1 + \varpi < 1$, as proven by [1].
Three parameters of the seasonal component require prior specification: the overall mean m and the conditional variance parameters, ϖ and $\vec{\alpha} = (\alpha_0, \alpha_1)^\top$. For the autoregressive and heteroskedastic parameters of the GARCH model, we propose non-informative priors satisfying the positivity constraint. For the overall mean parameter, we rely on a more informative Normal prior centered around the mean suggested by posterior analysis of preliminary versions of the model. In particular:

$$m \sim N(\mu_{m_0}, \Sigma_{m_0}) \tag{8}$$

$$\vec{\alpha} \sim N_2(\mu_\alpha, \Sigma_\alpha)\, I\{\vec{\alpha} > 0\} \tag{9}$$

$$\varpi \sim N(\mu_\varpi, \Sigma_\varpi)\, I\{\varpi \geq 0\} \tag{10}$$

where $\vec{\alpha} = (\alpha_0, \alpha_1)$ is a bidimensional vector. We complete the model specification assuming that the parameters are statistically independent and noticing that the hypothesis needed for wide-sense stationarity do not translate into actual prior conditions on the parameters. Hence, one of the objects of our analysis becomes to test whether the constraint $\alpha_1 + \varpi < 1$ holds true.
Because of the recursive definition of the conditional variance, no conjugate model exists for the GARCH parameters. Hence, we rely on an adaptive version of the Metropolis Hastings algorithm for posterior updates. In particular, for parameters m, ϖ and $\vec{\alpha}$ we build an adaptive scale Metropolis such that the covariance matrix of the proposal density adapts at each iteration to achieve an *optimal* acceptance rate [2]. We ran our sampler for $50,000$ iterations, with a burn-in period of 50% and a thinning of 5. We analyzed posterior samples for a variety of function estimates at different time points and for a variety of athletes, and the other model parameters. No issues emerged regarding convergence and mixing of the chains.

4 Results

Our goal is in estimating trajectories for athletes' performances. To this end, we generate a fine grid of equispaced time points, $\{t_k\}_{k=1}^{T}$, over our time span and evaluate the trajectory in performance on this grid.
Since we modelled the seasonal mixed effects function as a piecewise continuous function taking individual- and season-specific values, when estimating such function on any point in the time grid, we need to determine which season the time point belongs to. As discussed in Section 2, time is rescaled so that equal values across individuals indicate the same day of the year, possibly in different years. Therefore, season changes, that occur at new year's days, can be easily computed by straightforward proportions. In the following Equation, the indicator variable $\chi_{(t\in s)}$ determines to which season each time point t belongs to and index g ranges over the total number of iterations G:

$$\widehat{y_i(t)} = \frac{1}{G}\sum_{g=1}^{G}\sum_{s=1}^{S_i}\mu_{is}^{(g)}\chi_{(t\in s)} \quad \text{for } t = t_1,\ldots,t_T. \tag{11}$$

Equation (11) represents the point estimate of athlete i's performance at time t. Similarly, 95% credible intervals can be computed to quantify uncertainty around our point estimate. Estimated trajectories, credible bands and one season ahead prediction are displayed in Figure 2 for a random selection of shut put athletes.

5 Discussion

We proposed a hierarchical Bayesian model for the analysis of athletes' performances in a longitudinal context. We addressed the issue of seasonal gathering of sports data with a mixed effects model with GARCH errors, providing evolving random intercepts over different time intervals in the data set. While the motivation of our work comes from the analysis of shot put performance data, the methodology presented in this work is applicable to the analysis of performance data collected in all measurable sports.
The comprehensive nature of the data set suggests exploiting it further, possibly by including the contribution of covariates on the response. In particular, we believe there is potential for a better understanding of the effects of doping, not only on single performances, but on the overall evolution of a career. Further, we hope also doping detection might be targeted. Additional future developments include more sophisticated modeling choices both for the intraseasonal variability and the seasonal intercepts themselves. A nonparametric Bayesian approach to the hierarchy with the intent of clustering observation both across athletes and seasons is already forthcoming. This way we hope to recognize common patterns in similarly evolving careers for enhanced prediction purposes.

The x-axis denotes the time measured in days from January 1st of the first season of career, whereas on the y-axis there is the length of throw in meters. Vertical lines represent calendar years (seasons in our notation). The final part of each trajectory (grey) for which no observations are available, represents one-season-ahead performance prediction.

Bayesian Optimization with Machine Learning for Big Data Applications in the Cloud

Ottimizzazione Bayesiana Integrata col Machine Learning per Applicazioni Big Data su Cloud

Bruno Guindani, Danilo Ardagna and Alessandra Guglielmi

Abstract Bayesian Optimization is a promising method for efficiently finding optimal cloud computing configurations for big data applications. Machine Learning methods can provide useful knowledge about the application at hand thanks to their predicting capabilities. In this paper, we propose a hybrid algorithm that is based on Bayesian Optimization and integrates elements from Machine Learning techniques to tackle time-constrained optimization problems in a cloud computing setting.
Abstract *L'ottimizzazione bayesiana è un metodo promettente per trovare configurazioni ottimali di applicazioni big data eseguite su cloud. I metodi di machine learning possono fornire informazioni utili sull'applicazione in oggetto grazie alle loro capacità predittive. In questo articolo, proponiamo un algoritmo ibrido basato sull'ottimizzazione bayesiana che integra tecniche di machine learning per risolvere problemi di ottimizzazione con vincoli di tempo in sistemi di cloud computing.*

Key words: acquisition function, cloud computing, Gaussian Process

1 Introduction

Big data analytics are employed in several industries to allow organizations and companies to make better decisions. The most suitable execution environment of big data analytic applications is a cluster of virtual machines (VMs) which allows the adjustment of the allocated resources (CPU, memory, disk, network) to match the application current needs. Choosing the right cloud configuration to minimize execution times and reduce costs is essential to service quality and business competitiveness. However, due to the diverse behavior and resource requirements of analytic jobs, choosing the best configuration for a broad spectrum of applications is a challenging process [1].

Bayesian Optimization (BO) has recently gained notoriety as a powerful tool to solve global optimization problems in which expensive, black-box functions are involved; see the recent paper [6] or the popular tutorial paper [3]. BO is a sequential design strategy that requires few steps to get sufficiently close to the true optimum,

while requiring no derivative information on the optimized function. Most commonly, it is initialized by choosing and evaluating a small handful of starting points, then fitting a Gaussian process (GP) using these points. The posterior distribution of the fitted GP provides an estimate of both the function value at each point and the uncertainty around the estimate. BO then iteratively chooses new points at which to evaluate the function in a such a way to balance exploration (high uncertainty) and exploitation (best estimated function value), as explained in [4], for instance.

The goal of this work is to integrate Bayesian optimization algorithms with Machine Learning (ML) techniques in the context of cloud computing optimization. The former have proven to be successful [1, 7] in exploring and finding optimal or near-optimal cloud configurations after a small amount of exploratory runs. On the other hand, the latter can provide useful information to be incorporated into the BO mechanism in several ways to improve its performance, for instance in the form of cheap estimates of target quantities to guide the exploration process. This work builds on previous results found in [1], in which the *CherryPick* system is successfully applied to benchmark applications on cloud computing frameworks such as Apache Spark. This system exploits pure BO to find optimal cloud configurations. Our work is motivated by the belief that ML can lend their predicting capabilities to BO to further improve its effectiveness. This topic has been explored in [5], which examines the performance of several ML models in carrying out predictions of execution times of Spark cloud jobs with different types of workloads. The hybrid BO algorithm we propose here is promising since it shows the usefulness of ML in the context of cloud computing configuration.

The setup of this paper is as follows. Section 2 describes the mathematical formulation of the problem, Section 3 presents our proposal of a BO algorithm, while Section 4 collects some preliminary experimental results.

2 Background and mathematical formulation

The goal of BO is to approximate, e.g., the minimum of a given function f, called objective function, by using as few iterations as possible. Namely, we want to find $\widehat{x}$ where $\widehat{x} = \arg\min_{x \in \mathscr{A}} f(x)$. Strong assumptions on f or on the minimization domain $\mathscr{A}$ are not required, and BO algorithms are derivative-free, i.e., they do not require any knowledge about the derivatives of f. For these reasons, BO is often used to optimize expensive black-box objective functions (see [2]), that is, functions for which little to no information is available, and whose evaluation has significant time, resource, and/or monetary costs.

We consider the mathematical formulation for our *constrained global optimization* problem similarly to [1]. Let $x \in \mathscr{A}$ denote the d-dimensional vector representing a configuration for the cloud job, including information such as the number of cores used for the job, with $\mathscr{A} \subset \mathbb{R}^d$ being the domain of all feasible configurations. The *objective function* to be minimized is the total cost $f(x) = P(x)T(x)$, where $T(x)$ is the unknown execution time and $P(x)$ is the price per unit (it is a known, deterministic function). We also assume the constraint that $T(x) \leq T_{max}$, where T_{max} is a given threshold. Hence the problem is to find the minimum of f,

$$\min_{x \in \mathscr{A}} f(x) = P(x)T(x) \quad \text{s.t. } f(x) \leq P(x)\,T_{max}. \tag{1}$$

In this paper, we assume the deterministic price function $P(x)$ as being proportional to the number of virtual machines or cores used by the application job, which is always included in the cloud configuration vector x. Other choices of the price function are possible.

The key idea of BO comes from the Bayesian approach to statistics, in which values taken by f are treated as random variables, and a *prior distribution* represents the a-priori information on the modeled phenomenon – in the case of BO, information on the location of the minimum. The prior distribution is then iteratively updated with information coming from the observed data, obtaining the *posterior distribution*. For the rest of the paper, we assume that observed data, i.e., the evaluations of f, are noise-free. This is justified by the analysis in [5] on the data considered for validation. In a more general context, data can be assumed to have independent, normally distributed additive noise with variance η^2.

In this context, the Gaussian process (GP) is the preferred choice for the prior for f. This means that for any $x \in \mathscr{A}$,

$$f(x) \sim \pi_x(\cdot) = \mathscr{N}(\mu_0(x), \sigma_0^2(x,x)).$$

Functions $\mu_0(\cdot)$ and $\sigma_0^2(\cdot,\cdot)$ are called mean and kernel functions, respectively, and are the GP model hyperparameters. In this work, we assume $\mu_0(\cdot) \equiv \mu_0$ and we use the Matérn kernel with smoothness parameter $\nu = 5/2$ (see [3]):

$$\sigma_0^2(x,x') := \frac{1}{2^{3/2}\Gamma(5/2)} \left(\sqrt{5}\|x-x'\|\right)^{5/2} K_{5/2}\left(\sqrt{5}\|x-x'\|\right).$$

Having observed values $H_n = \{(x_1, f(x_1)), \ldots, (x_n, f(x_n))\}$ of the objective function, one computes the posterior distribution of each $f(x)$, which is also Gaussian and it is characterized by the posterior mean $\mu_n(\cdot)$ and variance $\sigma_n^2(\cdot)$, i.e.

$$f(x)|H_n \sim \pi_x(\cdot|H_n) = \mathscr{N}(\mu_n(x), \sigma_n^2(x))$$

which can be computed by well-known properties of GPs (see, for instance, [3]).

BO is an iterative algorithm that obtains a new observation at each iteration by solving a proxy problem – the maximization of the *acquisition function* $g(x)$, which depends on the fitted GP model and measures the utility of evaluating the objective function at a given configuration x. This function is optimized at each round of the iterative algorithm, instead of directly optimizing the objective function itself, since it is available in closed form and inexpensive to evaluate. See Figure 1 for a summary of how BO works. Specifically, in the top panel, the objective function to be minimized (in gray) is approximated by the Gaussian Process, in the form of its posterior mean function (in dashed blue) and 95% credible interval (in light blue) after evaluating 3 points (red dots). The bottom panel shows the acquisition function given the current posterior distribution. The red cross indicates the maximum of the acquisition function, i.e. the next point which will be evaluated.

In this paper, we compare different acquisition functions. The *Expected Improvement* (EI) over the best value f_n^* found by the optimization process so far is:

$$EI_n(x) := \mathbb{E}_{\pi_x(\cdot|H_n)}[\max(f_n^* - f(x), 0)] \quad \text{with} \quad f_n^* = \min_{i \le n} f(x_i).$$

The expectation is taken under the current posterior distribution $\pi(\cdot\,|H_n)$ of $f(x)$, given history H_n. We consider a generalization of EI to the constrained optimization setting – the *Expected Improvement with Constraints* (EIC) acquisition function (see [8]), which accounts for the probability of a point of respecting the constraints:

$$EIC_n(x) := EI_n(x) \cdot \mathbb{P}_{\pi_x(\cdot|H_n)}\big(f(x) \le P(x)\, T_{max}\big). \tag{2}$$

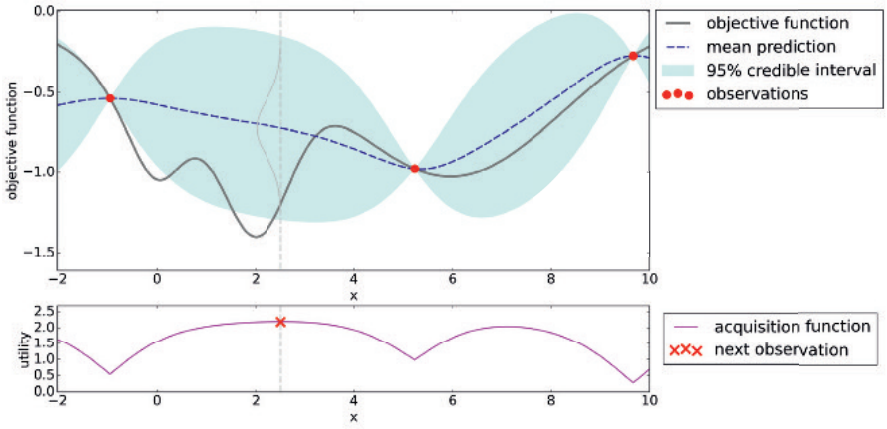

Fig. 1: Bayesian optimization after 3 iterations. Top panel: the objective function and its Bayesian approximation. Bottom panel: acquisition function.

3 Our hybrid algorithm

Our algorithm is based on pure BO, but it integrates elements coming from ML techniques. We use a memory queue for discrete features to prevent exploration of already visited values. The algorithm continues until the evaluated running time at the current iteration is sufficiently close to the time threshold: $T(x_n) \in [0.9\,T_{max},\ T_{max}]$. Our goal is to obtain a configuration that is compliant with the time threshold, but also uses as few resources as possible. Generally speaking, using more resources results in a lower execution time – meaning that a time which is just under the threshold consumes the least amount of resources for that configuration to be feasible. After termination, it is likely that we have found the true optimal configuration because of the convergence properties of the BO algorithm. Afterwards, we execute subsequent runs using such optimal or near-optimal configuration.

As far as the acquisition function is concerned, in this paper we use two variations of EIC (see (2)), which both integrate EIC with information coming from ML.

In particular, at each iteration, a ML model $\widehat{T}(\cdot)$ is trained on the current history H_n to accurately predict execution times $T(x)$ for any configuration x. Then, the EIC acquisition function in (2) is either multiplied by an exponential factor of $\widehat{T}(x)$ (variant B), or is set to zero for values in which $\widehat{T}(x)$ is larger than the threshold T_{max} (variant C). The former encourages the search process towards configurations which respect the time constraint, while the latter prevents the search outright in areas which are predicted to violate such constraint.

4 Experiments

We present preliminary results using the techniques we have discussed in Section 3. We use variants B and C of the algorithm, as well as pure BO, on the Query26 application from the TPC-DS industry benchmark run on Apache Spark with input data size equal to 250 GB and time threshold equal to 150 s. In this case, we optimize the total cost in (1) on the number of cores x. The same three fixed initial points were used for all variants. Figure 2 shows the comparison of pure BO (top row) with variants B (middle row) and C (bottom row) at each algorithm iteration. The left panels display the number of cores x selected by the algorithm, while the middle panels show the cumulative costs of the selected configurations. The percentage errors between the actual execution time and the one predicted by the ML model are displayed on the right column. We apply Ridge regression since [5] shows that it is the most accurate in this context, with a mean absolute error smaller than 5%.

Using our new algorithm, we are able to reduce the number of iterations which produce unfeasible configurations from 15 to 1 or 2. Similarly, cumulative costs associated to unfeasible runs are reduced from 11.67 to 0.80 and 1.51. At the very first iteration, all variants explore high values of the number of cores since there is no enough information on that part of the domain. This also explains the large prediction errors at the same iteration. After that, our ML model is able to predict the execution time of subsequent iterations with very good accuracy. Finally, the termination criterion (see the vertical dotted line in Figure 2) correctly assesses the optimality of the configuration with $x = 22$ cores, and stops the exploration phase.

Confidence distributions and fusion inference for intractable likelihoods

Distribuzioni di confidenza e inferenza combinata per verosimiglianze intrattabili

Elena Bortolato and Laura Ventura

Abstract In the context of inference in complex models, involving intractable likelihood functions, we show how Confidence Distributions for a parameter of interest can be constructed with an efficient simulation strategy. The procedure is quite similar to those used in Approximate Bayesian Computation, but without requiring an arbitrary tuning tolerance. The proposed methodology allows us to derive proper likelihoods and enables to perform fusion inference, when the sources of information are non homogeneous or partial. An illustrationin the context of meta-analysis is discussed.

Abstract Si considerano problemi di inferenza in modelli complessi, in cui la funzione di verosimiglianza non è trattabile, e si mostra come poter costruire una distribuzione di confidenza per un parametro di interesse, con una strategia di simulazione simile a quella adottata negli approcci *Approximate Bayesian Computation*, senza richiedere una soglia arbitraria per il livello di approssimazione. La metodologia proposta rende possibile il recupero di una funzione di verosimiglianza ed è adattabile ai contesti inferenziali in cui le fonti di informazione non sono omegenee. Il metodo è illustrato in un esempio di metanalisi.

1 Introduction

In many fields of science, it is needed to fuse together information from potentially different types of sources or complex models. In these settings, it has been becoming common practice to consider simulation-based inference (Sisson et al. 2018). Indeed, in the Bayesian framework, Approximate Bayesian Computation (ABC) and Bayesian Synthetic Likelihood (BSL) methods escape the problem of impossible likelihood evaluation. Then, several methods are well established for combining uncertainty from multiple information or models: by updating the posterior distribution when data arrive sequentially, by using robust Bayesian methods, or model averaging (Berger 1990, Wasserman 2000). On the contrary, in the frequentist approach, performing inference with complicated models and models made of modules may be more problematic. For example, Lindley (1958) shows that paradoxes easily arise when combining p-values. Instead of simply considering p-values for the purpose, one could appeal to confidence distributions (CD); see Hannig and Xie (2012). We observe that these can be derived even in complex settings, where an underlying pivotal distribution is not available in closed form.

The outline of this work is the following. In Section 2 and 3 we summarize the essentials of CD and likelihood free inference. In Section 4 we present the proposed construction of the CD and in Section 5 we describe how to suit the methodology within a fusion inference framework. Some examples are discussed in Section 6.

2 Towards confidence distributions and fiducial inference

Confidence distributions are sample-based distribution functions on the parameter space that convey and resume the frequentist inferential results, similarly to the counterpart Bayesian posterior. In order to formalize the mathematical setting, let y_n be the $n-$size sample, realization of a random variable $Y \in \mathscr{Y}$, and let $\theta \in \Theta \subseteq \mathrm{R}$ be the scalar parameter of interest.

Definition 1. *Confidence distribution*
A function $H_n(\cdot) = H_n(y_n, \cdot)$ on $\mathscr{Y} \times \Theta \to [0,1]$ is called a confidence distribution for a parameter θ, if

C1 For each given $y \in \mathscr{Y}$, $H_n(\cdot)$ is a cumulative distribution function on Θ;
C2 At the true parameter value $\theta = \theta_0$, $H_n(\theta_0) = H_n(y_n, \theta_0)$, as a function of the sample y_n, follows the uniform distribution $U(0,1)$.

Definition 2. *Confidence density and CD random variable*
A random variable ξ such that

$$\xi | Y = y_n \sim H_n(\cdot)$$

is called a CD random variable and its probability distribution, called confidence density, is given by $\frac{\partial H_n(\cdot)}{\partial \xi}$.

The CD random variable represents the uncertainty in the estimation of the parameter of interest, or can be seen as a random estimator of it. For any couple of values θ_L and θ_U, the included mass-area under the CD measures the evidence associated to the interval $[\theta_L, \theta_U]$. In practice, exact or asymptotic CDs can be derived from the cumulative distribution of a pivotal quantity, or can be generated using bootstrap methods (see Ruli and Ventura 2021, and references therein). CDs are also related to fiducial inference and structural models (Fraser 2004), which aim at constructing a measure on the parameter space without a prior.

3 Simulation based inference for intractable likelihoods

For some complex models, for which the likelihood cannot be evaluated in a practical amount of time, both in the frequentist and the Bayesian framework, some methods have been proposed to overcome the numerical difficulties, these are mainly based on simulations.

In the frequentist approach, one possibility for the inspection of the likelihood is based on the use of an auxiliary model $M^*(\psi)$ (Gourieroux et al. 1993), where ψ is a parameter. The model is fitted to the data in order to obtain a point estimator, $\hat{\psi}$, then a binding function $\psi(\theta)$ among the original and the auxiliary model is considered and the map is estimated by simulation. In some cases, other solutions for the problem are given by composite likelihoods, see for instance Varin et al. (2011) and reference therein.

Approximate Bayesian Computation (ABC), instead, aims at finding the posterior distribution for the parameter of interest, simulating from the joint distribution of the parameter and the data, $p(y,\theta) = \pi(\theta)p(y|\theta)$, retaining those simulates values θ^*, for which the simulated samples y^* match the observed sample y_n. The statistic $t(\cdot)$ used to compare the actual sample and the simulated ones, is typically low dimensional and possibly sufficient. Also, the matching criterion is relaxed, according to the definition of a distance $d(\cdot,\cdot)$ and a small tolerance ε: thus the values θ^* are accepted if $d(t(y^*),t(y_n)) < \varepsilon$. The choice of a metric together with the summary statistic determine the precision of the results. ABC has also been used in the frequentist approach to obtain approximations of the likelihood function, eventhough the amount of inexactness is notoriously difficult to quantify, and the procedure is non-consistent (Frazier et al. 2015).

4 CD for intractable models

In the preface of their book, "Confidence, probability and likelihood" (2016), Schweder and Hjort state "The price to be paid for an epistemic distribution not based on a prior is that in most models only approximate confidence distributions are available, and they might be more computationally demanding than the Bayesian posterior". While some recent works improved the approximation of CDs,

a lot has to be done on the side of using them for complex models and in likelihood free framework. We note that it is possible to build an exact confidence distribution together with a confidence density from an accept-reject scheme, a summary statistic and the auxilium of a proposal distribution as done in ABC. In Algorithms 1 and 2 the simulation strategy is described. If the distribution of the chosen statistic $t(\cdot)$ is stochastically ordered in the parameter of interest (i.e. $Pr(t(y) < s|\theta_1) \leq Pr(t(y) < s|\theta_2)\ \forall s,\ \theta_1 > \theta_2$, and strictly for at least one s), C1 in Definition 1 is satisfied. Instead, C2 holds since the defined CD has meaning of a p-value function. Note that it is not required that $t(\cdot)$ is a pivotal quantity (i.e. its distribution doesn't depend on the parameter of interest), neither that $t(\cdot)$ is sufficient or its distribution known. The assumption can be checked *a posteriori*, by verifying that the CD is monotone non decreasing.

Algorithm 1 Confidence distribution

Choose a proposal $q(\theta)$, M the number of iterations, a summary statistic $t(\cdot)$, compute $t_n = t(y_n)$
1- sample $\theta^* \sim q(\theta)$ and $y^* \sim p(y|\theta^*)$
2- compute $t^* = t(y^*)$
3- accept θ^* if $t^* \leq t_n$ else reject
4- repeat (1-2-3) M times
5- sample θ^{**} from the accepted θ^* with replacement and probability $1/q(\theta^*)$
Output: $\theta^{**} \propto H_n$ a confidence distribution

Algorithm 2 Confidence density

Fix a desired size R
1- define a grid of values $G = (1/R, 2/R, \ldots, 1)$
2- compute the quantiles of the CD : $\xi \sim H_n^{-1}(G)$
Output: $\xi \sim c(\theta)$ is a CD random variable

5 From confidence to likelihood

It is possible to retrieve a likelihood function by considering the implied likelihood (Efron, 1993). This involves the construction of a fictitious second dataset, doubling the original $y^{II} = (y_n, y_n)$, whose likelihood function is $\mathscr{L}(\theta; y^{II}) \propto \mathscr{L}(\theta; y_n)^2$. The implied likelihood is retrieved by

$$\mathscr{L}(\theta) = \frac{c(\theta; y^{II})}{c(\theta; y_n)}, \tag{1}$$

where $c(\theta; y)$ is the confidence density. In practice, it is possible to perform this step resampling the CD random variables obtained from the analysis of the doubled dataset with importance weights given by the distribution of the CD random variables obtained on the original data.

6 Examples

6.1 Inference in the lognormal model

Consider the lognormal model. Assume to observe as a summary statistic $t_n = 1.439$, the mean of $n = 5$ realizations:

$$t_n = n^{-1} \sum_{i=1}^{n} e^{z_i}, \quad z_i \sim Z \sim N(\mu, 1), \quad i = 1, \ldots, n.$$

For $n > 2$ an analytical form for the distribution of t_n is not available; thus, furnishing a confidence interval for μ based on t_n, despite the formal simplicity of the model, is a very sophisticated problem. We apply our method proposing 10^5 values from the Uniform in (-4,4), when the true parameter is $\mu = 0$. The difference between the acceptance probability (about 49%) is remarkable compared to the ABC's (0.1%). Then, we run a simulation study in which we compute the 95% confidence intervals obtained with CDs and with the approximate likelihood via ABC with a small tolerance ($\varepsilon = 0.01$). The resulting empirical coverage based on 10^4 simulations and 10^4 proposal values for each of them is 94.9% (se= 0.2%), against ABC's 77.1% (se= 0.3%). We show in Figure 1 the CD and the coverage of the intervals along the iterations.

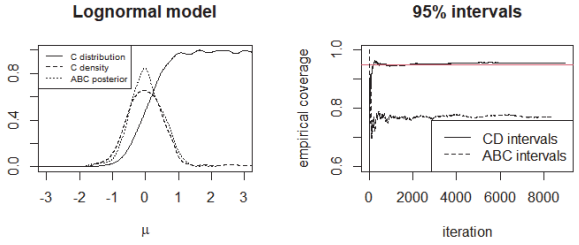

Fig. 1 *Left*: Confidence distribution, confidence density and ABC posterior given $t_n = 1.439$. *Right*: empirical coverage of intervals from a simulation study comparing CD to ABC credible intervals.

6.2 Implied likelihood via CD and Meta-analysis

Suppose three independent laboratories have measured the same quantity of interest, from a sample of size $n = 18$, and we are interested in combining the results to make inference for a parameter μ representing the mean of the phaenomenon. The first lab has analysed the data with a normal model and reported the mean ($S_1 = 31.04$). The second lab preferred to give the median ($S_2 = 30.69$), having observed some presumed outliers, while the third lab considered the logarithm of the measures, trying to correct for some observed asymmetric behaviour, and furnishes the mean of the logarithms ($S_3 = 3.43$). We build the CDs, obtain the implied likelihoods (IL) and combine them, taking the product. We show the results in Figure 2. The comparison to the likelihood, available for the first lab's analysis, indicates good adaptation of

the procedure. The scheme illustrated is quite general, can be used in presence of in-

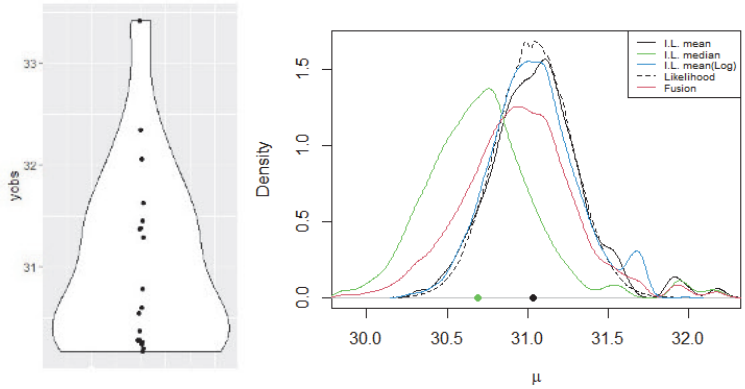

Fig. 2 *Left*: sample analysed by the laboratories. *Right*: combined likelihood (red line), obtained by fusion of three IL, related to different CDs. Black and green dots represent the statistics given by the first and the second lab (S_1, S_2), the third is not in the support of the x-axis $(S_3 = 3.43)$.

tractable or multiple competitor models, trying to account for misspecification. The combined IL, in contrast to p-value recombination, avoids paradoxes and naturally conveys a distribution estimator, without further assumptions.

Wasserstein distance and applications to Bayesian nonparametrics

Distanza di Wasserstein e applicazioni in statistica bayesiana nonparametrica

Marta Catalano, Hugo Lavenant, Antonio Lijoi, Igor Prünster

Abstract Bayesian nonparametric models are able to learn complex distributional patterns in the data by leveraging on infinite-dimensional parameters, typically consisting in vectors of random measures. To perform a principled BNP model comparison one thus needs a measure of discrepancy between vectors of random measures. In recent works the authors have proposed two different metrics based on the Wasserstein distance. We here provide new perspectives to our findings, highlighting a universal relation between the two metrics.

Abstract *I modelli bayesiani nonparametrici (BNP) sono in grado in imparare assetti distribuzionali complessi nei dati facendo leva su parametri infinito-dimensionali, che tipicamente consistono in vettori di misure aleatorie. Per portare avanti un paragone tra modelli BNP basato su fondamenta solide, è dunque necessario definire una misura di discrepanza tra vettori di misure aleatorie. In alcuni lavori recenti gli autori hanno proposto due diverse metriche basate sulla distanza di Wasserstein. In questo contributo forniamo una nuove prospettiva che mette in evidenza una relazione universale tra le due metriche.*

1 Introduction

The Wasserstein distance provides a comprehensive way to quantify the comparison between two random objects. Its first definition traces back to [8], though it then appeared independently in many other scientific fields. As a result, one can find this *simple measure of discrepancy* (using Gini's words) under different names, such as Gini distance, coupling distance, Monge-Kantorovich distance, Earth Moving distance and Mallows distance; see [5, 12, 11] for reviews.
Random structures are the key to statistical modeling and inference, especially in a Bayesian framework where the parameter of the model is random as well. We argue that a principled way to perform Bayesian model comparison is then to measure the discrepancy between the random parameters of the models, by relying on the Wasserstein distance.
In this contribution we focus on Bayesian nonparametric (BNP) models, which are based on infinite-dimensional parameters typically consisting on vectors of random measures. For example, most BNP models for *partially exchangeable sequences* [4] are built as follows. First, one considers a vector of dependent random measures $\tilde{\mu} = (\tilde{\mu}_1, \dots, \tilde{\mu}_d)$, such as the *completely random vectors* (CRVs) introduced in Section 3. Then, one models d groups of observations $\boldsymbol{X}^i = (X_1^i, \dots, X_{n_i}^i)$ as conditionally independent given $\tilde{\mu}$ with

$$\boldsymbol{X}^i | \tilde{\mu} \overset{\text{ind}}{\sim} T(\tilde{\mu}_i)$$

for $i = 1, \dots d$, where T is some transformation of the random measure.
To perform a BNP model comparison one thus needs the definition of a distance between CRVs, whose law is specified through a multivariate Lévy intensity. Following [3, 2, 1] we here describe two different ways of defining such a distance, one at the level of the random measures and one at the level of the underlying Lévy measures. Generalizing the findings in [1], we highlight that the two metrics are intimately connected and provide a universal relation between them that allows the practionner to exploit the best properties of each one.

2 Wasserstein distance

In its classical formulation, the Wasserstein distance provides the means for comparing two probability measures on a Polish space $\mathbb{X}$ with metric d. Recent developments allow to extend the comparison from probability measures (that is, measures with mass 1) to generic measures with possibly different masses. A particularly interesting scenario arises when the masses are infinite, as in the case of infinitely active Lévy measures. In this section we describe both the Wasserstein distance and its extended version.
We first recall the notion of coupling. Given two probability measures P^1, P^2 on a Polish space $(\mathbb{X}, d)$ we define a coupling to be the law of any random vector (X, Y)

on the product space $\mathbb{X}\times\mathbb{X}$ such that $X\sim P^1$ and $Y\sim P^2$. We denote by $\Gamma(P^1,P^2)$ the set of couplings between P^1 and P^2. A probability P^1 has finite p-th moment if for any $x\in\mathbb{X}$,

$$\int_{\mathbb{X}} d(s,x)^p \mathrm{d}P(s) < +\infty.$$

Definition 1. Let P^1 and P^2 be probability measures on $(\mathbb{X},d)$ with finite p-th moment. The *Wasserstein distance* of order p between P^1 and P^2 is

$$\mathscr{W}_p(P^1,P^2)^p = \inf_{(X,Y)\in\Gamma(P^1,P^2)} \mathbb{E}(d(X,Y)^p).$$

We observe that the finiteness of the p-th moment guarantees the finiteness of the Wasserstein distance thanks to the triangular inequality of the metric d. A very common choice for $(\mathbb{X},d)$ is $\mathbb{R}^d$ endowed with the Euclidean norm $\|\cdot\|$. In this case, P has finite p-th moment if and only if $\int \|x\|^p \mathrm{d}P(x)$ is finite.
Starting from this scenario we extend the definition to Lévy measures on $\Omega_d = [0,+\infty)^d \setminus \{\mathbf{0}\}$. This distance was studied in [7, 9, 1] for $p=2$. To this end, we insist on an equivalent definition of coupling in terms of pushforward measures, which will be easier to generalize to Lévy measures. For a point $(\boldsymbol{s},\boldsymbol{s}')\in\mathbb{X}\times\mathbb{X}$, we denote by $\pi_1(\boldsymbol{s},\boldsymbol{s}')=\boldsymbol{s}\in\mathbb{X}$ and $\pi_2(\boldsymbol{s},\boldsymbol{s}')=\boldsymbol{s}'\in\mathbb{X}$ its projections. For any measure spaces $\mathbb{X}^1$ and $\mathbb{X}^2$, if μ is a measure on $\mathbb{X}^1$ and $f:\mathbb{X}^1\to\mathbb{X}^2$, the pushforward measure of μ by f is the measure on $\mathbb{X}^2$ defined by $(f_{\#}\mu)(A)=\mu(f^{-1}(A))$. Then an equivalent way of defining a coupling $\gamma\in C(P^1,P^2)$ is as a probability measure on $\mathbb{X}\times\mathbb{X}$ such that $\pi_{i\#}\gamma = P^i$ for $i=1,2$. Thus,

$$\mathscr{W}_p(P^1,P^2)^p = \inf_{\gamma\in\Gamma(P^1,P^2)} \int_{\mathbb{X}\times\mathbb{X}} d(x,y)^p \mathrm{d}\gamma(x,y).$$

We now extend the Wasserstein distance to Lévy measures on $\Omega_d=[0,+\infty)^d\setminus\{\mathbf{0}\}$ with p-th finite moment, that is, the set of positive Borel measures ν such that

$$\int_{\Omega_d} \|s\|^p \mathrm{d}\nu(s) < +\infty.$$

We observe that the finite moment condition does not prevent the mass from being infinite. Indeed, there can be an accumulation of infinite mass around the origin, as is the case with infinitely active Lévy measures.
Let ν^1,ν^2 two Lévy measures. An extended coupling γ between ν^1 and ν^2 is a Lévy measure on Ω_{2d} such that $\pi_{1\#}\gamma|_{\Omega_d}=\nu^1$ and $\pi_{2\#}\gamma|_{\Omega_d}=\nu^2$. We denote $\Gamma_*(\nu^1,\nu^2)$ the set of all extended couplings.

Definition 2. Let ν^1 and ν^2 be Lévy measures on $(\Omega_d,\|\cdot\|)$ with finite p-th moment. The *extended Wasserstein distance* of order p between ν^1 and ν^2 is

$$\mathscr{W}_{*,p}(\nu^1,\nu^2)^p = \inf_{\gamma\in\Gamma_*(\nu^1,\nu^2)} \iint_{\Omega_{2d}} \|\boldsymbol{s}-\boldsymbol{s}'\|^p \,\mathrm{d}\gamma(\boldsymbol{s},\boldsymbol{s}'). \tag{1}$$

The main difference between a coupling and an extended coupling is that extended couplings are not defined on $\Omega_d \times \Omega_d$ but rather on Ω_{2d}, which is strictly larger since it also contains the axis $\{\mathbf{0}\} \times \Omega_d$ and $\Omega_d \times \{\mathbf{0}\}$. This is fundamental to ensure the compactness of extended couplings which, in turn, guarantees the existence of an *optimal extended coupling*, that is, a coupling that attains the minimum in the definition of extended Wasserstein distance.

3 Completely random vectors

The key component of Bayesian nonparametric models is the use of random measures to learn complex distributional patterns in the data. Among these, completely random measures stand out for combining inferential flexibility with analytical tractability. Quantifying the discrepancy between two completely random measures or their multivariate extension - completely random vectors - is key to establishing a principled approach to the comparisons between the induced Bayesian nonparametric models. This can be done through the Wasserstein distance at two different levels: either at the level of the random measures or at the level of their underlying Lévy intensity. We here describe these notion and extend a result by [1], which shows that these two levels are intimately connected.
Let $\mathscr{M}(\mathbb{X})$ denote the set of boundedly finite measures on $\mathbb{X}$ endowed with the weak$^\sharp$ topology [6]. We recall that a sequence of measures μ_n converges weakly$^\sharp$ to μ if and only if $\int f \mathrm{d}\mu_n \to \int f \mathrm{d}\mu$ for every bounded continuous f vanishing outside a bounded set. A random measure is a random element on $\mathscr{M}(\mathbb{X})$. Similarly, a d-dimensional random vector of measures $\tilde{\mu} = (\tilde{\mu}_1, \ldots, \tilde{\mu}_d)$ is a random element on the product space $\mathscr{M}(\mathbb{X})^d$.

Definition 3. A random vector of measures is a *completely random vector* (CRV) if for every finite collection of pairwise disjoint bounded sets $\{A_1, \cdots, A_n\}$ in $\mathscr{B}(\mathbb{X})$, $\{\tilde{\mu}(A_1), \cdots, \tilde{\mu}(A_n)\}$ are mutually independent.

The definition of completely random vector was first given by [2] and it extends the notion of completely random measure (CRM [10]) in a natural way. In particular, a CRM is a 1-dimensional CRV. Every CRV can be decomposed as the sum of three independent components, $\mu + \tilde{\mu}_f + \tilde{\mu}$ in distribution, where μ is a deterministic vector of measures, $\tilde{\mu}_f$ is a random vector of measures with fixed atoms and $\tilde{\mu}$ is a random vector of measures without fixed atoms. In the rest of the contribution we will focus on CRVs without fixed atoms. Remarkably, for every such CRV there exists a measure ρ on $\Omega_d \times \mathbb{X}$ such that

$$\mathrm{d}\tilde{\mu}(x) = \int_{\Omega_d} s \, \mathrm{d}\mathscr{N}(s,x)$$

in distribution, where $\mathscr{N}$ is a Poisson random measure with Lévy intensity ρ on $\Omega_d \times \mathbb{X}$. In particular, $\tilde{\mu}(A)$ is an infinite divisible distribution with Lévy measure

$d\nu_A(s) = \int_A d\rho(s,x)$ on Ω_d. Thus, to assign a probability distribution to a CRV it suffices to provide a set of Lévy measures $(\nu_A)_A$.
It is then clear that the comparison between CRVs can be based either at the level of the random measures or at the level of the Lévy measures. In the first case, given two CRVs $\tilde{\mu}^1$ and $\tilde{\mu}^2$ one defines

$$d_{\mathscr{W},p}(\tilde{\mu}^1,\tilde{\mu}^2) = \sup_A \mathscr{W}_p(\mathscr{L}(\tilde{\mu}^1(A)),\mathscr{L}(\tilde{\mu}^2(A))), \tag{2}$$

where $\mathscr{L}$ denotes the law of a random object. We observe that $\mathscr{L}(\tilde{\mu}^i(A))$ is a probability measure and thus $\mathscr{W}_p$ is the classical Wasserstein distance in Definition 1. In the second case one defines

$$d_{\mathscr{W}_*,p}(\tilde{\mu}^1,\tilde{\mu}^2) = \sup_A \mathscr{W}_{*,p}(\nu_A^1,\nu_A^2). \tag{3}$$

Here, ν_A^i is a Lévy measure on Ω_d and thus $\mathscr{W}_{*,p}$ is the extended Wasserstein distance in Definition 2.
The advantage for (2) is that, being defined directly on the the random object, it has a very interpretable definition. On the other hand the advantage of (3) is that, being defined directly on the Lévy measure, it is easier to compute. The next result generalizes the findings in [1] and can be proved following the same technique therein. We provide a universal relation between the two distances that allows to keep the best of the two worlds: we can now base the computations on (3) though maintaining the interpretability of (2).

Theorem 1. *Let $\tilde{\mu}^1,\tilde{\mu}^2$ be CRVs with Lévy measures $(\nu_A^1)_A$ and $(\nu_A^2)_A$, respectively, with finite p-th moment. Then for every Borel set A,*

$$\mathscr{W}_p(\mathscr{L}(\tilde{\mu}^1(A)),\mathscr{L}(\tilde{\mu}^2(A))) \leq \mathscr{W}_{*,p}(\nu_A^1,\nu_A^2).$$

Network Analysis and community detection

Community detection in networks: a heuristic version of Girvan Newman algorithm

Identificazione delle comunità nei grafi: una versione euristica dell'algoritmo di Girvan Newman

Ilaria Bombelli and Lorenzo Di Rocco

Abstract Complex problems in different fields can be modeled by graph data structures. An important and challenging task is the community detection, i.e. the identification of highly connected components. The Girvan Newman algorithm identifies high-quality communities but is not computationally suitable for huge graph analysis. Therefore, we propose a heuristic version of this algorithm, by considering an approximated measure of the edge betweenness. We evaluate the performances of our proposal on benchmark networks.

Abstract *I grafi permettono di modellare problemi complessi di diversa natura. Una delle questioni più stimolanti e importanti è il rilevamento delle comunità, cioè l'identificazione di componenti altamente connesse. L'algoritmo di Girvan Newman è in grado di identificare tali componenti con successo, ma non è computazionalmente adatto ad un'analisi di grafi di grandi dimensioni. Pertanto, proponiamo una versione euristica di questo algoritmo, approssimando la misura di betweenness degli archi. Analizziamo le prestazioni della nostra proposta utilizzando reti benchmark.*

1 Introduction

Networks are interesting tools to represent complex problems that arise in different situations: for example, in a society, networks can represent how class students interact with one another; in technological field, networks can represent flights routes between cities.

In a network framework, a really challenging task is the detection of *communities* (or clusters of nodes). Plenty of literature deals with this task and, among the hierarchical algorithms, the most famous ones are Louvain [2] and Girvan Newman [5]. The former follows an *agglomerative* approach, while the latter is characterized by a *divisive* one.

The Girvan Newman (GN) algorithm suffers from an important drawback: it is unfeasible for community detection problems on large-scale networks, as also the authors highlight [5]. Indeed, the GN algorithm is based on the computation of the edge betweenness, which is practically an extremely expensive task.

For this reason, we propose a Heuristic Girvan Newman (HGN) algorithm, considering an approximation of the edge betweenness. In this way, the computational effort of each iteration of the GN algorithm is reduced.

In Section 2, we explore deeply the methodology underlying our proposal. In Section 3, we assess the performances of our proposal on benchmark networks. Finally, in Section 4 final remarks and future research directions are discussed.

2 Methods

Complex networks of highly connected data are commonly represented by graphs. A graph $G = (V,E)$ is a data structure built on top of a set of vertices (V) and a set of edges (E). The vertices are considered to be the entities of the network, while the edges describe the occurring interactions.

In network science, hubs identification is an important task and aims to identify pivotal vertices. Different measures have been proposed in the literature to quantify the importance of a vertex. Freeman's *betweenness* [4] is a widely used index that evaluates the centrality of a vertex considering the number of shortest paths passing through the vertex.

The definition of betweenness can be extended to the edges [5]. The so-called *edge betweenness* for an edge $e \in E$ is defined as follows :

$$ebw(e) := \sum_{\substack{j,k=1,\dots,|V| \\ j \neq k}} \frac{\sigma_{jk}(e)}{\sigma_{jk}} \tag{1}$$

where σ_{jk} is the number of shortest paths connecting node v_j and node v_k, and $\sigma_{jk}(e)$ is the number of shortest paths connecting node v_j and node v_k that run along the edge $e \in E$.

The greatest values of this index are usually associated with *bridge-like* edges, i.e. those connecting different communities of the network. The GN algorithm is one of the main methods for communities detection and it is based on a recursive procedure that at each iteration deletes the edge(s) with the greatest betweenness.

This divisive procedure provides high-quality clustering performances but is unpractical for large-scale graph processing. This drawback is due to the shortest paths search, which is particularly expensive from a computational viewpoint. A possible solution consists in parallelizing the elaborations on a High Performance Computing architecture, obtaining in this way a significant performance speed-up. However, it is worth considering also high-quality approximations of the edges betweenness to reduce the computational effort.

In this work, we propose a heuristic version of the GN algorithm that estimates the edges betweenness through an accurate sampling technique. More precisely, we take into account the approximation proposed by [8], which we call DIAM, as suggested by [1]. This approach evaluates an appropriate sample size r according to the graph structure, it randomly selects a sample of paths $S = \{p_i, i = 1, \ldots, r\}$ and it returns for each edge $e \in E$ the following estimator:

$$\widehat{ebw} = \frac{1}{r} \sum_{p \in S} \mathbb{I}_p(e) \tag{2}$$

where $\mathbb{I}_p(e)$ is 1 if e belongs to p, 0 otherwise. In the following, we provide more details about the procedure.

Firstly, the estimates of the edge betweenness $\{\widehat{ebw}_i, i = 1, \ldots, |E|\}$ are all set to 0. Then, r pairs of vertices are sampled uniformly from V. For each sampled pair (u, v): (a) all the shortest paths $S_{u,v}$ between u and v are computed, (b) a path p is selected uniformly at random from $S_{u,v}$, (c) the betweenness estimates of the edges belonging to p are increased by $1/r$.

The sample size formula is obtained considering an application of the Vapnik-Chervonenkis dimension [9] and it is defined as follows:

$$r := \frac{c}{\varepsilon^2} \left(\lfloor \log_2(\tilde{D}(G) - 1) \rfloor + 1 + \ln \frac{1}{\delta} \right) \tag{3}$$

where c is a positive constant (typically set to 0.5, as [7] suggested), $\varepsilon \in [0, 1]$ is the additive error, $1 - \delta$ (with $\delta \in [0, 1]$) is the probability of the error and $\tilde{D}(G)$ is the 2-approximation of the diameter of the graph $D(G)$ [8].

Summing up, the HGN algorithm is based on the following steps:

1. Calculate the approximated betweenness for all edges using DIAM.
2. Remove the edge(s) with the highest betweenness.
3. Recalculate the approximated betweenness for all edges affected by the removal.
4. Repeat from step 2 until no edges remain.

It is worth mentioning that in the worst-case scenario at each iteration GN computes all the shortest paths between $n(n-1)$ pairs of vertices, while HGN only between r

pairs. Moreover, our implementation allows to stop the algorithm when the required number of communities K is reached.

3 Experimental Analysis

We evaluate the performances of our proposal on benchmark networks in terms of *modularity* [3] and *Adjusted Rand Index* (ARI) [6]. We briefly describe the networks and then we show the main results.

3.1 Dataset

The benchmark networks that we consider are both characterized by an underlying known community structure. *Zachary karate club network* ([10]) represents social ties among the members of a university karate club collected by Wayne Zachary in 1977. *American college football network* ([5]) represents American football games between Division IA colleges during the regular season of Fall 2000. The former contains 78 edges, 34 vertices, and $K = 2$ known communities; the latter contains 616 edges, 115 vertices, and $K = 12$ known communities.

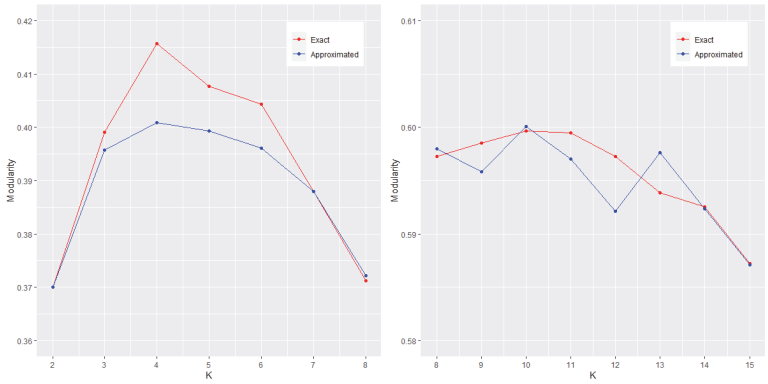
3.2 Results

As a preliminary analysis, we assess the accuracy of DIAM, since, to the best of our knowledge, there are no benchmarks in the literature. We notice that DIAM recognizes the highest-scoring edges, but, by sorting the edges in a decreasing order w.r.t the betweenness, mismatches between approximated ranking and exact one can occur. This implies that the edge deleted by HGN at i-th iteration does not always correspond to the one deleted at the same iteration by the GN algorithm. Anyway, HGN provides good performances in solving community detection problems.

Figure 1 (a) shows that the modularity trends of HGN and GN, when applied to Zachary karate club dataset, are similar: therefore, $K = 4$ is the number of communities that maximizes the modularity in both cases. Moreover, by fixing $K = 2$ as the true partition suggests, both methods induce the same partition of the network, misclassifying only two units. Indeed, when comparing the two partitions against the true one, we got the same value of the ARI.

When applied to Football network, HGN leads to an oscillatory behaviour of the modularity (see Figure 1 (b)). For $K \in \{8, 10, 14, 15\}$ the values of the modularities corresponding to GN and HGN are almost the same, while greater differences are observed for $K \in \{9, 11, 12, 13\}$. However, the greatest difference, observed for $K = 12$, is equal to 0.00513. Therefore we can conclude that all the values are close to

the exact ones. Fixing $K = 12$, HGN leads to an ARI equal to 0.883, while the ARI of GN is equal to 0.885. Hence, HGN provides good results in terms of the ARI index. Indeed, comparing Figure 2 (a) and (b), we observe that the number of misclassifications in both the partitions is almost the same and the communities are made up of almost the same units.



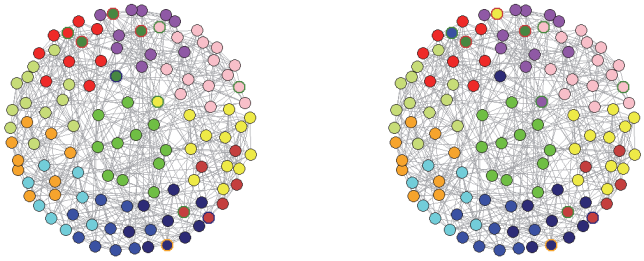
(a) Karate (b) Football

Fig. 1: Modularity values, as a function of the number of communities K, obtained by applying the exact (GN) and the approximated (HGN) algorithm with $\varepsilon = 0.05$ and $\delta = 0.1$.

4 Conclusion

In this work, we proposed a heuristic reformulation of the GN algorithm to face the problem of community detection. Since nowadays many complex problems can be represented by large-scale graphs, this approach can be a useful tool to avoid computationally heavy procedures.

Considering the good results obtained on small benchmark networks, future direction may involve the application of our method on a larger graph to accurately assess the computation time gain. Moreover, we are considering also other approaches to improve the edge betweenness approximation.



(a) GN (b) HGN

Fig. 2: Partitions obtained by applying GN and HGN on Football network with $K = 12$, $\varepsilon = 0.05$ and $\delta = 0.1$. Nodes belonging to the same community are identified by the same color. Nodes border colors compare the true partition with the obtained one: if the border is black, the units are correctly classified; otherwise, the color border identifies the belonging community in the true partition.

Geographically weighted regression for spatial network data: an application to traffic volumes estimation

La regressione geografica ponderata per dati su network spaziali: un'applicazione alla stima dei volumi di traffico

Andrea Gilardi, Riccardo Borgoni and Jorge Mateu

Abstract Estimating traffic volumes on road networks represents a critical issue in various areas of research such as transport studies and road safety analyses. In these cases, the traffic figures are usually recorded via sparse manual counts or expensive automatic tools (e.g. cameras or inductive loops). However, given the increasing availability of mobile sensors (e.g. smartphones and GPS sat-nav), in the last years several methods were developed to extract traffic information from geo-referenced mobile devices. This paper proposes a geographically weighted regression (GWR) approach to combine fixed counts and GPS data to estimate traffic flows, re-adapting the appropriate statistical methods to the spatial network context. The suggested methodology is exemplified using data collected in the City of Leeds (UK).
Abstract La stima dei volumi di traffico rappresenta un problema rilevante in diversi ambiti come la mobilità urbana e le analisi sulla sicurezza stradale. I dati sul traffico vengono solitamente ottenuti da conteggi manuali o costosi strumenti automatici (e.g. telecamere o spire induttivi). Tuttavia, data la sempre maggiore disponibilità di sensori mobili (come smartphone e dispositivi GPS), negli ultimi anni sono stati sviluppati diversi approcci per ricavare stime di traffico da devices portatili. In questo articolo si propone un modello di regressione geografica ponderata (GWR) per la stima dei volumi di traffico che unisce dati GPS a conteggi manuali, riadattando la metodologia alla rete stradale. Il lavoro viene testato analizzando i conteggi stradali registrati nella città di Leeds (UK).

1 Introduction

Estimating traffic volumes on urban networks represents a critical issue in several areas of research such as transport studies [3], road safety analyses [6], and investigations on street networks efficiencies [5]. In these cases, the traffic flows can be used to quantify transportation demand, simulate driving and commuting behaviours, or approximate road risk exposure.

The traditional ways to compute traffic figures involve manual counts with ad-hoc cameras or automatic counts with road-fixed sensors (e.g. inductive loops and spirals). Unfortunately, both techniques have several limitations linked to their limited spatial coverage, high economical costs of installation and maintenance, and error proneness. For these reasons, in the last years several authors explored different approaches to extract traffic information from geo-referenced mobile sensors (e.g. smartphones and sat-navs), creating a complementary way to estimate the road counts. The mobile sensors have several benefits, such as extremely detailed spatial resolution and (usually) extensive coverage. However, since not all vehicles driving in a road network are equipped with GPS devices, the figures inferred from the data may actually underestimate the real traffic flows.

Hence, in this paper we propose a geographically weighted regression (GWR) approach to combine the two data sources (i.e. classic road counts and GPS figures) into a unique traffic estimate. Moreover, considering that traffic flows measurement from fixed and mobile data represents a classical example of a phenomenon occurring in a spatial network, we re-adapt the suggested statistical technique to this particular spatial domain.

2 Geographical weighted regression for network data

GWR is a local form of spatial analysis that allows the estimation of relationships between a dependent variable and a set of predictors that vary over space [4]. More precisely, given a sample of n units in a region S observed at locations $\mathbf{s}_i$, $i = 1,\dots,n$ according to a given coordinate reference system, the GWR model writes as

$$y(\mathbf{s}_i) = \alpha(\mathbf{s}_i) + \mathbf{x}'(\mathbf{s}_i)\beta(\mathbf{s}_i) + \varepsilon(\mathbf{s}_i), \quad i = 1,\dots,n, \tag{1}$$

where $y(\mathbf{s}_i)$ denotes the response variable, $\alpha(\mathbf{s}_i)$ is the intercept, $\mathbf{x}(\mathbf{s}_i)$ a q-column vector of explanatory covariates, $\beta(\mathbf{s}_i)$ are the corresponding spatially-varying coefficients, and $\varepsilon(\mathbf{s}_i)$ is a zero mean random error. Since the parameters depend upon the spatial locations, this approach permits one to map the variation in the regression coefficients, gaining understandings of the spatial patterns between the predictor and response variables.

Parameter estimation at a selected location $\mathbf{s}_j \in S$ can be carried out using locally weighted least squares

$$\hat{\beta}(\mathbf{s}_j) = \left[\mathbf{X}'(\mathbf{s})W(\mathbf{s}_j)\mathbf{X}(\mathbf{s})\right]^{-1}\mathbf{X}(\mathbf{s})'W(\mathbf{s}_j)y(\mathbf{s}_j), \tag{2}$$

where $W(\mathbf{s}_j) = diag(w_{1j},\ldots,w_{nj})$ is a local weighting square matrix, w_{ij} is the weight associated to unit i when the regression is estimated at location $\mathbf{s}_j$, and $\mathbf{X}(s)$ represents the design matrix. The weights are defined in terms of a kernel function K that decays gradually with d_{ij}, i.e. the distance between the ith observation and the point $\mathbf{s}_j$. In particular, a Gaussian kernel function is adopted in this paper

$$K(d_{ij}) = \exp\{-d_{ij}^2/2h\}, \tag{3}$$

where the bandwidth parameter h determines the spatial range of the kernel. In the case study presented in the next section, the value of h is selected using cross-validation by minimising the mean square error of traffic flows predictions.

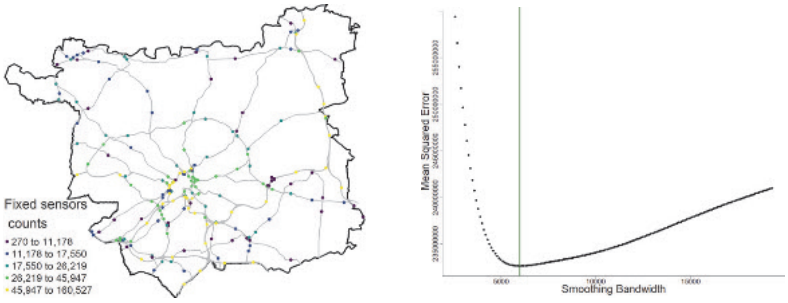
Usually, the inputs in Equation (3) are Euclidean distances in a planar setting, e.g. $d_{ij} = ||\mathbf{s}_j - \mathbf{s}_i||$. However, in our context, the sample units are observations recorded at a set of n road segments represented by their centroid locations $\mathbf{s}_i, i = 1,\ldots,n$. Hence, the distance d_{ij} should be calculated preserving the graph structure of the road network. In the rest of the paper we refer to the shortest path distance in order to take into account the spatial domain of the data. More precisely, indicating by $L = (V,E)$ the one-dimension graph object generated by the street network (where V and E denote the sets of vertices and edges, respectively), a path ρ_{ij} connecting any two generic locations $\mathbf{s}_i$ and $\mathbf{s}_j$ on the network is defined as a finite sequence $\{\mathbf{p}_m\}_{m=1}^{M}$ of adjacencent vertices in V such that the edges with endpoints $[\mathbf{s}_i, \mathbf{p}_1]$ and $[\mathbf{p}_\mathbf{M}, \mathbf{s}_j]$ belong to E. The length of ρ_{ij} can be computed as

$$||\mathbf{s}_i - \mathbf{p}_1|| + \sum_{m=1}^{M-1} ||\mathbf{p}_{m+1} - \mathbf{p}_m|| + ||\mathbf{p}_M - \mathbf{s}_j||,$$

and we define d_{ij} as the minimum length of all paths connecting $\mathbf{s}_i$ and $\mathbf{s}_j$ [1, 2].

3 Estimation of traffic flows in Leeds: data and results

The case study considered in this section is based on fixed and mobile daily traffic volumes recorded in the road network of Leeds (UK) from January to December 2019. The network and the GPS counts, which represent the spatial domain and the covariate used in our model (see Equation (1)), were obtained from TomTom Move service (`https://move.tomtom.com/`). The spatial network is composed by 8959 geo-referenced segments that are associated to traffic volumes estimated using mobile devices connected to cars and anonymous GPS-equipped smart-



(a) (b)

Fig. 1 Leeds road network and locations of fixed cameras used to detect traffic counts by the Department for Transport (a); MSE curve for bandwidth cross validation (b).

phones. Hence, the TomTom data have a reasonable spatial coverage, although they are known to underestimate the real flows.

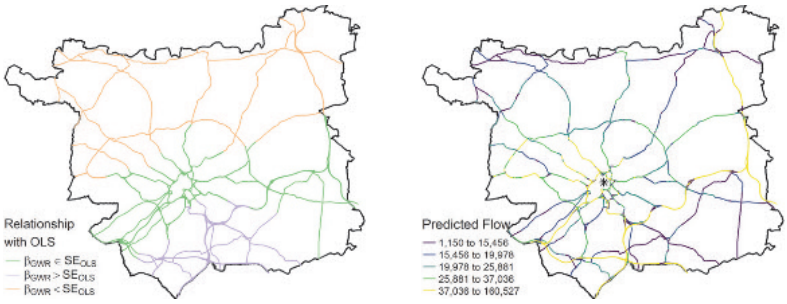
The regular counts, which are derived from fixed traffic cameras, were downloaded from the section Road Bulk Downloads of the platform Road Traffic Statistics developed by the UK Department for Transport (`https://roadtraffic.dft.gov.uk/downloads`). The 197 available count points locations were projected onto the road network, and, for each fixed camera, we assigned the corresponding traffic estimate to the overlapping road segment. The GWR was implemented assuming the actual frequencies observed at each count point as the response variable and the traffic flows measured by the mobile devices as predictor. Figure 1(a) displays the road network and the count points locations, which are distributed in several parts of the municipality.

As already mentioned, the smoothing parameter h in Equation (3) was estimated using leave-one-out cross-validation by minimising the mean squared error of traffic flows predictions. More precisely, we selected a series of bandwidth values in the range of the observed shortest path distances among all road cameras, and we calculated $\sum_{i=1}^{197}[y_i - \hat{y}_{\neq i}(h)]^2$ for all possible values of h. The quantity y_i denotes the observed road count, while $\hat{y}_{\neq i}(h)$ is the predicted flow obtained using bandwidth h and all observations but the ith one. The MSE estimates are reported in Figure 1(b) which suggests an optimal bandwidth as large as 5500 approximately.

Considering the smoothing parameter associated to the minimum MSE, we estimated the geographically weighted regression and predicted the traffic counts for

Table 1 Comparison between values detected by GPS sensors (first row), fixed cameras (second row) and predicted counts (third row) according to the model described in Equation (1).

	Minimum	1st Quartile	Mean	3rd Quartile	Maximum
GPS counts	0	865	1452	2272	12420
Fixed sensors counts	1150	12320	20999	38177	160527
Predictions	2820	16636	22965	32830	147694



(a) (b)

Fig. 2 Predicted daily traffic flows according to the model described in Equation (1) (a); Comparison with OLS estimates (b).

all segments in the network. As we can see from the equations reported above, the GWR is a local approach, which implies that each prediction requires the estimation of a different set of parameters. We explored this aspect more precisely by developing a comparison between the estimator detailed in Equation (2) and a classical OLS. The results are reported in Figure 2(a), where a segment is coloured in violet if the corresponding GWR estimate lays above the 95% confidence interval (CI) of the overall OLS estimate, in orange if the GWR estimate lays below the CI, and green otherwise. A clear spatial pattern has been found in the estimated coefficients. This points out that the relationship between point and GPS traffic measurements is not stationary in space and suggests the adoption of the local approach.

We report in Figure 2(b) a choropleth map of the estimated traffic counts at the road segment level. The figure clearly highlights several roads corresponding to a motorway (i.e. the yellow segments connecting the south area with the north/north-east) and the most important arterial thoroughfares reaching the city centre (i.e. the black star in the middle of the map). Roads in the north-west suburbs are found to be exposed to lower traffic flows as compared to the rest of the city.

As already mentioned, the TomTom figures underestimate the real flows, while the fixed cameras are too sparse to provide useful traffic estimates. The GWR approach, integrating the two data sources, combines their benefits. Table 1 details a convenient summary of the road counts employed in this paper, highlighting the merits of the GWR estimates. More precisely, the first and second rows summarise the GPS and camera data, respectively, and clearly point out that the mobile counts underestimate the real flows. The last row reports a summary of the predicted counts according to the GWR introduced in the previous paragraphs. We can observe that the predicted flows have a similar scale than real traffic data from fixed cameras while preserving a global coverage of the entire network. To conclude, we calculated the pseudo R^2 of the GWR finding values that ranged from 0.67 to 0.99 with a median value equal to 0.91. These quantities indicate a good performance for the estimated model.

4 Conclusions

This study demonstrates that GWR is a powerful tool to predict traffic flows at the road network level, combining data detected with fixed devices and GPS sensors. The classical approach was adjusted to take into account the particular spatial domain, substituting the Euclidean distances with the more appropriate shortest path distances. Our case study focused on daily traffic flows in the road network of Leeds from January to December 2019, and we showed that the suggested methodology allows a realistic estimation of traffic counts in all segments of a street network, combining the main benefits of the two data sources. In fact, the results detailed in Section 3 prove that the proposed model is suitable for the problem at hand.

We plan to extend the analysis presented in this work in several directions. First, the spatio-temporal dynamics of traffic flows could be explored, developing a traffic counts estimate for different hours of the day or different days of the week. Furthermore, we will enhance the geographically weighted regression including a few external covariates (e.g. road types, speed limit and road curvature) that could improve the model's fit.

Asymmetric Spectral Clustering: a comparison between symmetrizations

Spectral clustering asimmetrico: un confronto tra simmetrizzazioni

Cinzia Di Nuzzo and Donatella Vicari

Abstract In this work, spectral clustering of asymmetric data is addressed. In particular, two different methods to perform clustering have been compared: the application of spectral clustering on directed graphs represented by an asymmetric matrix; and the application of the classical spectral clustering algorithm once transformed the directed graph into an undirected one. To this end, some symmetrizations are described to convert the directed graph to an undirected one.

Abstract *In questo lavoro viene trattato lo spectral clustering di dati asimmetrici. In particolare, sono state confrontate due diverse metodologie per effettuare il clustering: l'applicazione dello spectral clustering su grafi diretti rappresentati da una matrice asimmetrica; e l'applicazione del classico algoritmo di spectral clustering dopo la trasformazione del grafo diretto in uno non diretto. A tal fine, sono stati descritte alcune simmetrizzazioni per convertire il grafo diretto in uno non diretto.*

Key words: spectral clustering, directed graph, symmetrizations

1 Introduction

Clustering on directed graphs has several useful applications, just think of network and social network analysis. So far, few spectral methods have been proposed for clustering this type of data, see [8], [3] and [2]. Many clustering methods on directed graphs rely on the symmetrization of the weighted matrix of the data by taking into account the out-degrees between the vertices of the graph. Once such a symmetrization has been computed, an undirected graph can be associated with the resulting symmetric matrix, and the standard clustering methods on undirected graphs can be applied. Here, we propose to apply the spectral clustering method proposed by [5]. In particular, three different ways to symmetrize an asymmetric matrix are presented: the first method is based on the symmetrization of the asymmetric weighted matrix associated with the directed graph; the second one is based on the symmetrization of the weighted matrix considering the out-degrees of the graph, while the last symmetrization takes into account both the in-degrees and out-degrees of

the directed graph. The spectral clustering, proposed in [5] and applied to these three symmetrizations, has been compared with the asymmetric spectral clustering proposed by [8]. The rest of the paper is structured as follows: in Section 2, some definitions on directed graphs are given. In Section 3, the symmetrizations of the asymmetric matrix associated with the directed graph, and the undirected spectral clustering method are summarized. In Section 4 the asymmetric spectral clustering proposed by [8] is summarized. Section 5 provides a numerical example where a comparison is carried out.

2 Background theory

Let $\mathscr{G} = (V,E)$ be a directed graph, where $V = \{v_1,\ldots,v_n\}$ is the set of n vertices or nodes, $E \subseteq V \times V$ is the set of the edges or arcs. In a directed graph, an edge is an ordered pair (v_i,v_j), where $v_i,v_j \in V$ for $i,j \in \{1,\ldots,n\}$. A tuple of vertices $(v_1,v_2,\ldots,v_p)$ with $(v_h,v_{h+1}) \in E$ for $1 \leq h \leq p-1$, is a *path*. If for each pair of vertices v_i and v_j there is a path where $v_1 = v_i$ and $v_p = v_j$, then the directed graph is *strongly connected*. When $\mathscr{G}$ is a strongly connected graph, there is an integer $l \geq 1$ and a unique partition $V = V_0 \cup V_1 \cup \cdots \cup V_{l-1}$ such that for all $0 \leq r \leq l-1$ each edge $(v_i,v_j) \in E$ with $v_i \in V_r$ and $v_j \in V_{r+1}$, and where $V_l = V_0$. The graph $\mathscr{G}$ is *weighted* when there is a weight function $w : E \to \mathbb{R}^+$ which associates a positive value $w((v_i,v_j))$ to each edge $(v_i,v_j) \in E$. Let $\mathscr{G} = (V,E,W)$ be a weighted directed graph, where W is the *asymmetric weighted matrix* associated to $\mathscr{G}$. The out-degree and the in-degree of a vertex v_i are defined by $d_i^+ = \sum_{j=1}^n w_{ij}$ and $d_i^- = \sum_{j=1}^n w_{ji}$, respectively. Let $D_o = \text{diag}(d^+)$ be the diagonal matrix of the vertex-out degrees. Given a weighted directed graph $\mathscr{G}$, there is a natural random walk on the graph with *transition probability matrix of the Markov chain* equal to matrix $P = D_o^{-1}W$ with entries $p_{ij} = w_{ij}/d_i^+$. When $\mathscr{G}$ is assumed to be a strongly connected graph, the Markov chain P is *irreducible* and has a unique stationary distribution π, i.e. a unique probability distribution π (with n non-negative entries summing to one) that satisfies the following balance equations

$$P'\pi = \pi, \tag{1}$$

where $\pi = (\pi_1,\ldots,\pi_n)'$. Let us denote Π the diagonal matrix having π as main diagonal.

3 Symmetrizations of the asymmetric matrix W and spectral clustering algorithm

Several attempts have been made to generalize the spectral graph theory of undirected graphs to directed graphs and they have been mainly addressed towards the symmetrization of the weight matrix associated to the graph. The graph symmetrizations proposed in literature are summarized below (see [6] for further details).

First symmetrization: $W + W'$. The simplest symmetrization is obtained as

$$U = W + W'. \tag{2}$$

Note that this symmetrization does not take into account the in- or out- links between the vertices of the graph.

Second symmetrization: Random walk. The random walk symmetrization proposed by [1] is defined as

$$U_{rw} = \frac{\Pi P + P'\Pi}{2}. \tag{3}$$

This symmetrization is based on the stationary distribution Π of the graph and does not take into account the in-degrees in each vertex.

Third symmetrization: Degree-discounted. In order to symmetrize the graph, both in- and out- degrees are taken into account in [6].The idea behind this is to look for a similarity measure that takes into account the in- and out-degrees between the vertices of the directed graph. In fact, nodes with high degrees will share many common edges (in- or out-) with other nodes simply by virtue of their higher degrees. The idea is to weigh the edges so that vertices with high (in- or out-) degree are weighted less in the symmetrization process. The reason is very simple: vertices with high (in- or out-) degrees are actually less informative in describing the links between the vertices of the graph than nodes with lower degrees. The symmetrization proposed in [6] is given by the following expression

$$U_d = D_o^{-1/2} W D_i^{-1/2} W' D_o^{-1/2} + D_i^{-1/2} W' D_o^{-1/2} W D_i^{-1/2} \tag{4}$$

where D_i =diag(d^-) is the diagonal matrix of the in-degrees.

Once a directed graph has been transformed into an undirected graph, the spectral clustering algorithm proposed in [5] can be can be run as summarized in Algorithm 1.

Algorithm 1 Spectral Clustering algorithm (see [5])

Let $\mathscr{G}_u = (V_u, E_u, W_u)$ be a undirected weighted graph, where $V_u = \{v_1^u, \ldots, v_n^u\}$ is the set of the vertices, E_u is the set of the edges, and $W_u = \left(w_{ij}^u\right)$ is the symmetric weighted matrix associated to $\mathscr{G}_u$.

Input: Symmetric weighted matrix W_u; number of clusters K.

1. Compute the degree matrix D_u =diag(d_i^u) associated to the undirected graph $\mathscr{G}_u$, where d_i^u is the degree of the vertex v_i^u associated to the undirected graph $\mathscr{G}_u$ and it is computed as $d_i^u = \sum_{i \neq j} w_{ij}^u$
2. Calculate the normalized symmetric Laplacian matrix $L_{\text{sym}} = D_u^{-1/2} W_u D_u^{-1/2}$.
3. Consider matrix Y having the eigenvectors associated to the K largest eigenvalues of L_{sym} as columns
4. Re-normalize the rows of Y to have unit length yielding $X \in \mathbb{R}^{n \times K}$.
5. Perform k-means algorithm on matrix X.

4 Asymmetric Spectral Clustering

Let us suppose to divide the graph into K subgraphs. In order to find the best partition of the graph $\mathscr{G}$, in the standard undirected spectral clustering method a normalized cut is introduced and the clustering is obtained thanks to a minimization of this cut (see [7] and [4]). An extension to directed graphs has been introduced by [8], where the directed *Ncut* of a cluster C is defined as

$$Ncut_{dir}(C) = \frac{\sum_{i \in C, j \in \bar{C}} \pi_i p_{ij}}{\sum_{i \in C} \pi_i} + \frac{\sum_{i \in C, j \in \bar{C}} \pi_j p_{ji}}{\sum_{j \in \bar{C}} \pi_j}. \tag{5}$$

In [8], the $Ncut_{dir}$ is minimized by the eigenvectors of the following matrix

$$\Theta = \frac{\Pi^{1/2} P \Pi^{-1/2} + \Pi^{-1/2} P' \Pi^{1/2}}{2}. \tag{6}$$

The Asymmetric Spectral Clustering is summarized in Algorithm 2.

Algorithm 2 Asymmetric Spectral Clustering algorithm (see [8])

Input: Asymmetric weighted matrix W associated to directed graph $\mathcal{G}$; number of clusters K.

1. Compute the transition matrix P and the diagonal matrix Π from its unique stationary distribution P.
2. Compute the (symmetric) Laplacian matrix Θ (6).
3. Consider the eigenvectors of Θ and introduce matrix Z with columns equal to the eigenvectors $\gamma_1, \ldots, \gamma_K$ associated with the K largest eigenvalues of Θ.
4. Perform k-means algorithm on matrix Z.

5 Numerical experiments

In order to compare the methods described in Sections 3 and 4, we present an example with artificial data.

The artificial data are described in Figure 1, the graph $\mathcal{G} = (V, E, W)$ is composed by three groups: $C_1 = \{v_1, v_2, v_3\}$, $C_2 = \{v_4, v_5\}$ and $C_3 = \{v_6, v_7, v_8\}$. Specifically, in Figure 1-*a*) the edges of the graph $\mathcal{G}$ are displayed with different thickness according to their weights (i.e., solid , dashed and dotted lines represent weights in descending order, respectively).

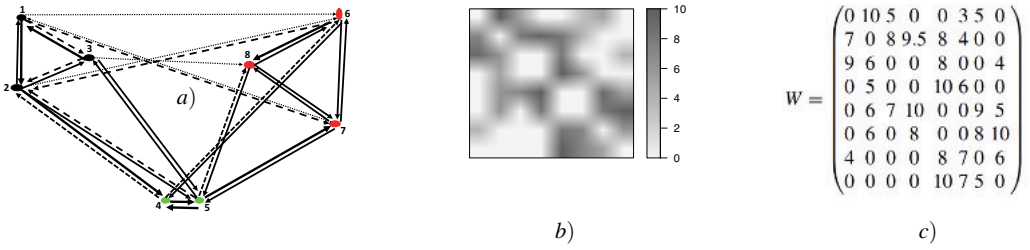

Fig. 1: *Artificial data*. *a*) Representation of the graph $\mathcal{G}$. *b*) Heat map of the asymmetric matrix W. *c*) Asymmetric weighted matrix W associated to graph $\mathcal{G}$.

In Figure 2, the geometric features of the spectral clustering algorithm (Algorithm 1) applied on the three symmetrizations described in Section 3 have been represented. The correct clustering results are attained from the U and U_{rw} symmetrizations; conversely, the spectral clustering applied on the U_d symmetrization does not provide the correct classification, because the accuracy is equal to 0.5 and the confusion matrix is

$$\begin{bmatrix} 2 & 0 & 1 \\ 1 & 1 & 1 \\ 0 & 1 & 1 \end{bmatrix}.$$

The asymmetric spectral clustering described in Algorithm 2 has been also carried out, the geometric features of the algorithm are shown in Figure 3, and the correct clustering is obtained.

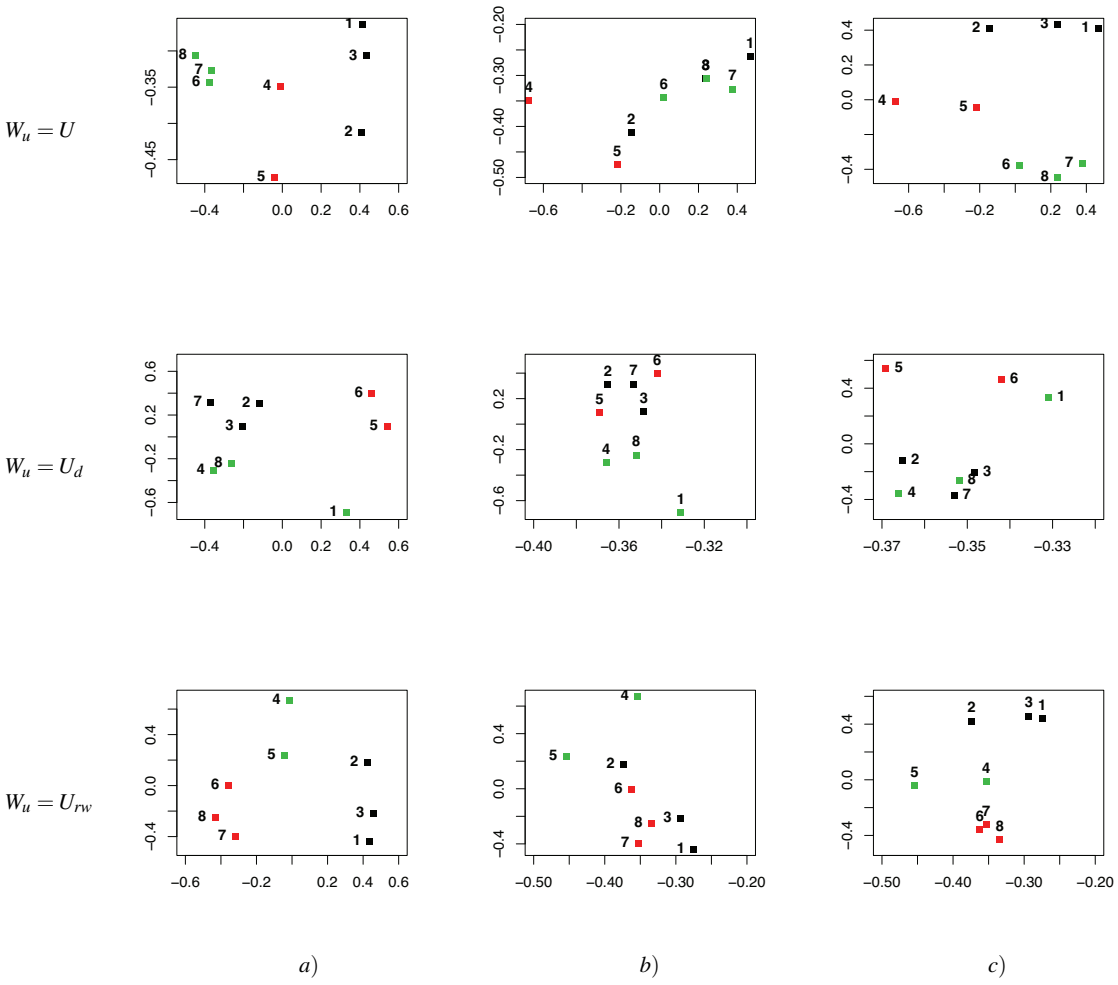

Fig. 2: *Spectral clustering after symmetrizations*. Embedded data associated to L_{sym} according to: a) the first two eigenvectors; c) the first and third eigenvector; d) the last two eigenvectors (different colors denote different clusters).

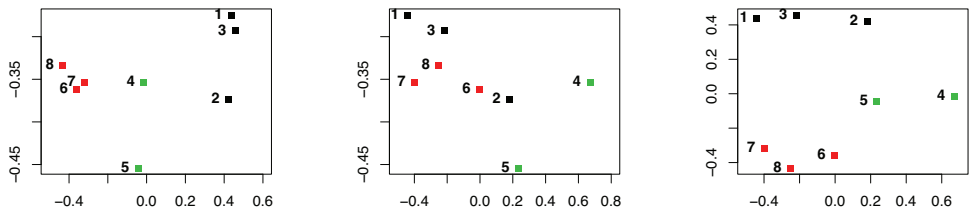

a) *b*) *c*)

Fig. 3: *Asymmetric spectral clustering (Algorithm 2)*. Embedded data associated to Θ according to: *a*) the first two eigenvectors; *c*) the first and third eigenvector; *d*) the last two eigenvectors (different colors denote different clusters).

To conclude, the asymmetric spectral clustering described in Algorithm 2 provides the correct classification, while the spectral clustering applied after the symmetrizations provides the correct results only when the U_{rw} and U symmetrizations are used. Finally, the Laplacian embedding structure provided by the U_d symmetrization, shown in Figure 2, is different from the others, because U_d also takes into account and incorporates the information from the in-degrees of the nodes of the directed graph $\mathscr{G}$. Therefore, this lays the groundwork for further studies on the information extracted from the different symmetrizations by carrying out studies on both artificial and real data.

Community detection of seismic point processes

Identificazione di comunità in processi di punto sismici

Valeria Policastro, Nicoletta D'Angelo, and Giada Adelfio

Abstract In this paper, we combine `robin` and Local Indicators of Spatio-Temporal Association (LISTA) functions. `robin` is an R package to assess the robustness of the community structure of a network found by one or more methods to give indications about their reliability. We use it to propose a classification algorithm of events in a spatio-temporal point pattern, by means of the local second-order characteristics and the community detection procedure in network analysis. We demonstrate the proposed procedure on a real data analysis on seismic data.

Abstract *In questo articolo, uniamo* `robin` *con le funzioni LISTA (Indicatori spazio-temporali locali di associazione).* `robin` *è un pacchetto R per valutare la robustezza della struttura in comunità di una rete ottenuta da uno o più metodi, per dare indicazioni sulla loro affidabilità. In particolare, proponiamo un algoritmo di classificazione degli eventi in un pattern di punti spazio-temporale, attraverso le caratteristiche locali del secondo ordine, e la procedura di identificazione delle comunità nell'analisi di rete. La bontà della procedura proposta viene valutata a partire da un catalogo sismico.*

Key words: network analysis, community detection algorithm, second-order characteristics, spatio-temporal point processes, statistical validation, earthquakes

1 Introduction

In network analysis, many community detection algorithms have been developed. However, their implementation leaves unaddressed the question of the statistical validation of the results. `robin` (Policastro et al., 2021) (ROBustness In Network) is an R Core Team (2022) package which answers this question, assessing the robustness of the community structure of a network found by one or more methods to give indications about their reliability. The procedures implemented in `robin` detect whether the community structure found by a set of algorithms is statistically significant and compare two selected detection algorithms on the same graph to choose the one that better fits the network of interest. We propose the use of the package on an application to the spatio-temporal point process theory, with the use of Local Indicators of Spatio-Temporal Association (LISTA) functions (Siino et al., 2018). In particular, our aim is to analyse seismic data, in order to identify different types of events, which could represent the background and the triggered events (Siino et al., 2020).

The structure of the paper is as follows. Section 2 presents the `robin` package of the statistical software R Core Team (2022). Section 3 recalls the LISTA functions and proposed a distance for building the adjacency matrix to built the network. Section 4 contains the application to seismic data. Conclusions come in Section 5.

2 Comparison and validation of communities with `robin`

The R Core Team (2022) package `robin` assesses the robustness of the community structure of a network found by one or more methods to give indications about their reliability. The aim is twofold: to compare two selected detection algorithms on the same graph to choose the one that better fits the network of interest, and to detect whether the community structure found by an algorithm is statistically significant.

For the first aim, the second workflow described in Policastro et al. (2021) can be used. It helps to choose, among different community detection algorithms, the one that best fits the network of interest, comparing their robustness two at a time.

Once the best community detection algorithm is found, the stability of the partitions can be tested against random perturbations of the original graph structure through the first workflow (also in Policastro et al. (2021)). To address this issue, a null model and a stability measure must be specified. For the construction of the null model, we explored the *dk* null random model provided in Orsini et al. (2015), using the parameter *dk* 2 in this paper. See Policastro et al. (2021) for further methodological details.

The first workflow finds a partition C_1 for the real network and a partition C_2 for the null network, it perturbs both networks, it retrieves two new partitions $C_{1(p)}$ and $C_{2(p)}$, and it calculates two clustering distances (for the real network and the null network) between the original partitions and the ones obtained from the perturbed network as $M(C_{1(p)}, C_1)$ and $M(C_{2(p)}, C_2)$. This process is carried out at different

perturbation levels $p \in [0 : 0.05 : 0.6]$ to create two curves, one for the real network and one for the null model, and to test their similarity by two functional statistical tests. The comparison between the two curves enables to reconsider the problem regarding the significance of the retrieved community structure in the context of stability/robustness of the recovered partition against perturbations. The basic idea is that if small changes in the network cause a completely different grouping of the data, the detected communities are not reliable. The second workflow has the same structure of the first one, but instead of comparing the real network with the null network, it takes the real network and apply two different community detection algorithms on it to compare them. `robin` embeds all the community detection algorithms present in `igraph`. They can be classified as modularity based methods, divisive algorithms, methods based on statistical inference, dynamic algorithms, and some alternative methods. Moreover, it provides the possibility to input a custom external function to detect the communities.

3 Classification of events using LISTA functions

We consider a spatio-temporal point process with no multiple points as a random countable subset X of $\mathbb{R}^2 \times \mathbb{R}$, where a point $(\mathbf{u},t) \in X$ corresponds to an event at $\mathbf{u} \in \mathbb{R}^2$ occurring at time $t \in \mathbb{R}$. The Local Indicators of Spatio-Temporal Association (LISTA) functions are a set of functions that are individually associated with each of the points of the point pattern and can provide information about the local behaviour of the pattern (Siino et al., 2018). Several second-order characteristics of point processes are considered for building LISTA functions, such as the K-function, the pair correlation function, and the product density function. In this paper, we consider the local spatio-temporal pair correlation function $\hat{g}^{(i)}_{\varepsilon,\delta}(r,h) = \frac{1}{4\pi r|W\times T|\hat{\lambda}^2}\sum_{j\neq i}\frac{\kappa_\varepsilon(||\mathbf{u}_i-\mathbf{u}_j||-r)\kappa_\delta(|t_i-t_j|-h)}{\omega(\mathbf{u}_i,\mathbf{u}_j)\omega(t_i,t_j)}$, where r and h are some spatial and temporal distances, κ_ε and κ_δ are kernel functions with bandwidths ε and δ, respectively, and ω is the edge correction factor. Both kernels are computed using the Epanechnikov kernel and the bandwidths are estimated with a direct plug-in method. Extending González et al. (2021) to space and time, LISTA functions consist of a functional dataset $\{\hat{g}^{(i)}_{\varepsilon,\delta}\}_{i=1}^n$, on some compact region $W \times T = [\varepsilon, r_{max}] \times [\delta, h_{max}]$, where r_{max} and t_{max} have to be prior chosen (by using Diggle's rule for instance). We start by defining, for any r and h, the following transformation $g^*_i(r,h) = \hat{g}^{(i)}_{\varepsilon,\delta}(r,h) + \hat{\mathbb{E}}_!\left[\hat{g}^{(i)}_{\varepsilon,\delta}(r,h)\right]$, where $\mathbb{E}_!\left[\hat{g}^{(i)}_{\varepsilon,\delta}(r,h)\right]$ is the Palm expectation. We follow Siino et al. (2018) and consider $\hat{\mathbb{E}}_!\left[\hat{g}^{(i)}_{\varepsilon,\delta}(r,h)\right]_{Poisson} = \lambda^2 + \frac{\lambda}{|W\times T|}$. These translated LISTA functions are above one for any $r \in W$ and $h \in T$ and hold that property for some fixed r and h, and individual surfaces are interpretable as long as they are not isolated from the others. The higher transformed LISTA functions have associated points with the most crowded neighbourhoods. We can simplify that relative information by standardising $\rho_i(r,h) = \log\frac{g^*_i(r,h)}{\sum_i g^*_i(r,h)}$. Each component $\rho_i(r,h)$

represents a relative weight as part of a whole, which in this case is a linear transformation of the pair correlation. Some multivariate methods map the observations in the Euclidean space while accounting for LISTA functions geometry. We employ the Euclidean metric in L_2 by letting $\rho_i(r,h), \rho_j(r,h)$ be two transformed LISTA functions, with distance given by

$$d^2(\rho_i, \rho_j) = \int_T \int_W [\rho_i(r,h) - \rho_j(r,h)]^2 \mathrm{d}r\mathrm{d}t. \tag{1}$$

After applying this distance, all the standard methods of multivariate statistics that rely on dissimilarity measures can be employed.

4 Application

The analysed data concern 1111 earthquakes occurred in Greece between 2005 and 2014. They come from the Hellenic Unified Seismic Network (H.U.S.N.), and they have been recently analysed in D'Angelo et al. (2022) by means of local point process models. First, a network is built by computing the LISTA functions $\hat{g}^{(i)}_{\varepsilon,\delta}(r,h)$ on each point of the pattern, and then, an adjacency matrix is provided, taking as links only the pair of points whose distance (1) is less than the 5% percentile of the resulting distribution of distances. We then apply the second workflow (`robinCompare()` function) on the network, to choose the community detection algorithm that better fits it. We found that the `infomap` algorithm was the most stable algorithm for our network (Figure 1). This belongs to the community detection methods based on statistical inference, and it is based on information-theoretic principles: basically, it finds the community detection structure that minimizes the description length for a random walk on the graph given by the map equation over possible network partitions (Rosvall and Bergstrom, 2008). Therefore we proceed testing also the stability of the partitions found by `infomap` against random perturbations of the original graph structure (`robinRobust()` function). So we construct the curves in Figure 2(a) that represent the measure between the partition of the original unperturbed graph and the partition of each perturbed graph (blue curve). The red curve is obtained in the same way but considering the random graph as the original one. Constructed the curves, we can proceed testing with the Interval Testing Procedure (`robinFDATest()` function) in Figure 2(b-c), which lead to most of the p-values being significant. We also run the Gaussian Process test (`robinGPTest()` function) that, with a Bayes Factor equal to 126, indicates an extreme evidence that the two curves come from two different processes. Therefore the communities identified on the proposed network by `infomap` are statistically significant. The results of the community detection and a possible interpretation follow. Figure 3 depicts the points belonging to the largest cluster found (left panel), and the remaining ones. This means that the points in the left panel are the most similar in terms of local second-order structure, belonging to the same cluster, while the

remaining clusters exhibit more variability (right panel). This is a promising result as it gives us more insight into the local structure of the analysed point pattern, basically splitting it into two sub-patterns. Indeed, separating point patterns into clutter and feature is a common problem in point process theory (e.g. Siino et al. (2020)). In particular, the two regions with the highest density in the left panel of Figure 3, are the same identified by D'Angelo et al. (2022), where points exhibit a different behaviour in terms of local structure, and by Siino et al. (2018) as the background.

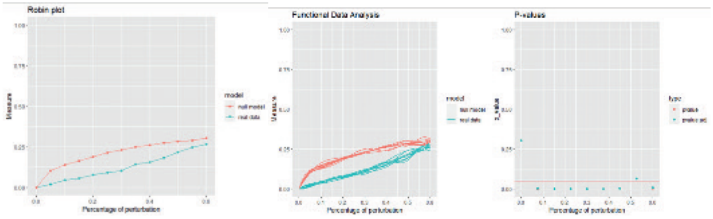

Fig. 2: (a) Curves of the null model and the real data applying `infomap` algorithm. (b) Curves for the testing procedure. (c) Corresponding p-values and adjusted p-values for all the intervals with the horizontal red line on to the critical value 0.05.

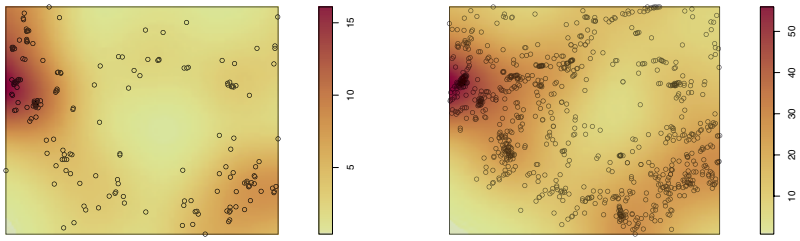

Fig. 3: Kernel smoothed intensity functions from the two point patterns, resulting from the largest cluster with 189 points (left panel) and the remaining ones belonging to smaller clusters (right panels). Overlaid in black, the observed point pattern.

5 Conclusions

In this paper, we have proposed a classification algorithm of events generated by a spatio-temporal point pattern, by means of the local second-order characteristics (LISTA functions) and the community detection procedure in network analysis. The R Core Team (2022) package `robin` helped to choose, among different community detection algorithms, the one that best fits the network of interest, comparing their robustness two at a time. Doing so, we found that `infomap` was the most stable clustering for our network. We then tested the stability of the partitions found by `infomap` against random perturbations of the original graph structure, finding that the identified communities on the proposed network build on distances among LISTA functions are significant. This paper represents a preliminary work on this proposal. In future we aim at first, changing the number of points "linked" into the network. This could be done by selecting a distance with some specific meaning into the context of application. Then, the proposed procedure could be tested on a large number of simulation studies.

An Explorative analysis of Different Distance Metrics to Compare Unweighted Undirected Networks

Analisi Esplorativa di Differenti Metriche di Distanza per Confrontare Reti Non Orientate e Non Pesate

Anna Simonetto[1], Matteo Ventura[2], Gianni Gilioli[1]

Abstract Networks are mathematical structures that make it possible to represent complex systems by characterising the relationships existing between the various elements of the network. In order to understand the differences between two different systems, tools are needed to quantify these differences. The purpose of this work is an exploratory analysis of the impacts that different distance metrics have on the comparative evaluation of two networks, at increasing levels of network perturbation. Preliminary results show that, depending on the chosen metric, it is possible to amplify or reduce the effect of perturbation. As the disturbance increases, the differences between the distance assessment systems are reduced.

Abstract *Le reti sono strutture matematiche che permettono di rappresentare sistemi complessi caratterizzando le relazioni esistenti tra i vari elementi della rete. Al fine di comprendere le differenze tra due sistemi diversi, sono necessari strumenti per quantificare queste differenze. Lo scopo di questo lavoro è un'analisi esplorativa degli impatti che diverse metriche di distanza hanno sulla valutazione comparativa di due reti, a livelli crescenti di perturbazione della rete. I risultati preliminari mostrano che, a seconda della metrica scelta, è possibile amplificare o ridurre l'effetto della perturbazione. All'aumentare della perturbazione, le differenze tra i sistemi di valutazione della distanza si riducono.*

1 Comparing networks

A network is a data structure describing the interaction pattern existing between a set of elements (e.g., in an ecological perspective the elements could be species, individuals, habitats) by the properties of the links that connect each pair of elements, defined as arcs. In unweighted networks the arc is characterized only by the presence/absence (its value is 1 or 0, respectively). In weighted networks, the weight is proportional to the intensity of the relationship existing between the two elements, usually varying in the range [0, 1] or [-1, 1] in the case of signed networks. The comparison of two networks allows the differences in the two systems to be assessed in terms of the differences in the relationships between the elements.

In research on complex systems, the problem of comparing networks is ubiquitous and not trivial. A tradeoff among interpretability, effectiveness of the results and computational efficiency is needed [8]. In fact, the method applied to measure differences between networks influences the result of network comparison. The choice of the correct method must therefore firstly be based on a clear identification of which differences are to be measured and then on an understanding of how the different methods considered represent these differences.

Some authors have already explored several methods to compare networks. For instance, Tantardini et al. [8] presented a review on methods for comparing networks, both for networks with node correspondence and for networks with unknown node correspondence and tested them on synthetic random networks under some types of perturbations. Wilson and Zhu [9] examined the performance of spectra as graph representation. Specifically, the authors investigated the cospectrality of various matrix representations and compared the Euclidean distance between spectra and the edit distance between graphs.

The aim of the work is to understand how the different used distance metrics describe situations of diversity between networks. Specifically, we explored the performances of three distance measures and three spectral methods applied to compare networks created with the same nodes.

A simulation study was conducted to understand the specific response characteristics of the investigated methods. Specifically, we considered as perturbation the deletion of an edge and with these simulations we aimed at understanding: i) how these metrics react to an increasing number of perturbations, ii) what is the reaction when a node is completely disconnected, and iii) the impact of node degree on the value of the distance.

2 Distance metrics

Mathematically, the network can be represented by a graph. A graph is described by $G = (V, E)$, where $V = \{1, \dots, n\}$ is the set of vertex, i.e. the nodes or elements of the network, and E is the edge set, that is a subset of the set $V \times V$ of ordered pairs of distinct vertices or nodes. The graph is said to be undirected if the edge (i, j) and its

opposite (j, i) are both in E [4]. A graph can be represented by a squared $N \times N$ adjacency matrix $\boldsymbol{A}$ where each row/column corresponds to a node and each cell represents an edge, set to one if the edge exists and zero otherwise. The adjacency matrix of an undirected graph is symmetric [2].

Two classes of methods for comparing networks are exposed hereafter: (1) distances between adjacency matrices, (2) spectral methods.

2.1 Distances between adjacency matrices

Given two $N \times N$ adjacency matrices $\boldsymbol{A}_1$ and $\boldsymbol{A}_2$, four distances are identified: Minkowski, Manhattan, Euclidean and Chebyshev distance.

Minkowski Distance Also known as $L_p -$ metric. It is identified by the following expression [6]:

$$d_{MK}(\boldsymbol{A}_1, \boldsymbol{A}_2) = \left[\sum_{i,j=1}^{N} |a_{1,ij} - a_{2,ij}|^p\right]^{\frac{1}{p}} \qquad p \geq 1. \tag{1}$$

Manhattan Distance Also known as $L_1 -$ metric. Its definition is based on Minkowski distance, using $p = 1$ [7]. It corresponds to the sum of the absolute differences, i.e., all the matrices' elements are equally weighted.

Euclidean Distance Also known as $L_2 -$ metric. It is a specific case of Minkowski distance, using $p = 2$ [3]. With this distance, greater weight is attached to longer distances.

Chebyshev Distance It is also called $L_\infty -$ metric and it is a special case of Minkowski distance where p goes to infinity [1], i.e., only the highest difference influences the metric value:

$$d_{CH}(\boldsymbol{A}_1, \boldsymbol{A}_2) = \lim_{p \to \infty} \left[\sum_{i,j=1}^{N} |a_{1,ij} - a_{2,ij}|^p\right]^{\frac{1}{p}} = \max_{i,j} |a_{1,ij} - a_{2,ij}|. \tag{2}$$

2.2 Spectral methods

These approaches are based on spectral theory, that allows to describe networks' structural properties through eigenvalues and eigenvector of a matrix.

The spectrum $\boldsymbol{\Lambda}$ is the sorted sequence of matrix eigenvalues λ and the spectral distance between two graphs is the Euclidean distance between the two correspondent matrices' eigenvalues [9]:

$$d_\lambda(\boldsymbol{\Lambda}_1, \boldsymbol{\Lambda}_2) = \sqrt{\sum_{i=1}^{N} \left(\lambda_{1,i} - \lambda_{2,i}\right)^2}. \quad (3)$$

In addition to the adjacency matrix, there are two other possible matrix representations of a graph: the Laplacian and Normalised Laplacian matrix.

The Laplacian matrix $\boldsymbol{L}$ is defined as $\boldsymbol{L} = \boldsymbol{D} - \boldsymbol{A}$, where is the adjacency matrix of the graph and $\boldsymbol{D}$ is the diagonal degree matrix [9].

The Normalised Laplacian matrix, instead, is defined as:

$$\boldsymbol{\mathcal{L}}(i,j) = \begin{cases} 1 & if\ i = j \text{ and } d_i \neq 0 \\ -\dfrac{1}{d_i d_j} & if\ i \neq j \text{ and } i \text{ is adiacent to } j, \\ 0 & \text{otherwise} \end{cases}$$

where d_i and d_j are respectively the degree of the node i and the degree of the node j. The Normalised Laplacian can be also written as $\boldsymbol{\mathcal{L}} = D^{-\frac{1}{2}} L D^{-\frac{1}{2}}$.

3 Simulation study

In this section we test the responses of the above proposed metrics through a simulation experiment. All the analyses have been implemented in R [5].

We started from a full connected, unweighted network composed by twelve nodes. At each iteration the distance between the fully connected network and a disturbed network will be calculated. At step 0 the disturbed network is equal to the fully connected network and itself. At each subsequent iteration the comparison network is perturbed by removing a connection arc. After each perturbation the distance of the disturbed network from the full connected one was measured. This is aimed at checking the distances response with increasing number of removed edges, and thus, with decreasing graph density.

To investigate the distances response to the decrease of the node degree and to the complete disconnection of a node, an ordered edge removal criterion was applied. Considering the upper triangular half of the completely connected graph's adjacency matrix, the ordered removal consists in turn into zero the elements of the first row and proceed with the next row only when the previous is full of zeroes; namely, if we consider a graph, the ordered removal consists in removing all the edges from a node and proceed with another node only when the previous one is completely disconnected from the network. This edge removal criterion leads to the generation of a set of nested networks, i.e., the edges removed from the network with n perturbations do not exist in all the subsequent networks with $n + m$ removed edges.

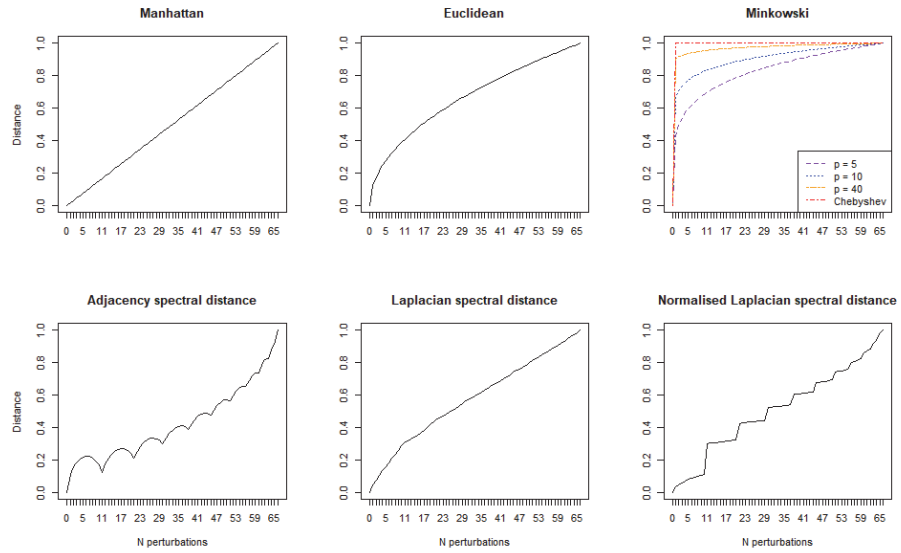
From the results reported in Figure 1, it appears that all the distance metrics have a growing monotonous pattern. We note that, considering the Minkowski distance,

when p increases, the metric distances tend to weight equally the perturbations independently of the number of deleted edges. Namely, the Manhattan distance weight equally all the perturbations, up to the extreme case represented by Chebyshev distance that weights in the same way one perturbation or infinite perturbations.

Instead, spectral methods show some interesting patterns: both the adjacency and the Normalised Laplacian spectral distance show a non-monotonous pattern. We observe level-shifts that seem to be dependent on the position of the removed edges, indeed, spectral methods present a step pattern where the level change happens when, once a node is completely disconnected, the first edge of another node is removed.

This first study shows that, particularly for disturbances of less than 50% of the number of arcs in the fully connected network, the choice of comparison metric influences the assessment of the distance between the compared networks.

Figure 1:Results of the ordered edge removal



4 Conclusions

In this work we compare different distance metrics to estimate the differences between two or more networks.

The simulation study highlights the differences in the distances estimation using four distance metrics and three spectral methods. The networks comparison is performed according to an increasing levels of perturbation. The Manhattan distance estimation resulted not influenced by the disturbance levels, Euclidean distance weighs more heavily on differences at low disturbance levels, Normalised Laplacian spectral

distance weighs more heavily on disturbances that lead to completely disconnecting a network node.
Further developments of the study will be devoted to deep the possible dependance of the distance estimation from the order in which edges are removed.

Gender, attitudes and family ties

Parents of a disabled child in Italy: less healthy but more civically engaged

Avere un figlio disabile in Italia: Genitori meno in salute ma più socialmente impegnati

Nicoletta Balbo and Danilo Bolano

Abstract This article provides novel evidence of spillover effects of children disability on different life domains of their parents. We focus on health and social and civic engagement of the parents. Using data from a nationally representative household survey in Italy (Aspetti di Vita Quotidiana), we show that parents of a disabled child report lower levels of health both in terms of general health and mental health. At the same time these parents show a higher propensity to be socially engaged.

Abstract *Questo articolo mostra come la disabilità nei minori sia un fenomeno che trascende il minore stesso ma ha diramazioni importanti sui genitori. Gli autori, utilizzando dati dall'indagine ISTAT - Aspetti di Vita Quotidiana, mostrano la presenza di effetti negativi sulla salute (salute generale e salute mentale) dell'avere un figlio disabile ma anche una propensione piu' elevata di questi genitori ad essere impegnati socialmente*.

Key words: Disability in family, Italy, Parental effect, Spillover effets.

1 Introduction

According to the most recent Eurostat estimates (data from 2016), approximately 4% among individuals under age 16 have some disabilities and over 15 million

[1] Nicoletta Balbo, Bocconi University – Dondena Center. email: nicoletta.balbo@unibocconi.it
Danilo Bolano, Bocconi University – Dondena Center; email: danilo.bolano@unibocconi.it

school-age children have been identified as having special educational needs (estimates from the European Commission). These disabilities limit children in their everyday activities and impact the lives of their families in myriad ways. There is indeed some evidence suggesting that being confronted with the disability of a child may substantially affect the life and well-being of family members, shaping their social, demographic, and economic trajectories. Parents may experience negative physiological and psychological effects, such as higher levels of anxiety, stress, and uncertainty, and they may have less resources, time and energy to pursue employment [2]. A relevant weakness of the existing literature is that many studies rely on data from small convenience samples, often focusing on one specific type of child disability and rarely have sufficient data to consider other, crucial factors. All this makes any generalizations to the population level, as well as to a broader scientific setting, unfeasible.

This paper investigates the relationship between having a disabled child and parental health and social participation. We do so, by studying different health outcomes, namely self-rated health, and emotional well-being, to better understand the mechanisms through which child disability affects parents' health. Next to this, we also examine the unexplored association between child disability and parental civil engagement to uncover whether parents of disabled children show more pro-social and altruistic behaviours.
The proposed research contributes to the existing literature in several ways. For the first time, the analysis of how child disability can affect parental health and behaviours will be carried out within the Italian context. Italy is an extremely interesting test-bed because it is a country with a strong familialistic welfare regime, where the family is the main responsible for the care of children or non-independent/sick family members. Therefore, we can expect Italian parents to be especially affected by the disability of a child. Second, this paper adopts a population approach using an Italian nationally representative survey (Aspects of Daily Life Italy - AVQ). This will allow us to compare parents with a disabled child with their counterpart with a healthy child, and enable us to control for relevant socio-economic factors, that may act as confounders in the relationship under study. Third, we explore a novel and very much understudied life dimensions of parents' life, that is their social participation and civil engagement and how that is shaped by having a disabled child. Specifically, we aim at investigating whether parents with a disabled child are more likely to engage in associationism, volunteering and political activities, as a signal of higher altruism.

2 Background

The existing literature on families with a disabled child is scattered, with evidence based on small convenience samples, mostly focusing on a specific disease. The resulting evidentiary basis is inconclusive with respect to many outcomes (e.g., parents' fertility, union dissolution and mental health) and results are hardly

generalizable. A population approach is appropriate for adjudicating whether contradictory findings are driven by sampling biases, selection processes, or suggestive of legitimately differential effects by population subgroup.

2.1 Health

Studies of children's disability and family members' health show mixed findings. Most report adverse effects on parents' health [3, 9]. However, there is also evidence that mothers who care for a disabled child have even better health compared to mothers with a healthy child [6]. Along the same lines, other studies suggest that having a child with a disability is associated with a higher frailty in terms of mental health, and emotional stress for parents [1]; at the same time, a few studies highlight the ability of such families to adjust and develop coping strategies and resilience [4]. We therefore aim at studying how child disability influences parents' health considering different aspects of their well-being, to shed further light on which health dimensions are affected the most and how by the disability of a child. We specifically focus on self-rated health, which has been shown to be a good proxy also for physiological issues. We also examine the relationship between child disability and emotional well-being to uncover whether we observe higher distress deriving from the heightened care burden or, rather, we find evidence that the "disability paradox" [10] – according to which disabled individuals tend to perceive higher quality of life than non-disabled individuals because of their lower expectations and structural limitations - applies to the other family members as well.

2.2 Civil Engagement

The existing literature on disability and social participation focuses almost exclusively on disabled individuals themselves. Social participation in school activities, social and physical activities is associated with higher physical, emotional and social well-being for children with disabilities [18], but we know very little about how child disability affects social participation of parents. The evidence we have suggests that family members experience higher barriers to social participation [5] due to scarcity of time and resources but, conversely, have larger support networks. In this paper we aim at investigating potential positive effects of children disability on parents' civil engagement. The existing literature tends to focus on negative consequences and inequalities associated with children disability. However, the positive spillover effects also have a crucial societal relevance: these families create valuable social capital for civil society, broadly speaking. Some studies show that affected families develop higher levels of altruism and pro-social behaviours [7], but we do not know whether that translates into higher probability of engaging in volunteering activities, associationism, and political participation. In this paper we aim at addressing this issue empirically.

3 Data and Methods

For our analyses we use the nationally representative cross-sectional survey "Aspects of Daily Life - AVQ" administered every year since 1993 to around 25,000 households residing in Italy. AVQ covers a wide range of topics, namely schooling, employment, household characteristics, family life, health, political and social participation, and leisure time. In this survey each member living in the household is a respondent.

Independent variable. A measure of (children's) limitation in daily activities was introduced in 2013 using the Global Activity Limitation Indicator (GALI) based on the question: "*For at least the past six months, to what extent has your child been limited because of a health problem in activities that people usually do?*". That is the question we use to identify the presence of a disabled child in the household.

We pool together the last two available waves of AVQ, administered in 2018 and 2019, and we restrict our sample to mothers and fathers who have the oldest child aged 17 or younger. The total sample consists of 12,988 individuals, but due to the presence of missing observations in some of the variables included in the models, the working samples vary across models. While the prevalence of disabled children within the age group 0-17 in 2019 is equal to 5,04%, in our sample we reach a share of 6,17% children whose daily activities are limited or severely limited.

Outcome variables. As aforementioned, this study considered several health outcomes and social behaviour indicators. We considered the self-rated health (dichotomised in being in a poor health or not); emotional wellbeing, a 0-100 scale constructed from the corresponding five items of the Short Form SF-36 questionnaire [11]; and three indicators if the respondent was participating in any kind of associations, active in politics, and active in volunteering activities.

Control variables. We control for a series of socio-demographic characteristics that according to the literature might be associated with health condition and/or social engagement: gender, age, level of education (below high school diploma, diploma, degree or above), number of children in the household, employment condition (employed, unemployed, inactive), and region of residence (NUTS 1 level). Since we pooled together the last two waves of data, we include the year of interview as well.

To test our research hypotheses, a series of multivariate regression models is employed (results reported in Table 1). We run a logit model while analysing the SRH, and the three social and political engagement indicators. A linear regression model has been used when the outcome considered was emotional wellbeing. Since within a couple we might have a mutual influence across partners, the standard errors were clustered at household level.

4 Results and Conclusions

Table 1 shows the findings of our multivariate analyses. Results suggest that parents with a disabled child under the age of 17 are more likely to declare poor health both in terms of general health (self-rated health - Model 1) or mental health (emotional wellbeing - Model 5).
Model 2 to 4 instead show that parents with a disabled child are more likely to be engaged in associationism or volunteering, whereas no difference with their counterpart parents with a healthy child is observable in case of political participation.
In terms of the effect of our socio-demographic controls, the results are consistent with the literature. Women are less engaged and reported a lower level of health probably because of being primary caregiver of the disabled children. Older adults, those with lower levels of education and those unemployed are less healthy and less engaged. We observe as well interesting regional differences with respondents living in the South of Italy reporting lower levels of health and lower propensity to be socially and politically engaged.

Overall, our analyses suggest that parents of a disabled child are more likely to report poor health and lower subjective well-being, but at the same time they are more civically engaged. The present study looked at each outcome separately, but it is possible to look at the interdependence across them as well. These novel results point out that disability must be considered as a family level "condition" with strong effects that crossover family members, parents in this case, and spillover multiple life domains (wellbeing, social and civic engagement for instance). Further research can investigate whether there are relevant heterogeneous effects by mothers and fathers in these as well as other life dimensions. Similarly, studies on siblings or other individuals related to the disabled children (peers, grandparents to cite some) are welcome.

Of course, no causal inference can be made, because many unobservable factors may confound the relationships under study. Nevertheless, the provided evidence suggests that these families are frailer from an emotional and health-related point of view, but the societal contribution they provide in terms of creation of social capital is relevant. Therefore, by further supporting these parents, to improve their well-being, we might expect societies can further gain in terms of social participation and cohesion.

Searching the nexus between women's empowerment and female genital cutting (FGC)

Potenziamento femminile e FGC: Quale relazione?

Patrizia Farina, Liva Ortensi, Thomas Pettinato, and Enrico Ripamonti[1]

Abstract Female genital mutilation/cutting (FGC) is still present in many African countries, as well as a few others. We used DHS data from seven African countries and considered both the empowerment and the FGC modules. We selected empowerment variables based on Kabeer's conceptual framework and used multilevel logistic models to evaluate the effect of empowerment in support for discontinuing the practice. We found a protective role of education. Other variables, including justification of intimate partner violence and having experienced FGC, were associated with FGC support. The relationship between decision-making and FGC support appears complex, while the unmet need for contraception and job conditions do not seem to play a role.

Abstract *La mutilazione genitale femminile (FGC) è ancora presente in molti paesi dell'Africa, così come in pochi altri. Abbiamo utilizzato i dati del DHS relativi a sette paesi africani e abbiamo considerato sia i moduli di potenziamento femminile che quelli di FGC. Abbiamo selezionato le variabili di potenziamento in base alla concettualizzazione proposta da Kabeer. Quindi, abbiamo utilizzato modelli logistici multilivello per valutare il possibile ruolo del potenziamento a sostegno dell'interruzione della pratica nella generazione successiva. I modelli multilivello hanno evidenziato l'effetto protettivo dell'istruzione. Altre variabili, tra cui la giustificazione della violenza da parte del partner e l'aver subito FGC, sono associate al supporto al FGC. La relazione tra il processo decisionale e il sostegno al FGC appare complessa, mentre, almeno dalle nostre analisi, il bisogno insoddisfatto di contraccezione e le condizioni di lavoro non sembrano svolgere un ruolo.*

Keywords: female genital cutting, empowerment, decision-making, education

1. Introduction

Female Genital Cutting (FGC) is internationally recognised as an extreme violation of the rights of women and girls since these practices contravene the principle of equality and non-discrimination based on gender, as well as the right of not being exposed to torture or cruel, inhuman punishment [1–4]. FGC is normally performed over girls before the age of puberty, causing short- and long-term health complications, including infections, increased risk of HIV transmission, chronic pain, birth complications, infertility, and, in worst cases, death [5–7]. Four main types of FGC have been described, ranging from total removal of the clitoris to infibulation, and including other types of modification like stretching, cauterisation and piercing. FGC is currently quite prevalent in Africa and the Middle East, spanning at least 31 countries and affecting over 200 million girls and women (UN estimates). Decades of actions of International Agencies, governments, civil society, communities, and individuals accelerated the secular decline of FGC. Herein, we aim to assess the relevance of women empowerment on individual support to FGC continuation. In particular, we targeted the putative protective effect of mothers' empowerment on the next generation of girls, controlling for the background and the socio-economic conditions of adult women.

2. Data and methods

We selected seven African countries in which information on FGC, gender violence and empowerment modules were simultaneously recently collected: Burkina Faso, Ivory Coast, Egypt, Ethiopia, Mali, Nigeria and Togo. We used data from the Demographic and Health Surveys (DHS) carried out between 2008 and 2016 [8]. The binary dependent variable is represented by the women's support to the continuation of the practice. Covariates include an indicator of empowerment, women's age, FGC personal experience (being cut or not), the wealth index, unmet need for contraception, employment status, educational level, children ever born, religion, and FGC regional prevalence. Operationalisation of women's empowerment has been done following Kabeer's [9,10] theoretical framework. To carry out the analysis, we fitted multilevel logistic models.

3. Results

We found that the education level was negatively correlated with FGC support, along with age at first cohabitation. Experience of FGC, on the contrary, was strongly correlated with support for the continuation of FGC. The ideal number of children, the justification of intimate partner violence (IPV), and whether decision-making was mainly left to the respondent or other persons (compared with equal

decision-making within the couple) were associated with more substantial FGC support. Interestingly, the unmet need for contraception and job conditions were not significantly correlated with FGC support.

Predicted probabilities based on the model (Figure 1) confirmed the relevance of the link between indicators of empowerment and FGC. Support for continuing FGC decreases when the educational level increases, suggesting that the higher a woman's education level, the easier is for her to make empowered choices. It is worth observing that predicted probabilities seem to be similar for three clusters: {Burkina Faso}, {Egypt, Mali, Nigeria}, {Ivory Coast, Ethiopia, Togo}. This may indicate underlying similar cultural contexts that have not been investigated in the present context.

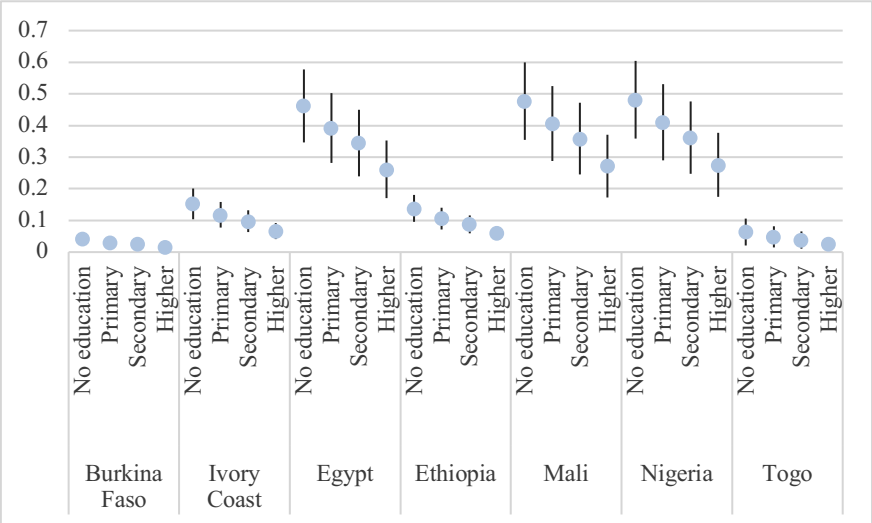

Figure 1. Predicted probabilities by country and education (other variables kept at their average level)

4. Final remarks

Our analyses underline the importance of linking FGC support and empowerment. In this regard, we found a role played by education did emerge. Other relevant factors were personal experience with FGC, and justification of IPV. Such dimensions describe different levels of empowerment, reflecting existing social and gender norms that act upon resources and agency and are internalized by individual women (e.g., IPV justification).

In the measurement of empowerment what has come to be more influential is the dimension of agreement among women on the subordinate role they have in the couple. This is explicitly linked to the legitimization of men's violence. Being it an important empowerment component, policy actions to enforce empowerment must

go firstly in the direction of changing this legitimization, breaking the crystallized unbalance of gender gap shared by women, erasing the role of a punitive husband and a "disrespectful" wife who fully aim to be able and entitled to truly make decisions [11] with no fear of violent consequences.

As from the international organization literature, policies must go not only in the direction of human rights enforcement but also and most notably in the elimination of gender discrimination (as from WHO [4]). As such, gender role changes reflect the definition of empowerment as reported in Kabeer [9,10].

Specific cultural characteristics of different contexts must be taken into consideration to understand the mechanisms operating in one defined territory. It is a limitation of the present analysis both to have a definition of empowerment linked to the available data and to reflect on applying a standardized definition to different cultures as well social contexts. Thus, the influence of empowerment on FGC should be further studied, as well as put in relation to other regional and local contexts.

Social stratification, gender, and attitudes towards voluntary childlessness in Europe: A double machine learning approach

Stratificazione sociale, genere, e atteggiamenti verso la scelta di essere senza figli: un approccio double machine learning

Danilo Bolano and Francesco C. Billari

Abstract Childnessness, and its links with educational change and inequality, is emerging as a key issue in the study of population change. In this paper we study the intersection between social stratification and gender in shaping the gendered attitudes towards voluntary childlessness in Europe, using data from two rounds of the European Social Survey (ESS). The ESS includes a randomised design that allows to derive experimental results on gender attitudes. We apply a double machine learning approach and find that, in general, higher education has an impact on more favourable attitudes. Our findings are consistent with educational expansion having a causal role in the increase of favourable attitudes towards childlessness in Europe.
Abstract *La scelta di essere senza figli è una decisione sempre piu' comune nelle società occidentali seppure ancora osteggiata in quanto non conforme al concetto che uomo/donna adulto è da considerasi tale se genitore. Studi sul legame tra una tale scelta e stratificazione sociale sono quindi fondamentali per comprendere l'evoluzione della struttura della popolazione. Questo studio si focalizza sull'interesezionalità tra stratificazione sociale e genere nel definire gli atteggiamente verso la scelta di essere senza figli in Europa. Utilizzando un approccio causale di tipo double machine learning su dati dell'European Social Survey, questo studio dimostra come l'espansione del livello di istruzione abbia reso piu' favorevole il giudizio circa la scelta di un individuo di non avere figli.*

Key words: Social Norms, Social Stratification, Lasso, Average Treatment Effect, Gender

1 Introduction

Europe has experienced, over time, a U-shaped trend in childlessness over time, with data pointing to a general rise in the recent decades both from a period and a cohort perspective [8]. This shift is linked to a higher acceptance of voluntary childlessness, which for a long time, and in many parts of Europe, was running against established social norms. In line with the rise in its prevalence, the acceptance of childlessness has generally risen over the last decades [7].

In the recent literature, gender and social stratification have figured prominently as key forces that shape choices. It has, for instance, been argued that "Future fertility trends are shaped at the intersection of gender and social stratification" [6]. We focus on this issue, and study the intersection of gender and social stratification on attitudes towards voluntary childlessness. We do so by exploiting, on the gender side, an experimental design that was implemented in two waves of the European Social Survey (ESS), and by applying, on the social stratification side, a double machine learning approach.

2 Data and survey design

We exploit data from two rounds of the European Social Survey: round 3 (2005–06), and 9 (2017–18). The ESS is a biennial, cross-sectional, multi-country survey that collects information on attitudes and behavior in almost 30 European countries. It is a representative survey of all persons aged 15 and over living in each country. In rounds three and nine, a specific rotating module on the "Timing of life", was included [3]. Importantly, the module included questions on attitudes towards voluntary childlessness, and a split-ballot design that allowed to randomly ask questions about women or about men. For our analyses, we pool together the two rounds, ending up with almost 80,000 respondents across Europe. Here we shortly describe the main measures used in our analyses.

Outcome variable: Attitude towards voluntary childlessness. We use the question "How much do you approve or disapprove if a woman/man chooses never to have children?", with answers on a scale from 1 (strongly disapprove) to 5 (strongly approve). Answers are standardised for ease of interpretation.

Randomized design on gender. As we mentioned, to (about) half of the respondents were asked about male behavior (i.e., how much the respondent approve or disapprove if a man chooses never to have a children), and to the remaining half were asked about female behavior (i.e., how much the respondent approve or disapprove if a woman chooses never to have a children). This split-ballot design on the gender of the "target" allows to integrate the advantage of having a (randomized) experimental design (internal validity) and information from a nationally representative survey (external validity) [1]. We create a treatment variable with four values, interacting the gender of the respondent and the gender of the target.

Social stratification: educational level of the respondent. As a social stratification factor, we include a dummy variable indicating whether the respondent has completed at least secondary education (ISCED 3 or above, which we code as high level of education), or not.

Control variables. We include a series of variables which, according to the literature, might be associated with either respondent's educational attainment or attitudes toward childlessness. In particular, age, marital status, current employment status, having children, level of religiosity, being native or migrant, citizenship, educational level of both parents, if the parents were born in the same country the respondent currently live in. Finally we consider the year of interview and country of living. For parsimony, we cluster countries considering family policies and social values simultaneously as follows: egalitarian (Sweden, the Netherlands, Denmark, United Kingdom, Norway, Finland), pro-natalist (France and Belgium), Eastern European (Bulgaria, Czech Republic, Poland, Hungary, Slovenia, Estonia, Croatia, Romania, Latvia, Russian Federation, Slovakia), traditional (Austria, Germany, Switzerland, Ireland), and Southern European countries (Spain, Italy, Greece, Portugal, Cyprus).

3 Methods

While the gender of the respondent is exogenously given, and the gender of the target has been randomised, in order to estimate the causal impact of education on attitudes towards voluntary childlessness, we need a specific empirical strategy. We here apply a strategy that makes an optimal use of the set of available control variables, i.e. an Average Treatment Effect (ATE) model with lasso.

More specifically, being y_i the outcome variable (the approval of childlessness), and T the treatment binary variable (having a high level of education or not), and $\mathbf{X}$ a vector of controls, broadly speaking the outcome model can we written as $y_i = g_0(T_i, \mathbf{X}_i) + u_i$ with $E(u_i|T_i,_i) = 0$.

Where $g_0(T_i = 0, \mathbf{x}_i) + u_i$ is then the expected outcome when the treatment T takes value 0 (when the respondent is low educated in our study). Conversely $g_0(T_i = 1, \mathbf{x}_i) + u_i$ when the respondent is highly educated). Of course, we can only observe one of the two expected outcomes. The treatment model can be written as $T_i = m_0(\mathbf{Z}_i) + v_i$ with $E(v_i|\mathbf{z}_i) = 0$.

where $\mathbf{Z}$ is another vector of controls and $m_0(\mathbf{Z}_i)$ is the probability of being treated given the vector of controls Z. It is possible to use different controls for the treatment model ($\mathbf{Z}$) and for the outcome model ($\mathbf{X}$). The objective is to estimate the ATE: $E(g_0(T = 1, \mathbf{x}_i) - g_0(T = 0, \mathbf{x}_i))$

Given the nature of our outcome variable (standardised count variable), and of our treatment (dummy variable), we estimate the $g_0(\cdot)$ using a linear model and $m_0(\cdot)$ using a logistic model.

Crucially, instead of pre-selecting the controls to be included in the model, we use lasso techniques within an ATE approach [5]. This strategy allows to estimate $g_0(1, \mathbf{x_i})$, $g_0(0, \mathbf{x_i})$ and $m_0(0, \mathbf{z_i})$, selecting only relevant controls over a potential

large set of covariates. More specifically, this strategy allows at the same time to include several different variables to potentially satisfy the conditional independence assumption (i.e., that that given the controls, the outcome is independent of the treatment), while reducing the risk of violating the overlap assumption (i.e., that given the controls there must be always a positive probability of each unit of being not treated). The estimated effect is then robust to model selection, and as well as (doubly) robust to functional form miss-specification either in the outcome or the treatment model. Moreover, we report the estimates from a "double machine learning estimator" [5]. Using both cross-fitting and re-sampling, the double machine learning estimator relaxes the sparsity assumption allowing to include (i.e., to control for) more confounders than a traditional lasso approach. The estimated ATEs are then an average across the different cross-folds and resamples.

Leveraging the randomised design of ESS on questions about attitude, we estimate ATEs separately by gender of respondent and gender of the target.

4 Results

Attitudes toward childlessness have become more favorable over time. The level of approval is increased from 26.6% of approval (approve and strongly approve) in 2005 (ESS round 3) to 36.09% in 2017 (ESS round 9). Simply controlling for ESS round and country of residence, we observe a clear gender difference in approval. The highest predicted approval is observed among women when the question is about a woman, the lowest among women about a man. We now report our estimates separately for each of the four groups.

The ATE approach allows to have a separate set of controls for the treatment (educational attainment) model and for the outcome (approval). Potentially confounders of childlessness approval are age of respondent (5 levels), the marital status (3 levels), level of religiosity (4 levels), whether the respondent had a child, country group (4 levels) and year of interview. Level of education (treatment model) is instead expected to be influenced by the age of respondent (that in our case being a cross-sectional analysis also corresponds to cohort), whether the respondent is born/citizen of that country, as well as characteristics of family of origin (level of education of both parents, whether the parents were born in the same country of the respondent). Also for the treatment model we include country group and and year of interview as fixed effects. Using lasso for model selection in both treatment and outcome model allows us to include more controls than in a traditional ATE approach. We include then also interaction effects among each of the variables aforementioned and country group. As conventional, we use one-hot encoding for categorical variables. We end up then with more than 200 controls. In order to obtain robust estimates, we cluster the standard error by country of residence (28 clusters) and use a double machine learning approach [5] with a 5-fold cross-validation over three split samples.

Comparing the results obtained with and without double machine learning (i.e., applying lasso within an ATE estimate, but without cross-validation and re-sampling, results not shown), the number of controls selected by lasso almost doubled while applying the double machine approach, bringing to potentially more robust results.

We found (Table1) that being highly educated has a significantly positive effect on level of childlessness approval of about 10% of a standard deviation (ATE of .096 on the standardised outcome). These effects are heterogeneous by gender and target. While education does not have a significant impact on childlessness men when the respondent is a man, a positive effect of education on approval is observed in all other cases, with the highest value when to a woman is asked about the approval of be a childless women (increase of 11.5% of a standard deviation).

In terms of controls selected by lasso, and using as an example the last model (when women reply on women behavior)[1], lasso for the treatment model selected the age of respondent, and the level of education of the mother and the father, conventional indicators of parental socio-economic status. The country of origin seems instead is not selected. In the outcome model, lasso selected the age of respondent and religiosity in particular for those living either in an "egalitarian" country, or in an Eastern European country.

Table 1 ATE of having high level of education. Estimate with lasso double machine learning

Model	Effect	p-value	95% CI	N of controls retained
Overall sample[a]	.096 (.034)	.005	[.029, .163]	54
Male respondent on men's behavior	.036 (.042)	.391	[-.047, .119]	56
Male respondent on women's behavior	.111 (.041)	.007	[.0298, .192]	52
Female respondent on men's behavior	.104 (.037)	.004	[.032, .177]	48
Female respondent on women's behavior	.115 (.041)	.004	[.036, .1947]	58

Note: Robust standard errors reported in parentheses clustered by country. Outcome is the standardised level of childlessness approval.

[a] We control also for gender of respondent and gender of target in the outcome model; and we control for respondent's gender in the treatment model.

5 Discussion

Leveraging the experimental design of the module Timing of the Life of the European Social Survey, we investigated the combining causal effect of gender and social

[1] The results refer to the first cross-fold and first re-sample.

stratification on the approval of voluntary childlessness in Europe. Overall, our results are consistent with the idea that achieving a high level of education *causes* a more positive attitude towards childlessness, with the only exception of men answering about approval if a man chooses never to have children. Moving from the individual to the population level, our findings are therefore consistent with the hypothesis that educational expansion played a specific causal role in decreasing the attitudes towards voluntary childbearing in Europe.

This work can be extended in several directions. Firstly, in terms of the effect of the institutional setting. The lasso variable selection model suggests that country typology matters in explaining variations in attitudes towards childlessness. Secondly, further analyses might shed light at the role of social origin and parental background in accepting behavior that is not "traditional", as the decision of not having children over the life course.

The general contribution of this work is twofold. On demography, it provides robust evidence on a large number of European countries and individuals of the role of the intersection of gender and social stratification in potential explanations of childlessness. From a methods point of view, it contributes to a growing literature that uses machine learning approaches to answer questions related to demography and life-course trajectories [2, 4].

Integrating structuralism and diffusionism to explain the new Italian emigration

Interpretazioni strutturaliste e diffusioniste della nuova emigrazione italiana

Francesca Bitonti

Abstract Diffusionism gained momentum as a viable approach to uncover the dynamics underlying the decline in marital fertility that occurred across Europe during the past century. This theory challenges the traditional adaptative explanations to fertility transition posed by the structural approach. This work aims at borrowing and integrating diffusionist and structuralist interpretations of fertility transition to give meaningful insights into the recent new wave of Italian emigration. An extended version of the Bass model, extensively employed to study the diffusion of new products and behaviours across a population, is proposed. The preliminary results highlight the underlying dynamics governing the new Italian emigration flow and provide a novel interpretation of a recent international emigration process.

Abstract *Il diffusionismo è emerso in demografia nello studio delle dinamiche alla base del declino della fecondità avvenuto in Europa nel secolo scorso. Questa teoria sfida le tradizionali spiegazioni "adattative" del crollo della fecondità proposte dall'approccio strutturale. L'obiettivo di questo lavoro è quello di prendere in prestito e integrare diffusionismo e strutturalismo dagli studi sulla transizione della fecondità per dare una spiegazione significativa alla recente nuova emigrazione italiana. Si propone una versione estesa del modello Bass, ampiamente utilizzato per studiare la diffusione di nuovi prodotti e comportamenti in una popolazione. I risultati preliminari evidenziano le dinamiche e forniscono una nuova interpretazione del recente processo di emigrazione internazionale italiana.*

Key words: diffusionism, international migration, Bass diffusion model, new Italian emigration

1 Introduction

The diffusionist theory finds its roots in the field of social sciences to explain the spread of new ideas and practices among the members of a population [26,29]. The ground idea of diffusionism is that the interplay of social influence mechanisms, as interpersonal information exchange, social norms, and emulative processes, shape individual conduct. The diffusionist approach has found wide application also in demographic studies. From a demographic standpoint, an innovation may be intended as any idea or practice having implications on the population dynamics, namely fertility, mortality, and migrations [35]. In this sense, examples are contraceptive adoption, childbearing postponements, smoking behaviour, novel migration practices, and the like. Diffusionism gained momentum with the necessity to give a plausible explanation to the decline in marital fertility that occurred across Europe during the past century. This approach challenged the classical demographic transition theory, which argued that modernisation and structural changes in society were the main driving forces for fertility variations. Roughly speaking, the rising cost and declining economic value of children is the key factor leading to fertility change [5,7]. The diffusionist considerations instead argued that new ideas and norms about fertility have diffused through social interaction modifying the macro-level fertility dynamics [10]. In the 80s, the Princeton European Fertility Project and the World Fertility Survey were the two seminal works suggesting that the fertility decline could have been influenced by the diffusion of modern contraceptive practices, new values, and new ideas of family among people [11,12,33]. After this introduction in the demographic debate, the diffusionist vision has been the theoretical background for several studies of fertility choices and family planning, and for the promotion of public health campaigns aimed at contrasting the spread of diseases and health-damaging behaviours [1,2,3,6,20,24,25,31,34]. Recently, modernisation and diffusionist arguments have no longer been considered distinct or in opposition. Rather, they are conceptualised as strictly embedded explanations to demographic changes [27]. In adherence to this strand of thought, the objective of this work is to analyse and convey meaningful insights of international migration processes in terms of both diffusionist and structuralist approach. In particular, the analysis focuses on a novel emigration flow involving Italy in recent times. The work is organised as follows: the next section illustrates the so-called new Italian emigration; the third section introduces the methodology implemented and describes the data analysed; the fourth one discusses the main results of our applications, while the last reports the conclusions of the work.

2 The new Italian emigration

In recent years, Italian emigration had considerably grown compared to the 80s and 90s, when the phenomenon was ongoing but at a smaller scale. The current

emigration presents specific peculiarities, configuring a situation different from the past, which in literature is known as “the new Italian emigration”.

Among the novelties, an increased share of women and well-educated individuals leaving the country has been recorded [13,15,30]. Furthermore, although the Southern regions continue, as in the past, to contribute to the outgoing movements, recently, the more advanced northern Italy has become the main outflow area [8,30]. Another relevant feature is that the destinations preferred by Italian migrants mainly converge to the EU and EFTA countries [8]. Finally, the new Italian emigration appears to be paired with a change in attitude towards international migration. The globalisation of the world and the availability of new communication technologies could have overcome several of the barriers hindering movements in the past, allowing Italians, especially the youngsters, to approach international mobility in a novel and more confident way [32].

Overall, the interaction among the global economic downturn, the EU integration process [14,21,23], and the change in attitude towards outward mobility appear to have shaped a new migration behaviour that has diffused across Italy. The novel aspects characterising the Italian emigration configure an innovative migrant behaviour that diffuses among the population through particular communication channels and according to established social dynamics, but also in accordance with the economic cycle of origin and destination countries.

3 Methods and data

The Bass model [4] is extensively employed in market research studies to analyse the diffusion process of new ideas, products, and behaviours (called “innovations”) in a given population. According to the model, the pace of diffusion is driven by two forms of communication: the *external* one, such as mass media advertisement or awareness and prevention health campaigns, and the *internal* one, including social influence, word of mouth, and imitation. These two drivers of diffusion shape two categories of adopters: the innovators, mainly influenced by the external source, and the imitators, who adopt in response to their interaction with prior adopters. The Bass model consists of a simple first-order differential equation

$$Y'(t) = \left(p + \frac{q}{m}Y(t)\right)\left(m - Y(t)\right) = p\left(m - Y(t)\right) + q\frac{Y(t)}{m}\left(m - Y(t)\right) \quad (1)$$

where the variation of adoption $Y'(t)$ over time is proportional to the residual susceptible population $(m - Y(t))$, with m being the constant overall susceptible population, and $Y(t)$ the cumulative adoptions at time t. Rearranging the left-hand side equation (1) it is possible to notice that the instantaneous adoptions $Y'(t)$ is the result of the sum between two components, the external one governed by parameter p and the internal one modulated by q. Parameter p is the so-called coefficient of innovation, representing the effect of the external influence to adopt. Parameter q is the coefficient of imitation and reflects the inter-personal influence individuals can exert on each other. The basic Bass model and its extensions have found empirical

applications not only in marketing studies but also in the demographic field: e.g. to analyse the diffusion of oral contraception [28], to clarify the dynamics in vaccination propensity and address public health policy [19,22], and to study the diffusion of disease-related information during an epidemic outbreak [18]. In the present work, we propose an extended version of the traditional Bass model to capture both structural and diffusionist explanations to the new Italian emigration:

$$\frac{dY_{it}}{dt} = p_{it}(m - Y_{it}) + \frac{q_{it}}{m} Y_{it}(m - Y_{it}) \quad (2)$$

where the coefficients p and q depend on the structural characteristics of the destination countries the emigration flow is directed to:

$$p_{it} = \alpha_0 + \alpha_1 U_{it} + \gamma_2 D2_i + \gamma_3 D3_i + \cdots + \gamma_n Dn_i + \epsilon_{it} \quad (3)$$

$$q_{it} = \beta_0 + \beta_1 U_{it} + \delta_2 D2_i + \delta_3 D3_i + \cdots + \delta_n Dn_i + \epsilon_{it} \quad (4)$$

$i=1,\ldots,n$ are the destination countries at each time interval t, U_{it} is the unemployment rate for destination country i at time t, $D2_i + \cdots + Dn_i$ are $n-1$ dummy variables identifying the $i=2,\ldots,n$ destination countries respectively, lastly the erratic component is defined as $\epsilon_{it} \sim N(0, \sigma^2)$. The extended version of the Bass model has been fitted using an ad-hoc numerical optimization algorithm minimizing the root relative squared errors (RRSE) in the R software, which automatically estimated all the model parameters. The main advantage of the proposed model is to parsimoniously provide the time-varying parameters p and q for each destination country considered. With the same interpretative rather than forecasting objective found in literature [9,16,17], this work intends to offer a combined diffusionist and structuralist perspective of the new Italian emigration process. The basic reasoning is that the Italian crisis, combined with the spread of mass media information about the more dynamic labour market and the better living conditions in some EU countries, might have acted as external drivers of influence. On the other end, the information conveyed by actual emigrants about the possibility to be better-off could have triggered word-of-mouth effects and emulative behaviours.

Annual counts of Italian citizens who emigrated from 2002 to 2018 towards the main EU destination countries (Austria, Belgium, France, Germany, Spain, and United Kingdom – pre-Brexit) were retrieved from the Italian National Institute of Statistics (Istat) repository. Data on unemployment rates come from the World Bank online database.

4 Results and conclusions

The results of the extended Bass model fit are displayed in Figure 1. During the period 2002-2018, the outgoing flows (black dots) have increased for each destination country, with Germany, France, and United Kingdom accounting for the highest portion of movements. The global model (black lines) shows, in general, a good fit to the real data, loosing goodness of fit when the data present

discontinuities. The external component (light grey dashed lines) accounts for a little proportion of emigrations, while the internal one (dark grey dashed lines) is the main driver of the outgoing trends. Progresses in the EU integration and the 2007 financial crisis have accelerated the spread of novel migratory behaviours in Italy, characterized by an increased attitude towards international mobility and imitation. We proposed an interpretation of the new trends in Italian out-migration flows combining diffusionist and structuralist reasoning in an ad-hoc methodological framework. The proposal is that of a "toy model", namely a simplistic model aimed to provide interpretation to complex real-world phenomena; a typical example is the Lotka–Volterra model in population ecology.

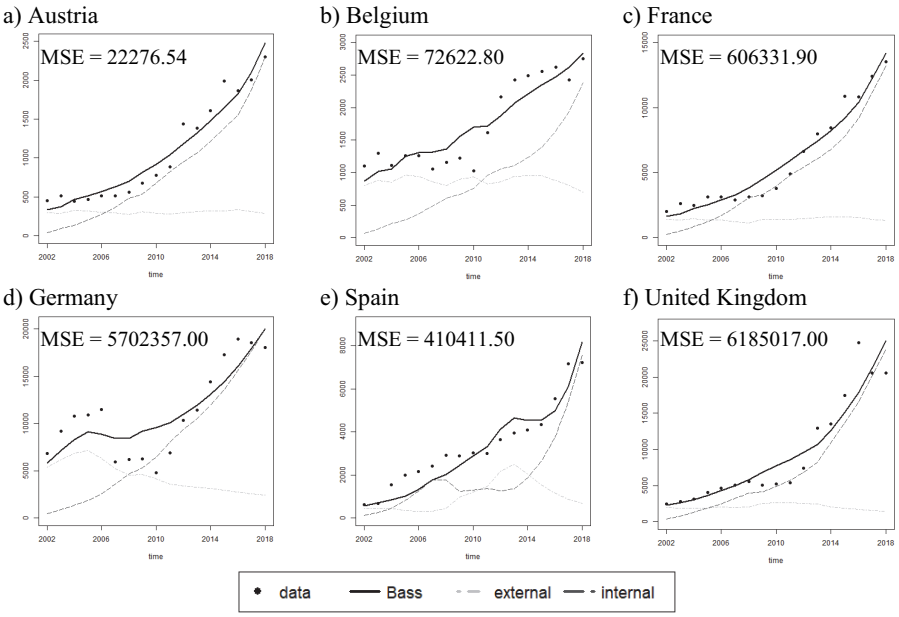

Figure 1: Extended Bass model fitting to the Italian annual emigrations toward the main EU destination countries. Time period: 2002-2018 (different y-axis scales).

On the effects of rooted family ties in business networks: The South of Italy in the 19^{th} century

Un'analisi sugli effetti dei legami familiari radicati nelle reti di affari: il Mezzogiorno nel XIX secolo

Roberto Rondinelli, Giancarlo Ragozini and Maria Carmela Schisani

Abstract In the economics literature, rooted family ties, mainly associated to backward areas, are related to factors disruptive to economic growth. We study the effects of bonding family ties (associated to family-firms) in the entrepreneurial environment of the 19^{th} century South of Italy, to answer some significant questions about its economic delay over the national Unification. Using original data and the analytical approach of the informational content of surname we compute the assortativity of surnames (as proxy of family ties) within firms. We find that the presence of bonding ties, scattered over all the business networks, is highly differentiated by sector, by time span and related to the number of economic actors involved in a firm.

Abstract *Nella letteratura economica, i legami familiari radicati, tipici di aree arretrate, sono legati a fattori avversi alla crescita economica. Noi studiamo gli effetti dei legami familiari "bonding", tipici delle imprese familiari, nell'ambiente imprenditoriale del Mezzogiorno dell'800, a cavallo dell'Unità, per rispondere a domande ancora irrisolte sulle radici del suo ritardo economico. Utilizzando dati originali e l'approccio analitico del "contenuto informativo del cognome" calcoliamo l'assortitività dei cognomi (come proxy dei legami familiari) all'interno delle imprese. Come risultati, osserviamo che la presenza di legami "bonding", sparsi su tutte le reti di imprese, è fortemente differenziata per settore, per tempo e per numero di attori economici coinvolti in un'impresa.*

Key words: Family ties, Informational content of surnames, Assortativity, Permutation test

1 Introduction

Rooted family ties in a society may be regarded as being of less of benefit to activating the forces of economic change, modernization and innovation [2, 12, 1]. Particularly for the South of Italy this form of "bonding" solidarity within families or kinship webs has been considered as a determinant of its backwardness [12]. In the literature, claims about the entrenched power of the "logic of surname" [8] – primarily regarding the traditional Southern landowning aristocratic elite and narrow middle-class groups of the late 18^{th} and 19^{th} century rising bourgeoisie [5, 8] – have been largely speculative and backed up with qualitative evidence.

We address the topic by a new different perspective by studying the effects of family ties in the entrepreneurial environment of the Southern largest city, Naples. We use original archival data on the universe of Naples enterprises to build the networks of business relations between economic actors for the twenty-year periods before and after Unification, between 1820 to 1880.

Given the framework of graph theory, we investigate the probability of having family ties in a firm. More specifically, adopting the analytical approach of the informational content of surname [6, 3], we compute the assortativity of surnames (used as proxy of family ties) within firms. We classified these latter by sector of economic activities for three time spans. We test the significance of the observed probabilities by randomly reshuffling the ties and generating their distributions under the hypothesis of random graphs [11]. We find that the presence of bonding ties, even though scattered over all the business networks, is highly differentiated by sector, by time span and is related to the number of economic actors involved in a firm. These results can be explained in connection to historical institutional changes.

Section 2 introduces a brief review of the literature on the role of family ties in economics. Section 3 describes data e methodology, while Section 4 discusses the main results.

2 The role of families in the economics: a brief review

As the earliest and most fundamental institution able to shape human activity, the family has been extensively studied in its capacity to generate major implications in terms of socio-economic outcomes that have, in turn, an influence on economic development [12]. In the economics literature, rooted family ties, mainly associated to backward areas characterized both by weak formal institutions [10] and weak social capital [2, 12], are regarded as being of less of benefit to activating the forces of economic change and modernization. Also in the most recent years, in the empirical literature focused on social capital, family ties are deemed to be related to a number of factors disruptive to economic growth: aversion to change and lower levels of innovation, trust, geographical mobility and economic dynamism [1]. Through qualitative evidence, a similar argument has been made for the South of Italy to explain the origins and the causes of its economic delay. By insisting on the entrenched

power of the "logic of surname" [8], the socio-economic literature has suggested this traditional form of rooted "bonding" solidarity within families or kinship webs as a determinant of the Southern backwardness [2, 12].

Family relationships, when translated into the context of business organizations, can be broadly classified as bonding or bridging [7] with ambivalent contents. For example, the capacity of family firms (bonding ties) to "fit" into the local community can be alternatively defined in the negative terms of paternalism as well as in the more positive view as a component of corporate social performance [4]. On the other hand, considering family relations in large companies, closer to bridging functions, the business literature underlines how this type of control relations are especially good at political rent-seeking in underdeveloped economies, where a lack of general trust, official corruption and family control of large firms are mutually reinforcing factors that combine to crowd-out growth [9]. On the other hand they are seen as facilitating the firm's access to external resources, crucial for enhancing growth [12].

In the present work, we focus on the bonding function of family ties and we adopt a quantitative approach relying on social network analysis.

3 Data and Methodology

Our work is based on a unique and original proprietary database, storing data on the universe of enterprises and companies operating in Southern Italy between 1800 and 1913. The database IFESMez (www.ifesmez@unina.it, acronym for Imprese, Finanza, Economia e Società nel Mezzogiorno) has been conceived as a large multi-source relational database[1], gathering interrelated datasets on economic and socio-political individual and collective actors. Data directly collected from original local, national and international archival sources are organized to show relations among actors, among firms and among firms and actors. At present, the database contains information regarding 3,500 firms – created and/or operating in Naples and its province – and almost 28,000 people.

Given such a database, we built three complex networks, namely three time-varying two-mode networks representing the relationships among economic actors and firms over three twenty-year spans between 1820 and 1880. These networks are also attributed and weighted. Formally, such time-varying two-mode attributed networks can be represented by a set of three two-mode networks $\{\mathscr{G}_t\}_{t=1,\ldots,3}$. The t index refers to different time spans. Each network $\mathscr{G}_t$ consists of a 6-tuple $\mathscr{G}_t(\mathscr{A}_t,\mathscr{F}_t,\mathscr{R}_t,\mathscr{W},\mathscr{S},\mathscr{C})$, where $\mathscr{A}_t = \{a_{1t},a_{2t},\ldots,a_{N_t}\}$ are the sets of N_t economic actors at time t; $\mathscr{F}_t = \{f_{1t},f_{2t},\ldots,f_{J_t}\}$ represents the set of J_t firms in which the actors are involved in each time span; $\mathscr{R}_t \subseteq \mathscr{A}_t \times \mathscr{F}_t$ is the set of the edges $r_{ijt} = (a_{it},f_{jt})$, $r_{ijt} \in \mathscr{R}_t$, i.e. each edge is an ordered couple indicating whether or not an actor a_{it} plays one, or more then one, role in the firms f_{jt}; $\mathscr{W} : \mathscr{R} \to \mathbb{N}$,

[1] The primary source of data is the Mercantile Court archival funds (from 1883 on, Civil Court) available at the Naples State Archive. For a detailed description of the database and of the information therein see [13].

with $\mathscr{W}(r_{ijt}) = w_{ijt} \in \mathbb{N}$, the number of roles of the actor a_{it} in the firm f_{jt}. Both the economic actors and the firms are featured by attributes: $\mathscr{S} : \mathscr{A}_t \rightarrow dom(\mathscr{S})$, where $\mathscr{S}(a_{it}) = s_i \in dom(\mathscr{S})$ is the *surname* of the actor a_{it}, with $dom(\mathscr{S})$ the set of surnames; $\mathscr{C} : \mathscr{F}_t \rightarrow dom(\mathscr{C})$, where $\mathscr{C}(f_{jt}) = c_j \in dom(\mathscr{C})$ is the *ATECO code* of the firm f_{jt}, with $dom(\mathscr{C})$ the list of the first-level classification of the economic sectors.

Given this complex data structure and aiming at analyzing the presence of family ties in the business network, we first adopt the logic of surnames, i.e. as we have missing information on the kinship ties (except for a relative small number of families), we use the surname as proxy of being part of the same family [3]. Hence we assume that two actors a_i and $a_{i'}$ with the same surname, $\mathscr{S}(a_i) = \mathscr{S}(a_{i'})$, participating to the same firms f_j, $r_{ij}, r_{i'j} \in \mathscr{R}$, are relatives. This assumption works well in our context given that the large part of economic actors are males and the transmission of surname follows the paternal line. Then we compute the assortativity by surname of the economic actors, dividing the firms by their *ATECO code*. Considering each twenty-year span, for each firm with more than one actor, the assortativity by surname is defined by the following probability:

$$P_{f_{jt}}(\mathscr{S}|c^*) = P(\ \mathscr{S}(a_{it}) = \mathscr{S}(a_{i't}) \wedge r_{ijt}, r_{i'jt} \in \mathscr{R} \mid \mathscr{C}(f_{jt}) = c^*\ ) \quad \forall\, d(f_{jt}) > 1, \tag{1}$$

where $d(f_{jt})$ is the weighted degree of the $j-th$ firm at time t. The probability that two randomly selected actors linked to the same firm belong to the same family can be interpreted as a measure of the bonding effect of families, i.e. the propensity of actors to form business ties with members of the same family and to be embedded in family firms. In order to test the hypothesis that such bonding effect exists, we combine the informational content of surname proposed by [6] and the random permutation test in networks [11]. More precisely, we first compute the observed average probability $\bar{P}_t(\mathscr{S}|c^*)^T$ with true surnames for each time span and *ATECO code*, and then we compute 1000 times the same probability reshuffling the surnames, i.e. under a fake distribution of surnames, $\bar{P}_t(\mathscr{S}|c^*)^F_l, l = 1, \ldots, 1000$. These latter values yield the distribution of the assortativity by surname under the null hypothesis that there is no informational content in the true surname distribution. Note that reshuffling the surnames it is equivalent to reshuffle the edges taking constant the network structure characteristics.

4 Main results

The three networks show an increasing number of vertices both in terms of existing firms and actors involved in them, denoting a more crowded market. Specifically, 286 firms and 1,905 actors in the first time span increase to 1,266 firms and 11,693 actors in the third time span, respectively, passing through 639 firms and 2,803 pre-Unification. We observe such efflorescence since after Unification when the number of limited liability companies increases mainly in the financial and industrial sectors, determining a sharp increase of actors involved. The networks are quite sparse and

the density decreases over the time reaching the value of 0.0012 in the last time span (the initial value was 0.0058). The presence of 127, 280 and 563 components (disconnected subgraphs), for the three time span, suggests that several firms (and their members) are isolated with respect to the main core of the network. Furthermore, a relevant part of these components is represented by the single dyads actor-firm or by the single triads actor-actor-firm. For example the dyads are the 22% of the components in the first period, while the triads are the 49% in the third time span. This mirrors the common and persisting trait of Southern business to be organised in individual or very small family firms. Focusing on the node-level characteristics of the networks, a strong core-periphery structure is suggested by the distributions of the degree centrality of the economic actors. In the first two periods, 67% of the actors has degree equal to 1 - i.e. they take part in one firm -, while only the 0.3% for the first period and the 0.5% for the second one, has degree higher than 10. The same happens in the third period, where the percentage of actors with degree equal to 1 increase to 77%, while the 0.4% (41 actors) shows degree higher than 10.

As said, as a second step, we test the probabilities of having family ties within firms with respect to random distribution of the surnames. Comparing the distribution of $\bar{P}_t(\mathscr{S}|c^*)_l^F$ with the observed values of $\bar{P}_t(\mathscr{S}|c^*)^T$ for all ATECO codes and all the time spans, we have that for 28 over 45 cases $\bar{P}_t(\mathscr{S}|c^*)^T >> \max_l(\bar{P}_t(\mathscr{S}|c^*)_l^F)$. Then all probabilities are significantly greater than the fake ones: the largest $p-value$ equal to 0.011 corresponds to the public utilities for the electricity and gas supply (D) in the 1860-1880. This entails that there is a tendency to have bonding ties in all sectors.

Given this result, in Figure 1 we report the values of the average probabilities for the main sectors for the three time spans. The size of the dots is proportional to the average degree of the firms in that sector. In the first time span, the highest probabilities are in trade (G) and banks (K4), with values greater than 0.3, as well as in the sectors of manufacturing (C) and construction (F). Trade and manufacturing are both characterized by many small economic activities like shops or artisans' workshops mainly run by members of the same family. For different reasons, in the first decades of the 19th century banks are generally family-based private firms, owned by members of the narrow inner circle of the local financial elite. In pre-Unification the trend to establish family ties increases or remains stable, for almost all the sectors. This is especially true for trade and banks. After the Unification, the increasing number of large joint stock companies and large cooperatives, both after the liberal turn of the Italian governments and the introduction of the 1882 Italian Commercial Code, yields a decrease in the tendency to form family ties. This is especially true in the banking sector due to the creation of large cooperatives with thousands shareholders, and in the trade sector due to the increasing trades and the enlarged competition. Marine insurances (K1) and other insurances (K2) show an almost constant and low (but still significant) tendency to have family ties. However such probabilities is lower due to the need of reducing risks by diversifying investments within the same family.

Finally note that in all the time spans there is a negative correlation between the probability to have family ties and the average size of firms: such correlation ranges

from -0.38 in pre-Unification to -0.54 post. This is quite expected: the larger is the number of people in a firm, the lower is the probability of having family ties. This directly entails that the presence of family ties is associated to family firms and hence to the bonding effects.

Fig. 1 *Observed probability of the main economic sector per twenty-year period.*

Methods and Applications in Clustering

A semi-supervised clustering method to extract information from the electronic Word Of Mouth

Un metodo di clustering supervisionato per estrarre informazioni dalle review online.

Giulia Contu, Luca Frigau, Maurizio Romano, Marco Ortu

Abstract In time, electronic Word Of Mouth has become a resource to support the decision-making process. Different techniques have been proposed to extract information from online textual data. We propose a semi-supervised clustering model able to identify clusters homogeneous with respect to the overall sentiment of the analyzed texts. The model is built by combing Sentiment Analysis, and Network-based Semi-supervised Clustering. We apply the model to the Booking.com data related to the Sardinian hotels. The first results highlight the presence of different clusters non-overlapped in terms of the distribution of the overall sentiment.

Abstract *Nel tempo, il passaparola online è diventato una risorsa a supporto del processo decisionale. Sono state proposte diverse tecniche per estrarre informazioni da dati testuali online. Proponiamo un modello di clustering semi supervisionato in grado di identificare cluster omogenei rispetto al sentiment complessivo dei testi analizzati. Il modello è costruito combinando diverse metodologie come Sentiment Analysis e Network-based Semi supervised Clustering. Applichiamo il modello ai dati di Booking.com relativi agli hotel che operano in Sardegna. I primi risultati evidenziano la presenza di diversi cluster non sovrapposti con riferimento alla distribuzione del sentiment complessivo.*

1 Introduction

In time, Internet has produced a huge amount of information through social network feed, emails, blogs, online forums, survey responses, corporate documents, news, call center logs, and electronic Word Of Mouth (e-WoM). Particularly relevant in the tourism field is the information extracted by e-WoM. It has been defined by [9] as *any positive or negative statement made by potential, actual, or former customers about a product or company, which is made available to a multitude of people and institutions via the Internet* [9, p. 39]; and, by [3] as *any positive, negative or neutral comment, rating, ranking of a product, a service, a brand, or a person supposedly made by a former customer and that is shared with other consumers in an unstructured format* [3, p. 47].
Different techniques have been proposed to extract information from textual data with the aim to convert large volumes of text into information able to support the decision-making process [5]. These techniques are for instance cluster analysis, natural language processing, machine learning, neural networks, predictive modeling, regression models, social network analysis, sentiment analysis, signal processing, and data visualization [2].
We build on the existent literature proposing a new semisupervised clustering method useful to extract information from the e-WoM. Different researchers have previously used semi-supervised clustering to classify texts and documents. Semi-supervised clustering is a variant of the traditional clustering paradigms. It aims to obtain a better partitioning of data considering and incorporating background knowledge [6, 8]. Researchers as [11] and [12] have used this kind of approach to identify clusters inside the data using labeled information. For instance, [11] have proposed a *Semi-Supervised Cluster tree method* (SSC). It is a tree-like semi-supervised classifier built taking into account both labeled and unlabeled data. [12] have theorized the *TExt classification using Semi-supervised Clustering* (TESC) in order to improve text classification. They have used semi-supervised clustering to identify text components and, later, to use text components to predict labels of unlabeled documents. [7] have proposed a semi-supervised learning algorithm for the classification of text documents. It is defined using K-means algorithm for partitioning both labeled and unlabeled data collection. K-means algorithm is applied recursively until each partition contains labeled documents of a single class. Finally, cluster centroids are used for classifying an unknown text document.
In this paper, following the classification proposed by [1], we consider a Semi-supervised clustering model with respect to an outcome variable to identify clusters that are internally homogeneous with respect to a specific text. It involves an outcome variable and previous information about the outcome variable. The algorithm is built combing different methodologies such as Sentiment Analysis (SA), and Network-based Semisupervised Clustering (NeSSC). The proposed method is applied on the online reviews published on Booking.com.
Four sections, besides the introduction, complete this study. In Section 2 we present the real data of online reviews published on *Booking.com*. The methodological

framework is described in Section 3. In Section 4 the results are presented and, finally, in Section 5 concluding remarks are discussed.

2 Data

We have investigated the Booking.com data. Booking.com is an online platform that offers the possibility to book hotels, homes, and transport options. It promotes more than 28 million accommodation listings, including over 6.2 million listings alone of homes, apartments, and other unique places to stay. In fact, it supports the travelers in the tour planning giving the possibility to plane some of the most relevant aspects necessary to make a trip. Moreover, it gives the possibility to write a review of the travel experience to support the potential tourists in the decision process. The tourist that decides to write a review can distinguish his judgment in two different sections: one where it is possible to express the positive aspects of the experience, the other the negative aspects. To guarantee the reliability and the quality of the reviews, only the customers who have bought the service through Booking.com can publish reviews.
We have focused the analysis on the reviews of 619 hotels located on the Sardinia's coast, an Italian island. We have scraped the data from the platform *Booking.com*. We have taken into account the reviews published between 2015 to 2018. We have collected 106,800 sentences: 62,291 are positive reviews, whilst 44,509 are negative reviews.
We have carried out the analysis taking into account specific topics presented in the reviews. We have identified $M = 12$ main categories of words, as shown in Table 1. They are grouped in four main relevant aspects that influence the judgement of the hotel experience. They are the elements related to the room quality, the provided services, the staff, and the hotel characteristics.

Feature	Description	
Provided Services	bar	bar service, minibar or affiliated bars around the structure
	general services	quality of services provided by the hotel
	food	food quality served in the hotel structure or affiliated restaurant
	wifi	Wi-Fi connection quality, such as general coverage and lags
Room quality	cleaning	cleaning of the room and of the hotel structure
	comfort	comfort perceived by guests during their stay
	room	room quality referred to the type of room
	sleep-quality	quality of sleep such as bed, pillows and noises
Hotel characteristics	structure	quality of physical structure
	position	position quality of the hotel structure
	quality-price-rate	quality-price rate
Staff	staff	kindness, courtesy, professionalism of the staff

Table 1 Reference categories of words.

3 Methodology

As evidenced before, we propose a semisupervised clustering method associated with an outcome variable. The clusters are identified considering a specific outcome variable and using the previous information about it [1].
The model is built combining Sentiment Analysis (SA), and Network-based Semisupervised Clustering (NeSSC). This combination allows identifying clusters homogeneous with respect to the overall sentiment of the texts analyzed.
It operates in different steps. More in detail, in the first stage the data has been analyzed and cleaned to homogenize the text and to remove all unnecessary words, stop words, acronyms. Later, Sentiment Analysis (SA) is applied in order to firstly categorize them into positive or negative classes, secondly to identify an overall sentiment score of the texts. The score is estimated through the log-likelihood ratio of the specific categories that can be or not in a sentence. This information allows us to evaluate the relevance of specific categories of words and how this category can influence positive or negative reviews.
In the last stage, the previously estimated score becomes the outcome variable used to define the clusters. In this phase, the Network-based Semisupervised Clustering (NeSSC) is used to partition the instances into K disjoint groups [4]. NeSSC identifies the pairwise affinity of the instances through a classifier and uses this information to organize them into a complex network. It operates in three steps. They are called initialization, training, and agglomeration. The initialization and training steps deal with the estimation of the affinities between observations by using an iterative process. These two steps aim to estimate an affinity matrix Π, where the amount of time that two generic elements i and j are classified together measures the propensity to behave in the same manner to sentiment scores, $\mathbf{y}$.
Finally, the affinity matrix Π has been transformed into a set of complex networks, where the observations correspond to nodes and the entries $\pi_{i,j}$ of the affinity matrix defines the strength of the edge between the two generic observations i and j. Later, a community detection algorithm is trained on the nodes of the networks in order to find, for each network, a certain number of homogeneous communities corresponding to the groups defining a proper partition of the original data. Finally, among all the partitions, the optimal one is that presenting the lowest minimum penalized average overlapping in terms of the distribution of the overall sentiment, the latter computed alternatively as the weighted mean of the pairwise group overlapping index [10]. Broadly speaking, the overlapping index η between two probability density functions $f_A(x)$ and $f_B(x)$ is defined as

$$\eta_{A,B} = \int_{\mathbb{R}} \min\left[f_A(x), f_B(x)\right] dx \tag{1}$$

where the integral can be replaced by summation in the discrete case. Usually, $\eta_{A,B}$ is normalized to one, thus to easily indicate that the two distributions $f_A(x)$ and $f_B(x)$ might be not overlapped ($\eta_{A,B} = 0$) or fully overlapped ($\eta_{A,B} = 1$).

4 Results

The results show the presence of five clusters significantly characterized by a different level of the overall sentiment (Table 2). Each cluster presents specific characteristics and a specific average value of the outcome variable and of the four most important variables.
The first cluster presents a very large and positive overall sentiment. All variables characterized positively and significantly the cluster highlighting how the positive sentiment is influenced by all categories taken into account. The clusters two and three present in a similar way a positive overall sentiment; however, some differences can be observed. Specifically, the sentiment of cluster two is influenced positively by the categories room and staff. On the contrary, only the category staff influences the third cluster. Finally, the last two clusters are characterized by an overall sentiment lower than the mean. The unique element that is significant for cluster four is the staff. On the contrary, cluster five is characterized for a negative impact of the room, the staff, and the provided services. Only the characteristics of the hotel are not able to influence the overall rating of this cluster.

5 Conclusions

This paper has proposed Semi-Supervised Sentiment Clustering on natural language Texts framework for clustering textual data according to the overall sentiment expressed in their texts. The method is built by combining different statistical and natural language processing techniques and methodologies. The framework has been applied to *Booking.com* dataset concerning hotel structures of Sardinia (Italy). The results highlight the feasibility and interpretability of the framework with real data: we were able to find well-defined, non-overlapping in terms of the distribution of the overall sentiment, and interpretable clusters among the hotel structures. The implication of the results from the managerial point of view highlighted actionable insights spendable in decision-making support.

Spectral approach for clustering three-way data

Un approccio spettrale per il clustering di dati matriciali

Cinzia Di Nuzzo and Salvatore Ingrassia

Abstract Spectral methods are a quite recent approach for both data clustering and dimensionality reduction based on the properties of the Laplacian matrix of the pairwise similarity matrix coming from a suitable kernel function. In this paper, a spectral clustering approach for the three-way data is presented, where three-way data are composed by a $t \times p$ matrix for each statistical observation, so each unit is represented by a matrix. The relationship between the matrices are here described a new kernel function based on the $L_{2,1}$ norm. The performance of this approach is illustrated on the ground of a real three-way data set.

Abstract *I metodi spettrali costituiscono un approccio abbastanza recente di clustering e di riduzione dimensionale di insiemi di dati basato sulle proprietà del Laplaciano di una matrice di similarità derivante da un'opportuna funzione kernel. In questo articolo, si presenta un metodo di clustering spettrale per dati matriciali, che sono costituiti da una matrice di dimensione $t \times p$ per ogni osservazione statistica; in particolare, ogni unità è rappresentata da una matrice. Al fine di descrivere la relazione tra le matrici, viene introdotta una nuova funzione kernel basata sulla norma $L_{2,1}$. La proposta viene illustrata presentando un'applicazione su dati reali.*

Key words: Spectral clustering, Kernel function, Three-way data

1 Introduction

Spectral clustering methods are based on the graph theory, where the units are represented by the vertices of an undirect graph and the edges are weighted by the

Department of Economics and Business - University of Catania, e-mail: s.ingrassia@unict.it

pairwise similarities coming from a suitable kernel function, so the clustering problem is reformulated as a graph partition problem, see e.g. [14], [7].

Here, we present a spectral clustering approach for clustering *three-way data*, where a suitable kernel function based on $L_{2,1}$ norm between two matrices is introduced.

Three-way data derives from the observation of various attributes measured on a set of units in different situations; some examples are longitudinal data on multiple response variables and multivariate spatial data. In particular, this kind of data is composed of three objects: n units (matrices), p variables (columns), and t times (occasions). Clustering of three-way data has attracted a growing interest in literature, see e.g. [12], [1]. Moreover, model-based clustering of three-way data has been introduced by [13]; in particular, in the framework of matrix-variate normal mixtures, [8] handle on parsimonious models for modeling matrix data, [9] consider the elliptical heavy-tailed generalization of the matrix-variate normal distribution, [10] deal with three-way data clustering using matrix-variate cluster-weighted models and [11] present an application to educational data via mixtures of parsimonious matrix-normal distribution.

The rest of the work is organized as follows: in Section 2 the three-way spectral clustering is introduced; in Section 3 an application based on real three-way data is presented. Finally, in Section 4 we provide concluding remarks.

2 Three-way spectral clustering

Three-way data is organized in three modes: n units, p variables, and t occasions. Therefore, given n matrices that represent the vertices of the graph, each matrix is composed by p columns that represent the variables and t rows that represent the time or another feature. So we have a tensor of dimension $n \times t \times p$, thus the data set is a tensor $\{\mathbf{X}\}_{ijk}$ for $i = 1,\dots,n$, $j = 1,\dots,t$, $k = 1,\dots,p$.

Let $V = \{X_{1jk}, X_{2jk}, \dots, X_{njk}\} \subset \mathscr{X}$, for $j = 1,\dots,t$, $k = 1,\dots,p$, be a set of vertices in an undirect graph. In order to group the data V in K cluster, the first step of a spectral clustering algorithm consists of the definition of a symmetric and continuous function $\kappa : \mathscr{X} \times \mathscr{X} \to [0,\infty)$ called the *kernel function*. In the following, we consider the so-called *adaptive density aware kernel* (a two-way version of this kernel is introduced in [6], where the Euclidean distance is considered),

$$\kappa : \mathbf{X} \times \mathbf{X} \to [0,+\infty), \qquad \kappa(i_1,i_2) = \exp\left(-\frac{\sum_{k=1}^{p}\sqrt{\sum_{j=1}^{t}|X_{i_1jk} - X_{i_2jk}|^2}}{\varepsilon_i \varepsilon_j CNN(X_{i_1jk}, X_{i_2jk})}\right). \quad (1)$$

where

- ε_i is the distance between X_{i_1jk} and its h-th neighbor X_{hjk};
- $CNN(X_{i_1jk}, X_{i_2jk}) = |\mathscr{B}(X_{i_1jk}, \tau) \cap \mathscr{B}(X_{i_2jk}, \tau)|$, where $\mathscr{B}(X_{i_1jk}, \tau)$ is the sphere centered in X_{i_1jk} with radius τ.

Afterwards, a *similarity matrix* $W = (w_{i_1 i_2})$ can be assigned by setting $w_{i_1 i_2} = \kappa(i_1, i_2) \geq 0$, for $X_{i_1 jk}, X_{i_1 jk} \in \mathscr{X}$ and finally the *normalized graph Laplacian* matrix $L_{\text{sym}} \in R^{n \times n}$ is introduced as

$$L_{\text{sym}} = I - D^{-1/2} W D^{-1/2}, \tag{2}$$

where $D = \text{diag}(d_1, d_2, \ldots, d_n)$ is the *degree matrix* and d_i is the *degree* of the vertex $\mathbf{X}_i$ defined as $d_i = \sum_{j \neq i} w_{ij}$ and I denotes the $n \times n$ identity matrix. The Laplacian matrix L_{sym} is positive semi-definite with n non-negative eigenvalues. For a fixed K, let $\{\gamma_1, \ldots, \gamma_K\}$ be the eigenvectors corresponding to the smallest K eigenvalues of L_{sym}. Then the *normalized Laplacian embedding* is defined as the map $\Phi_\Gamma : \{\mathbf{X}_1, \ldots, \mathbf{X}_n\} \to R^K$ given by

$$\Phi_\Gamma(\mathbf{X}_i) = (\gamma_{1i}, \ldots, \gamma_{Ki}), \quad i = 1, \ldots, n,$$

where $\gamma_{1i}, \ldots, \gamma_{Ki}$ are the i-th components of $\gamma_1, \ldots, \gamma_K$, respectively. In other words, the function $\Phi_\Gamma(\cdot)$ maps the data from the input space $\mathscr{X}$ to a feature space defined by the K principal subspace of L_{sym}. Afterwards, let $Y = (\mathbf{y}_1', \ldots, \mathbf{y}_n')$ be the $n \times K$ matrix given by the embedded data in the feature space, where $\mathbf{y}_i = \Phi_\Gamma(\mathbf{X}_i)$ for $i = 1, \ldots, n$.

Remark 1. In the spectral clustering algorithm, the embedded data Y are clustered according to some clustering procedure; usually, the k-means algorithm is taken into account in literature. However, here, the Gaussian mixtures have been proposed because have more flexible cluster shapes with respect to the k-means, see [5] and [2]. Finally, we point out that the performances of other mixture models based on non-Gaussian component densities have been analyzed, but Gaussian mixture models can be considered as a good trade-off between model simplicity and effectiveness, see [3] for details.

Remark 2. The spectral clustering algorithm requires to set the number of clusters K and the kernel function κ. In order to select the number of clusters K, in the following we consider the method proposed in [4]. In practice, K is detected by a joint analysis of the number of blocks in the Laplacian matrix, the maximum eigengap between two consecutive eigenvalues of the Laplacian matrix, and the number of spikes of the embedded data that can be visualized after the Laplacian embedding.

Remark 3. Finally, we point out an important advantage of the three-way spectral clustering approach with respect to others approaches. As matter of fact, differently from approaches based on mixtures of matrix-variate data, the number of variables of the data set is not a critical issue because the spectral clustering algorithm is based on distance measures.

3 Example: Satellite data

Here, we analyze a matrix data set purchased by NASA from the Australian Center for Remote Sensing, it has already been analyzed in [13] and in [8]. The Satellite data set is included in the `MatManlyMix` R package and contains 845 units composed of 4×9 matrices. Thus, we have $n = 845$, $t = 4$ and $p = 9$. In particular, it represents a neighborhood of 9 pixels of satellite images of the same scene using 4 different spectral bands: two belonging to the spectrum of the visible region (green and red) and two of infrared. The units of satellite images correspond to 3 types of soil: gray soil, damp gray soil, and soil with vegetation stubble. Therefore, Satellite data has $K = 3$ labeled classes and, in order to perform the validity of our proposal, we will use ARI and accuracy.

In Figure 1, we present the graphic features of the spectral clustering process setting $h = 7$ and τ equal to the first quartile of the $L_{2,1}$ distribution that is defined by

$$\delta_{2,1}(X_{i_1 jk}, X_{i_2 jk}) = \sum_{k=1}^{p} \sqrt{\sum_{j=1}^{t} |X_{i_1 jk} - X_{i_2 jk}|^2}, \qquad for \quad i_1, i_2 = 1, \ldots, n. \tag{3}$$

From the number of blocks in Figure 1-a), the maximum eigengap in Figure 1-b), and the number of spikes in Figure 1-c), we can deduce that the number of clusters is 3. The three-way spectral clustering algorithm has been carried out and the resulting accuracy is equal to 0.8722. Finally, comparing our approach with [8], we can state that our method improves clustering performance, because in [8] the best model had an ARI equal to 0.42, while our method yields an ARI of 0.68. On the contrary, comparing our approach with [13], we get a slightly worse result, indeed the classification error rate in [13] is equal to 0.11 while in our approach it is equal to 0.13.

4 Conclusion

A spectral approach to cluster three-way data has been proposed. The matrix data are organized in a tensor, thus the vertices in the graph are represented by the matrices of dimension $t \times p$. In order to weight the vertices in the graph, a kernel function based on the $L_{2,1}$ norm between the matrix difference has been introduced. The performance of the three-way spectral clustering algorithm has been shown in one real three-way data set. The spectral method is competitive with respect to other clustering methods proposed in the literature to perform matrix-data clustering. Finally, in order to provide suggestions for future research, other kernel functions can be introduced considering different distances with respect to the $L_{2,1}$ norm.

Double clustering with a matrix-variate regression model: finding groups of athletes and disciplines in decathlon's data

Doppio clustering con il modello di regressione matriciale: ricercare gruppi di atleti e discipline in dati di decathlon

Mattia Stival and Mauro Bernardi and Manuela Cattelan and Petros Dellaportas

Abstract Decathlon is a two-day track and field competition in which athletes compete in 10 different disciplines placed in an invariant order. In this work we propose a co-clustering method using a generalization of the Bayesian matrix-variate regression model, in which both athletes and disciplines are grouped according to the observed data. Specifically, we describe the model and briefly outline the inferential strategy, based on a Gibbs sampling algorithm. The model provides powerful insights that can be used by coaches and athletes to improve their performances.
Abstract *Il Decathon è una gara dell'atletica che si svolge in due giorni in cui gli atleti si sfidano in* 10 *discipline diverse che seguono un ordine fisso. In questo lavoro proponiamo un metodo di co-clustering utilizzando una generalizzazione del modello di regressione matrice-variato, in cui sia gli atleti sia le discipline vengono raggruppati sulla base dei dati osservati. In questo articolo viene descritto il modello e si delinia brevemente la strategia inferenziale. Il modello fornisce spunti interessanti che possono essere utilizzati da atleti e allenatori per migliorare i loro risultati.*

In the first row, the boxplots represent the marginal distribution of points earned by each athlete during two decathlon competitions (2016 and 2018 national championships). In the second row, the boxplots represent the marginal distribution of points earned by the same athletes in different disciplines.

1 Introduction

Decathlon is a two-day track and field competition in which athletes compete in 10 different disciplines placed in an invariant order. In the first day, the athletes compete in the following disciplines: 100meters, long jump, shot put, high jump, and 400 meters; in the second day, athletes compete in: 110 meters hurdles, discus, pole vault, javelin and 1500 meters. During the competition, athletes are evaluated according to an international scoring system (see, www.worldathletics.org), useful for evenly evaluating their performances and for deriving the final ranking of a competition. From a sports science point of view, the disciplines are typically grouped in running, jumping and throwing disciplines, however, [4] showed the existence of an alternative grouping structure that highlights different relations among the 10 disciplines. If, one side, clustering disciplines can provide insights on the relations between disciplines that are useful for both training and competition purposes, on the other side, recognizing how one athlete performs is a key aspect from a coaching point of view. For example, knowing that one athlete performs better in a group of disciplines with respect to the others can suggest which are the important disciplines to train, in order to improve the total score. Grouping athletes means recognizing differences between them and, thus, showing strengths and weaknesses of each subject. Differences among athletes are indeed typically expected, with some athletes stronger in some disciplines and other athletes who are better performers in others.

In this work, we propose a double clustering strategy for finding groups of disciplines and athletes in different decathlon Italian championship competitions, yearly

held in the period 2012–2021 (source of data: www.fidal.it). The results observed in two championships are summarized in Figure 1. Double clustering (co-clustering) is a statistical technique that allows to find groups of rows and of columns in a matrix of observations [2]. We tackle the double clustering problem within a matrix-variate regression framework, in which matrix of results in different competitions are explained by means of a low dimensional matrix of means. Matrix-variate regression modelling is a topic which has recently catalyzed increasing attention in statistics, in light of the need to analyze datasets in which observations of different units arise in the form of a matrix [3, 1]. Our contribution differs from standard matrix-variate regression models as we let the left and right design matrices to be random selection matrices, allowing, by means of a compact representation, the clustering of rows, corresponding to different athletes participating in a competition, and the clustering of columns, corresponding to different decathon's disciplines. In the following, Section 2 presents the model and briefly outlines the inferential strategy, Section 3 presents the results of the real data application.

2 The model

Let $\mathbf{Y}_t \in \mathbb{R}^{P_t \times Q}$ be the matrix storing the results of the t–th decathlon competition in the sample, where the rows of $\mathbf{Y}_t$ store different athletes and the columns of $\mathbf{Y}_t$ store different disciplines. Here, P_t denotes the number of athletes participating in the t–th competition, which is different for each race, and $Q = 10$ denotes the number of disciplines in decathlon, and T the total number of independent races in the sample.

We consider the following model:

$$\mathbf{Y}_t = \mathbf{L}_t \mathbf{M} \mathbf{R}^\top + \mathbf{E}_t, \quad \mathbf{E}_t \sim MN_{P_t \times Q}(\mathbf{0}, \Sigma_t).$$

The matrix $\mathbf{E}_t$ is a matrix of errors, and follows a zero-mean matrix-variate normal distribution with covariance $Cov(\varepsilon_t) = \Sigma_t$, with $\varepsilon_t = Vec(\mathbf{E}_t)$ with $Vec(\cdot)$ denoting the vec-operator. For simplicity, in this work we assume $\Sigma_t = \sigma^2_\varepsilon \mathbf{I}_{P_t Q}$, meaning that the errors within $\mathbf{E}_t$ are independent and are characterized by the same scale regardless of the athlete and the discipline we are considering. The matrix $\mathbf{M} \in \mathbb{R}^{J \times G}$ is a matrix of means, storing, on different rows, the means related to each group of athletes, and, on the columns, the means related to different group of disciplines. Typically, J and G are assumed to be $J \ll \sum_{t=1}^{T} P_t$ and $G \ll Q = 10$, allowing for a parsimonious model in which few groups explain data of large dimensions.

The matrices $\mathbf{L}_t$ and $\mathbf{R}$ are left and right random selection matrices of dimensions $P_t \times J$ and $Q \times G$, respectively. The p_t–th row of $\mathbf{L}_t$ is $\mathbf{l}_{p_t} = [I(l_{p_t} = 1), \ldots, I(l_{p_t} = J)]$, where $l_{p_t} \in \{1, \ldots, J\}$ is a random cluster allocation of athlete l_{p_t}, and $I(\cdot)$ is the function such that $I(l_{p_t} = j) = 1$ if athlete p_t belongs to the j–th group of athletes, and 0 otherwise. Thus, the role of $\mathbf{L}_t$ is to indicatite to which of the J groups of athletes each athlete participating to competition t belongs to, as well as to select the specific row of $\mathbf{M}$ associated to each athlete. In a similar way, the q–th row of

the matrix $\mathbf{R}$ is $\mathbf{r}_q = [I(r_q = 1), \ldots, I(r_q = G)]$, where $r_q \in \{1, \ldots, G\}$ is the random cluster allocation of discipline, indicating to which of G groups of disciplines the discipline r_q belongs to. Thus, the role of $\mathbf{R}$ is indicating to which of the G groups of disciplines each discipline belongs to, and to select the corresponding columns of $\mathbf{M}$ for each discipline. Cluster allocations for both athletes and disciplines are assumed to be independent multinomial distributions, such that $l_{p_t} \sim Mult(1, \pi_L)$ and $r_q \sim Mult(1, \pi_R)$, where $\pi_L = (\pi_{L1}, \ldots, \pi_{LJ})$ and $\pi_R = (\pi_{R1}, \ldots, \pi_{RG})$ are vector of probabilities such that $\sum_{j=1}^{J} \pi_{Lj} = 1$ and $\sum_{g=1}^{G} \pi_{Lg} = 1$, with $\pi_{Lg} \geq 0$ and $\pi_{Rj} \geq 0$.

Due to the limited space, we only derive the scalar version of the model, in which the (p_t, q)–th entry of $\mathbf{Y}_t$ is

$$y_{p_t q,t} = \sum_{j=1}^{J} \sum_{g=1}^{G} I(l_{p_t} = j) I(r_q = g) \mu_{jg} + \varepsilon_{p_t q,t},$$

where μ_{jg} indicates the (j, g)–th entry of $\mathbf{M}$. The scalar μ_{jg} represents the conditional mean of the result $y_{p_t q,t}$ when athlete p_t belonging to group j (of athletes) competes in a discipline of group g (of disciplines). We refer to the literature related to the matrix variate regression model for alternative ways of interpreting the model [3, 1].

2.1 Posterior distribution and Gibbs sampling

Let $\mathscr{L} = \{\mathbf{L}_1, \ldots, \mathbf{L}_T\}$, $\mathscr{Y} = \{\mathbf{Y}_1, \ldots, \mathbf{Y}_T\}$, and also $\Theta = \{\sigma_\varepsilon^2, \mathbf{M}, \mathbf{P}_{R0}, \pi_L, \pi_R\}$. We adopt a Bayesian approach and derive the augmented likelihood, which is

$$p(\mathscr{L}, \mathbf{R}, \mathscr{Y} | \Theta) \propto \prod_{t=1}^{T} \left[p(\mathbf{Y}_t | \mathbf{L}_t, \mathbf{M}, \mathbf{R}, \sigma_\varepsilon^2) p(\mathbf{L}_t | \pi_L) \right] p(\mathbf{R} | \pi_R),$$

where we have assumed

$$p(\mathbf{L}_t | \pi_L) = \prod_{p_t=1}^{P_t} \prod_{j=1}^{J} \pi_{Lj}^{I(l_{p_t}=j)}, \quad p(\mathbf{R} | \pi_R) = \prod_{q=1}^{Q} \prod_{g=1}^{G} \pi_{Rg}^{I(r_q=g)}.$$

We adopt a conditionally conjugate approach, in which the prior probability of Θ factorizes as follows

$$p(\Theta) = p(\mathbf{M} | \mathbf{P}_{R0}) p(\mathbf{P}_{R0}) p(\sigma_\varepsilon^2) p(\pi_R) p(\pi_L).$$

Here, $\pi_L = (\pi_{L1}, \ldots, \pi_{LJ}) \sim Dir_J(\mathbf{1}_J^\top / J)$ and $\pi_R = (\pi_{R1}, \ldots, \pi_{RG}) \sim Dir_G(\mathbf{1}_G^\top / G)$, which are conjugate priors under the multinomial model. We assume also that $\sigma_\varepsilon^2 \sim IG(1, 1)$, and set $\mathbf{M} | \mathbf{P}_{0R} \sim MN_{J \times G}(\mathbf{M}_0, \mathbf{P}_{0R} \otimes \mathbf{I}_J)$, and let $\mathbf{P}_{0R} \sim IW_G(\nu, \mathbf{P}_{00})$ be an inverse Wishart with large variance. Under these assumptions, it is possible to obtain a sample of the posterior distribution

$$p(\Theta, \mathscr{L}, \mathbf{R}|\mathscr{Y}) \propto p(\mathscr{L}, \mathbf{R}, \mathscr{Y}|\Theta)p(\Theta)$$

by deriving a Gibbs sampling algorithm that iteratively simulates from the following full conditionals:

1. $p(\mathbf{M}|\mathscr{L}, \mathbf{R}, \sigma^2_\varepsilon, \mathbf{P}_{R0}, \mathbf{Y}_t) \propto p(\mathbf{M}|\mathbf{P}_{R0}) \prod_{t=1}^{T} p(\mathbf{Y}_t|\mathbf{L}_t, \mathbf{M}, \mathbf{R}, \sigma^2_\varepsilon)$;
2. $p(\mathbf{P}|\mathbf{M}) \propto p(\mathbf{M}|\mathbf{P}_{R0})p(\mathbf{P}_{R0})$;
3. $p(\sigma^2_\varepsilon|\mathscr{L}, \mathbf{M}, \mathbf{R}, \mathscr{Y}) \propto p(\sigma^2_\varepsilon) \prod_{t=1}^{T} \left[p(\mathbf{Y}_t|\mathbf{L}_t, \mathbf{M}, \mathbf{R}, \sigma^2_\varepsilon)\right]$;
4. $p(\mathbf{L}_t|\mathbf{R}, \mathbf{M}, \sigma^2_\varepsilon, \pi_L, \mathbf{Y}_t) \propto p(\mathbf{Y}_t|\mathbf{L}_t, \mathbf{M}, \mathbf{R}, \sigma^2_\varepsilon)p(\mathbf{L}_t|\pi_L)$, for $t = 1, \ldots, T$;
5. $p(\mathbf{R}|\mathbf{M}, \mathscr{L}, \sigma^2_\varepsilon, \pi_R, \mathscr{Y}) \propto \prod_{t=1}^{T} \left[p(\mathbf{Y}_t|\mathbf{L}_t, \mathbf{M}, \mathbf{R}, \sigma^2_\varepsilon)\right] p(\mathbf{R}|\pi_R)$;
6. $p(\pi_L|\mathscr{L}) \propto p(\pi_L) \prod_{t=1}^{T} p(\mathbf{L}_t|\pi_L)$ and $p(\pi_R|\mathbf{R}) \propto p(\pi_R)p(\mathbf{R}|\pi_R)$.

Steps 1-3 are simply updates of a Bayesian linear model, obtained by deriving the full conditional of the model in its vectorized form, since the selection matrices are given. Steps 4-5 are cluster-allocation updates, in which (conditional) independent updates are obtained for each row of $\mathbf{L}_t$ and $\mathbf{R}$. Finally, step 6 are standard Dirichlet updates.

3 Application

We apply our method under three different scenarios, where $J = G = 3$ for all the scenarios. In the first case, we consider the data using the original grading system, in which no transformation of the data is required. In the second case, we center the observations with respect to the discipline-specific mean of each competition, i.e. we apply the following transformation $y^\star_{p_t q,t} = y_{p_t q,t} - \frac{1}{P_t} \sum_{p=1}^{P_t} y_{pq,t}$, for $p_t = 1, \ldots, P_t$, $q = 1, \ldots, Q$, and $t = 1, \ldots, T$. In the third case, we apply the following transformation: we first center the observations with respect to the discipline-specific mean of each competition to obtain $y^\star_{p_t q,t}$, and re-center the transformed data with respect to the athlete-specific mean of the centered data, i.e. $y^{\star\star}_{p_t q,t} = y^\star_{p_t q,t} - \frac{1}{Q} \sum_{q=1}^{Q} y^\star_{p_t q,t}$, for $p_t = 1, \ldots, P_t$, $q = 1, \ldots, Q$, and $t = 1, \ldots, T$. In the first scenario (original data), the model recognizes three groups of athletes (index J) that differ with respect to the group-specific means of all the groups of disciplines (index G). More specifically, we recognize an ordering in the performance of the three groups of athletes (J), with respect to the points earned by the athletes in different disciplines (the higher the points, the better the performance). Group 1 (blue) in Figure 2 is overall better than group 2 (orange) and group 2 is overall better than group 3 (green) for all the groups of disciplines. By looking at how disciplines are grouped we recognize disciplines that allow to earn many points (group $j = 2$: 100 m, long jump, high jump, 400 m, 110 hs), disciplines with few points (group $j = 3$: pole vault and 1500 m), and intermediate disciplines that allows to earn, on average, a number of points in between group 2 and 3. In light of these results, it seems that there are disciplines that allow athletes to score more points due to the ranking system rather than actual differences between disciplines. For this reason, the performances of the athletes in different disciplines were centered with respect to the discipline-specific mean of

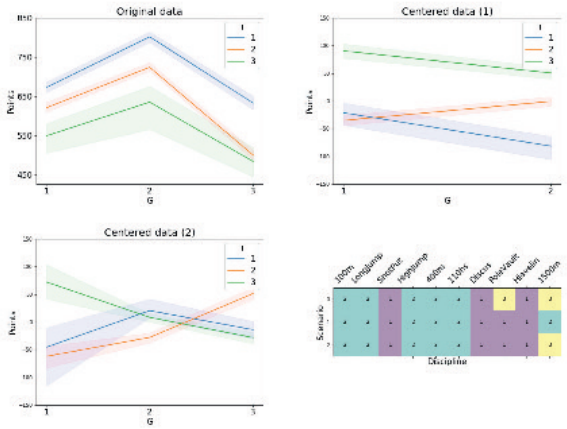

Fig. 2 The first three graphs show the median and the 90% quantile-based credible interval for the posterior distribution of the matrix of means **M** for the considered scenarios. The bottom-right panel shows how different disciplines are grouped in the three considered scenarios according to MAP.

each competition. In this case—i.e. centered data (1)—one discipline-specific group is not filled, leading to only two groups of disciplines. Athletes are clustered in three groups. Group 3 (green) is the group with the highest scoring athletes in both groups of disciplines. On the contrary, groups 1 (orange) and 2 (green) score similarly with respect group $g = 1$ of disciplines, but are characterized by differences between the number of points earned in group $g = 2$ of disciplines (shot put, discus, pole vault, javelin). In the third scenario performances were centered with respect to both the discipline- and athlete-specific means, in order to detect differences between groups that are not influenced by the personal strength and the scoring system. In this case, larger differences in scoring were found between group $j = 3$ and the others, the former characterized by a large positive mean in group of discipline $g = 1$, composed of throwing disciplines and the pole vault.

Classification of the population dynamics

Classificazione delle dinamiche di popolazione

Federico Bacchi[1] and Laura Neri[2]

Abstract Italy's population is chronically shrinking, especially at local level. An original classification method, based on the demographic trend observed during the last seventy years, is proposed to classify 7914 Municipalities. Considering the population dynamic as a Markov Chain, a division into groups is proposed. As a result of a series of statistical analysis, we observe that the earthquake risk and the quality of internet connection are connected with population dynamics:

Abstract *Questo lavoro propone un metodo di classificazione originale, per classificare 7914 Comuni, basato sulle tendenze demografiche osservate negli ultimi settanta anni. Considerando la dinamica della popolazione come una catena di Markov, si propone una suddivisione in gruppi distinti. Come risultato di una serie di analisi statistiche, si osserva che il rischio sismico e la qualità della connessione a internet sono caratteristiche associate con le dinamiche demografiche.*

Key words: demographic trend, Markov Chain, population dynamics.

1 Introduction

Population declines and depopulation associated with strong out-migration of some specific geographic areas is attracting the attention of both researchers and policy makers. Over the last decades, different demographic trends have been observed across European countries, especially at local level [3].

Italy has shown a gradual growth of its population, but this was not uniformly distributed throughout time and space. Particularly after the Second World War, Municipalities have recorded different patterns of population growth. It might be interesting to understand if there exists a link between those patterns and other specific characteristics. To address this issue, we follow two steps. Firstly, focusing

on demographic data, we classify the Italian Municipalities into groups showing similar demographic trends. None of the classic clustering methods are useful for the purpose, so, it is necessary to come up with original solutions. The second step concerns the study of the characteristics of the groups, complementing the demographic figures with data from other sources: geographical, socio-demographic and institutional variables.
Even though the topic is becoming increasingly popular, there are only few scientific publications about the relationship between population dynamics and other features of the geographic areas and, to the best of our knowledge, most of the contributions available are focused on continents or nations while only few specific analysis are conducted at Municipality level [4].
For these reasons, we get more in-depth on this topic.

2 Data

To analyse the dynamics of the Italian municipalities' population over the past 70 years, census data about population have been downloaded from the National Statistical Institute (ISTAT) website. The target variable to evaluate the phenomenon of depopulation is the resident population at municipality level; such information was historically collected by the Population Census. The first one was in 1951 and, until 2011, the census was conducted every ten years. Since 2018, ISTAT has started the so called "permanent census" which allows to collect data yearly. Thus, data on the resident population at municipality level, is available for the years 1951, 1961, 1971, 1981, 1991, 2001, 2011, 2018, 2019. We construct a dataset composed of 7914 rows and 10 columns: each row stands for each Italian municipality, at 31/12/2019[1]; the first column identifies the municipality code; columns 2 to 10 represent the resident population in each census time. This dataset allows classifying the units into clusters, representing a common observed pattern in demographic trend.

3 Classification methods

To identify clusters of Italian Municipalities based on their population's patterns, we propose two different methods. Both are based on the following idea: eight indicators, specified as dummy variables – one for each census couple of years – whose value is equal to 1 when the resident population of the municipality has increased, 0 otherwise. Thus, the data structure for the next analysis is the 7914 x 9 matrix for which the first three rows are reported in Table 1.

[1] The time series of the resident population (1951-2019) is based on the existing municipalities at 31/12/2019 (https://esploradati.censimentopopolazione.istat.it/databrowser/#/it).

Table 1: Few rows of the dataset containing indicators for the increasing or decreasing population for the census couple of years: Italian Municipalities.

Code	*51_61*	*61_71*	*71_81*	*81_91*	*91_01*	*01_11*	*11_18*	*18_19*
001001	0	1	0	1	0	1	0	0
001002	0	1	1	1	1	1	0	0
001003	0	0	0	1	0	0	0	0

3.1 Sum of dummy variables

The simplest way to induce if a municipality has shown an increasing or a decreasing demographic trend is to compute a new variable (Growth1), counting in how many periods its population has grown. Empirically, this is equivalent to sum all the dummy variables defined previously.
Now, it is possible to classify the 7914 Italian municipalities into different clusters, that can be defined according to two different options: i) deciding the number of clusters; ii) or the dimensions of these ones. Here we choose option (i) considering the classification according to 5 or 3 clusters. Thus, two new variables - Trend1 and Trend1bis - are introduced, to identify respectively the grouping into five or three clusters, as shown in Table 2.

Table 2: Values of "Growth1" and corresponding groups.

Growth1	*Trend1*	*Trend1bis*
0	Decreasing	Decreasing
1	Decreasing	Decreasing
2	Tendentially Decreasing	Decreasing
3	Tendentially Decreasing	Alternate
4	Alternate	Alternate
5	Tendentially Increasing	Alternate
6	Tendentially Increasing	Increasing
7	Increasing	Increasing
8	Increasing	Increasing

According to the previous method, the variable Growth1 assumes value 2 if the population growth in two subsequent or detached periods. It is strong assumption, based on the hypothesis that all the time points have the same importance in the definition of the demographic trends and, consequently, on the clustering process.

3.2 Population dynamics as a Markov Chain

Aiming at removing the overmentioned assumption, we wonder whether it seems reasonable to think that the dynamic of the population in *(t; t+1)* depends only on

the dynamic in *(t-1; t)*. In probability theory, a sequence of possible events in which the probability of each event depends only on the state attained in the previous event is the Markov Chain. Thus, we wonder if the population dynamics observed between 1951 and 2019 on the Italian municipalities could be represented as a Markov Chain. First, it is necessary to verify if the Markov property holds for the variables describing the population trends. The Chi-square statistics is close to 0, thus the dynamic of the population across the nine periods can be treated as a Markov chain. In general, any Markov chain is characterized by the "transition matrix" describing the probabilities of transitioning from one state to another. We address the problem of the estimation of the transition matrix by using the maximum likelihood method. In Table 3 the transition matrix (by rows) estimated and the standard errors.

Table 3: ML estimate of the transition matrix: estimated probabilities and SE (in parenthesis).

		Future State	
		0	***1***
Present	***0***	0.777 (0.005)	0.223 (0.003)
State	***1***	0.297 (0.003)	0.703 (0.005)

The practical meaning of the transition probability is very important for our purpose, in fact, for instance, the figure 0.703 represents the probability of an increase in population in the next period, given an increase in the present period. Now we can compute the vector of the probability to observe "1" in future, given "1" in the present state as

$\boldsymbol{w} = ((0.703)^7,(0.703)^6,(0.703)^5,(0.703)^4,(0.703)^3,(0.703)^2,(0.703)^1,(0.703)^0)$.

Now, let us consider the matrix M obtained from the one shown in Table 1 deleting the first column, M has dimension 7914x8 and each row m_i. *(i = 1,..,7914)* contains the indicators for the increasing/decreasing of population for each census couple of years. The variable "Growth2", for each municipality, can be computed as the vectorial product, $\boldsymbol{t}_i \times \boldsymbol{w}^T$. According to "Growth2" we can define a new classification of the Italian municipalities. In Table 4 the main quantiles of "Growth2" are shown.

Table 4: Main quantiles of "Growth2".

Min	***20%***	***25%***	***33,3%***	***40%***	***Median***	***60%***	***66,7%***	***75%***	***80%***	***Max***
0	0.206	0.348	0.622	0.842	1.117	1.442	1.666	2.047	2.168	3.168

Now, we group the municipalities, again into three or five clusters, considering new thresholds for the groups definition based on Growth2's quantiles (Table 5).

Table 5: Bounds of "Growth2" and groups according to Trend2 and Trend2bis.

Lower	***Upper***	***Trend2***	***Lower***	***Upper***	***Trend2bis***
[0	0.206)	Decreasing	[0	0.622)	Decreasing
[0.206	0.842)	Tendentially Decreasing	[0.622	1.666)	Alternate
[0.842	1,442)	Alternate	[1.666	3.168]	Increasing
[1.442	2.168)	Tendentially Increasing			
[2.168	3.168]	Increasing			

4 Empirical Analysis

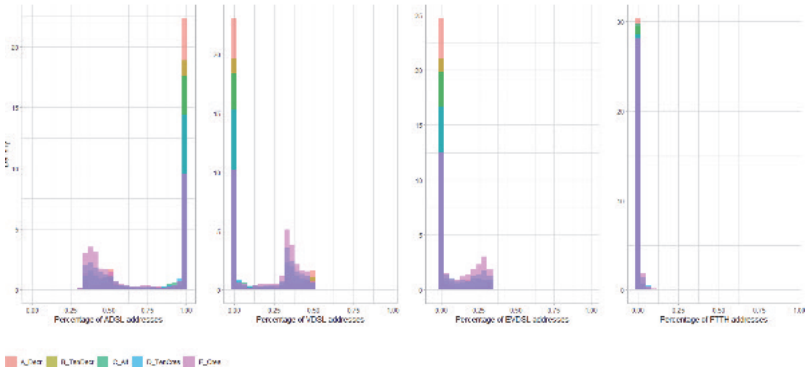
The next empirical analysis will concern the clustering method based on the Markov chain. Following are just a few of the analyses carried out. First of all, we check how the municipality classified by the Dipartimento per lo Sviluppo e la Coesione Economica, as Centro ("Polo", "Polo Intercomunale", "Cintura") or Area Interna ("Intermedio", "Periferia", "Ultraperiferia") are in turn classified according to our groups. The results appear to be reasonable: the percentage of "Decreasing" Municipalities increases as the distance of the Municipality from the "Centro" increases and, on the other hand, the percentage of "Increasing" or "Alternate" ones becomes higher as the distance of the Municipality from the "Centro" decreases.
We can expect that geological and physical characteristics of an area may influence population dynamics, so it seems reasonable to suppose an association between the clustering variable and the seismic risk index. For this reason, a discrete variable representing the Earthquake risk - defined by Protezione Civile – is assigned to each Municipality a seismic risk zone: where "Zone 1" is the most dangerous and "Zone 4" is the least dangerous area. Tables 6 suggests that the seismic risk influences population dynamics. Indeed, most of the statistical units with higher levels of earthquake risk have shown a decreasing (or tendentially decreasing) trend, while most of municipalities with lower levels of earthquake risk have shown an increasing (or tendentially increasing) trend. The results are coherent with the observations depicted by the literature, see for instance [1] that observe a general framework of demographic distress for areas most affected by the seismic events.

Table 6: Cross tabulation of "Trend2" and seismic risk index (percentage).

	Seismic Risk			
Trend2	***Zone 1***	***Zone 2***	***Zone 3***	***Zone 4***
Decr.	39.34	27.93	11.88	18.07
Tend. Dec.	31.33	17.60	13.73	20.58
Alternate	16.74	20.31	25.32	22.22
Tend. Inc.	8.44	16.03	20.94	17.37
Increas.	4.15	18.13	28.14	21.75
Total	100.0	100.0	100.0	100.0

Finally, it seems reasonable to suppose that geographic areas having better infrastructure and services may attract more people [2]. Nowadays, the quality of internet connection could be considered as an indicator of the quality of life. Accordingly, data from AGCOM website (year 2019), on inhabitants classified by type home connection are considered. The four types of connection, listed from the worst to the best, are: ADSL, VDSL, EVDSL, FTTH. The frequency polygon of the percentage of different home connections (Figure 1) show that better connections are more likely to be present for municipalities presenting increasing demographic trends.

Figure 1: Frequency polygon of the % of connections across the level of "Trend2".



5 Conclusions

Original classifications methods have been adopted to classify the Italian municipalities into groups of statistical units showing a similar demographic trend during the last seventy years. To avoid the implicit assumption that all the past time points have the same influence on the future trend, we introduced a vector of weights based on the estimated transition matrix of a Markov Chain and, we divided the 7914 units into five or three groups. This classification seems to be coherent with the official one. Considering several characteristics of the units, we observe that the ones presenting a stronger association with demographic trends are the home connection quality and the earthquake risk.

The analysis presented in this work do not aim to be exhaustive. Indeed, it would be interesting to consider fuzzy indicators, instead of dummy variables for intercensal trends, and to extend the set of variables which may influence depopulation. Moreover, it might be interesting to build a predictive statistical model for future demographic trend based on specific characteristics of the units.

Locating γ-Ray Sources on the Celestial Sphere via Modal Clustering

Individuazione di sorgenti di raggi γ sulla sfera mediante clustering non parametrico

Anna Montin, Alessandra R. Brazzale, Giovanna Menardi

Abstract Searching for as yet undetected γ-ray sources is a major target of the Fermi LAT Collaboration. In this paper, we present an algorithm capable to identify such type of sources by non-parametrically clustering the directions of arrival of the high-energy photons detected by the telescope. Using statistical tools from hypothesis testing and classification, we furthermore present an automatic way to skim off sound candidate sources from the γ-ray emitting diffuse background and to quantify their significance. The algorithm was calibrated on simulated data provided by the Fermi LAT collaboration and will be illustrated on a real Fermi LAT case-study.

Abstract *L'individuazione di sorgenti di raggi gamma è uno degli obiettivi dichiarati della Collaborazione Fermi LAT. Presentiamo qui un algoritmo per l'individuazione di queste sorgenti basato sul clustering non parametrico delle direzioni di arrivo dei fotoni ad alta energia rilevate dal telescopio. Sfruttando risultati della teoria dei test statistici e dell'apprendimento supervisionato, presentiamo, inoltre, come scremare le sorgenti candidate dalla componente diffusa della radiazione di fondo e attribuire loro una misura della significatività. L'algoritmo è stato calibrato su dati simulati forniti dalla Collaborazione Fermi LAT e sarà illustrato su un caso di studio reale.*

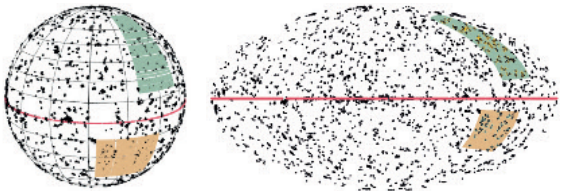

Fig. 1 Fermi-LAT γ-ray photon count maps for a 5-year observation period. Left: in polar coordinates. Right: in Galactic coordinates. Yellow: analysed region. Green: training set for post-processing classifier. Red: Galactic plane.

1 Motivation and rationale

In γ-ray astronomy, the data typically consist of an event list which gives the direction in the sky of each detected photon together with additional information. If the distance to the emitting source is not relevant, the data points are placed on the celestial sphere with Earth at its center and unit radius, as shown in the left panel of Figure 1. Directions are often expressed in *galactic coordinates*, which place the origin of the Cartesian system in the center of our galaxy — the Milky Way — and align the x-axis with the galactic plane (right panel of Figure 1). To overcome mismatches due to projecting data on the 2-dimensional sky map, we rather express directions through *polar coordinates*, that is, co-latitude (θ) and longitude (ϕ) in geographical terms, which can easily be back-transformed to Cartesian coordinates $\mathbf{x} = (\cos\theta, \sin\theta\cos\phi, \sin\theta\sin\phi)^\top$ on the unit sphere.

Discovering and locating high-energy emitting sources in the whole sky map is a declared target of the Fermi Gamma-ray Space Telescope collaboration. An astronomical source is an object in outer space which, in our case, emits γ-ray photons, that is, quanta of light in the highest energy range. Traditionally, analyses are based on so-called *single-source models* [4, § 7.4], which require the whole sky map to be split into small regions. The presence of a possible new source is assessed on a pixel-by-pixel basis using Poisson regression and likelihood ratio testing. Conversely, *variable-source-number models* address the problem from a more global perspective, as they simultaneously model and locate all sources in a sky map [4, § 7.3]. A most recent example of application to the γ-ray count maps accumulated by the LAT — the principal scientific instrument on board the Fermi spacecraft — is [7].

In this paper, we present a flexible algorithm for the efficient identification of γ-ray sources. In particular, we address the problem from the global perspective of variable-source-number models while working on the sphere. From the modeling point of view, the sources will be represented by highly concentrated clusters. [2] provide an illustration of directional *model-based* clustering of Fermi LAT data using a finite mixture of von Mises-Fisher distributions. Our approach uses *modal clustering*, which combines the advantages of both, model-based clustering and non-parametric methods, to guarantee the required flexibility. The corresponding methodological background is reviewed in Section 2. We will illustrate our proposal through a case-study of Fermi LAT data in Section 3.

2 Modal clustering on the sphere

General framework. Allocating objects to an unknown number of groups according to a set of observed attributes or features is a natural activity of any science. A surge of techniques has been proposed over the years, which differ significantly in their definition of what a "group" is. The non-parametric formulation, referred to as *modal* clustering, associates clusters with the domain of attraction of the modes of the underlying density, which are usually estimated non-parametrically [6]. Modal clustering can be recast into the frame of a standard statistical problem by considering the observed data $(\mathbf{x}_1,\dots,\mathbf{x}_n)$ as a sample of n realisations of a d-dimensional random vector $\mathbf{X}$ from a probability density function $f:\mathscr{X}\subseteq\mathbb{R}^d\to\mathbb{R}^+$. The modes of $f(\cdot)$ represent the archetypes of the clusters, which are in turn described by the surrounding regions.

Mode hunting. In our setting, directions in $\mathbb{R}^3$ are represented as unit vectors $\mathbf{x}$, that is, as points on the sphere $\Omega^2=\{\mathbf{x}\in\mathbb{R}^3:||\mathbf{x}||_2=x_1^2+x_2^2+x_3^2=1\}$ with unit radius and centre at the origin. Density estimation is performed by a suitable extension of a kernel density estimator to the directional setting [1]

$$\hat{f}_n(\mathbf{x})=\frac{c_h(K)}{n}\sum_{i=1}^{n}K\left(\frac{1-\mathbf{x}^\top\mathbf{x}_i}{h^2}\right), \tag{1}$$

where $K(\cdot)$ is a kernel function, $c_h(K)$ the associated normalizing constant, and the bandwidth parameter $h>0$ controls the smoothness of the estimator.

To account for the rugged nature of the data, which exhibit highly heterogeneous levels of concentration over the sphere, the estimator (1) is extended to account for a variable bandwidth $h=h(\mathbf{x}_i)$, selected according to scientific input. In particular, we use the scale parameter of the *point spread function*, which describes the response of the LAT to the point source. Grossly, this amounts to associating smaller values of h with precise events characterized by higher energies and which are usually disclosed around the direction of photon emission. The choice is consistent with the requirement of reducing the amount of smoothing nearby the high-density regions, as it is usually acknowledged by variable kernel density estimators.

A popular choice for the directional kernel is linked to the von Mises-Fisher (vMF) distribution [5]

$$f_{\text{vMF}}(\mathbf{x};\mu,\kappa)=c_3(\kappa)e^{\kappa\mathbf{x}^\top\mu},$$

where c_3 is a normalizing constant, $\mu\in\Omega^2$ is the mean direction, and κ is a concentration parameter around the mean. Here, κ is set to vary inversely with the bandwidth, i.e. $K(\cdot)=f_{\text{vMF}}(\cdot;\mathbf{x}_i,1/h)$. This distribution describes observations which scatter symmetrically around their mean value and can be regarded as the generalization of the normal distribution to spherical data.

Sources are aimed to be identified by pursuing the explicit task of mode detection, and modal regions are formed by sets of points along the steepest ascent path towards a mode. This is achieved by adapting the *mean-shift* algorithm [6, § 2.2] to be used with the directional kernel estimator (1). Starting from a generic point

$\mathbf{x}^{(0)}$, the algorithm recursively shifts it to a local weighted mean, until convergence. Denoted by $w_i(\mathbf{x}^{(s)})$ the vector of weights of the components of $\mathbf{x}_i$ at step s, at the next step

$$\mathbf{x}^{(s+1)} = \sum_{i=1}^{n} w_i(\mathbf{x}^{(s)})\mathbf{x}_i = \mathbf{x}^{(s)} + M(\mathbf{x}^{(s)}),$$

where $M(\mathbf{x}^{(s)}) = \sum_{i=1}^{n} w_i(\mathbf{x}^{(s)})\mathbf{x}_i - \mathbf{x}^{(s)}$ denotes the mean shift. Up to a normalising factor, the weights $w_i(\mathbf{x})$ are specified as $\nabla K\left(h^{-2}(1-\mathbf{x}^{\top}\mathbf{x}_i)\right)$, where $\nabla K(\cdot)$ is the gradient of the kernel function.

Post-processing. To separate the signal of the supposed emitting source from the diffuse γ-ray background, which spreads over the entire area observed by the telescope, we propose a post-processing procedure that combines the findings of two parallel quests.

On one hand, we supervise a suitable classifier, based on a training sample drawn from the available LAT catalogue, for which information on the earlier detected sources is available. The classifier integrates additional information on the photons such as their energy, position, the number present in the same cluster, the density estimates for the signal and the background model and various types of distances to the detected mode. This allows us to skim off the photons emitted from high-energy emitting sources from those which originate from the diffuse background.

In parallel, we evaluate the significance of each candidate mode. Here, we consider an adaptation of [3] who verify whether the maximum eigenvalue of the Hessian matrix of the kernel density, evaluated at the mode, is negative. In the directional setting, due to the constraints induced by working on the surface of the sphere, one eigenvalue is necessarily zero. An $1-\alpha$ level confidence interval for the second largest eigenvalue is hence constructed using bootstrap resampling. The mode is considered as such if the interval includes only negative values. The same allows us to infer the significance of the candidate source.

By super-imposing the findings from the two quests, we can identify candidate sources which are both, statistically significant and qualified as such by the non-parametric classifier. A by-product of our post-processing algorithm is the assignment of the photons to their assumed emitting source.

3 A Fermi LAT case study

Mode hunting. The two yellow regions in Figure 1 show a portion of the Southern sky of size $(l,b) \in [95^\circ, 135^\circ] \times [-40^\circ, -10^\circ]$ for which the LAT accumulated 3,849 photon counts over a five-year period of observation.[1] Of these, about 26% were emitted by the 44 sources present in the area, while the remaining 74% originated from the diffuse γ-ray background. The left panel of Figure 2 plots the estimated kernel density (1) using a von Mises-Fisher kernel. Here, the bandwidth parame-

ter h was set according to scientific input, as described in Section 2. This choice revealed to be the most performing one in terms of adjusted Rand index (ARI), average distance between the true source direction and the reconstructed one ($\bar{d}(s,\hat{s})$) and number of identified sources (n_s), according to an extensive numerical investigation (results not shown here) we carried out. In all, the mean-shift algorithm identified 876 modes.

Post-processing. To further refine the list of candidate sources we proceeded in two steps as outlined in Section 2.

1. A tree-based classifier to discriminate between source and background photons was trained on the 6,814 photon counts highlighted in green in the right panel of Figure 1 using as predictor variables those listed in the right panel of Figure 2. The most discriminating features are the number of photons assigned to a cluster, the difference between the two photon densities for, respectively, the all sky and background counts only, and the density observed for each photon. This reduces the original 876 modes to 39 candidate sources, which are shown as blue circles in the left panel of Figure 3. The table on the right reports the performance of our classifier in terms of ARI and average distance $\bar{d}(s,\hat{s})$. The true positive rate for single photon classification is 98.5% rate, while the percentage of false positives is 22.9%. Indeed, the five missed sources are the less photon emitting ones.
2. In parallel, we tested all the 555 clusters which contain two or more photons at a significance level of 5% while applying Bonferroni's correction. This skimmed off 448 modes, for a total of 107 remaining candidate sources, shown in the left panel of Figure 3 as red crosses. Here, the true positive rate for single photon classification is 85.0% and the false positive rate is 11.2%.

By super-imposing these two findings, we obtain in all 27 sources which are both, statistically significant and qualified as such by the non-parametric classifier. The global true positive rate for single photon classification is 94.6% while the false positive rate is 14.1%.

Fisher's Noncentral Hypergeometric Distribution for Population Size Estimation

La distribuzione ipergeometrica noncentrale di Fisher per la stima di numerosit di popolazione

Veronica Ballerini and Brunero Liseo

Abstract Fisher's noncentral hypergeometric (FNCH) distribution naturally suits biased sampling processes. Indeed, this distribution describes a biased urn experiment where balls of different colors are associated with different weights. Despite its potentiality, FNCH distribution has never been applied to official statistics problems, such as the size estimation of heterogeneous populations. Such underuse is mainly due to the computational burden given by its probability mass function, which makes the evaluation of the likelihood function challenging. We present a methodology to estimate the posterior distribution of FNCH parameters, exploiting extra-experimental information and the computational efficiency of MCMC methods. We assess the robustness to weights prior specifications via simulation studies.
Abstract *La distribuzione ipergeometrica non centrale di Fisher (FNCH) si adatta naturalmente a situazioni in cui il processo di campionamento è affetto da distorsione. Tale distribuzione descrive un esperimento di urna distorto, in cui palline di colori diversi sono associate a pesi diversi. Nonostante le sue potenzialit, la FNCH non mai stata applicata a problemi di statistica ufficiale, come la stima della numerosit di popolazioni eterogenee. Tale sottoutilizzo principalmente dovuto all'onere computazionale dato dalla funzione di massa di probabilit, che rende non banale la valutazione della funzione di verosimiglianza. In questo lavoro, presentiamo una metodologia per stimare la distribuzione a posteriori dei parametri della FNCH, sfruttando informazioni extra-sperimentali e l'efficienza computazionale dei metodi MCMC. La robustezza alle diverse specificazioni delle a priori sui pesi valutata tramite studi di simulazione.*

1 Fisher's noncentral hypergeometric distribution

In 2008, Agner Fog clarified the distinction between two distributions, both known in the literature as "the" noncentral hypergeometric distribution (see [7] and [6]). He first solved the nomenclature issue, naming them *Wallenius*' and *Fisher*'s, after the persons who first proposed them (see [5] and [11]).

The main difference between the two distributions resides in the dependence structure of the draws. Assume an urn of size N contains M_1 balls of color 1 and M_2 balls of color 2. The univariate Wallenius' noncentral hypergeometric distribution describes a situation in which the balls are drawn without replacement until n balls are sampled, and the probability to sample X_1 balls of color 1, and X_2 balls of color 2 depends on the colors' relative weights. Such weights can be seen as the probability to retain a ball of that color when drawn (as suggested by [4]). The competing draws make Wallenius' distribution fit perfectly the context of preference or ranking data (see [8]).

Instead, the univariate Fisher's noncentral hypergeometric (FNCH) distribution describes a biased urn experiment when the balls are drawn independently, without replacement, and the sample size n is observed only at the end of the experiment. It is the conditional distribution of two independent Binomial distributions given their sum ([9]):

$$\begin{aligned} X_1 &\sim Binom(M_1, \zeta_1) \\ X_2 &\sim Binom(M_2, \zeta_2) \end{aligned} \tag{1}$$

$$X_1 | X_1 + X_2 = n \sim FNCH(M_1, M_2, n, w_1, w_2) \tag{2}$$

where the weights w_c are the odds $\zeta_c/(1-\zeta_c)$, $c = 1, 2$. The weights w_c are defined up to a positive constant k; then, FNCH distribution is identified by the odds ratio $w = w_1/w_2$. Since $M_2 = N - M_1$ and $x_2 = n - x_1$, the formulation (2) is equivalent to:

$$X_1 | n \sim FNCH(M_1, N, n, w)\ . \tag{3}$$

Consider ζ_1, ζ_2 in (1) to be the two capture probabilities of the respective two population groups; then, the ratio w may be interpreted as the relative "exposure" of group 1 over group 2 in that capture occasion. As an alternative interpretation, we may consider ζ_1, ζ_2 as the two groups' "non-missing probabilities". In this case, w would be a measure of non-randomness in the missing data mechanism.

Given such considerations, it is clear that FNCH distribution has a great potentiality in the official statistics field. It can manage situations where n units belonging to a heterogeneous population of unknown size N are observed, and such units' capture, or non-missing, probabilities vary according to the population's subgroup they belong to. Such a situation is typical of survey data when the response rates of various groups differ according to their characteristics.

2 Bayesian inference for FNCH

We aim to estimate the size of the heterogeneous population N, or the subgroups' sizes M_1 and M_2. Whether both M_1 and M_2 are unknown, even if w is known and fixed, we can only estimate the relative size of the two groups in the population. Nevertheless, we might have some prior information on one of the groups: such a situation is common when dealing with administrative data. Indeed, consider a sample of resident (group 1) and non-resident (group 2) persons living in a city; given the reliable information contained in the municipal registries, including genuine prior information on M_1 would be legitimate. Moreover, assume data about a sample of self-employed individuals to be available, collecting information on their working situation. Self-employed workers may have (group 1) or have not (group 2) a VAT number. Since people with a VAT number must be listed in social security registers, we still may assume a reasonably concentrated prior on M_1. Finally, imagine we want to estimate the number of unemployed (group 1) and employed (group 2) young Italian graduates of a specific cohort; their respective sizes are unknown. Nevertheless, the National Student Register provides the annual total number of graduates, N; since the associated error is very small, we can elicit a concentrated prior for N.

The subjective elicitation is a debated issue since the attribute "subjective" is often perceived as including personal beliefs in a negative sense. Instead, we consider the elicitation process a rational way to incorporate experts' knowledge and take advantage of their experience; for a deep and detailed discussion about the probabilities' elicitation process, see [3] and [10].

Now, let us assume the following hierarchical model:

$$X_1 | X_1 + X_2 = n \sim FNCH(M_1, M_2, n, w) \tag{4}$$

$$M_1, M_2 \overset{\text{ind}}{\sim} \pi(M_c; \boldsymbol{\theta}^{M_c}) \, , c = 1, 2 \tag{5}$$

where $\pi(\cdot)$ denotes a generic distribution depending on some parameters $\boldsymbol{\theta}$.

If also w is unknown, we must elicit a prior on w:

$$w \sim \pi(w; \boldsymbol{\theta}^w) \, . \tag{6}$$

To use a noninformative prior on w is mathematically legitimate. However, we must notice that this parameter plays a crucial role which is often peculiar to the specific data set, and the use of genuine extra-experimental information is strongly suggested here. In the next section, we assess the sensitivity of the posterior to different specifications of w.

We denote with $\pi(M_1, M_2, w)$ the joint prior distribution; it can be factorized into $\pi(M_1)\pi(M_2)\pi(w)$ assuming that the odds ratio for the two groups of being included in the sample is independent on the groups' sizes. We also denote with $L(x_1; M_1, M_2, n, w)$ the likelihood function. Hence, the joint posterior distribution is

$$\pi(M_1, M_2, w | x_1, n) \propto L(x_1; M_1, M_2, n, w)\pi(M_1)\pi(M_2)\pi(w) \, . \tag{7}$$

Table 1: Sensitivity of M_2 to different prior specifications of w. Average variation between the posterior mean of M_2 and the value used to simulate the data, and average standard deviation, estimated on 50 samples for $N = 1000$.

σ_w	Average B_{M2}	Average $sd(\bar{M}_2^*)$
$\sigma_w = 0.2$	0.15	183.2
$\sigma_w = 0.4$	0.17	198.4
$\sigma_w = 1$	0.22	228.3

The posterior in (7) can be easily computed via MCMC methods, e.g., using a Metropolis-within-Gibbs algorithm.

3 Simulation studies

This section shows how the posterior of the subgroups' size changes as the prior specified for the odds becomes wider.

We simulate 50 samples setting $n = 50$ and $w = 2$ for two different population sizes, i.e. $N = 1000$ and $N = 10000$. We assume a very concentrated prior for M_1, namely a Poisson centered on its simulated value, and a discrete Uniform prior distribution for M_2, defined between x_2 and a large upper bound U_{M_2}; we set U_{M_2} equal to 5000 and 15000 for the two population sizes, respectively. Finally, for w we assume a Log-normal prior with parameter $\mu = 2$, and let the standard deviation σ_w vary; see Table 1 and Table 2.

For the two population sizes, Tables 1 and 2 show the average variation between the M_2 posterior and the value we used to simulate data, and the average standard deviation of the M_2 posterior. For each sample, we define our measure of variation as

$$B_{M_2} = \frac{1}{D} \sum_{d=1}^{D} \frac{(M_{2,d} - M_2)}{M_2} \tag{8}$$

where $M_{2,d}$ is d-th draw from the M_2 posterior.

For both population sizes, the mean standard deviation increases as the prior on w becomes wider; moreover, introducing more uncertainty leads to an increasing (upward) mean bias for the posterior mean. This bias is due to the large upper bound we elicit for M_2 prior.

Figures 1 and 2 shows how, however, the posterior is way more concentrated on the true M_2 value than the dashed flat prior (one sample only).

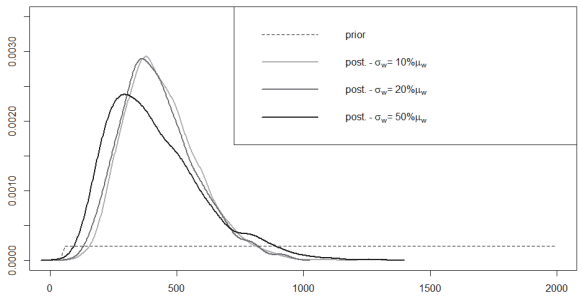

Fig. 1: M_2 prior vs. posteriors with different prior specifications of w. $N = 1000$.

Table 2: Sensitivity of M_2 to different prior specifications of w. Average variation between the posterior mean of M_2 and the value used to simulate the data, and average standard deviation, estimated on 50 samples for $N = 10000$.

σ_w	Average B_{M2}	Average $sd(\bar{M}_2^*)$
$\sigma_w = 0.2$	0.13	1774.2
$\sigma_w = 0.4$	0.17	2051.0
$\sigma_w = 1$	0.29	2818.4

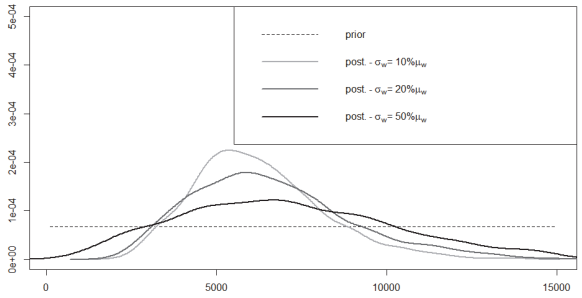

Fig. 2: M_2 prior vs. posteriors with different prior specifications of w. $N = 10000$.

4 Conclusions

Undercoverage is a pervasive issue, mainly addressed in the capture-recapture framework. Although widespread, the single-list case does not boast such vast literature, especially when the target population is elusive — e.g., non-resident inhabitants in a big city, homeless people, irregular migrants. We addressed the problem of

size estimation of a heterogeneous population when a single list is available, or we have multiple lists, but we lack unique identifiers. Our model considers the different sources' reliability and the different units' propensity to be captured. Genuine prior information is needed to manage such sources of uncertainty together; a Bayesian model comes naturally in such a situation.

In this short paper, we only discuss the use of our methodology in a simulation study. In [1], an application to the problem of size estimation of unemployed young graduates is presented. The authors exploit the accurate information on the total number of graduates made available by the National Student Register of the Italian Ministry of University and Research. We are currently working to extend the model to the multivariate case. In such a case, the repeated evaluation of the likelihood is prohibitive; thus, a vanilla MCMC algorithm is computationally intractable. As a result, it is needed to use algorithms that avoid the direct evaluation of the FNCH likelihood function. A viable approach is then based on Approximate Bayesian Computation methods, as discussed in [1] and to a more general extent in [2].

Small area models for skew and kurtotic distributions

Modelli per piccole aree riferiti a distribuzioni con asimmetria e curtosi

Maria Rosaria Ferrante and Lorenzo Mori

Abstract Models for small area estimation, used in the economic field, often have the necessity to assume or to lead back through appropriate transformations to the normality of the dependent variable. This work tries to extend the well known methodology of small area estimation at unit level with a family of models (Generalized additive model for location, scale and shape), which do not need the assumption of normality but which, as special case, has in itself most of the uni-variate models presented in literature.

Abstract *I modelli di stima per piccole aree, utilizzati in ambito economico, hanno spesso l'esigenza di assumere, o di ricondursi attraverso opportune trasformazioni, alla normalità della variabile dipendente. In questo lavoro si cerca di estendere la metodologia di stima per piccole aree a livello unit ad una famiglia di modelli (Generalized additive model for location, scale and shape), la quale non necessita dell'assunzione di normalità ma che, come caso particolare, comprende la maggior parte dei modelli univariati utilizzati nell'ambito della stima per piccole aree.*

Key words: Small area estimation, unit level models, GAMLSS, exponential family

1 Introduction

Small area methods attempt to solve the low representativeness of surveys within areas or the lack of data for specific areas/sub-populations. This is accomplished by incorporating information from outside sources. Unit-level models, originally defined in the form of nested error linear regression model [10], were generalized with few more complex and flexible models. The fil-rouge that links all those models is

Maria Rosaria Ferrante and Lorenzo Mori
Department of statistical science P. Fortunati , Via Belle Arti, 41 - Bologna - Italy e-mail: maria.ferrante@unibo.it and e-mail: lorenzo.mori7@unibo.it

the attempt to release assumptions, in particular the normality one, present in the basic unit level model. Many economic continuous variables, are distributed on the positive real line and can be significantly skewed. The standard technique of transforming variables by means of log is not always helpful to achieve a normal distribution. In the field of the frequentist approaches, generalized linear (mixed) models (GLMM) with random area effects were proposed and they are well summarized in [5]. In [6] it was proposed a generalized additive (mixed) models (GAMM) approaches to SAE. In the filed of the Bayesian approaches a skew normal distribution was used in [2] and a multivariate beta regression in [13]. Following the time line of the models development, speaking out of small area contest, a generalization of GLM, GAM, GLMM and GAMM is the generalized additive models for location, scale and shape (GAMLSS). Rigby and Statiunopolus [11] introduced these models where the response distribution is not restricted to belong to the exponential family. Those models, at the best of our knowledge, were never been used for Small Area Estimation (SAE). In our opinion, they can be not only a generalization of the models presented in literature but, above all, the possibility to define each parameter of a distribution in terms of covariates and random effects could bring to a reduction of the mean square error.

2 Generalized additive model for location, scale and shape

GAMLSS models, assume independent observations y_i, $i = 1,\ldots,n$ from a random variable Y_i, with probability density function $f(y_i|\theta^i)$, conditional on $\theta^i = (\theta_{i1},\ldots,\theta_{ip})$ a vector of p distribution parameters[1], each of which can be a function to the explanatory variables. Rigby and Statiunopolus [11] define the original formulation of a GAMLSS model as follows. Let $y_i^T = y_1,\ldots,y_n$ be the n length vector of the response variable. Also for $k = 1,\ldots,p$, let $g_k(\cdot)$ be known monotonic link functions relating the distribution parameters to explanatory variables by:

$$g_k(\theta_k) = \eta_k = X_k\beta_k + \sum_{j=1}^{J_k} Z_{j_k}\gamma_{j_k} \tag{1}$$

where θ_k and η_k are vectors of length n, e.g. $\theta_k^T = (\theta_{1_k},\ldots,\theta_{n_k})$ and $\beta_k^T = (\beta_{1_k},\ldots,\beta_{J_k'k})$ is a parameter vector of length J_k', X_k is a known design matrix of order $n \times J_k'$, Z_{j_k} is a fixed known $n \times J_k$ design matrix and γ_{j_k} is a J_k-dimensional random variable. The population probability (density) function $f(y|\theta^i)$ in model 1 is deliberately left general with no explicit conditional distributional form for the response variable. In GAMLSS, in fact, the exponential family distribution assump-

[1] The first two population distribution parameters $(\theta_{i1},\theta_{i2}) = (\mu_i,\sigma_i)$ are usually characterized as location and scale parameters, while the remaining parameters, if any, are characterized as shape parameters, e.g., skewness and kurtosis parameters. For many families of population distributions a maximum of two shape parameters $\nu(=\theta_3)$ and $\tau(=\theta_4)$ suffice.

tion for the response variable, y, (essential in GLMs and GAMs), is relaxed and replaced by a general distribution family, including highly skew and kurtotic distributions[2].

GAMLSS allows a variety of smooth functions[3] ($\sum_{j=1}^{J_k} Z_{j_k}\gamma_{j_k}$) of explanatory variables but, given that our interest is on small area estimation techniques, we will refer to γ_{j_k} always as parametric random-effect.

2.1 GAMLSS for small area estimation

In SAE a finite population Ω with N units is distributed into J sub-population $\Omega_1,\ldots,\Omega_J$, called domains or areas, of size $N_1,\ldots,N_J$, where $N=\sum_{\omega=1}^{\Omega} N_J$. In this case, Y_{ji} is the measurement of the target variable in unit i form area j. The main aim is to estimate area parameters in the form $H_j = h(Y_j)$, $j=1,\ldots,J$, where $h(\cdot)$ is a real measurable function. These area parameters are estimated using the data coming from the sample s of size n drawn from the population Ω with sub-sample $s_j = s\cap\Omega_j$ from area s of size n_j with $n=\sum_{j=1}^{J} n_j$. We will denote by $r_j=\Omega_d - s_j$ the sample complement from the same area, $j=1,\ldots,J$. Following [12], we can define the following model using area random effects:

$$\begin{aligned} g_1(\mu) &= \eta_1 = X_1\beta_1 + Z_1\gamma_{j1} \\ g_2(\sigma) &= \eta_2 = X_2\beta_2 + Z_2\gamma_{j2} \\ g_3(\nu) &= \eta_3 = X_3\beta_3 + Z_3\gamma_{j3} \\ g_4(\tau) &= \eta_4 = X_4\beta_4 + Z_4\gamma_{j4} \end{aligned}$$

where the $Z's$ can now be complex design matrices depending on the number and type of random effects and contains area level covariates. With $\gamma_k \overset{iid}{\sim} N(\mathbf{0},\Psi_k)$ for $k=1,2,3,4$. The Ψ's are matrices associated with the variance-covariance structure of the random effects. Random effects are also supposed to be independent among themselves. Hence considering a distribution model, called $\mathscr{F}$, the conditional distribution of Y, by including a random effect term in each of the models for the parameters μ,σ,ν and τ is:

$$Y_{ij}|\gamma_{j1},\gamma_{j2},\gamma_{j3},\gamma_{j4} \sim \mathscr{F}(\mu_{ij},\sigma_{ij},\nu_{ij},\tau_{ij}) \tag{2}$$

Independently for $j=1,\ldots,J$ and $k=1,2,3,4$. With a series of arguments reported in [11] it is possible to conclude that the β_ks and the γ_{j_k}s are estimated within the GAMLSS framework by maximizing a penalized likelihood function l_p given by:

[2] For a list of the possible distributions: https://www.gamlss.com/

[3] For more details: Statiunopolus et *al.* [12], Ch 10.

$$l_p = \sum_{i=1}^{n} \log\{f(y_i|\theta^i)\} - \frac{1}{2}\sum_{k=1}^{p}\sum_{j=1}^{J_k} \gamma_{j_k}^T \Psi_{j_k}^{-1} \gamma_{j_k}, \quad \text{given } \theta^i \; \forall \; i = 1,\ldots,n \qquad (3)$$

The model fitting [4] of a GAMLSS is achieved by either of two different algorithmic procedures which maximizing the penalized likelihood of the data eq. 3. The first algorithm (RS) is based on the algorithm that was used for the fitting of the mean and dispersion additive models (based on Newton–Raphson algorithm), whereas the second (CG) is based on the Cole and Green algorithm which one is a "transformation" of the Fisher scoring algorithm.

2.2 Special cases and mean square error estimation

GAMLSS models using random effects, can be viewed as a generalization of a certain number of small area unit level models.[5] A linear mixed model is easily obtained form eq. 2 using a normal distribution with identity link function, identity matrix Z and with $g_2(\sigma) \sim 1$. If Z is a matrix of area level covariates this model is equal to the "two-level" small area model [10], par. 4.5.3, In the same way, choosing an appropriate distribution and a link function for $g_1(\mu)$ is possible to obtain a GLMM model. For example the model presented in [10], par. 4.6.1, can be rewrite in GAMLSS terms as a dichotomous dependent variable with a logit link function. With similar arguments is also possible to rewrite the models in [10], par. 4.5.4 and par. 4.6.4.

All those models need a specific formulation of Mean Square Error (MSE). Following [10] and [4] for the linear mixed models obtained through GAMLSS is possible to use an algorithm, based on a parametric bootstrap, that is almost equal to the ones used in [10] for the empirical best. The only difference is that for GAMLSS it's necessary to use a correction for the variance matrix of the error term $\hat{\Lambda}$ obtaining $\hat{\Lambda}_k^N$. This correction, proposed by Nelder in [9], is given due to the MAP estimation of random effects within GAMLSS. The other points of the algorithm are exactly the same with the models used in [10] replaced by the GAMLSS model described above. The estimated CV's obtained from those two models are at most equal.

3 Preliminary results and further developments

A preliminary result was obtained using the data set "Cornsoybean" [1]. To estimate area under corn and area under soybeans for each of $j = 12$ counties in north-central Iowa, using farm interview data in conjunction with LANDSAT satellite data were

[4] For an in-depth on the algorithms: Statiunopolus et *al.* [12].

[5] For all the model that we will present in this paragraph we will refer to Rao and Molina [10], in which is possible to find more accurate references to every single model.

used the EBLUP method and the GAMLSS model. Those last with a normal distribution with identity link function for μ and a log link function for σ. We use the same variables as [1] for μ but adding a random effect term in σ^2:

$$\mu = X_1\beta_1 + \gamma_{j1} \tag{4}$$
$$\log(\sigma) = \gamma_{j2} \tag{5}$$
$$\tag{6}$$

given eq. 4 the dependent variable has a normal distribution:

$$Y_{ij}|\gamma_{j1},\gamma_{j2} \sim \mathcal{N}(\mu_{ij},\sigma_{ij}) \tag{7}$$

Using random effects for σ^2 we could be able to capture the variation in terms of different dispersion of Y in the areas. Following [4] the MSE estimation for the GAMLSS models was obtained with a parametric bootstrap method for finite populations. As follows:

1. Fit the GAMLSS model eq. 4 to the sample data y_s, obtaining estimate for the model parameters;
2. For each $b = 1,\ldots,B$, with B large, generate are vectors $y_j^{(b)}$, $j = 1,\ldots,J$ form the normal population model Eq. 7 with the estimated parameters at point 1. Let $H_j^{(b)} = h(y_j^{(b)})$ be the true bootstrap parameter for area j;
3. Take the sample part of $y_j^{(b)}$, denoted $y_{js}^{(b)}$, $j = 1,\ldots,J$. With the whole sample data fit the GAMLSS model Eq. 4 and compute the small area estimation, $\hat{H}_j^{(GAb)}$ of $H_j^{(GAb)}$;
4. A bootstrap estimator of the MSE of $\hat{H}_j^{(GAb)}$ is obtained as

$$mse_B(\hat{H}_j^{(GAb)}) = \frac{1}{B}\sum_{b=1}^{B}\left(\hat{H}_j^{(GAb)} - H_j^{(b)}\right)^2$$

Here, having to estimate the mean of Corn Hec. ($\hat{y_j}$) in 12 counties, following [10] we use

$$\hat{y}_j = \frac{1}{N_j}\left(\sum_{i\in s_j} y_{ij} + \sum_{i\in r_j}\tilde{y}_{ij}\right) \tag{8}$$

where $\tilde{y}_{ij}$ is is the predicted value for non-sample unit $i \in r_j$ given by replacing the mean area values of covariates into the μ equation of Eq. 4. Note that define also a specific function for σ in term of random effect only does not involve changes in the formula for the estimation of the mean. The mean values obtained from the two model are at most equal. The correlation between them is 0.98. The estimated CVs are less for the GAMLSS model with respect to EBLUP in 7 out of 12 counties, in 2 perform in the same way and in the remaining three it is the worst. From this first simple application we could conclude that defining a different σ_j^2 for each area

bring to an increase in precision of estimate. For sure more study are necessary to verify applicability and precision of those models. Authors are working on model and design simulations whit an higher number of both areas and sampled unit for each area.

What is presented is a first step to introduce the GAMLSS models into the SAE theory. Those models, releasing the assumption of the exponential family, could be very useful to implement functional-regression in a more accurate way than the ones that assume normality for the dependent variable. As shown, as special case, most common unit level small area models can be preform using GAMLSS models and these last seems to use very stable numerical-algorithms. Further directions of research involve expanding it, in particular for the MSE estimation, for those distributions whose supports are limited. Developing a simultaneous correlated system of estimation extending results in [8] and [7] to SAE.

The use of remotely sensed data in sampling designs for forest monitoring

L'uso dei dati telerilevati nei disegni campionari per il monitoraggio forestale

C. Bocci, G. Chirici, G. D'Amico, S. Francini and E. Rocco

Abstract Technology development has led to a large availability of increasingly precise remotely sensed data ready-to-use, but several countries' forest monitoring programs are still based on the traditional systematic sampling design of National Forest Inventories (NFIs). It is well known that, in order to improve surveys estimates, auxiliary data can be used both in the design phase and in the estimation phase. Recent literature has presented some proposals of using remote sensing (RS) data to improve NFIs but all are limited to specific countries or areas. Our aim is to investigate how RS data can be exploited to produce global forest estimates in a more cost-efficiently way. We assess the use of a global Landsat-based cloud/noise free Best Available Pixel (BAP) composite image in the design phase in order to produce reliable estimates of the biomass and soil carbon density.

Abstract *Nonostante lo sviluppo tecnologico abbia portato a un'ampia disponibilità di dati telerilevati sempre più precisi e pronti per l'uso, i programmi di monitoraggio forestale di diversi paesi si basano ancora sul tradizionale disegno di campionamento sistematico degli inventari forestali nazionali. E' noto che l'utilizzo di informazioni ausiliarie, sia in fase di disegno che in fase di stima, produce stime campionarie più efficienti. Recenti proposte in letteratura hanno introdotto l'uso di variabili ausiliare telerivevate negli inventari forestali nazionali, ma tutte si concentrano su singole aree o paesi. Il nostro obiettivo è di investigare come i dati telerilevati possano essere sfruttati per ottenere stime di variabili forestali a livello globale in modo efficiente in termini di costi. In questo studio valutiamo l'uso in fase di disegno di immagini satellitari globali composite di fonte Landsat per produrre stime attendibili della densità di Carbonio da biomassa e suolo.*

1 Introduction

Forest ecosystems are a critically important component of the global terrestrial carbon cycle absorbing almost 3 billion tons of anthropogenic carbon annually, or 30% of the total emissions associated with fossil fuel burning and net deforestation [1]. Unfortunately, the vast array of goods and services provided by forests are threatened by climate change, and monitoring forests and supporting decision-makers with reliable data is more important than ever. For this reason, monitoring the biomass and biomass variations due to human activities or climate changes is more essential than ever. On the other hand, while information related to tree structure is of great interest, such information is often not available wall-to-wall and over large areas due to large survey and processing costs.

Usually, forest variables estimates are provided by a design-based approach with data collected in the field in the frameworks of traditional National Forest Inventories (NFIs) [2, 5]. Estimates aggregated for large geographic areas are requested in the context of national and international reporting. However, NFI data are expensive, since they require long and costly field campaigns, so a major scientific challenge is to develop new methods to derive useful forest information in a more cost-efficiently way [8]. In the last decades, recent advancements of earth observation technologies opened the possibilities to use remote sensing (RS) data to support forest inventories, so that the strategies to collect information and derived estimates in the context of forest inventories changed consequentially ([7], [2], [4] among others). However, at best of our knowledge, most of these contributions limit their applications to specific countries or areas.

Our aim is to investigate how RS data can be exploited to produce global forest estimates in a more cost-efficiently way. RS data in combination with field data can be used to enhance the precision of large-scale forest inventories both in the design phase and in the estimation phase, but in this first contribution we limit our analysis to the design phase.

2 Data

The target population consists of all the pixels of a harmonized global map (with a resolution of 300 meters) of above-and-below-ground terrestrial carbon storage (tonnes (t) of Carbon per hectare (ha)) in biomass and soil for the reference year 2010 [6]. This map depicts the 'total' carbon density (CD) at global scale and is obtained by combining data from multiple publicly available datasets. A detailed description of the dataset can be found at the source website[1].

To produce estimates at global scale we require auxiliary variables with the same coverage, which can be obtained by composition. The Best Available Pixel (BAP) image compositing application in Google Earth Engine GEE-BAP enables the gen-

eration of annual global Landsat-based cloud/noise free BAP composite images. This kind of image represent a new paradigm in remote sensing that is no longer reliant on scene-based analysis and the Normalized Difference Vegetation Index (NDVI) calculable from it is used as auxiliary variable in our analysis. Landsat, and so the composite map, has a resolution of 30 meters; to be consistent with the CD we aggregate (using average) the BAP composite map at 300 meters resolution. The two maps of the target and auxiliary variables are showed in Figures 1(a) and 1(b).

3 Sampling strategy

The global study area is tessellated into squared cells, with a size of 6 degrees of latitude $\times$ 6 degrees of longitude (which roughly corresponds to the whole Italian surface). Each of these cells is a domain of study, that is we are interested in providing estimates globally as well as for each cell of the grid. For this, we can assume that each cell is a sort of stratum and from each of them we select a sample independently from the others. All the cells have the same size and include the same number of pixels L, but the actual size of the eligible population N_h varies between cells since there could be areas in which the target variable is not defined (over the oceans, lakes, deserts, etc...).

We assume that the sample size is constant for all the cells with the same eligible population. This value is then reduced proportionally for those cells with a lower number of eligible pixels. The sample size should be chosen considering the trade-off between the need to produce precise estimates and the organizational and cost constraints of the survey. To evaluate the influence of this choice, we consider three different settings: 10000, 5000 and 2000 sampled units.

Performance of the following different sampling designs is assessed through a simulation study. All designs exploit the geographical location of the study units and/or the values of the auxiliary variable NDVI.

1. **SPAT_LPM**: Spatially balanced sampling through Local Pivotal Method (LPM), suggested by [3], with equal inclusion probabilities $\pi_i s$. The LPM in its original

formulation produces samples that are well spread in the geographic space. It can be considered as a proxy of the systematic sampling commonly used for NFIs.
2. **AUX_LPM**: Sampling balanced through LMP in the space spanned by the auxiliary variable, with equal $\pi_i s$.
3. **BIV_LPM**: Sampling balanced through LMP in the space spanned by both the geographical coordinates and the auxiliary variable, with equal $\pi_i s$.
4. **UNEQ_LPM**: Spatially balanced sampling through LMP with unequal inclusion probabilities $\pi_i s$ proportional to the auxiliary variable.
5. **STRp_AUX_LPM** and **STRn_AUX_LPM**: Stratified sampling with AUX_LPM design in each stratum. The cell is partitioned in 100 sub-areas (strata) and then the AUX_LPM is applied in each stratum. Two allocation rules are considered: Proportional and Neyman's with respect to the variance of the auxiliary variable.
6. **STRp_BIV_LPM** and **STRn_BIV_LPM**: Stratified sampling with BIV_LPM design in each stratum. The same stratification designs described in the previous point, but with BIV_LPM applied in each stratum.

In addition, as a comparison, simple random sampling (SRS) is considered both over the entire area and within strata.

The basic idea of LPM introduced by [3] is to avoid that units close in distance appear together in the sample. First an inclusion probability $0 < \pi_i \leq 1$ is assigned to each unit so that their sum over the population is equal to the fixed sample size. The $\pi_i s$ can be either equal for all the units in the population or unequal (we considered unequal $\pi_i s$ in design 4). The sample is then obtained in at most N steps, where N is the population size. At each step one unit i is selected randomly from the available population and another unit j is chosen among the remaining units in the population by minimizing a distance function among them. This can be a univariate or a multivariate function that measures the distance with respect to one or more auxiliary variables, among which we can include the spatial coordinates. When all the variables are continuous the Euclidean distance is commonly used. Moreover, when multiple auxiliary variables are used, they are usually standardized in order to balance the contribution of each variable. After the selection of the unit i and j their inclusion probabilities are updated by using the following rule:

$$\begin{aligned}
&\text{if } \pi_i + \pi_j < 1 \text{ then } (\pi_i', \pi_j') = \begin{cases} (0, \pi_i + \pi_j) \text{ with probability } \frac{\pi_i}{\pi_i + \pi_j} \\ (\pi_i + \pi_j, 0) \text{ with probability } \frac{\pi_j}{\pi_i + \pi_j} \end{cases} \\
&\text{if } \pi_i + \pi_j \geq 1 \text{ then } (\pi_i', \pi_j') = \begin{cases} (1, \pi_i + \pi_j - 1) \text{ with probability } \frac{1-\pi_j}{2-\pi_i-\pi_j} \\ (\pi_i + \pi_j - 1, 1) \text{ with probability } \frac{1-\pi_i}{2-\pi_i-\pi_j} \end{cases}
\end{aligned} \tag{1}$$

As a result, in each step at least one unit is definitively excluded from the population, either because its probability becomes zero, and consequently it is definitely excluded from the sample, or because its probability becomes one and therefore is included in the sample. The procedure continues, updating at each step the probabilities of inclusion obtained in the previous step, until all units in the population

Table 1 Descriptive statistics of the study and the auxiliary variables.

Cell	μ_{CD}	μ_{NDVI}	CV_{CD}	CV_{NDVI}	$\rho_{CD,NDVI}$
1	28.49	0.424	0.856	0.516	0.501
2	63.14	0.735	0.468	0.145	0.317
3	27.69	0.487	1.643	0.342	0.390
4	32.21	0.414	1.141	0.514	0.615
5	177.42	0.798	0.177	0.108	0.348
6	19.86	0.469	1.307	0.445	0.739

are processed. LPM selects the units with the same probability $\pi_i s$ initially assigned to them, therefore the population mean can be estimated with the usual Horvitz-Thompson estimator.

4 Simulation results and discussion

We briefly present some first results of our simulation study. The performance of the designs described in the previous section is evaluated through Monte Carlo experiments in 6 cells, selected across the globe, which differ in the distributions of the auxiliary and study variables and in their relation (see Figures 2(a)-2(f) and 2(g)-2(l), and the descriptive statistics in Table 1).

Table 2 presents the root mean squared errors (RMSEs) for each sampling design with a sample size of 5000 units[2], obtained with 500 Monte Carlo replications. Results show that the use of any auxiliary variables (geographical location or NDVI) is always preferable to the basic SRS. Moreover, they confirm the usefulness of including the geographical information in the sampling design. About the use of

[2] Tables for the other sample sizes are not included for lack of space

the additional auxiliary variable, our preliminary results are not straightforward. It seems that its contribution to improving the estimates' efficiency depends on many factors, particularly on the correlation with the study variable and on the variability of both study and auxiliary variables. Moreover, we found that the usefulness of the additional auxiliary variable increases as the sample size decreases.

Analyzing different causes of one–inflation in capture recapture models for criminal populations.

Modelli cattura–ricattura per la stima di popolazioni criminali: analisi delle diverse cause di one–inflation.

Davide Di Cecco, Andrea Tancredi and Tiziana Tuoto

Abstract Our goal is the estimation of the size of various criminal populations on the basis of administrative data on criminal proceedings by exploiting capture–recapture models for repeated count data. The data at our disposal exhibit an abundance of units that are captured exactly once, which suggests the necessity of explicitly modeling this deviation. We distinguish three possible causes for this phenomenon, namely, the erroneous inclusion of out–of–scope units, a particular behavioural effect preventing subsequent captures after the first one, and missed links in a Record Linkage step. We then propose three families of "one–inflated" models to estimate the number of uncaptured units which we compare on datasets of Italian criminal proceedings.

Abstract *L'utilizzo di modelli cattura ricattura per stimare il numero di criminali non è nuovo in letteratura. In questo lavoro intendiamo stimare il numero di individui connessi a specifiche attività criminali in Italia sulla base dei dati sul numero di provvedimenti giudiziari individuali. I dati mostrano chiaramente la necessità di modellizzare l'eccesso di individui catturati solo una volta. Individuiamo 3 cause possibili per questo fenomeno noto come "one–inflation": la presenza di unità che andrebbero escluse dalla popolazione; un behavioural effect già noto nela stima delle popolazioni animali; e la presenza di mancati abbinamenti in una fase preliminare di Record Linkage. Proponiamo di conseguenza 3 strategie per le 3 possibili cause.*

Key words: Criminal populations. Capture-recapture. Official statistics.

1 Introduction

Estimating the number of people involved in certain illegal activities helps us in allocating the police forces to counter it, in evaluating the effectiveness of prevention and counteraction policies, and in evaluating the economic value associated to those activities. The European Parliament and Council identified the smuggling of goods, prostitution exploitation and drug trafficking as the main sources of illegal economic transactions to report in the national accounts aggregates. In this work we aim at estimating the number of people involved in these three illegal activities in Italy during 2014 by exploiting administrative data on criminal proceedings in a capture–recapture model.

Data from the Ministry of Justice report alleged crimes for which the judicial authority started a criminal proceeding. We count the number of times each individual appears in the Prosecutor's offices registers. Under a (reasonable) assumption of time–homogeneous capture probabilities, the data can then be summarized as counts of units captured j times, $\{n_j\}_{j=1,2,\ldots}$.

Figure 1 depicts our data. We observed a total of 3349 smugglers (top figure), 2740 prostitution exploiters (mid), and 34964 drugs traffickers (bottom).

The common parametric approach to estimate the number n_0 of individuals unreported to the justice system, is to define a counting distribution for the observed (truncated in zero) number of captures in the population. We considered various distributional alternatives: Poisson, Geometric, Negative Binomial, finite mixtures of Poisson and of Geometric. Even considering different parametric options, in all three observed distributions the number of units captured exactly once exceeds the expectation under the model hypothesis. This phenomenon is known in literature as "one–inflation" and is of particular importance, as it typically implies a substantial difference in the estimates of n_0.

2 Causes of one–inflation

One–inflation might be generated by different factors, and we have identified the following three possible mechanisms:

1. a specific behaviour of the units, which learn how to avoid subsequent captures after the first one;
2. the presence of spurious units which do not belong to the reference population;
3. errors in re-identifying the units (linkage errors), due to the lack of unique identifiers and error-prone soft identifiers.

In our data we cannot exclude any of the previous factors having an impact on the observed excess of "ones".

The first mechanism generating one–inflation can be viewed as an extreme form of what in animal abundance analysis is called "trap shy" behaviour. In our case, we suppose that, after the first capture, a portion of persons involved in illegal activities

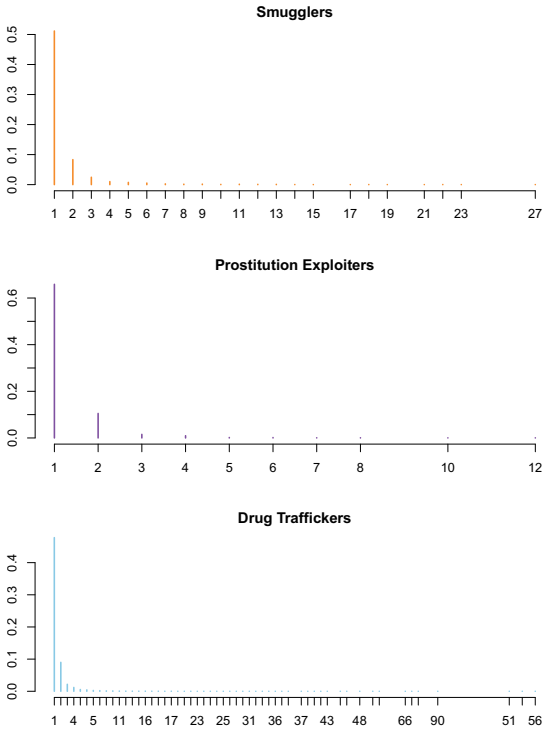

Fig. 1 Relative frequencies of observed number of captures for smugglers (top), prostitution exploiters (mid), and drug traffickers (bottom) in Italy in 2014

acquires the necessary knowledge/ability to avoid any subsequent capture. This can be formalized as a latent subpopulation presenting right–censored data, as we only know that their potential number of captures is larger than one. This hypothesis has been explored in depths in several recent papers (see, e.g., [6], [7], [8], [1]).

We cannot exclude the presence of spurious cases as source of one–inflation in our data. Indeed, we analyse records from the reported offences for which the judicial authority started a proceeding. However, we actually do not have information on whether the person reported was sentenced in court or acquitted. Then, a portion of the units captured once may be out–of–scope, and should be discarded from the analysis. The presence of out–of–scope or spurious captures has been considered, for example, in [2], [5]. Under this hypothesis, the observed value n_1 represents an upper bound for the real number of criminals captured once.

Finally, due to privacy issue, our data are not provided with a unique identifier, hence, we cannot exclude the possibility of one–inflation deriving from linkage errors. In fact, when matching information does not suffice to recognise multiple captures of the same individual, the resulting missing links erroneously increase the number of singletons. The effect of linkage errors on population size estimates in the

multiple system estimation framework has been investigated both with a Bayesian perspective, see [9] and with a frequentist approach [3], and [4].

To the best of our knowledge, the explicit modeling of linkage errors in repeated count data for population size estimation is a topic not previously considered. In this contribution, we will show some possible linkage errors modeling in this setting, to derive population size estimates that will take into account the linkage uncertainty. In addition, we compare and discuss the estimates produced by the different sources of one–inflation.

3 Linkage errors in repeated count data

The lack of unique identifiers is a common situation both in social science and in natural science applications. Linkage procedures allow recognising the same unit even in the absence of a unique identifier, hence they are a prerequisite for population size estimates. Usually, the linkage is far from being a simple operation and it might introduce some errors, namely false and missed links. The linkage procedure finds a trade–off between the two kinds of linkage errors. In addition, the two errors have opposite effects on repeated count data, and consequently on population size estimates. The false links erroneously increase counts greater than one, since different units are erroneously recognised as the same one. On the other side, missed links, i.e. failure in recognising the same unit, increase the number of singletons.

Since the linkage procedure is actually a statistical activity, the one-inflation generated by linkage errors can be considered from both a primary and a secondary analysis perspective. In the former, the linkage and the population size estimate are viewed as components of a unique process and, via a hierarchical structure, as in [9] and [10], we are able to propagate the uncertainty between the parameter estimation step and the matching procedure. A clear advantage of this approach is that we are able to take into account at the same time both the two types of linkage errors.

Due to its relevance in real life application, we also consider the secondary analysis perspective, that is we assume that the linkage has been performed by someone else, and only quality indicators like linkage errors are available to be included in the subsequent analysis. In this perspective we explicitly model the one–inflation caused by missed links, since usually the linker tries to minimise the false matches, at the price of accepting some highest level of missed link errors. A specific characteristic of this model is the additional uncertainty affecting the total number of distinct units, as a consequence of the linkage error itself. Actually, assuming that our data is affected by missed links reduces the sample size in terms of distinct units and the observed one can be considered an upper–bound of the true one. On the contrary, when modeling the one–inflation due to the behavioural effect and spurious cases, we can consider as fixed the observed number of distinct units.

4 Results

For the sake of brevity, we only show in Table 4 some results on prostitution exploiters data, considering both non inflated and one–inflated models and other standard estimates for the proposed setting. For the one-inflation model generated by linkage errors we assume a secondary analysis framework. In particular we show the results obtained by taking a Poisson and a Geometric distribution for the individual captures y^* and assuming that the observed captures y are given by a Binomial variate with size $y^* - 1$ and that $y^* - y$ extra singletons are added to the data set. The idea underlying the model is that when the individual records subsequent to the first capture are compared with the initial record we may fail to link the records reducing the number of captures for that individual from y^* to $y^* - m$ where m is the number of missing links. Moreover the missing links cannot be matched to any other records. In fact, we exclude both the possibility to have false matches and the chance to reconstruct, by the missing links, a sub-cluster of records referring to a given individual. This way the missing links may provide only single captures. Note also that while for the one-inflation caused by behavioural effects and spurious cases, Bayesian inference can be obtained via standard Markov Chain Monte Carlo simulation algorithms, for the one-inflation model caused by linkage error, due to the likelihood intractability, we opted for an approximate Bayesian computation (ABC) approach.

Estimator/Model	$\hat{N}$	95%CI.$\hat{N}$	
Ignoring one–inflation			
Poisson	7210	6780 - 7689	
Geometric	13332	12415 - 14394	
Chao	9851	8961 - 10868	
Zelterman	10030	9033 - 11027	
Poisson Mixture model	10073	9049 - 11110	
Modeling one–inflation		behavioural effect	$\hat{\omega}$
One-inflated Poisson	3895	3656 - 4156	0.645
One-inflated Geometric	8182	7406 - 9233	0.478
One-inflated Poisson mixture model	6613	5284 - 9870	0.261
Modeling one–inflation		spurious cases	$\hat{\psi}$
One-inflated Poisson	3154	3035-3304	0.560
One-inflated Poisson mixture model	4711	3744 - 8799	0.163
Modeling one–inflation		linkage error	$\hat{\mu}$
One-inflated Poisson	2362	2090 - 2681	0.645
One-inflated Geometric	9384	7896 - 10720	0.323

Table 1 Prostitution exploitation data: posterior mean and credible intervals for the population size N, posterior mean for the one-inflation parameters ω,ψ and μ accordingly to the source of one-inflation.

Specification on the different models and additional results will be presented during the conference and in an extended version of this contribution.

Administrative database and official statistics: an IT and statistical procedure

Database amministrativi e statistiche ufficiale: una procedura statistico-informatica

Caterina Marini, Vittorio Nicolardi

Abstract The availability of a complete harmonized database that includes all information, both administrative and statistical, on the phenomenon under investigation is a precious analytical instrument very often unavailable because of issues related to important obstacles that involve both statistical and computer problems, and administrative and legal impediments. In this work, we depict the IT and Statistical procedure used to provide the first Full Information Harmonised Real Estate Database in the analysis of the real estate economy.

Abstract *La disponibilità di un database completo e armonizzato che includa tutte le informazioni, sia amministrative che statistiche, riguardanti il fenomeno in analisi è uno strumento analitico prezioso molto spesso non disponibile a causa di problemi legati a importanti ostacoli che coinvolgono sia aspetti statistici e informatici, sia impedimenti amministrativi e legali. In questo lavoro, noi descriviamo la procedura informatica e statistica usata per produrre il primo Database Immobiliare Armonizzato a Informazione Completa da usare nell'analisi del fenomeno economico del settore immobiliare.*

Key words: Administrative Data, Big Data, Real Estate Economy, Harmonised Database.

1 Introduction

Vittorio Nicolardi, Department of Economics and Finance University of Bari Aldo Moro, email: vittorio.nicolardi@uniba.it

The debate about the administrative databases and their use to provide a statistical information that is not differently affordable is internationally considered significant and relevant to face the nowadays scientific challenge. Many issues are involved, and all are basically fundamental to provide a complete depiction of the socio-economic scenario in a world that is becoming more complex to be analysed. It is believed that the administrative data are largely available and readily usable, and this is one the most common errors that is unconsciousness committed. When working with administrative data, the main problem is the integrated use of data that are yielded by independent administrative offices, sometimes belonging to the same organisation, public authority or company, and differently collected for specific administrative purpose. Furthermore, in most cases databases are structurally diverse because of well-established IT and administrative procedures that are not updated to align all information for users. As a consequence of their nature, administrative data can be affected by material and human errors, such as duplication, missing values and erroneous information, and therefore they are not controlled and statistically correct. Another aspect that is important to consider is that administrative data are a little part of the more complex phenomenon known as Big Data. In literature, the Big Data aspect of the problem is widely discussed (Harford, (2014); Kitchin, (2014 a, b); Marini and Nicolardi, (2020) (2021)). Finally, it is crucial the harmonisation of the administrative data, which are raw information, with the official statistical data as yielded by the National Statistical Institutes (NSIs, hereafter) and, therefore, consolidated statistically. In some of our recent works, we provided an original fully comprehensive statistical tool to describe the phenomenon of the real estate economy: the full information harmonised database is referred to the real estate phenomenon where administrative data and Italian NSI's data are perfectly aligned and the Big Data crucial aspects solved. In view of the current Italian government intention to reform the Italian National Registry of private and public properties (known as "catasto") as stated in the National Recovery and Resilience Plan document as part of the Next Generation EU programme, we consider our Full Information Harmonised Real Estate Database (FIHRE-DB, hereafter) and the economic experiment we run on a sole city to be an important starting point towards a fair reform. In this work, we describe the IT and statistical procedure we defined to create the FIHRE-DB. The full procedure needed SAS software and QGIS software to yield geo-maps and overlapping steps.

2 The Data

In our work, the experiment is restricted to the territory of the city of Bari, in southern Italy, because that was part of a national research project. The databases used to create the FIHRE-DB are essentially 5 key databases (DBs, hereafter) and 3 instrumental DBs, the latter useful for harmonising all data. The 5 key DBs are independent administrative DBs, generally managed by independent Public Administration (PA, hereafter) offices of the city of Bari, and provide autonomous real estate information. Four of 5 key DBs belong to the Real Estate Registry (RER,

hereafter) and contain all information related to the real estates. The last key DB belongs to the Real Estate Italian Observatory (REIO, hereafter) of the Italian Revenue Agency. The 3 instrumental DBs are mutually fully independent because they belong to independent PA: the first belongs to RER and allows the final connection between the administrative data and the official statistical data; the second belongs to REIO and the last belongs to the Italian NSI, and both are the geo-localisation datasets used for the final overlapping action.

3 The Method

The method we proposed is a *step by step* procedure, depicted in the subsections that follow, to obtain the final outcome, that is the FIHRE-DB. A first study of all databases highlights that the 5 RER DBs needed an inevitable prior action of cleaning because of the many duplicated, missing and erroneous data. Afterwards, that was possible to proceed with the harmonisation of all data based on key fields.

3.1 RER Databases

The administrative RER DBs are fundamental to create the final harmonised database and, at the same time, those that required more effort in terms of cleaning. Furthermore, the analysis of data highlighted also that a recoding action was necessary to correct some information that, in the past, was erroneously recorded because of some administrative territorial process that involved the inclusion of some little municipalities in the city. Therefore, the cleaning and recoding actions have been important to homogenise information provided by RER and align the 5 RER DBs. The first RER DB includes a list of records that contains all technical and economic information of each unit. Therefore, without affecting the statistical significance of the analysis we deleted the incomplete and duplicated records in this first RER DB. That is a double step procedure. The first step allowed to sort data by means of two key fields: *Id_Property*, which identifies each real estate in RER, and *Ordinal_Number*, which identifies the mutations corresponding to the units:

```
proc sort data=name_Database1;
by Id_Property DESCENDING Ordinal_Number;                    [1]
```

The second step of the procedure permitted to clean the DB and utilises as key field *Id_Property* to delete the oldest data related to each real estate mutation:

```
proc sort data= name_Database1 out= name_Database2 nodupkey ;
by Id_Property;                                              [2]
```

Furthermore, we proceeded to also delete all real estate units without income:

```
data mainDatabase1;
set name_Database2;                                          [3]
where (Income not in (.));
```

The second RER DB comprises other real estate information, mainly the Urban

Section and the Registry Sheet, Subordinate and Parcel. This second RER DB includes a much higher number of records than that of the first RER DB because of both duplications, caused by some administrative change, and the presence of some real estate unit whose record has not been deleted though the building was demolished. Therefore, we deleted the incomplete and duplicated records in this second RER DB and proceeded to recoding some field. That is a multiple step procedure. The first step allowed to sort data by means of two key fields: i.e. *Id_Property* and *Urban Section*:

```
proc sort data= name_Database3;
by Id_Property DESCENDING Urban Section;                    [4]
```

The second step of the procedure permitted to clean the DB and utilises as key field *Id_Property* to delete duplicated data for each real estate:

```
proc sort data= name_Database3 out= name_Database4  nodupkey ;
by Id_Property;                                             [5]
```

Furthermore, we proceeded to also delete all records where the real estate units have an erroneous code for the field *Registry Sheet*.

```
data name_Database5;
set name_Database4;                                         [6]
where (Registry Sheet in (report the right "Registry Sheet
numbers/code" set));
```

The third step of the procedure allowed to recode the sole field *Urban Section* in this final DB:

```
data name_Database6;
set name_Database5;                                         [7]
if (Urban Section in (report the old "Section code" set)) then
Section =  report the new "Section code";
…;
```

Finally, to homogenise information between the two achieved DBs the last step deleted all the records that were in the second DB and not in the first DB. That is a *right join* between the *name_Database6* and *mainDatabase1*. This final step yielded the *mainDatabase2*. The third RER DB comprises the toponyms of each real estate unit that are important to identify the exact localisation of each unit on the urban territory. This third RER DB shows many duplications because of the modifications of some toponym and/or building number. Therefore, a cleaning action is necessary and a double step procedure was defined. The first step allowed to sort data by means of two key fields: *Id_Property*, which identifies each real estate in RER, and *Ordinal_Number*, which identifies all the mutations in toponyms and/or building number corresponding to the real estate:

```
proc sort data= name_Database7;
by Id_Property DESCENDING Ordinal_Number;                   [8]
```

The second step of the procedure permitted to clean the database and utilises as key field *Id_Property* to delete the oldest data related to each real estate mutation:

```
proc sort data= name_Database7 out= name_Database8 nodupkey ;
by Id_Property;                                             [9]
```

Finally, to homogenise information between the two previous achieved databases a final step of the procedure deleted all the real estate records that are in this third database and not in the previous two. That is a *right join* between the

name_Database8 and *mainDatabase1*. This final step yielded the *mainDatabase3*.

The final step of the procedure that is referred to the first 3 key RER DBs is the creation of a sole omni comprehensive DB that aligned data by means of the key field *Id_Property*:

```
data mainDatabaseRER;
merge mainDatabase3 mainDatabase2 mainDatabase1;
by Id_Property;
```

The last RER DB contains all data referred to the Real Estate Income and Value, both administrative data, and the corresponding council tax rate. The cleaning and recoding problems we found in this last RER DB are the same we encountered in the second RER DB previously described. In this last RER DB the codification of the real estate is based on the taxpayer in a framework of Urban Section, Registry Sheet, Subordinate and Parcel. Duplication rises because more than one taxpayer can pay the council tax for the same building in a co-ownership status. Therefore, we followed exactly the same steps of the procedure as in [5] - [7] and worked out the needed databases: first the *name_DatabaseT1* starting from the raw database; second the *name_DatabaseT2* as the outcome of the procedure [6] and [7], and finally the *mainDatabaseCT* as the result of the procedure [5].

3.2 REIO Database

The REIO DB is the last key DB we use in our work and one of the most reliable sources of data to analyse the real estate monetary value dynamics in the Italian real estate market. The REIO real estate value data are calculated based on the trade price per square meter of the properties. They are open data on a biannual basis referred to the minimum and maximum price for all the different types of real estates at the level of the council territory. To use a univocal REIO value in the analysis, the midrange value for each record was calculated. In the REIO dataset, the council territory is split into homogeneous areas that experience the same economic and socioenvironmental characteristics, i.e. the REIO zones. The REIO DB comprises statistical valued data. Therefore, no cleaning and recoding actions were necessary.

3.3 Full Information Harmonised Real Estate Database

Once the RER DBs have been achieved in a homogenous format, the last section of the work is the creation of the FIHRE-DB. The most crucial step in this last part of the procedure is to find out a method to connect and merge all the RER data with the REIO data. In fact, both *mainDatabaseRER* and *mainDatabaseCT* cannot be connected with REIO DB by any field. Therefore, the instrumental databases as describe previously play an important role to obtain the FIHRE-DB. They are all geo-referred and, therefore, a geo-localised process is suitable to solve the problem. In fact, we defined a multiple procedure of merging all the key databases through

the geo-localised information. First, the creation of a "linking table" named BRIDGEDB allowed to connect the REIO zones with the Italian NSI census sections. In other words, the procedure allows to link the Italian NSI census sections, and indirectly all real estate units, with each REIO zone and, consequentially, the statistical information with all the administrative data. Second, the multiple procedure of merging all the key databases to yield a *Final Administrative DB* was composed of the following steps:

1. merging Italian NSI census sections and *mainDatabaseRER* through the key fields *Urban Section*, *Registry Sheet* and *Subordinate*
2. merging Italian NSI census sections and *mainDatabaseCT* through the key fields *Urban Section*, *Registry Sheet* and *Subordinate*
3. merging *mainDatabaseRER* and *mainDatabaseCT* through the key field *Id_Property*

Finally, the BRIDGEDB allowed to connect the *Final Administrative DB* to the REIO DB by means of Italian NSI census sections. This is the final outcome of our work, that is FIHRE-DB.

4 Concluding remarks

The importance of the analysis yielded in this work is unique and original in its attempt to provide a new omni comprehensive database that includes all information, both administrative and statistical, related to the analysis of the real estate economy.

The experiment we run to solve the dearth of a complete information because of the practical non-existence of a full information harmonized database can be an important input to replicate the procedure for any dimensional geographical area and for any other economic analysis. As seen in this work, the IT and statistical procedure we describe to create the Full Information Harmonised Real Estate Database is quite complex because of the many issues that need to be faced and the dimension of databases. However, in view of the current Italian government intention to reform the Italian National Registry of private and public properties, our outcome can be an important starting point towards a fair reform.

Spatial modeling and Analyses

Spatial statistics analysis using microdata: an application at agricultural sector

Uso dei microdati per l'analisi statistica spaziale: una applicazione al settore agricolo.

Daniela Fusco, Maria Antonietta Liguori, Valerio Moretti, Francesco Giovanni Truglia

Abstract The increasing availability of geo-referenced microdata has led to important changes in the production of official statistics. These changes were been driven also by the need of policy makers to have information related to territorial characteristics. Agriculture is the sector that more than any other is linked to the territory and an analysis of the sector today cannot be separated from spatial analysis. The aim of the research is to analyse, through spatial statistical analysis, the territorial connections of farms, identified at the microdata level, which have survived at the changes of the last twenty years.

Abstract *La disponibilità crescente di microdati georeferiti ha condotto importanti cambiamenti nella produzione delle statistiche ufficiali. Tali cambiamenti sono stati condotti anche dalla necessità dei policy maker di disporre di informazioni legate alle caratteristiche territoriali. L'agricoltura è il settore che più di ogni altro è legato al territorio e una analisi del settore non può prescindere oggi dall'analisi spaziale. Obiettivo della ricerca è analizzare, attraverso l'analisi statistica spaziale, le connessioni territoriali delle aziende agricole, individuate a livello di microdati, sopravvissute ai cambiamenti dell'ultimo ventennio.*

1 Introduction

The new attention to specifying, estimating, and testing for the presence of spatial interaction in the mainstream of applied and theoretical econometrics can be attributed to two major factors [3]: the growing interest in the interaction of an economic agent with other heterogeneous agents in the system and the need to handle spatial data. This has been stimulated by the explosive diffusion of geographic information systems (GIS) and the associated availability of geocoded data.

It was be possible by the ever-increasing availability of statistical and geospatial data [5]. As the volume of geospatial data has been increasing exponentially, the European Statistical System (ESS) has undergone a comprehensive process of reform covering most aspects of its statistical production. This new statistical approach involved each study sector, particularly agriculture. Agriculture is essentially a spatial phenomenon, which is not independent of location. The integration between statistical and geospatial data is fundamental to improve the monitoring of development outcomes: land use and land cover changes are the result of the interplay between socio-economic, institutional and environmental factors [9]. Driving forces, which guide the changes, are generally subdivided into two groups: proximate causes and underlying causes. Proximate causes are the activities and actions that directly affect land use, e.g. wood extraction or road building. Underlying causes are the 'fundamental forces' that underpin the proximate causes, including demographic, economic, technological, institutional and cultural factors [8]. This allows differentiation into spatial and temporal expectations of change.

In Italy, the result of changes is an increase in the average farm size went from 5.5 hectares in 2000 to 8.4 in 2017. The livestock sector too is affected by a rationalization of resources and a conspicuous increase in intensive farming, leading to a progressive growth in the average size of the animals per farm [6]. In this period, some farms, unable to resist at the changes, are died and other were born. The linkage at micro data level identifies a panel of 531,536 farms surveyed for the first time in 2000 and listed in 2017. The aim of the analysis is to explore and describe the territorial dimension of "resilient" farms. The basic hypothesis is that the presence of territorial clusters formed by municipalities with a high density of farms favoured this feature.

2 Methodology: data used, global and local autocorrelation index

The reference panel was obtained through the combination of the Statistical Register of Italian farms (Farm Register 2017) with the results of the V and VI Agricultural Census (2000 and 2010). Only the farms that have not undergone changes of ownership during the reference period were considered, in accordance with the hypothesis that this would be equivalent to a substantial continuity of the

company's mission. In the first instance, the farms survived between the two censuses were identified applying a deterministic model of equality, using the Unique Code Farm as the coupling variable. Then the address and the name were linked applying a function of the distance of the strings via an indicator normalized between 0 and 1. It is defined as twice the number of terms common to compared entities divided by the total number of terms in both tested entities. Finally, the result was deterministically linked to the 2017 Farm Register through the Unique Code Farm only.

Measures of spatial autocorrelation have applied on the dataset. The concept of spatial autocorrelation is one of the most important issues of spatial statistics and it derives directly from the first law of geography by Tobler: "All Things Are Related, But Nearby Things Are More Related Than Distant Things" [12].
