Preface

This book includes the contributions presented at the Intermediate Meeting of the Italian Statistical Society (SIS) "SIS 2023 - Statistical Learning, Sustanaibility and Impact Evolution" held in Ancona at the Università Politecnica delle Marche, from June 21th to 23th of 2023.

The new challenges of digitalization, innovation and sustainability are showing the crucial role of data-driven approaches in supporting decision-making processes. Methodologies resulting from the integration of different know-how seem to be a reliable way to deal with the increasing need to measure the impact of the policies and to forecast scenarios. This meeting welcomed any attempt to face new challenges.

The conference registered more than 250 presentations, including 3 keynote speakers in 3 plenary sessions and 72 presentations in 24 invited sessions, all dealing with specific themes in methodological and/or applied statistics and demography. Furthermore, more than 180 contributions, with one or more authors, have been spontaneously submitted to the Program Committee and arranged in 30 contributed sessions.

The numerous participation of researchers in the conference shows how the challenges of sustainability, in its broadest sense, are of interest to both methodological and applied statistics.

With the publication of this book, we wish to offer to all members of the Italian Statistical Society, all international academics, researchers, Ph.D. students, and all interested practitioners, a good snapshot of the on-going research in the statistical and demographic fields.
We aim to provide all members of the Italian Statistical Society - as well as international academics, researchers, Ph.D. students, and interested practitioners - with a comprehensive overview of the ongoing research in the fields of statistics and demography.

We extend our heartfelt gratitude to all the contributors for submitting their works to the conference and to the researchers for their outstanding job in serving as referees and discussants with precision and timeliness.

A special appreciation goes to the Scientific and Organizational Committees for their tremendous efforts in managing all the organizational aspects, as well as to the Università Politecnica delle Marche and the Department of Economic and Social Science for making this event possible.

Finally, we wish to express our gratitude to the publisher Pearson Italia for all the support received.

1 Plenary Sessions

Inequality Indices: Accurate Simulation-Based Inference

Maria-Pia Victoria-Feser[a]

[a]Research Center for Statistics, Geneva School of Economics and Management, University of Geneva, Switzerland; maria-pia.victoriafeser@unige.ch

Abstract

In this presentation, we consider the problem of inference for general classes of inequality indices. Indeed, obtaining accurate inference, for example confidence intervals with a coverage that is approximately equal to the confidence level, is not an obvious task, as attested by numerous researchers. The inaccuracy of standard, and some times improved, methods, is particularly important when the income distribution has heavy tails. Therefore, we propose an alternative simulation-based method, based on parametric models, that guaranties theoretically a better accuracy (second order) and is found to provide very accurate inference, even in the presence of very heavy tails, through simulation studies.

Income distribution, indirect inference, bootstrap, heavy tails, second order accuracy.

1. Introduction

In this presentation, we consider the problem of inference for an inequality index functional T, i.e., quantities of interest that can be written as a function of the data generating model. Without loss of generality, we anchor the discussion in the framework of inequality indices (see e.g., Cowell, 2011). Given a sample $x_i, i = 1, \ldots, n$ and an associated distribution F such that one can assume that $X_i \sim F,\ i = 1, \ldots, n$, we are interested in computing Confidence Intervals (CIs) for $T(F)$. For that, there exists many different approaches that are based on either $T(F^{(n)})$ or $T(F_\theta)$, where $F^{(n)}$ is the empirical distribution (hence leading to a nonparametric approach) and $F_\theta,\ \theta \in \Theta \subset \mathbb{R}^p$ is a parametric model for which θ needs to be estimated from the sample (hence leading to a parametric approach).

2. State of the Art

Inference on the population quantity $T(F)$, can be done in the following manners.

1. The (nonparametric) jackknife produces an estimate of the sampling distribution of $T(F^{(n)})$, which is obtained by constructing samples made of all the observations minus one; for applications to inequality indices, see e.g., Giles (2004); Modarres and Gastwirth (2006).
2. The (nonparametric) bootstrap produces an estimate of the sampling distribution of $T(F^{(n)})$, which is obtained by constructing samples that are a drawn with replacement of the original sample; for application to inequality indices, see e.g., Mills and Zandvakili (1997) and Biewen (2002).
3. Another distribution-free approach consists in deriving the asymptotic variance of the inequality index using the Influence Function (IF) of Hampel (1974) as is done in Cowell and Victoria-Feser (2003) (for different types of data features such as censoring and truncating) and estimate it directly from the sample (see also Victoria-Feser, 1999; Cowell and Flachaire, 2015).

4. A parametric approach, given a chosen parametric model $F_{\boldsymbol{\theta}}$ for the data generating model, consists in first consistently estimating $\boldsymbol{\theta} \in \boldsymbol{\Theta} \subseteq \mathbb{R}^p$, say $\hat{\boldsymbol{\theta}}$, then, considering its asymptotic properties, such as its variance var $\left(\hat{\boldsymbol{\theta}}\right)$ and derive the corresponding asymptotic variance of $T\left(F_{\hat{\boldsymbol{\theta}}}\right)$ using e.g., the delta method (based on a first order Taylor series expansion). The later is estimated by plugging in the value of $\hat{\boldsymbol{\theta}}$.
5. The (parametric) bootstrap, produces an estimate of the sampling distribution of $T\left(F_{\hat{\boldsymbol{\theta}}}\right)$, which is obtained by constructing samples that are simulated from $F_{\hat{\boldsymbol{\theta}}}$. This approach is often referred to as the percentile parametric bootstrap.
6. Refinements and combinations of these approaches, such as the studentized bootstrap that is based on a (asymptotic) pivotal statistics.

While most would agree that the fully parametric and asymptotic approach based on the delta method cannot provide as accurate inference as the simulation-based methods, it is not clear that avoiding the specification of a parametric model is the way to go. Indeed, for example, Davidson (2009) note that the jackknife does not yield a reliable estimate of the standard error (and does not correct bias), and Cowell and Flachaire (2015) notice that nonparametric bootstrap inference on inequality indices is sensitive to the exact nature of the upper tail of the distribution, in that nonparametric bootstrap inference is expected to perform reasonably well in moderate and large samples, unless the tails are quite heavy. Similar conclusions are also drawn in Davidson and Flachaire (2007); Schluter and van Garderen (2009) and Davidson (2010).

These findings have motivated the construction of more refined inferential methods, based on second order accuracy, such as, for example, Schluter and van Garderen (2009) and Schluter (2012) who, using the results of Hall (1992), propose normalizing transformations of inequality indices using Edgeworth expansions, to adjust asymptotic Gaussian approximations. Another example is provided by Dufour et al. (2018) who propose an adjustment based on a Fieller-type method (Fieller, 1940, 1954).

Alternatively, Davidson and Flachaire (2007), Cowell and Flachaire (2007) and Davidson (2012) consider a semi-parametric bootstrap, where bootstrap samples are generated from a distribution which combines a parametric estimate of the upper tail, namely the Pareto distribution, with a nonparametric estimate for the other part of the distribution. Finally, Guerrier et al. (2018) propose a percentile parametric bootstrap based on a Generalized Method of Moment (GMM) estimator, with the inequality index as one of the moments, which allows to reduce the biases in the CIs coverage.

3. Motivation

Through a large simulation study, Cowell and Flachaire (2015) compare the actual coverage probabilities of 95% CIs for the Theil index, using, as data generating models, different distribution with varying parameters to increase the heaviness of the tail. Most of the different methods cited above are compared. Cowell and Flachaire (2015) conclude that, in the presence of (very) heavy-tailed distributions, even if significant improvements can be obtained on the fully asymptotic and the percentile (parametric) bootstrap methods, none of the alternative methods provides very good results overall.

This result is not surprising, and a simple rationale is given by the fact that any inferential method derived from a non linear function of random variables, specifically an inequality index as a function of estimators, if not directly targeted, adds (uncontrolled) uncertainty to the resulting inferential method. In other words, even if we can have an unbiased estimator for the parameters of a model, say $\hat{\boldsymbol{\theta}}$, so that $\mathbb{E}\left[\hat{\boldsymbol{\theta}}\right] = \boldsymbol{\theta}$, we cannot guaranty that $\mathbb{E}\left[T\left(F_{\hat{\boldsymbol{\theta}}}\right)\right]$ equals $T\left(F_{\boldsymbol{\theta}}\right)$. The parametric bootstrap corrects for the bias by improving the bootstrap estimator from an accuracy of $n^{-1/2}$ to n^{-1}, but, as has been stated in e.g. Andrews (2000), using as example the sample mean, the bootstrap is not consistent when the parameter's value is near a boundary of the parameter space. This is a typical feature of income distributions, in the sense that most parameters, especially the ones governing the thickness of the tail,

are typically positive. Moreover, because inequality indices are functions of estimators (in the parametric framework), a valid resampling method should be based on percentiles, which guaranties the *Parameter-Transformation* (PT) property, which is not the case, for example, with the studentized bootstrap or other refinements of the percentile (parametric) bootstrap.

4. Results

In this presentation, we propose a simulation-based parametric approach for inference about an inequality index $T(F_{\boldsymbol{\theta}})$ that has the following properties:

1. it satisfies the PT property,
2. it is not affected by the boundary problem like the bootstrap methods,
3. it is second order accurate.

Although specifying a parametric distribution for the data generating process can be considered as an additional risk of introducing "error" in the inferential procedure, common wisdom however suggests, at least with income distributions, that some parametric models are sufficiently flexible to encompass most of the data generating processes observed with real data. For example, the four parameters generalized beta distribution of second kind (GB2) proposed by McDonald (1984), which encompasses the generalized gamma, the Singh-Maddala (SM) (Singh and Maddala, 1976) and Dagum distribution (Dagum, 1977) (see also McDonald and Xu, 1995), can be considered as sufficiently general to model income data. If this is not the case, then one would wonder if the lack of flexibility of a general four parameter model is not due to a spurious amount of observations, and hence consider a robust estimation approach as proposed and motivated in Cowell and Victoria-Feser (1996) (see also Cowell and Victoria-Feser, 2000).

The proposed method is based on matching estimators in the spirit of indirect inference (Gouriéroux et al., 1993; Smith, 1993), which are simulated to provide their sample distribution. In Guerrier et al. (2018), it is shown that the estimation bias of such estimators is of order n^{-1}, which indicates that a properly constructed simulation-based inferential procedure can lead to more accurate inference. We show that we can build a simulation-based procedure that does not involve a double bootstrap such as is the case for the Studentized bootstrap, and the resulting method satisfies the properties stated above. Moreover, through simulation studies, we can confirm our theoretical results in that CIs computed for some inequality indices, under different parametric income distributions, also with very heavy tails, have almost exact coverage.

5. Inequality Indices Functionals

As a leading example, we consider T to be an inequality index and F an income distribution. Inequality indices are welfare indices which can be very generally written in the following quasi-additively decomposable form (see Cowell and Victoria-Feser (2002, 2003) for the original formal setting)

$$W_{\text{QAD}}(F) = \int \varphi\left(x, \mu(F)\right) dF(x), \tag{1}$$

where φ is piecewise differentiable in $\mathbb{R}$. The generalized entropy family of inequality indices given by

$$I^{\xi}_{\text{GE}}(F) = \frac{1}{\xi^2 - \xi}\left[\int \left[\frac{x}{\mu(F)}\right]^{\xi} dF(x) - 1\right], \tag{2}$$

is obviously obtained by setting

$$\varphi\left(x,\mu(F)\right)=\frac{1}{\xi^2-\xi}\left[\left[\frac{x}{\mu(F)}\right]^{\xi}-1\right]. \tag{3}$$

For example, the cases $\xi=0$ and $\xi=1$ are given by

$$\begin{aligned} I^0_{\mathrm{GE}}(F) &= -\int \log\left(\frac{x}{\mu(F)}\right) dF(x), \\ I^1_{\mathrm{GE}}(F) &= \int \frac{x}{\mu(F)} \log\left(\frac{x}{\mu(F)}\right) dF(x), \end{aligned} \tag{4}$$

with $I^0_{\mathrm{GE}}(F)$ being the Mean Logarithmic Deviation (see Cowell and Flachaire 2015) and $I^1_{\mathrm{GE}}(F)$ being the Theil index. A notable exception to the class in (1) is the Gini coefficient which can be expressed in several forms, such as

$$I_{\mathrm{Gini}}(F)=1-2\int_0^1 \frac{C(F;q)}{\mu(F)}dq, \tag{5}$$

with $C(F;q)=\int^{F^{-1}(q)} xdF(x)$, the cumulative income functional.

Abstract

Hybrid models that combine neural network structures within statistical models are increasingly useful to predict complex processes. Here, we demonstrate two such approaches for spatio-temporal data motivated by enviornmental problems. The first example combines an echo state network (ESN) within a spatio-temporal statistical level-set model to forecast the movement of a wildfire boundary. The ESN is used to model the speed of the fire front in the normal direction to the front via an implicit signed-distance function. The second problem is concerned with emulating complex environmental model output that can have dependent extremes. This is accomplished by combining a flexible statistical model for spatial extremes within a variational autoencoder. Both examples have the benefit of modeling complex processes while being computationally efficient.

Keywords: basis expansion, echo state network, ELBO, emulation, level set, variational autoencoder, wildfire

1. Introduction

Neural models and "deep learning" have dramatically altered the modeling landscape for dependent data. Indeed, for prediction and classification problems that have data with spatial and/or temporal dependence, these models (particularly convolutional neural networks and recurrent neural networks of various types) are often more successful than traditional statistical models, especially when there are large amounts of training data available. In statistics, deep models (i.e., Bayesian hierarchical models) have been used since the late 1990s to model spatial and spatio-temporal data in environmental statistical applications (see the overview in 2). In many ways, these models are not unlike the deep neural models in that they both learn handle complex dependence structure by a series of linked multi-level (or conditional) formulations (see the discussion in 13).

In recent years, there has been a great deal of interest in building hybrid neural-statistical (or machine learning-statistical) modeling methodologies for spatial and spatio-temporal data, particularly in the environmental sciences. For a recent overview, see (14). Such approaches borrow the black-box predictive strengths of the deep neural approaches and yet accommodate uncertainty quantification and other explainability approaches.

Here, we present two brief examples from our work at the interface of statistics and neural modeling. The first example, presented in Section 2, is a spatio-temporal model for modeling the spread of wildfire fronts that models the speed of boundary propagation with an echo state network (ESN) within a

statistical framework that is motivated by level-set dynamics. The second example, presented in Section 3, presents a novel variational autoencoder to emulate spatio-temporal processes that exhibit dependent extremes. This paper presents a brief conclusion in Section 4.

2. Modeling Wildfire Spread with Hybrid Level-Set/Echo State Network Models

Millions of acres of land are destroyed by wildfires every year, and they pose a significant threat to humans both in terms of property damage and potential loss of life, as well as significantly impacting the ecosystem. It is important to develop trustworthy models that can be used to manage and mitigate large wildfires. The majority of operational wildfire spread models are based on semi-empirical formulas and frequently assume that the environment is homogenous and well-known. That is, these models do well when the fire is burning over homogeneous fuel sources with relatively steady winds and relatively level terrain. They do not do so well in more complex real-world settings (e.g., in steep complex terrain with multiple fuel sources and where the fire itself generates winds). Recently (15) showed that one could use a level-set dynamic model (which is common in fire modeling) within a spatio-temporal statistical framework, and where the propagation speed was given by an echo state network (ESN), which is an effective and easily trained neural model. We briefly summarize that model here.

2.1 Level-Set Dynamics

A level set of a real-valued function ϕ of n real variables is a set where the function takes on a given constant value c:

$$L_c(\phi)\{(x_1, \ldots, x_n)|\phi(x_1, \ldots, x_n) = c\}. \tag{1}$$

A closed-contour fire front can be defined as the intersection between the level set function and the zero-plane (a zero level-set). The evolution of such an iimplicit function that depends on space and time, $\phi(\mathbf{s}, t)$, was first introduced by (12) in terms of an advection equation of the form:

$$\frac{\partial \phi(\mathbf{s}, t)}{\partial t} + \mathbf{v}(\mathbf{s}, t) \cdot \nabla \phi(\mathbf{s}, t) = 0, \tag{2}$$

where $\nabla\phi$ is spatial gradient of ϕ, and $\mathbf{v}(\mathbf{s}, t) = (v_x(\mathbf{s}, t), v_y(\mathbf{s}, t))^\top$ denotes the velocity vector, which also depends on time t and spatial location $\mathbf{s}$. If evolution is assumed to be in normal direction to the boundary (a reasonable assumption for fire spread), then

$$\frac{\partial \phi(\mathbf{s}, t)}{\partial t} + v_n(\mathbf{s}, t)\ ||\nabla \phi(\mathbf{s}, t)|| = 0, \tag{3}$$

where v_n is the scalar velocity (speed) in the normal direction (positive is outward and negative is inward), and $||\cdot||$ denotes ℓ_2 norm operation (magnitude).

It is most useful to consider the implicit function $\phi(\mathbf{s})$ for $\forall \mathbf{s}$ to be a signed-distance function, which is defined as:

$$\phi(\mathbf{s}) = \begin{cases} -d(\mathbf{s}), & \mathbf{s} \in \Omega^- \\ 0, & \mathbf{s} \in \partial\Omega \\ d(\mathbf{s}), & \mathbf{s} \in \Omega^+ \end{cases}, \tag{4}$$

where the distance function $d(\mathbf{s})$ is defined as $d(\mathbf{s}) = min(\mathbf{s} - \mathbf{s_I})$, for $\mathbf{s_I} \in \partial\Omega$, and $\partial\Omega, \Omega^+$ and Ω^- correspond to the boundary, exterior, and interior of interest, respectively.

A signed distance function also has the important property that $||\nabla\phi|| = 1$. Thus, in the case where ϕ is a signed distance function with flow in the normal direction, the advection equation can be written:

$$\frac{\partial \phi}{\partial t} + v_n(\mathbf{s}, t) = 0, \tag{5}$$

which can be approximated very simply by a forward Euler discretization that gives:

$$\phi(\mathbf{s}, t + \triangle t) = \phi(\mathbf{s}, t) - (\triangle t) v_n(\mathbf{s}, t), \tag{6}$$

where $\triangle t$ is time increment.

So, if we know the normal component of the velocity along the boundary, we can simply evolve the signed-distance boundary using this approximation. The challenge is that we do not know v_n for all spatial locations and time points; also, this simplification introduces some error. Traditionally, v_n is parameterized in fire models with a quasi-empirical relationship, which is not often appropriate for complex real-world fires. We wish to use the data to learn the normal velocity more generally and account for uncertainty in the observations and the simple dynamical representations.

2.2 Hybrid Statistical Model

Consider the vector representation of the physical-statistical Euler advection equation for a normal flow signed-distance function:

$$\boldsymbol{\phi}_t = \boldsymbol{\phi}_{t-\triangle t} - \mathbf{v}_{t-\triangle t} \triangle t + \boldsymbol{\eta}_t, \quad \boldsymbol{\eta}_t \sim Gau(\mathbf{0}, \sigma_\eta^2 \mathbf{I}), \tag{7}$$

where $\mathbf{v}_{t-\triangle t} = (v_n(\mathbf{s}_1, t - \triangle t), \ldots, v_n(\mathbf{s}_N, t - \triangle t))^\top$ is vector of speed in normal direction at time $t - \triangle t$ on a spatial grid $\{\mathbf{s}_i : i = 1, \ldots, N\}$, and σ_η^2 is common variance for process error $\boldsymbol{\eta}_t$. We model the v_n process in terms of an ESN.

ESNs are a type of reservoir computing in which an input signal goes into a hidden fixed "reservoir" that allows sparse neural linkages. Importantly, the fixed weights within the reservoir are selected randomly and are not trained, and only the output layer is trained – with a regularization penalty (e.g., ridge regression). (10; 11) introduced spatio-temporal ESNs to the statistics community and showed that they were excellent and forecasting, especially in situations where there was more limited training data. Embedding the ESN within the level-set model gives the following deep model.

$$\begin{aligned}
\text{output response}: \quad & \boldsymbol{\phi}_t = \boldsymbol{\phi}_{t-\triangle t} - \mathbf{v}_{t-\triangle t} \triangle t + \boldsymbol{\eta}_t \\
\text{spread speed}: \quad & \mathbf{v}_{t-\triangle t} = \mathbf{W}^{out} \mathbf{h}_{t-\triangle t} \\
\text{hidden states}: \quad & \mathbf{h}_{t-\triangle t} = (1 - \alpha_\ell)\mathbf{h}_{t-2\triangle t} + \alpha_\ell \tilde{\mathbf{h}}_{t-\triangle t} \\
& \tilde{\mathbf{h}}_{t-\triangle t} = g_h\left(\frac{\nu}{|\lambda_w|}\mathbf{W}^{in}\mathbf{h}_{t-2\triangle t} + \mathbf{U}\mathbf{x}_{t-\triangle t}\right) \\
\text{parameters}: \quad & \mathbf{W}^{in} = [w_{i,\ell}]_{i,\ell} : \gamma^w_{i,\ell} Unif(-a_w, a_w) + (1 - \gamma^w_{i,\ell})\delta_0 \\
& \mathbf{U} = [u_{i,j}]_{i,j} : \gamma^u_{i,j} Unif(-a_u, a_u) + (1 - \gamma^u_{i,j})\delta_0 \\
& \gamma^w_{i,\ell} \sim Bern(\pi_w) \\
& \gamma^u_{i,j} \sim Bern(\pi_u) \\
\text{hyperparameters}: \quad & \alpha_\ell, \nu, a_w, a_u, \gamma^w_{i,\ell}, \gamma^u_{i,j}, \pi_w, \pi_u, n_h
\end{aligned}$$

Note that ESN models, like most neural models, do not include an uncertainty quantification component. It is customary with ESNs to consider an ensemble of reservoirs because it is so inexpensive to fit these models (they are just regularized regression models with nonlinearly transformed inputs). As demonstrated in (15), we sample different ensembles by sampling hyperparameters from their prior distributions, and then calibrate the ensembles to obtain a prediction interval analogous to HPD intervals in Bayesian models.

2.3 Wildfire Prediction Example

As an example, (15) considered multiple simulations and two real-world fires. Here, we present a result on one of those fires, with inputs given by $\mathbf{x}_t = [\boldsymbol{\phi}_t^T, \boldsymbol{\phi}_{t-1}^T]^T$. In particular, we consider the Haypress

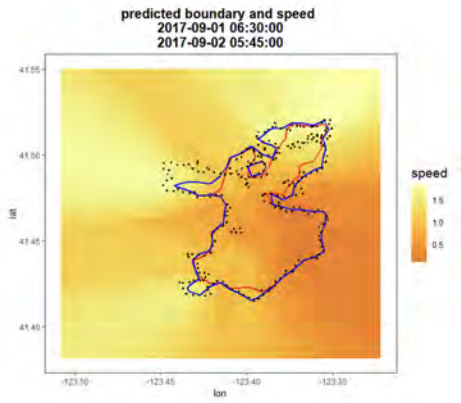

Figure 1: Forecast median and normal direction speed for the Haypress fire at time 05:45:00 on 2 September 2017. The dashed black line corresponds to the truth at the forecast time T, the solid blue line corresponds to the corresponding forecast median, and the solid red line corresponds to the true boundary at time $T - 1$. The background speeds correspond to the forecast from time $T - 1$.

fire, which burned over 27,000 acres in Siskiyou County, California (USA). The fire started in July 2017 and was contained in January 2018. We consider the first 10 observations of the fire boundary from the GeoMac database as training data (converted to signed-distance functions), and forecast the next observation. Figure 1 gives the forecast median boundary and corresponding forecast speed. Note that although the forecast boundary does not quite resolve the "finger" that extended to the west, the forecast interval (not shown) does cover it. More importantly, one can see that the boundary is responding to the forecast speeds by extending in the directions of maximum speed.

3. Emulating Spatial Extremes with Variational Autoencoders

Large mechanistic-based simulation models are crucial for understanding complex problems related to the environment. These models are ubiquitous in science and engineering. For example, earth system models couple complex climate models with physical, chemical, and biological models that include interactions between ocean, atmosphere, sea ice, the biosphere along with human population effects. Each component model in such systems is typically quite computationally expensive and, when combined, the computational and uncertainty quantification (UQ) challenges can be quite formidable. Examples of such challenges include model calibration, use of such models for inverse problems, UQ for forward simulations, and the specification of realistic model parameterizations for coupled processes. Surrogate model emulators (e.g., see the overview in (5)) have proven to be useful in recent years to facilitate UQ in these contexts, particularly when combined with Bayesian inference (7). In many cases, the interest in a mechanistic simulator is to quantify extreme events (e.g., mega-wildfires, drought, floods, pandemics, anomaly detection, etc.). In most cases these extreme events are dependent in space and time (e.g., drought in the desert southwest that lasts multiple years). Traditional methods for model emulation such as Gaussian processes, polynomial chaos expansions, and more recently, deep neural networks and generative models (generative adversarial networks (GANs) and variational autoencoders or VAEs) do not naturally accommodate extreme values, and certainly not dependent extreme values. Our interest is to demonstrate that one can modify a traditional VAE to model dependent spatial extremes.

3.1 Variational Autoencoders (VAEs)

Say we wish to generate realizations of a process, say $\mathbf{X}$. VAEs work by training a latent process, say $\mathbf{Z}$, given real-world examples of $\mathbf{X}$. This problem fits naturally into a Bayesian framework, where the pos-

terior distribution for $\mathbf{Z}$ is given by: $p(\mathbf{Z}|\mathbf{X}) \propto p_\theta(\mathbf{X}|\mathbf{Z})p_\alpha(\mathbf{Z})$, where we say the distribution $p_\theta(\mathbf{X}|\mathbf{Z})$, which depends on parameters $\boldsymbol{\theta}$ is the *decoder*. The posterior distribution $p(\mathbf{Z}|\mathbf{X})$ learns the appropriate distribution for the $\mathbf{Z}$ process, which has a prior distribution $p_\alpha(\mathbf{Z})$ that depends on parameters $\boldsymbol{\alpha}$. In practice, obtaining the normalizing constant that gives the posterior distribution is not available in closed form, yet samples from the posterior distribution can be obtained by computationally expensive Markov chain Monte Carlo (MCMC) methods. Alternatively, the VAE literature seeks a tractable approximation to the posterior, $q_\phi(\mathbf{Z}|\mathbf{X})$, which depends on parameters $\boldsymbol{\phi}$ and we call this the *encoder*. The variational approach then allows us to learn the parameters $\{\boldsymbol{\theta}, \boldsymbol{\phi}\}$ by maximizing the evidence lower bound (ELBO):

$$ELBO = -D_{KL}[q_\phi(\mathbf{Z}|\mathbf{X})||p_\alpha(\mathbf{Z})] + E_{q_\phi(\mathbf{Z}|\mathbf{X})}[p_\theta(\mathbf{X}|\mathbf{Z})],$$

where D_{KL} corresponds to the Kullback-Leibler divergence between the distribution on the left side and right sides of $||$. In practice, we can easily estimate the second term on the right-hand side via Monte Carlo, utilizing samples of the latent $\mathbf{Z}$ process from the encoder for different values of $\mathbf{X}$, and where a *reparameterization trick* is used to get these samples from $q_\phi(\mathbf{Z}|\mathbf{X})$. Thus, after we have optimized the ELBO to obtain the parameters $\boldsymbol{\theta}$ and $\boldsymbol{\phi}$, we can easily generate realistic realizations of $\mathbf{X}$ from the decoder after sampling a $\mathbf{Z}$. In practice, deep neural models are often used to specify the encoder and decoder, providing very expressive models. However, despite the effectiveness of these methods for most emulation tasks, none of these methods explicitly accounts nor is provably robust to dependent extreme values generated in the simulator.

3.2 Modeling Dependent Extremes

Classic extreme value theory has been widely used to study the tail behaviors of univariate climate and finance observations (3, Ch. 1–5). For multivariate observations over space and time, it is of primary interest to characterize the spatial and multivariate dependence in the joint tail but it is challenging to develop models that have flexible dependence properties. Under the spatial setting, well-known models like max-stable or generalized Pareto processes directly assume asymptotic results from multivariate extreme value theory that are too rigid to be applied on environmental data (4). In contrast, Gaussian processes always underestimate the risk associated with simultaneous occurrences of extremes due to its light joint tail. To better describe the nuanced tail behaviors such as those commonly seen in extreme weather events, we briefly introduce the following tail dependence measure.

Similar to variograms in spatial statistics, the extremal dependence structure is commonly described by the bivariate measure

$$\chi(u) = P\{F_2(X_2) > u | F_1(X_1) > u\} = \frac{P\{F_2(X_2) > u, F_1(X_1) > u\}}{P\{F_1(X_1) > u\}}, \tag{8}$$

in which $u \in (0, 1)$ and X_1 and X_2 are two variables with marginal distribution functions F_1 and F_2. In the spatial case, $X_1 = X(\mathbf{s}_1)$ and $X_2 = X(\mathbf{s}_2)$ are two observations from the process $\{X(\mathbf{s}); \mathbf{s} \in \mathcal{D} \subset \mathbb{R}^2\}$ at spatial locations $\mathbf{s}_1$ and $\mathbf{s}_2$. In the multivariate case, X_1 and X_2 are components of the d-variate random vector $\mathbf{X}$. When u is close to one, $\chi(u)$ quantifies the probability of simultaneous occurrences of events exceeding the high extremity level u given one variable is extreme. If $\lim_{u\to 1} \chi(u) = 0$, X_1 and X_2 are said to be *asymptotically independent* (AI), and if $\lim_{u\to 1} \chi(u) > 0$, X_1 and X_2 are *asymptotically dependent* (AD). The aforementioned max-stable or generalized Pareto processes have the property that $\chi(u)$ becomes independent of u for increasingly extreme events, resulting in a positive limit (6; 8). On the other hand, Gaussian processes (or multivariate Gaussian distributions) have the property that $\chi(u)$ will always converge to 0, no matter how close $\mathbf{s}_1$ and $\mathbf{s}_2$ are, or how similar the two components X_1 and X_2 are. Observed tail dependence in environmental processes often decays as events get more extreme and rare events often tend to be more spatially localized as the intensity increases. In this case, the stability property of max-stable and generalized Pareto models is a physically inappropriate restriction on the joint tail.

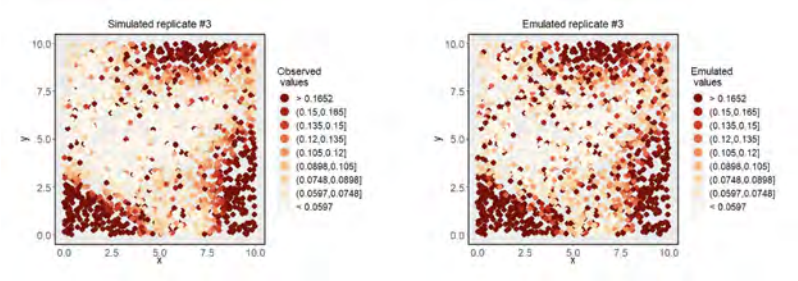

Figure 2: The left panel shows a simulated realization from a spatial extremes process. The right panel shows an emulated replicate corresponding to this process that was obtained from our extremes VAE.

3.3 Extreme Variational Autoencoder

As described in (9), we combine a flexible spatial extremes model with a VAE that has non-stationary and space-scale aware dependence flexibility. We base our extremes model on the max-infinitely divisible process proposed by (1), which allows for both short-range asymptotic independence and dependence along with long-range aysymptotic independence:

$$X_t(\mathbf{s}) = \epsilon_t(\mathbf{s}) Y_t(\mathbf{s}), \ \mathbf{s} \in \mathcal{D}, \tag{9}$$

where $X_t(\mathbf{s})$ is a spatio-temporal output from a simulator (e.g., high-resolution climate model), $\epsilon_t(\mathbf{s})$ is a white noise process with an independent Fréchet$(m, \tau, 1)$ marginal distribution, where $Y_t(\mathbf{s})$ is described by a low-rank basis expansion:

$$Y_t(\mathbf{s}) = \sum_{k=1}^{K} \omega_k(\mathbf{s}, r_k)^{1/\alpha} Z_{kt}, \tag{10}$$

where $\omega_k(\mathbf{s}, r_k)$, $k = 1, \ldots, K$ are compactly-supported basis functions centered at K knots, and Z_{kt} are latent basis expansion coefficients. The latent variables are lighter-tailed, exponentially tilted, positive-stable variables:

$$Z_{kt} \sim H(\alpha, \alpha, \theta_k), \ k = 1, \ldots, K, \tag{11}$$

where $\alpha \in (0, 1)$ is the concentration parameter, and lighter-tailed distributions of Z_{kt} are given by larger values of the tail index parameters $\theta_k \geq 0$.

Critically, the latent variables Z_{kt}, $k = 1, \ldots, K$ are used in the encoded space of a VAE. So, spatio-temporal inputs are compressed (encoded) into low (K) dimensional latent space, yet we keep the distributional assumptions given above when decoding the latent variables back to the initial space. In our case, the encoder and decoder are both deep neural networks with weights updated iteratively to minimize the ELBO. Reiterating, the goal here is to emulate the field $\{X_t(\mathbf{s})\}$. Because the latent variables enable a generative process, once trained, we can obtain many copies of the original field $\{X_t(\mathbf{s})\}$ that have similar properties to the original data, even in the joint tail.

Figure 2 shows a realization from a simulated dependent extremes process in the left panel, and the right panel shows an emulated realization from our extremes VAE. Although not shown here, estimates of the dependence measure, $\chi(u)$ shows agreement in the extremal dependence, whereas a Gaussian process emulator produced realizations that underestimate the dependence in the tails.

4. Conclusion

As machine learning and "AI" neural models become more prevalent, there are increasing opportunities to combine those models into a statistical framework to facilitate prediction and classification, yet with uncertainty quantification. Here, we present two approaches that illustrate such hybrid models. The first considers a model for wildfire spread that uses ESNs to estimate the rate of spread in the normal

direction to the fire front. This approach takes advantage of the fact that ESNs produce nonlinear evolution yet are simple to train do not require a large amount of training data. The second example, which is less mature, describes our initial approach to build spatial extremes into a VAE. Not only is this method flexible, but it is computationally more efficient than traditional Bayesian implementations of dependent spatial extremes models. The main use of our model is to emulate complex model output, such as output from climate models that exhibit extremes in space. Traditional emulation approaches for such models do not typically handle extremes in a realistic fashion.

Causal Discovery for complex survey data

Paola Vicard[a]

[a]Università Roma Tre; paola.vicard@uniroma3.it

Abstract

The association structure of a Bayesian network can be drawn based on subject matter or experts knowledge, or have to be learned from a database. In case of data driven learning, one of the most known procedures is the PC algorithm that is based on the assumption of independent and identically distributed observations. In practice, sample selection in surveys involves more complex sampling designs then the standard test procedure is not valid even asymptotically. In order to avoid misleading results about the true causal structure the sample selection process must be taken into account in the structural learning process. In this paper, a modified version of the PC algorithm is proposed for inferring casual structure from complex survey data. Finally, a simulation experiment is performed

Keywords: Complex survey design, Faithfulness, PC algorithm

1. Introduction

Bayesian networks (BN) are multivariate statistical models satisfying sets of conditional independence statements contained in a directed acyclic graph (DAG), see (9). The advantage of using BNs to represent probability distributions is that they graphically show causal and conditional independence relations between random variables making easier for decision makers to evaluate and use the model. The nodes of the graph correspond to random variables and edges between nodes represent dependencies between the associated variables. Augmented with a table of parameters representing marginal probabilities, BNs are capable of representing the probabilities over any discrete sample space: the probability of any sample point in that space can be computed from the probabilities in the BN.

In recent years BNs have been successfully applied to official statistic problems. In particular, BNs appear to be very useful in missing item imputation ((5), (6)) and contingency table estimation for complex survey sampling (1). The use of BNs to model measurement errors has also been investigated in (7). However, there are still some limitations that may complicate their large scale application in the official statistics context. The main one is how to take into account the complexity of sampling design in the structural learning process when BN methodology is applied to sample surveys.

Building BNs by hand can be a difficult and time-consuming task. The association structure can be known in advance by subject matter knowledge or have to be learned from a database. In case of data driven learning, one of the most known procedures is the PC algorithm by which the structure is inferred carrying out several independence tests and building a Bayesian network in agreement with tests results. The algorithm is presented in detail in (11).

The PC algorithm is based on the assumption of independent and identically distributed observations (*i.i.d.*, for short). However, most of the commonly used survey designs employ stratification and/or cluster sampling and/or unequal selection probabilities. The impact of complex designs on *i.i.d.* based methods can be severe, as shown in (10). In this paper a modified version of the PC algorithm for complex survey data is proposed; it is named PC complex.

The paper is organized as follows. First of all, in Section 2, the PC algorithm for *i.i.d.* data and the basic assumptions on which it relies are briefly recalled. Secondly, in order to take into account the complexity of the sampling design in the learning process, a procedure for testing the association in a two-way table in complex sample surveys is described in subsection 2.1. To evaluate the accuracy of the proposed algorithm, a simulation study is performed in Section 3.

2. Model selection in graphical modeling: the PC algorithm

Let $V = \{X_1, X_2, \ldots, X_d\}$ be a set of variables with joint probability distribution P whose casual structure can be represented by a DAG. The PC algorithm starts from a complete undirected graph and recursively deletes edges based on conditional independence decisions. More specifically, the algorithm consists of two phases. In phase 1 the skeleton of the graph is determined, in phase 2 arrows are oriented. The assumptions under which the PC algorithm correctly estimates the models are the following:

1. *Causal Sufficiency Condition* (CSC, for short). Variables that are the direct cause of at least two variables should be known.
2. *Causal Markov Condition* (CMC, for short) describes the independencies that follow from a causal structure: each variable is probabilistically independent from all its non-descendants conditional on its direct causes.
3. *Causal Faithfulness Condition* (CFC, for short) states that if a conditional independence relation is not entailed by the CMC, then it does not hold in the population. (12) decomposes the CFC in (i) *Adjacency-Faithfulness Condition*; (ii) *Orientation-Faithfulness Condition*. The former is necessary to recover the true skeleton. The latter is necessary for finding the correct orientations. The two conditions are strictly related to phase 1 and phase 2 of the PC algorithm, respectively.

Under the above assumptions and if the sample size is large enough for reliable inference on conditional independence, it is possible to infer the true causal graph from data. In practice, we need to do statistical inference based on a finite sample and the original graph could not be recovered due to errors in the statistical tests.

For instance, with regard to the CFC, it becomes very relevant to causal inference whether the probability distribution P, though faithful to the true casual structure, is far from or close to being unfaithful. Intuitively, a population distribution may be faithful but close to unfaithfulness, that is, the situation when independence seems to hold due to insufficient sample size. As a consequence, when applied to sample data, the PC algorithm can have problems of reliability.

The situation worsens for complex survey data. Roughly speaking, the CMC and the CFC may fail if the population is selected by a procedure that is biased toward two or more of the observed variables. In order to avoid misleading results about the true causal structure, the complexity of sampling design must be taken into account in the learning process. Here, a procedure (described in subsection 2.1) for testing the association in a two-way table for data coming from complex sample surveys is introduced in phase 1 of the PC algorithm giving rise to the PC complex algorithm.

2.1 Independence test for complex sample surveys via resampling

Denote by A and B two characters of interest with H and K categories, respectively. Furthermore, let the superpopulation parameters p^{hk}, $p^{h\cdot}$, $p^{\cdot k}$ be defined as

$$p^{hk} = Prob(A = A^h, B = B^k), \quad p^{h\cdot} = Prob(A = A^h), \quad p^{\cdot k} = Prob(B = B^k) \tag{1}$$

for $h = 1, \ldots, H$ and $k = 1, \ldots, K$. Let $\mathcal{U}_N$ be a finite population of size N, labeled by integers $1, \ldots, N$, generated from the superpopulation model (1). For each unit i let $Y_i^{h\cdot}$ ($Y_i^{\cdot k}$) be the variable taking the value 1 if the unit i assumes the modality A^h (B^k) and 0 otherwise, for $h = 1, \ldots, H$ ($k = 1, \ldots, K$) and let Y_i^{hk} be the variable given by the product $Y_i^{h\cdot} Y_i^{\cdot k}$.

For each unit i of the population $\mathcal{U}_N$, let D_i be a Bernoulli random variable (r.v.), such that i is in the sample whenever $D_i = 1$, whilst i is not in the sample whenever $D_i = 0$. Let $D = (D_1 \dots D_N)$. An unordered, without replacement sampling design P is the probability distribution of D, with $\pi_i = E_P[D_i]$ being the first order inclusion probability of unit i. Here we will consider fixed size sampling designs. Assumptions on the sampling design according to which the sample is drawn, are similar to those used in (3).

Let p_N^{hk},$p_N^{h\cdot}$, $p_N^{\cdot k}$ be the finite population parameters defined as

$$p_N^{hk} = \frac{1}{N}\sum_{i=1}^{N} Y_i^{hk}, \quad p_N^{h\cdot} = \frac{1}{N}\sum_{i=1}^{N} Y_i^{h\cdot} = \sum_{k=1}^{K} p_N^{hk}, \quad p_N^{\cdot k} = \frac{1}{N}\sum_{i=1}^{N} Y_i^{\cdot k} = \sum_{h=1}^{H} p_N^{hk} \tag{2}$$

$h = 1, \dots, H$, $k = 1, \dots, K$. The parameters (2) can be estimated using the classical Hájek estimators

$$\widehat{p}^{hk} = \frac{\sum_{i=1}^{N} \frac{D_i Y_i^{hk}}{\pi_i}}{\sum_{i=1}^{N} \frac{D_i}{\pi_i}}, \quad \widehat{p}^{h\cdot} = \frac{\sum_{i=1}^{N} \frac{D_i Y_i^{h\cdot}}{\pi_i}}{\sum_{i=1}^{N} \frac{D_i}{\pi_i}} = \sum_{k=1}^{K} \widehat{p}^{hk}, \quad \widehat{p}^{\cdot k} = \frac{\sum_{i=1}^{N} \frac{D_i Y_i^{\cdot k}}{\pi_i}}{\sum_{i=1}^{N} \frac{D_i}{\pi_i}} = \sum_{h=1}^{H} \widehat{p}^{hk} \tag{3}$$

$h = 1, \dots, H$, $k = 1, \dots, K$. Here, similarly to (4), in order to prove the existence of the limiting distribution of the Hájek estimators (3) as the sample size and the population size increase, we consider the stochastic processes:

$$W^{HK} = \sqrt{n}(\widehat{p}^{hk} - p^{hk}), \quad W^{H} = \sqrt{n}(\widehat{p}^{h\cdot} - p^{h\cdot}), \quad W^{K} = \sqrt{n}(\widehat{p}^{\cdot k} - p^{\cdot k}) \tag{4}$$

for $h = 1, \dots, H$, $k = 1, \dots, K$.

Each of these processes can be partitioned into the sum of two stochastic processes

$$\begin{aligned}
W^{HK} &= \{W_n^{HK} + W_N^{HK}, h = 1, \dots, H, k = 1, \dots, K\} \\
&= \{\sqrt{n}(\widehat{p}^{hk} - p_N^{hk}) + \sqrt{f}\sqrt{N}(p_N^{hk} - p^{hk}), h = 1, \dots, H, k = 1, \dots, K\}, \qquad (5) \\
W^{H} &= \{W_n^{H\cdot} + W_N^{H\cdot} h = 1, \dots, H\} \\
&= \{\sqrt{n}(\widehat{p}^{h\cdot} - p_N^{h\cdot}) + \sqrt{f}\sqrt{N}(p_N^{h\cdot} - p^{h\cdot}), h = 1, \dots, H\}, \qquad (6) \\
W^{K} &= \{W_n^{\cdot K} + W_N^{\cdot K}, k = 1, \dots, K\} \\
&= \{\sqrt{n}(\widehat{p}^{\cdot k} - p_N^{\cdot k}) + \sqrt{f}\sqrt{N}(p_N^{\cdot k} - p^{\cdot k}), k = 1, \dots, K\} \qquad (7)
\end{aligned}$$

where $f = \frac{n}{N}$. The components $W_n^{HK}, W_n^{H\cdot}, W_n^{\cdot K}$ depend on the sample selection randomness while the components $W_N^{HK}, W_N^{H\cdot}, W_N^{\cdot K}$ depend on the superpopulation randomness.

In Proposition 1 in (8) it is shown that processes (4) converge to a Gaussian distributions. Specifically, under the assumptions A1-A6 of Proposition 1 in (4), as n and N increase, the sequences:

1. W_n^{HK} and W_N^{HK} converge in distribution to degenerate multivariate normal distributions with mean zero and singular covariance matrices Σ_1^{HK} and Σ_2^{HK} of order HK, respectively. As a consequence, the whole process W^{HK} converges to a degenerate multivariate normal distribution with mean zero and singular covariance matrix $\Sigma^{HK} = \Sigma_1^{HK} + f\Sigma_2^{HK}$.
2. W_n^{H} and W_N^{H} converge in distribution to degenerate multivariate normal distributions with mean zero and singular covariance matrices Σ_1^{H} and Σ_2^{H} of order H, respectively. As a consequence, the whole process W^{H} converges to a degenerate multivariate normal distribution with mean zero and singular covariance matrix $\Sigma^{H} = \Sigma_1^{H} + f\Sigma_2^{H}$.
3. W_n^{K} and W_N^{K} converge in distribution to degenerate multivariate normal distributions with mean zero and singular covariance matrices Σ_1^{K} and Σ_2^{K} of order K, respectively. As a consequence, the whole process W^{K} converges to a degenerate multivariate normal distribution with mean zero and singular covariance matrix $\Sigma^{K} = \Sigma_1^{K} + f\Sigma_2^{K}$.

Next, we consider the hypothesis testing problem with null hypothesis of A and B independent, and alternative hypothesis of of A and B associated. Formally

$$\mathcal{H}_0 : p^{hk} = p^{h\cdot}p^{\cdot k} \quad \text{against} \quad \mathcal{H}_1 : p^{hk} \neq p^{h\cdot}p^{\cdot k}. \tag{8}$$

The following test statistic is used

$$\chi^2_H = n \sum_{h=1}^{H} \sum_{k=1}^{K} \frac{(\widehat{p}^{hk} - \widehat{p}^{h\cdot}\widehat{p}^{\cdot k})^2}{\widehat{p}^{h\cdot}\widehat{p}^{\cdot k}} \tag{9}$$

where $\widehat{p}^{hk}$, $\widehat{p}^{h\cdot}$ and $\widehat{p}^{\cdot k}$ are the Hájek estimators given in (3). In (8) it is shown that for complex survey data: (i) the test statistic (9) does have a limiting distribution; (ii) the limiting distribution does not necessarily approach to a Chi-square distribution because of the singularity of the matrices Σ^{HK}, Σ^{H} and Σ^{K}. More specifically, χ^2_H tends in distribution to a quadratic form of a degenerate multinormal distribution.

The limiting sampling distribution of test statistic (9) under the independence null hypothesis is estimated resorting to resampling methods for finite population. Different versions of the bootstrap have been proposed in the literature, see (3), (4) and references therein. In (4) a class of resampling techniques based on a two-step procedure is proposed. Such a methodology consists in cr eating an artificial population (called pseudo-population) from the initial sample, and drawing bootstrap samples from it using the original sampling scheme.

3. Accuracy evaluation

A Monte Carlo simulation has been performed to assess the accuracy of the proposed algorithm. A finite population of size $N = 10000$ has been generated according to the network in Fig. 1a. The probability distributions of the nodes X_1, X_2 and $X_3|(X_1, X_2)$ are reported in Tables 1-3. The finite population causal structure has been estimated using the function *pc()* in Package pcalg. The finite population CPDAG in Fig. 1a has been obtained.

The effect of the sampling design on the structural learning process has been studied selecting 500 samples of size $n = 3000$ from the finite population according to (i) a simple random sampling design; (ii) a conditional Poisson sampling design with inclusion probabilities proportional to the Z-values, defined as follows

$$Z = \begin{cases} N(200, 2) + 10 & X_2 = 0 \\ N(10, 2) + 5 & X_2 = 1 \end{cases} \tag{10}$$

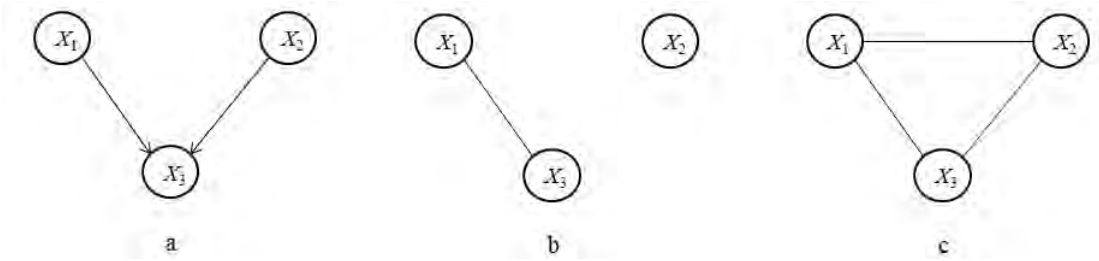

Figure 1: (a) True graph and finite population CPDAG, (b)-(c) Sampling design effects.

The significance level is fixed to 0.05. When the sample is selected according to a simple random sampling, the PC algorithm is not able to recover the true association structure in 3% of the selected samples.

The percentage of wrong graphs rises to 10.7% when the sample is selected according to a conditional Poisson sampling. Fig. 1 shows the effects of the survey design on the association structure. The edge between the nodes X_2 and X_3 is missing in 34% of the wrong graphs (Fig. 1b). An additional edge is placed between X_1 and X_2 in the remaining 66% (Fig. 1c).

Next, the PC complex has been applied. For each sample, a pseudo population has been constructed and $M = 1000$ bootstrap samples have been drawn. It results that the percentage of wrong graphs decreases to 3.2%.

Abstract

Statistical Matching, at a macro level, consists in estimating the joint distribution of variables separately observed in independent samples. As a consequence of the lack of joint information on the variables of interest, uncertainty about the data generating model is the most relevant feature of matching. In the present paper the use of graphical models to deal with the statistical matching uncertainty for multivariate categorical variables is considered, under both a model-based and a model-assisted perspective.

Keywords: Data integration, statistical matching, Bayesian networks, sampling design.

1. Introduction and basics

As a consequence of the *data deluge* phenomenon, in the last years there has been a considerable increase of available statistical data, coming from different sources: Official Statistics, Institutional entities, as well as private subjects. Data sometimes come from well-designed sample surveys, sometimes come from institutional archives (with some form of design), sometimes from surveys where sample units are essentially self-selected. The final effect of the data deluge is an increasing flow of data, including also data generated from online transactions, emails, videos, audios, images, click streams, logs, search queries, health records, social networking interactions, sensors and mobile phones, etc.. In different words, this is the big data era.

Using the above data has advantages and disadvantages.

- The main advantage is in terms of *cost*. An *ad hoc*, well-designed, sample survey where all variables of interest are observed is expensive, and frequently unaffordable. The availability of free data clearly offers an attracting alternative.
- The main disadvantages are two. First of all, freely available data hardly ever contain all variables of interest. In the second place, if data are collected through some form of self-selection of sample units, there is a potential bias that could make statistical estimates affected by serious errors.

Consider a finite population of N units, and let $(\boldsymbol{X}_i, \boldsymbol{Y}_i, \boldsymbol{Z}_i)$, $i = 1, \ldots, N$ be a superpopulation model composed by independent and identically distributed (*i.i.d.*) random variables (r.v.s) with joint (either discrete or absolutely continuous) distribution P. In other terms, $(\boldsymbol{X}_i, \boldsymbol{Y}_i, \boldsymbol{Z}_i)$ are independent copies of a r.v. $(\boldsymbol{X}, \boldsymbol{Y}, \boldsymbol{Z})$. With no essential loss of generality, it is assumed that $\boldsymbol{X}_i = (X_{i1}, \ldots, X_{iH})$, $\boldsymbol{Y} = (Y_{i1}, \ldots, Y_{iK})$, $\boldsymbol{Z} = (Z_{i1}, \ldots, Z_{iL})$ are vectors of r.v.s of dimension H, K, T, respectively. Furthermore, we will denote by $f(\boldsymbol{x}, \boldsymbol{y}, \boldsymbol{z})$ the joint density (w.r.t. either the counting measure - discrete case - or the Lebesgue measure - absolutely continuous case) of $(\boldsymbol{X}, \boldsymbol{Y}, \boldsymbol{Z})$. Statistical matching

at a macro level consists in estimating the joint distribution of $(\boldsymbol{X}, \boldsymbol{Y}, \boldsymbol{Z})$s (or possibly of some of its parameters) when:

1. $(\boldsymbol{X}, \boldsymbol{Y})$ are observed in a sample $\boldsymbol{S}_A$ of size n_A, possibly drawn according to a complex sampling design;
2. $(\boldsymbol{X}, \boldsymbol{Z})$ are observed in a sample $\boldsymbol{S}_B$ of size n_B, possibly drawn according to a complex sampling design;
3. $\boldsymbol{S}_A$ and $\boldsymbol{S}_B$ are independent, and the sets of observed units in the two samples do not overlap.

The main problem in estimating the joint distribution of $(\boldsymbol{X}, \boldsymbol{Y}, \boldsymbol{Z})$ is essentially a *missing values* problem, where missingness is inherent, because the units in $\boldsymbol{S}_A$ have $\boldsymbol{Z}$ as missing values and the units in $\boldsymbol{S}_B$ have $\boldsymbol{Y}$ as missing values. As a consequence, the joint distribution of $(\boldsymbol{X}, \boldsymbol{Y}, \boldsymbol{Z})$ is generally *not identifiable* from collected data because of the absence of joint observations of $\boldsymbol{X}, \boldsymbol{Y}, \boldsymbol{Z}$.

The oldest approach to overcome this problem is to assume that $\boldsymbol{Y}$ and $\boldsymbol{Z}$ are independent conditionally on $\boldsymbol{X}$. This is the well-known Conditional Independence Assumption (CIA, for short). Under CIA, the model is actually identifiable (12) and consistent estimates of the involved distributions can be constructed (1).

Another approach that makes the model identifiable consists in using techniques based on the external auxiliary information; the most relevant case occurs when an additional, possibly small-scale, sample $\boldsymbol{S}_C$ where $(\boldsymbol{X}, \boldsymbol{Y}, \boldsymbol{Z})$ are jointly observed is available; cfr. (14).

Unfortunately, in many cases CIA cannot be reasonably assumed, and an additional, complete sample $\boldsymbol{S}_C$ is hardly ever available. As a consequence of unidentifiability of the statistical model for $(\boldsymbol{X}, \boldsymbol{Y}, \boldsymbol{Z})$, even for a large sample sizes n_A, n_B, one can only obtain a "blurred" estimate of the distribution of $(\boldsymbol{X}, \boldsymbol{Y}, \boldsymbol{Z})$. The blurring effect of unidentifiability can be numerically quantified through a *measure of uncertainty* in statistical matching; cfr. (1; 4).

2. Bayesian Networks for Statistical Matching: model-based approach

The goal of the present section is to illustrate the use of Bayesian networks (BNs) to deal with the statistical matching uncertainty in multivariate categorical data. Throughout the present section, the following assumptions are made.

A1. $(\boldsymbol{X}, \boldsymbol{Y}, \boldsymbol{Z})$ is a discrete, multivariate r.v., with joint probability function (p.f.) $f(\boldsymbol{x}, \boldsymbol{y}, \boldsymbol{z})$ and marginal p.f.s $f_X(\boldsymbol{x})$, $f_{XY}(\boldsymbol{x}, \boldsymbol{y})$, $f_{XZ}(\boldsymbol{x}, \boldsymbol{z})$.

A2. The samples $\boldsymbol{S}_A$, $\boldsymbol{S}_B$ are independent, and selected according to ignorable sampling designs. In this way, the r.v.s $(\boldsymbol{X}_i, \boldsymbol{Y}_i)$, $i \in \boldsymbol{S}_A$ are *i.i.d.*, and the r.v.s $(\boldsymbol{X}_i, \boldsymbol{Z}_i)$, $i \in \boldsymbol{S}_B$ are *i.i.d.*, as well.

In the sequel, we will essentially focus on *model-based* inference, where the sampling designs used to select $\boldsymbol{S}_A$, $\boldsymbol{S}_B$ do not play any role. This allows to use standard methods both for parameters estimation and model construction.

The first attempt to use BNs in Statistical Matching of multivariate discrete data is in (7), where the CIA is assumed, and its connection with d-separation criterion exploited. Of course, under CIA both the dependence structure and the BN parameters are estimable from the sample data and there is no uncertainty. When CIA is unadequate, the final dataset may be significantly different from the one it would have been available if complete observations of $(\boldsymbol{X}, \boldsymbol{Y}, \boldsymbol{Z})$ were collected, and the application of standard inferential procedures may result in highly biased estimates.

A considerable step forward is (4), where Statistical Matching based on BNs without CIA is thoroughly studied. Differently from (7), BNs can help tackling the multivariate statistical matching problem both computationally and by targeting the effort for uncertainty assessment only to those components of the joint p.f. relative to variables separately observed in the two available samples.

A BN is a probabilistic graphical model encoding a joint probability distribution satisfying sets of conditional independence statements contained in a directed acyclic graph (DAG) (5). A graph is a pair $G = (V, E)$, where V is the set of vertices, and E is the set of directed edges between pairs of nodes. In particular, directed acyclic graphs are considered: it is not possible to start from a node and go back

to the same node following arrows directions. Each node corresponds to a random variable and missing arrows between nodes imply (conditional) independence between the corresponding variables. In a BN each node x_h, say, is associated with the distribution of the corresponding variable given its parents, $pa(x_h)$, namely all nodes linked to x_h by an arrow pointing to x_h. As a matter of fact, a BN consists of two components: the DAG and the set of the distributions parameters.

The use of BNs in the statistical matching problem is motivated by several advantages, listed below.

1. BNs can consider prior knowledge to be included in Statistical Matching.
2. BNs are widely used to describe dependencies among variables in multivariate distributions.
3. BNs admit convenient recursive factorizations of their joint probability useful for data integration and uncertainty evaluation in a multivariate context.

In Statistical Matching, the non-identifiability of the statistical model for $(\boldsymbol{X}, \boldsymbol{Y}, \boldsymbol{Z})$, due to the absence of joint observations on the variables of interest, implies that both the components of a BN (namely, the underlying DAG and its parameters) cannot be estimated from samples $\boldsymbol{S}_A$, $\boldsymbol{S}_B$. As a matter of fact fact, when BNs are used for Statistical Matching, two operations are necessary.

(i) Specification of the dependence structure of the variables $(\boldsymbol{X}, \boldsymbol{Y}, \boldsymbol{Z})$.
(ii) Estimation of the parameters, *i.e.*, the local probability distributions associated to the edges between the components of $\boldsymbol{Y}$ and $\boldsymbol{Z}$.

As a consequence, the two kinds of uncertainty reported below have to be accounted for.

1. Uncertainty on the DAG, namely on the dependence structure among the variables of interest.
2. Uncertainty on the parameters of the statistical relationships between $\boldsymbol{Y}$ and $\boldsymbol{Z}$ (namely on the corresponding conditional probabilities) given the DAG, *i.e.* given the factorization of the joint p.f. of $(\boldsymbol{X}, \boldsymbol{Y}, \boldsymbol{Z})$.

The above two forms of uncertainty will be discussed in the sequel. The steps on which the proposed Statistical Matching rests are listed below.

Step 1 Estimate the DAGs of $\boldsymbol{X}$, $(\boldsymbol{X}, \boldsymbol{Y})$ and $(\boldsymbol{X}, \boldsymbol{Z})$ from $\boldsymbol{S}_A \cup \boldsymbol{S}_B$, $\boldsymbol{S}_A$, $\boldsymbol{S}_B$, respectively.
Step 2 Extra sample information on the association structure between $\boldsymbol{Y}$ and $\boldsymbol{Z}$ must be inserted in the DAGs. For instance, if a variable Y_k is associated to Z_l then a link between the vertices Y_k and Z_l must be added.
Step 3 Consider the class of plausible DAGs for $(\boldsymbol{X}, \boldsymbol{Y}, \boldsymbol{Z})$, and compute the uncertainty due to the corresponding dependence structure.
Step 4 Select a model from the class of plausible DAGs defined in Step 3.
Step 5 Estimate the parameters of the local p.f.s associated to the edges between the components of $\boldsymbol{Y}$ and $\boldsymbol{Z}$, and compute the parameters estimation uncertainty.
Step 6 Compute the total uncertainty by adding the dependence structure uncertainty to the uncertainty in parameters estimation.

Step 3 requires the definition of a class $\mathcal{G}_{\boldsymbol{XYZ}} = \{G_{\boldsymbol{XYZ}}\}$ of plausible DAGs for the joint distribution of $(\boldsymbol{X}, \boldsymbol{Y}, \boldsymbol{Z})$. Generally speaking, the widest class of DAGs one may consider is the class of all joint distributions for $(\boldsymbol{X}, \boldsymbol{Y}, \boldsymbol{Z})$ that are *collapsible* over $\boldsymbol{Y}$, $\boldsymbol{Z}$, respectively. In formal terms, $f(\boldsymbol{x}, \boldsymbol{y}, \boldsymbol{z})$ is collapsible over Z_t if the estimate obtained for the probability function of $(\boldsymbol{X}, \boldsymbol{Y}, \boldsymbol{Z} \setminus Z_t)$ does coincide with the estimate obtained by marginalizing w.r.t. Z_t the estimate of the probability function of $(\boldsymbol{X}, \boldsymbol{Y}, \boldsymbol{Z})$. Collapsibility w.r.t. subsets $\boldsymbol{Z'} \subseteq \boldsymbol{Z}$ or $\boldsymbol{Y'} \subseteq \boldsymbol{Y}$ is similarly defined. As a matter of fact, the plausible class of DAGs can be also defined in terms of c-removability; cfr. (4).

The most favorable case occurs under CIA, because the class $\mathcal{G}_{\boldsymbol{XYZ}}$ of all probability functions for $(\boldsymbol{X}, \boldsymbol{Y}, \boldsymbol{Z})$ collapses on a single graph where Y and Z are d-separated by X, with joint p.f. defined as $f(\boldsymbol{x}, \boldsymbol{y}, \boldsymbol{z}) = f(\boldsymbol{x}) f(\boldsymbol{y}|\boldsymbol{x}) f(\boldsymbol{z}|\boldsymbol{x})$. When CIA does not hold, there is *uncertainty* on the dependence structure of $(\boldsymbol{X}, \boldsymbol{Y}, \boldsymbol{Z})$. As a matter of fact, there are *two* sources of uncertainty.

U1. Uncertainty of the specific graph $G_{\boldsymbol{XYZ}} \in \mathcal{G}_{\boldsymbol{XYZ}}$, *i.e.* on the independence structure of $(\boldsymbol{X}, \boldsymbol{Y}, \boldsymbol{Z})$. Each graph in $\mathcal{G}_{\boldsymbol{XYZ}}$ represents an *equivalence class* of probability functions $f(\boldsymbol{x}\ \boldsymbol{y}, \boldsymbol{z})$ all sharing the same structure of local independence.

U2. Uncertainty on the parameter estimates of the non-identifiable probability function(s) corresponding to the selected graph $G_{\boldsymbol{XYZ}}$.

Both sources of uncertainty are intrinsic in the statistical matching problem.

As an *uncertainty measure* for the class $\mathcal{G}_{\boldsymbol{XYZ}}$, namely a measure to compare the plausible independence equivalence classes in terms of graph density/sparsity, the Structural Hamming Distance (SHD, for short) can be used. Such a distance, applied to independence equivalence classes, can be defined as the number of edge insertions or deletions necessary to transform a given equivalence class into another equivalence class.

As far as uncertainty in parameter estimation is concerned, once a graph $G_{\boldsymbol{XYZ}} \in \mathcal{G}_{\boldsymbol{XYZ}}$ has been chosen, let $\theta_{\boldsymbol{XYZ}}$ be parameter vector of the corresponding joint probability function $f(\boldsymbol{x}, \boldsymbol{y}, \boldsymbol{z})$, and let $\theta_{\boldsymbol{X}\cdot\cdot}$ be the parameters vector of the marginal distribution of X, let $\theta_{\boldsymbol{XY}\cdot}$ be the parameters vector of the marginal distribution of $(\boldsymbol{X}, \boldsymbol{Y})$, and let $\theta_{\boldsymbol{X}\cdot\boldsymbol{Z}}$ be the parameters vector od the marginal distribution of $(\boldsymbol{X}, \boldsymbol{Z})$. Note that $\theta_{\boldsymbol{X}\cdot\cdot}$, $\theta_{\boldsymbol{XY}\cdot}$, $\theta_{\boldsymbol{X}\cdot\boldsymbol{Z}}$ are identifiable, and can be consistently estimated on the basis of sample data.

Due to the unidentifiability issue, one can only say that it belongs to a set Θ_R. At an estimation level, under the assumption that the sampling designs used to select $\boldsymbol{S}_A$, $\boldsymbol{S}_B$ is *ignorable*, this identifies the *likelihood ridge*, *i.e.* the set of estimates

$$\widehat{\Theta}_R = \left\{ \widehat{\theta}_{\boldsymbol{XYZ}} : \sum_{\boldsymbol{z}} \widehat{\theta}_{\boldsymbol{XYZ}} = \widehat{\theta}_{\boldsymbol{XY}\cdot}, \sum_{\boldsymbol{y}} \widehat{\theta}_{\boldsymbol{XYZ}} = \widehat{\theta}_{\boldsymbol{X}\cdot\boldsymbol{Z}} \right\}$$

where $\widehat{\theta}_{\boldsymbol{XY}\cdot}$, $\widehat{\theta}_{\boldsymbol{X}\cdot\boldsymbol{Z}}$ are the Maximum Likelihood Estimates (MLEs) of the joint probabilities of $f(\boldsymbol{x}, \boldsymbol{y})$ and $f(\boldsymbol{x}, \boldsymbol{z})$, respectively.

As a measure of uncertainty for $\widehat{\Theta}_R$, the most natural choice consists is using supremum of the Lebesgue measure of all open subsets contained in $\widehat{\Theta}_R$. The main issue related to this measure is its computation. A much simpler alternative is proposed in (4). Furthermore, as a global measure of uncertainty, the sum of measures corresponding to U1, U2 are taken.

Before closing the present section, a few remarks.

1. The MLEs $\widehat{\theta}_{\boldsymbol{XY}\cdot}$, $\widehat{\theta}_{\boldsymbol{X}\cdot\boldsymbol{Z}}$ can be legitimately used as a consequence of the ignorability assumption. More importantly, ignorability has to be intended *conditionally on design variables for all population units*; cfr. (13).
2. The assumption of ignorability also allows one to use well-consolidated methodologies for testing for the presence of arcs in the marginal graphical models for $(\boldsymbol{X}, \boldsymbol{Y})$, $(\boldsymbol{X}, \boldsymbol{Z})$.
3. Statistical Matching under non-ignorable sampling designs is investigated in (9). The authors apply a parametric approach, basing the inference on the sample distribution, namely the distribution holding for the observed sample data. However, the maximization of sample likelihood can be complicated numerically and result in unstable estimates, depending on the population model and the model assumed for the sample selection probabilities, given the observed data. For this reason, in (10) the use of the empirical likelihood, which enables estimating the parameters governing sample distribution without specifying the corresponding population model, is proposed.

3. Statistical Matching under model-assisted approach

The goal of the present section is to extend the approach of Section 2. to the case when samples $\boldsymbol{S}_A$, $\boldsymbol{S}_B$ are collected through complex, probabilistic sample designs. This case is of extreme interest in case of secondary analyses, where only design weights for sampled units are actually available. In these cases, that are actually very frequent in practice, the use of a model-based approach could be prone to a relevant source of bias, because the r.v.s $((\boldsymbol{X}_i, \boldsymbol{Y}_i) \;\; i \in \boldsymbol{S}_A)$ (or $((\boldsymbol{X}_i, \boldsymbol{Z}_i) \;\; i \in \boldsymbol{S}_B)$), given $\boldsymbol{S}_A$, $\boldsymbol{S}_B$, could be neither independent, nor identically distributed. In other terms, the conditional distributions of $\{(\boldsymbol{X}_i, \boldsymbol{Y}_i);\, i \in \boldsymbol{S}_A\}|\boldsymbol{S}_A$, $\{(\boldsymbol{X}_i, \boldsymbol{Z}_i);\, i \in \boldsymbol{S}_B\}|\boldsymbol{S}_B$ do not necessarily coincide with the corresponding

marginal distributions (which is exactly the assumption on which model-based inference rests); cfr. (13) and references therein for further considerations on this crucial point.

In the sequel, we will denote by π_{iA}, π_{iB} the first order inclusion probabilities of units of samples $\boldsymbol{S}_A$, $\boldsymbol{S}_B$, respectively. Moreover, the two samples $\boldsymbol{S}_A$, $\boldsymbol{S}_B$ will be still assumed independent.

The procedure described in Section 2. can be still used in a context of independent samples collected through complex sample designs, provided that two points remarked above (*i.e.* MLEs and model selection) are accounted for.

As far as estimates of $\widehat{\theta}_{\boldsymbol{XY}\cdot}$, $\widehat{\theta}_{\boldsymbol{X}\cdot\boldsymbol{Z}}$ are concerned, the simplest idea is to use an appropriate pseudo-likelihood. In addition to the notation already introduced, let us denote by $\theta_{\boldsymbol{Y}|\boldsymbol{X}}$ the parameters of the conditional distribution of $\boldsymbol{Y}|\boldsymbol{X}$, and by $\theta_{\boldsymbol{Z}|\boldsymbol{X}}$ the parameters of the conditional distribution of $\boldsymbol{Z}|\boldsymbol{X}$. Clearly, there is a one-to-one map between $(\theta_{\boldsymbol{X}\cdot\cdot}, \theta_{\boldsymbol{Y}|\boldsymbol{X}})$ and $\theta_{\boldsymbol{XY}\cdot}$, and a one-to-one map between $(\theta_{\boldsymbol{X}\cdot\cdot}, \theta_{\boldsymbol{Z}|\boldsymbol{X}})$ and $\theta_{\boldsymbol{X}\cdot\boldsymbol{Z}}$.

The parameters $\theta_{\boldsymbol{X}\cdot\cdot}$ are then estimated by maximizing the *pseudo-log-likelihood*

$$\widetilde{l}_{\boldsymbol{X}}(\theta_{\boldsymbol{X}\cdot\cdot}) = \sum_{i\in\boldsymbol{S}_A} \frac{1}{\pi_{i,A}} \log f_{\boldsymbol{X}}(\boldsymbol{x}_i) + \sum_{i\in\boldsymbol{S}_B} \frac{1}{\pi_{i,B}} \log f_{\boldsymbol{X}}(\boldsymbol{x}_i). \tag{1}$$

In the context of file concatenation, pseudo-likelihood has been considered in (6).

Similarly, the parameters $\theta_{\boldsymbol{Y}|\boldsymbol{X}}$, $\theta_{\boldsymbol{Z}|\boldsymbol{X}}$ can be estimated by maximizing the conditional pseudo-log-likekihoods

$$\begin{aligned}
\widetilde{l}_{\boldsymbol{Y}|\boldsymbol{X}}(\theta_{\boldsymbol{Y}|\boldsymbol{X}}) &= \sum_{i\in\boldsymbol{S}_A} \frac{1}{\pi_{i,A}} \log f_{\boldsymbol{Y}|\boldsymbol{X}}(\boldsymbol{y}_i|\boldsymbol{x}_i); \\
\widetilde{l}_{\boldsymbol{Z}|\boldsymbol{X}}(\theta_{\boldsymbol{Z}|\boldsymbol{X}}) &= \sum_{i\in\boldsymbol{S}_B} \frac{1}{\pi_{i,B}} \log f_{\boldsymbol{Z}|\boldsymbol{X}}(\boldsymbol{z}_i|\boldsymbol{x}_i).
\end{aligned}$$

In is not difficult to see that the estimated obtained in this way are essentially equivalent to Hájek estimates, and hence they possess the asymptotic, large sample properties established in (3). Of course, considerable simplifications can be obtained by exploiting local independency relationships in the graphical models for $(\boldsymbol{X}, \boldsymbol{Y})$ and $(\boldsymbol{X}, \boldsymbol{Z})$. Exactly as before, in testing for the presence/absence of arcs (a crucial step in model construction) a major role is played by the sampling designs used to select $\boldsymbol{S}_A$, $\boldsymbol{S}_B$. As shown in (11), ignoring the effect of sampling designs by using a purely model-based approach is a source of relevant bias. In the same paper, a new approach to model construction, based on resampling under complex sampling design, is proposed.

Further extensions of the model-assisted approach to non-probability samples $\boldsymbol{S}_A$, $\boldsymbol{S}_B$ may be considered, provided that for $\boldsymbol{S}_A$, $\boldsymbol{S}_B$ there are reference surveys $\boldsymbol{S}^*_{A'}$, $\boldsymbol{S}^*_{B'}$ allowing consistent estimates of the corresponding sample weights; cfr. (8) and references therein.

Abstract

The Attained Level of Education (ALE) of the Permanent Italian Census relies on a high amount of administrative information. Nevertheless, it is needed to resort to sample survey data to cope with delay of information and coverage problems. Due to the complexity and heterogeneity of the available information, the solution of the problem with standard statistical methods needs the construction of different imputation models with a strong effort in terms of human intervention. We study the use of a multilayer perceptron model to make the process more automatic, i.e., less costly in terms of human resources, and possibly more accurate in terms of estimates. Since a relevant quality aspect is the ability of the imputation process to provide a good estimate of the ALE frequency distribution, sampling weights are used in the estimation techniques. A comparison between different approaches in the use of weights for Machine Learning is carried out: results obtained from a weighted loss function are compared with those obtained from a data set expanded according to sampling weights.

Keywords: Register-based statistics, imputation, sampling weights, weighted machine learning, expanded data

1. Introduction

The Attained Level of Education (ALE) of the Permanent Italian Census exploits a high amount of administrative information. Nevertheless, it is needed to resort to sample survey data to cope with the delay of information and coverage problems. The official procedure for the estimation of the ALE for Italian resident population in 2018 relies on a mass imputation approach using log-linear models, see (5). Mass-imputation is adopted because administrative data are not available for all the units in the population, and because they have a temporal lag with respect to the reference time (generally one-year later). Machine learning techniques could provide a valuable and more automated alternative for the imputation task (2). In (3), a comparison between the official imputation approach based on log-linear models, and multilayer perceptron models (MLP) is discussed. In (4), the study is repeated by considering sampling weights that are introduced in the loss function of the algorithm used for estimating MLP. In this work, we extend the study in (4) by adopting a similar approach to the one used for log-linear imputation, based on the pseudo-likelihood approach, in fact MLP are applied to a data set obtained expanding units of the sample according to their weights.

The paper is structured as follows. In Section 2, MLP and the use of sampling weights are presented. The experimental application for the empirical evaluation of the proposal is carried out on a subset of real data and is described in Section 3.

2. Multilayer perceptron model and sampling weights

National Statistics Institutes (NSIs) routinely use complex sampling designs to carry out sample surveys. Statistical analysis on complex survey data make use of sampling weights that typically enter estimator expressions in the form of weights attached to the survey units.

The use of survey sampling weights in machine learning applications is receiving increasing attention in the research community, see for instance (1), (2), (7).

To take into account sampling weights, in (4) we adopt a loss function that is weighted with sampling weights (MLP1, hereafter). A similar idea in a different context is in (6) where weights are used to correct for the difference between train and target distribution.

More in detail, the procedure (MLP1) studied in (4) is the following:

- Input variables of the perceptron multilayer are encoded as one-hot encoding[1];
- MLP is estimated by minimizing the cross-entropy loss function considering sampling weights as follows:

$$loss_w = -\sum_{ic} w_i T_{ic} \cdot log(P_{ic})$$

  where w_i is the survey weight of the i-th training observation, c is the modality index in a one-hot representation, T_{ic} is the ground-truth value of the target variable for the i-th observation, and P_{ic} is the corresponding softmax function[2] output probability distribution of the MLP.
- The MLP output is a probability distribution on the 8 ALE items: for each record we impute the ALE item randomly extracted from the probability distribution of the corresponding pattern of covariates.

In a classical survey statistical framework, statistics are produced by weighting data with sampling weights. In practice, roughly speaking, a unit i with a sampling weight w_i represents other w_i units of the target finite population. Following this idea, we apply MLP on the data set obtained by repeating each unit of the sample according to the attached sampling weight (MLP2, hereafter). To limit the error that is made by rounding the weight associated with each individual, we duplicate the profile or cell that corresponds to individuals who have the same values of the input variables. The weight associated with a profile is given by the sum of the weights of all individuals with the same profile. We remark that in this case MLP is estimated by means of the not weighted cross-entropy loss function. Finally, the step of imputation through a random draw from the estimated ALE probability distribution is performed, as previously described.

The two approaches, MLP1 and MLP2, are applied to the estimation of ALE in the 2018 Italian resident population.

3. Experimental results

ALE for the Italian resident population in 2018 is estimated by using administrative data (covering the period from 2011 to 2017), traditional Census data (2011 Census) and 2018 sample survey data. In this work, we use data relatively to the 312,813 people residents in Lombardia region with no missing data on ALE 2018. The target variable is the self-declared ALE in the 2018 sample survey, which corresponds approximately to 5% of the total population of interest. Core information like age, gender, citizenship, marital status, place of birth and place of residence are available for all individuals. The classification adopted for ALE is composed by 8 items: 1 - Illiterate, 2 - Literate but no formal educational attainment, 3 - Primary education, 4 - Lower secondary education, 5 - Upper secondary education,

[1] equivalent to dummy variables in statistics but where the vector of all zero is not admitted

[2] softmax is a function which applies the standard exponential function to each element of the input vector and normalizes these values by dividing by the sum of all these exponentials

6 - Bachelor's degree or equivalent level, 7 - Master's degree or equivalent level, 8 - PhD level.

We apply MLP1 to sample survey data to obtain an estimate of the ALE variable. Then we apply MLP2 to the sample survey data expanded according to sampling weights as described above. Sample survey data provide the observed ALE for all the individuals allowing for supervised estimation and assessment of accuracy.

The results by MLP1 are produced with a neural network having two hidden layers, each of 128 neurons, and an output layer with 8 neurons (one per modality of the target variable). Instead the architecture of the neural network for estimating ALE by expanded dataset has three hidden layers, two of 256 neurons and one of 128 neurons, and an output layer with 8 neurons. For both the best configuration of some hyper-parameters (number of hidden neurons, dropout probability, learning-rate) was explored through a suitable grid-search, but the configuration found for the latter is more complex than the first one.

The comparison between the two approaches is evaluated by computing accuracy indicators and by using a k-fold approach with $k = 5$. In particular, the dataset is partitioned into 5 folds and

1. the model is estimated on the training set, consisting of 4 of the 5 folds;
2. the results are applied on the test set, composed of the remaining fold;
3. accuracy indicators are calculated only on the test set as the difference between estimated and observed ALE.

Tasks 1-3 are repeated 5 times so to reconstruct the entire data set. In order to take into account the variability introduced by the imputation obtained through a random draw from the estimated probability distribution, the procedure is repeated 100 times and the results are obtained as the average of indicators over these runs.

In Table 1, we report the percentage of correct classification obtained by comparing the imputation and the value observed in the sample (considered as the target value). This is an indicator measuring the error prediction, it is a micro-level accuracy indicator. The indicator is listed for each k-fold.

Table 1: Micro-level accuracy in the 5 test sets averaged over 100 runs: MLP1 *vs* MLP2.

K-fold	MLP1	MLP2
1	71.521	71.622
2	71.648	71.598
3	71.350	71.616
4	71.405	71.545
5	71.385	71.494
Mean	71.462	71.575
St. Dev.	0.110	0.049

The means of the micro accuracy computed in the two approaches are very similar (71.5 vs 71.6) while MLP2 shows a lower variance between folds due to the fact that each fold is a simple random sample of the target population.

In order to evaluate the two MLP procedures at a macro level, the estimated ALE is compared with the observed ALE, appropriately weighted. In particular, we focus on the differences between the frequency distributions of estimated ALE ($\widehat{ALE}$) and the target distribution computed on weighted sample data ($\widehat{ALE}_S$). A synthetic measure of the difference between distributions is given by the average of the absolute values of the differences between percentage of each item, in absolute (AD) and relative

(RD) terms. Specifically:

$$AD = \frac{\sum_i^8 D_i}{8} = \frac{1}{8}\sum_i^8 |fr(\widehat{ALE})_i - fr(\widehat{ALE}_S)_i| \quad (1)$$

$$RD = \frac{\sum_i^8 Dr_i}{8} = \frac{1}{8}\frac{\sum_i^8 |fr(\widehat{ALE})_i - fr(\widehat{ALE}_S)_i|}{fr(\widehat{ALE}_S)_i} \cdot 100$$

where $fr(\widehat{ALE})_i$ is the percentage frequency of estimated ALE item i by MLP1 or MLP2 and $fr(\widehat{ALE}_S)_i$ is the target percentage frequency of ALE item i estimated with the weighted sample.

Table 2: Macro-level accuracy in the 5 test sets averaged over 100 runs: AD and RD indicators for MLP1 and MLP2.

	AD		RD	
K-fold	MLP1	MLP2	MLP1	MLP2
1	0.131	0.045	3.069	2.231
2	0.086	0.072	3.327	3.324
3	0.129	0.104	5.476	5.013
4	0.118	0.088	3.098	2.496
5	0.119	0.106	4.101	3.909
Mean	0.117	0.083	3.814	3.395
St. Dev.	0.016	0.023	0.911	1.005

As shown in Table 2 the MLP2 gives origin to a slightly better macro-level accuracy: the mean AD decreases from 0.117 to 0.083 and the mean RD from 3.814 to 3.395. We remark that, the improvement is only due to the expanded format of the sample data and not to the use of additional information. The increase of variability for MLP2 with respect to MLP1 reflects the imputation phase of the procedures: for MLP1 the ALE item is randomly extracted from the probability distribution of the correspondent modality, whereas for MLP2 the extraction is made for each unit from the expanded dataset.

Table 3: Macro-level accuracy by ALE modality in test set 2 averaged over 100 runs: AD and RD indicators for MLP1 and MLP2 and percentage frequency of the ALE modality in the weighted sample (n%)

	AD		RD		
	MLP1	MLP2	MLP1	MLP2	n%
Illiterate	0.02	0.05	6.53	12.09	0.38
Literate but no ed. Att.	0.05	0.03	3.51	2.33	1.47
Primary education	0.09	0.13	0.62	0.83	15.21
Lower secondary ed.	0.12	0.09	0.41	0.32	28.14
Upper secondary ed.	0.15	0.14	0.38	0.35	36.09
Bachelor's degree	0.10	0.04	2.75	1.05	3.70
Master's degree	0.11	0.07	0.96	0.58	11.59
PhD	0.04	0.03	11.45	9.04	0.42

In Table 3, the difference between estimated and target ALE for each modality is reported for the two approaches. A relevant advantage in the use of MLP2 is obtained for the Bachelor's degree: this

modality is difficult to impute due to the heterogeneity of the individual course of studies.

To conclude, the standard MLP applied to the expanded dataset allows a gain in micro and macro level accuracy without any additional information, on the other hand, increasing the neural network complexity entails an increase of the computational time.

Abstract

The aim of this study is to analyse policy actions and institutional changes in local governance structures as determinants of air pollutant reductions in US urban areas. First, we construct a dataset on traffic-related air pollution and socio-economic characteristics across urbanized areas of the US. Some of these data are available through Google Earth engine, others are instead provided by institutional sources. In general, raw data come from application of machine learning techniques to either satellite images or monitoring station records and are available at different temporal and spatial resolutions. Then we adopt regression discontinuity design techniques for the evaluations of pollution reduction policies, exploiting the designation of US Transport Management Areas as a quasi-experimental framework.

Keywords: air pollution, policy evaluation, regression discontinuity design, machine learning

1. Introduction

Road traffic is one of the main contributors to air pollution and greenhouse gasses around the world (among others McDuffie et al., 2021). The mixture of vehicle exhausts from fuel combustion and non-exhaust from engine, brake, tire, and road surface wear and re-suspended street dust materials significantly contributes to particulate matter (PM), nitrogen oxides (NOx), and carbon dioxide (CO2) emissions (European Environment Agency, 2016). These emissions disperse into the ambient air as traffic-related air pollution (TRAP), which degrades ambient air quality.

Humans exposed to TRAP are at a higher risk of developing a wide range of adverse health effects, from premature mortality and cardiovascular illness to cognitive and metabolic effects (Fu et al., 2021; Khreis, 2020). On top of these direct effects, there are additional societal burdens: medical costs, missed school days and workdays (among others Nurmagambetov et al. 2018), reduced workers' productivity (Chang et al. 2016), and brain drain (Xue et al. 2021).

Most human exposures to TRAP happen in urban areas (Kura et al., 2013). Even if air quality in western countries has improved enormously in the past decades, most cities around the world struggle to meet air quality standards and guidelines (World Health Organization). Since the number of urban residents is expected to grow rapidly around the world (United Nations and Department of Economic and Social Affairs Population Division, 2022), a greater quantity of people will soon be at risk of TRAP exposure.

With this in mind, the aim of this work is to analyse policy actions and institutional changes in local governance structures as determinants of air pollutant reductions in US urban areas over the last decade. We exploit the designation of Transport Management Areas (TMAs) as a quasi-experimental framework. TMAs are designated by the US Secretary of Transportation for urbanized areas that overcome the population threshold of 200,000 as defined by the Bureau of Census, in recognition of the complexity of transportation issues. They are subject to several transportation planning requirements among which a Congestion Management Process and an Air Quality Plan.

From the methodological point of view, we rely on Regression Discontinuity Design (RDD) techniques, a long-standing way to obtain credible causal estimates that is gaining increasing popularity in recent times (among others, Cattaneo and Titiunik, 2022). Like other causal inference approaches, the RDD can benefit from the combination with machine learning methods, both to carry out supplementary analyses enhancing the credibility of the results and to handle specific computational issues, such as bandwidth determination (Athey and Imbens, 2017).

As for the data, we construct a dataset on TRAP and socio-economic characteristics across urbanized areas of the US. Some of these data are available through Google Earth engine, others are instead provided by institutional sources like NASA or Environment Protection Agency (EPA). In general, raw data come from application of machine learning techniques to either satellite images or monitoring station records and are available at different temporal and spatial resolutions. The preliminary aim of this work is to gather and merge data on specific variables from different sources and harmonize them to produce a novel dataset to be used for the main objective of the paper that is evaluating via RDD the effectiveness of policy actions implemented in US urban areas with the objective of containing TRAP.

The structure of the paper is as follows. In the second section we present our methodological framework. In the third section we describe the model and the data set. In the last section we illustrate some preliminary results.

2. Methods

In this section we will present our methodological framework.

2.1 Regression Discontinuity Design

A large literature on causal inference for policy evaluations has focused on methods for statistical estimation to answer a question about the counterfactual impact of change in a policy (or treatment). The policy change has not necessarily being observed before or may have been observed for a subset of the population. The goal is then to estimate the impact of small set of treatments using data from randomized experiments or, more commonly, observational studies (that is non-experimental data). The literature identifies a variety of assumptions that, when satisfied, allow the researcher to draw the same type of conclusions that would be available from a randomized experiment.

Drawing inference about the causal effect of a policy from observational data is rather challenging. The main issue is that there are factors, which may be unobserved that are said confounders in the sense that they induce correlation that is not indicative of what would happened if the policy had been changed. In this sense, identification strategies are central to causal inference and in economics the RDD is among the most credible, because it relies on weak and easy to implement non parametric identifying assumptions which permit flexible and robust identification and inference for local treatment. The key feature of RDD is the existence of a score, or running variable, for each unit of the sample, which determines treatment assignment via hard-thresholding: all units whose score is above a known cutoff are treated, while all units below the cutoff are not treated. Identification, estimation, and inference proceed by comparing the outcomes of units near the cutoff taking those below (control group) as counterfactuals to those above (treatment group). For extensive literature reviews, see, among others, Lee and Lemieux (2010) and Cattaneo and Titiunik (2022).

In this work we adopt the potential outcome (or continuity) approach[1], introduced by Hahn et al.

[1] As a complement to the potential outcome approach, Cattaneo et al. 2015, introduced the local randomization

(2001), where potential outcomes are taken as random variables, with the n units of analysis forming a random sample from an underlying population and the running variable, or score, X is assumed to be continuously distributed. Let $Y_i(0), Y_i(1)$ denote the pair of potential outcomes for unit i and let $T_i \in \{0, 1\}$ denote the treatment[2]. The realized outcome is $Y_i = Y_i(T_i)$. The treatment received is a function of the running (pretreatment) variable X_i, more specifically $T_i = I_{X_i \geq c}$, where c denotes the threshold or cutoff, that must be exogenous. Formally, the treatment effect is defined from the following identity

$$\tau = E\left(Y_i(1) - Y_i(0)|X = c\right) \tag{1}$$

The two key assumptions for identifications are: a) the regression functions $E\left(Y_i(0)|X_i = x\right)$ and $E\left(Y_i(1)|X_i = x\right)$ are continuous in x at c and b) the density of the running variable near the cutoff is positive. These assumptions capture the idea that units that are barely above and below the cutoff c would exhibit the same average response if their treatment status did not change. Then by implication, any difference between the average response of treated and control units at the cutoff can be attributed to the treatment and can be interpreted as the causal average effect, estimated as the discontinuity in the conditional expectation of Y_i as a function of the running variable at the cutoff:

$$\tau = lim_{X \to c^-} E\left(Y_i|X_i\right) - lim_{X \to c^+} E\left(Y_i|X_i\right) \tag{2}$$

In practice, we have

$$\begin{array}{c|c} -h \leq X_i < c & c \leq X_i < h \\ Y_i = \beta_{0-} + (X_i - c)\beta_{1-} + \epsilon_{i-} & Y_i = \beta_{0+} + (X_i - c)\beta_{1+} + \epsilon_{i+} \end{array}$$

where $\hat{\tau}_{RD} = \hat{\beta}_{0+} - \hat{\beta}_{0-}$ is the vertical distance between the two estimated expectations, h is bandwidth that guarantees that only units that are close to the cutoff c are involved, ϵ_{i-} and ϵ_{i+} are error terms.

The idea is to estimate regression functions for control and treatment group locally and this, in its most basic fashion, can be done by estimating

$$Y_i = \alpha + \tau_{RD} T_i + (X_i - c)\beta_1 + \epsilon_i, \quad -h \leq X_i \leq h \tag{3}$$

where $\hat{\tau}_{RD}$ is the desired estimated discontinuity and ϵ_i is the error term. As mentioned above, the regression is estimated on a subsample of the data that is statistically optimally close to the cutoff so that units are most comparable each other and this should reduce the influence of the confounding factors. However, this reduces also the number of available observations and thus makes estimates and causal inference increasingly imprecise, limiting the ability to access policies. Thus one needs to identify an optimal bandwidth around the cut-off that optimally balances variance and bias. There are several methods to find the optimal bandwidth (e.g. Imbens and Kalyanaraman, 2012). A very interesting recent proposal is a machine learning based method developed by Long and Rooklyn (2020)

Typically researches tend to estimate model (3) adopting local polynomial methods tailored to flexibly approximate, above and below the cutoff, the unknown conditional mean function of the outcome variable given the running variable. In practise, researchers often choose a local linear polynomial and perform the estimation using weighted linear least squares, giving higher weights to observations close to the cutoff. If present, this discontinuity is interpreted as some average response to the treatment at the cutoff, depending on the assumptions and the setting under examination.

2.2 Machine Learning Algorithms

The machine learning literature has traditionally focused on discovering pattern and on prediction, using data-driven approaches to build rich models and relying on cross-validation as powerful tool for model selection.

framework that is built on the idea that near the cutoff the RD design can be interpreted as a randomized experiment or more precisely as a natural experiment.

[2]See for example Imbens and Rubin (2015) for more details on this set-up.

Supervised machine learning tools could be useful for causal inference given that, similarly to regressions, can summarise linear and non-linear relationships in the data and make predictions (Varian, 2014). However, given the lack of interpretable coefficients for some of the algorithms and the lack of standard errors of the obtained coefficients, predictions tools from these literature cannot be readily used for causal inference. Nevertheless, one particularly mature strand of literature includes approaches that incorporate supervised machine learning techniques in the so-called supplementary analyses to improve the credibility of the policy evaluations, such as placebo analysis, internal validity, external validity for RDD methods (Athey and Imbens, 2017). Moreover, in causal inference many estimators involve the specification of parameters, such as the optimal bandwidth in RDD, which are not interest per se, but are necessary to estimate the target parameter, and their determination can be done via machine learning (Long and Rooklyn, 2020). Overall, while most machine learning methods cannot be used to infer causal effects, they can surely help the process.

From a different perspective, machine learning methods can have a fundamental role in the data processing that might be preliminary to subsequent causal inference analyses. This comes from the literature on machine learning methods to estimate variables investigated in geo- and environmental sciences (Wuepper and Finger, 2023). For example, in case of greenhouse gas emissions, data might not be available and researchers must rely on proxies. Most natural phenomena are non-linear, multivariate, highly variable and correlated at many spatio-temporal scales. The analysis and treatment of such complex data and their integration/assimilation with science-based models is a difficult problem that is addressed by contemporary machine learning approaches, e.g. random forest algorithms to generate new variables even directly in Google Earth Engine (2022). Given the growing abundance and improving resolution (spatial, temporal, and spectral) of satellite imagery, in a recent review of the field, Burke et al. (2021) discuss the rapidly increasing literature regarding satellite imagery and measurements of different human outcomes, with specific attention to approaches that combine imagery with machine learning. Researchers in economics also increasingly use satellite imagery, and particularly nightlights imagery, for a variety of applications (among others, Henderson et al., 2012).

3. Model and Data

In order to evaluate the impact of policy actions and institutional changes in local governance structures on air pollutant reductions in US urban areas we will consider the TMAs designation as quasi-natural framework. TMAs are designated by the US Secretary of Transportation for urbanized areas that overcome the population threshold of 200,000 as defined by the Bureau of Census, in recognition of the complexity of transportation issues. When an urban area is designated as a TMA, the Metropolitan Planning Organization (MPO) responsible for that urban area (an MPO is mandatory for urban areas with population over 50,000) is subject to several transportation planning requirements among which a Congestion Management Process

Here, with reference to TMA designation after 2010 Census, we estimate a (very preliminary) RDD model for year 2015. The statistical units are the urbanized areas and the running variable is the population. Treated units are those that, overtaking the threshold $c = 200,000$, have been designed as TMAs. The RDD model we have in mind is:

$$Y_i = \alpha + T_i \tau_{RD} + (X_i - c)\beta + \mathbf{Z}_i\gamma + \epsilon_i, \quad -h \leq X_i \leq h \tag{4}$$

where for each statistical unit i, Y is the level of traffic related pollutant C02, X is the population (running variables), $\mathbf{Z}$ is a vector of covariates, specifically income (proxied by the nightlights) and meteorological variables, such as wind and precipitations, ϵ_i is the error term. The regression is run considering urbanized areas whose value of the running variable is close to the cutoff $c = 200,000$, according to the bandwidth h.

To conduct this analysis, we build a novel dataset, from the following data sources:

Population, TMA designation (source US Census Bureau and US Federal Register): these sources provide information also on the shapefiles for the administrative boundaries of the urbanized areas.

Traffic-related CO2 (source NASA): DARTE (Database of Road Transportation Emissions) data set provides a 38-year, 1-km resolution inventory of annual on-road CO2 emissions for the contermi-nous United States based on roadway-level vehicle traffic data and state-specific emissions factors for multiple vehicle types on urban and rural roads.

Nightlights (source Google Earth Catalog): VIIRS Nighttime Day/Night Band Composites Version 1 provides monthly average radiance composite images using nighttime data from the Visible Infrared Imaging Radiometer Suite (VIIRS) Day/Night Band (DNB).

Wind and precipitations (source Google Earth Catalog): TerraClimate is a dataset of monthly climate and climatic water balance for global terrestrial surfaces.

4. Some results

In the presentation of some preliminary results, we show the estimation of the basic version of model (4), that is the RDD regression without covariates:

$$Y_i = \alpha + T_i\tau_{RD} + (X_i - c)\beta + \epsilon_i, \quad -h \leq X_i \leq h \tag{5}$$

Figure 1 shows the local estimation of model (5). It is a local polynomial estimation of degree 2, with triangular kernel where the bandwidth has been optimally selected by MSE minimization, as suggested in Calonico et al. (2014), leaving for a more advanced version of the paper the estimation with a bandwidth selected with machine learning criteria (see section Sect. 2.). In the graph it is evident the discontinuity at the cutoff of the conditional expectation of Y as a function of the running variable: this represents the local effect of the treatment.

Moving now to Table 1, we can see that the treatment effect is significant at 10% level and it has a negative sign, as expected. This confirms the idea of a possible effect of the TMAs designation on the levels of traffic related C02, that will be further explored in a more advanced version of the paper through the estimation of model (4), i.e. in the version including covariates. However, given that the effect is not so strongly significant, we shall also consider other case studies of pollution containment policies.

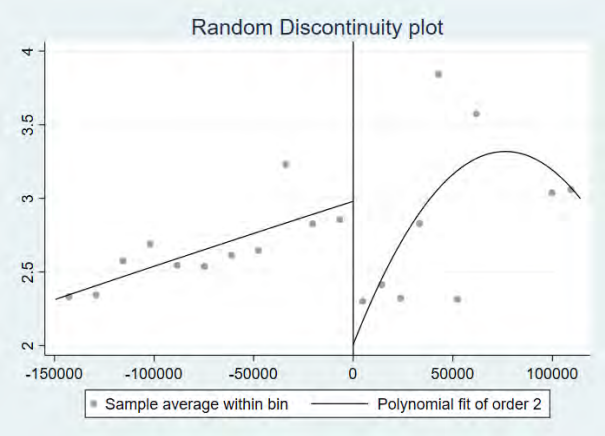

Figure 1: Random discontinuity plot for basic RDD with local polynomial regression

Table 1: Basic RDD estimation with local polynomial regression

Method	Coeff	Std. Error	z	$P > \|z\|$
Conventional	-1.2167	.68582	-1.7741	0.076
Robust	-	-	-1.7200	0.085

Abstract

Spatial prediction, accounting for spatial dependence, has been a topic of significant interest in spatial statistics. While the Gaussian process (GP) has been a popular tool for spatial prediction, it can be limited by the need to estimate a stationary spatial covariance function and its computational demands for large datasets. As a result, deep neural networks (DNNs) have emerged as an alternative to standard approaches, such as kriging, for spatial prediction. This paper briefly discusses the use of DNNs with basis functions as input variables for modelling spatial dependence and obtaining spatial predictions.

Keywords: Spatial Prediction, Gaussian process, Deep learning, Deep Gaussian processes, Low-rank models

1. Introduction

Spatial statistics is concerned with the analysis of data that have spatial locations associated with them. These spatial locations are used to model statistical dependence between the data, as they can provide important information about the underlying spatial process.

Statistical methods for modelling spatial data are well summarized in literature and relevant references are (2) and (4). The spatial data are treated as a single realization from a probability model that encodes the dependence through both fixed effects and random effects, where randomness is manifest in the underlying spatial process and in the noisy and usually incomplete measurement process. If $\mathbf{z} = \big(z(\boldsymbol{s}_1), \ldots, z(\boldsymbol{s}_n)\big)'$ are measurements observed at n spatial locations, $\boldsymbol{s}_1, \ldots, \boldsymbol{s}_n$, from a real-valued spatial process $\big\{Y(\boldsymbol{s}),\ \boldsymbol{s} \in D\big\}$, with $D \subset \mathcal{R}^d$, a widely used representation of the random process is:

$$Z(\boldsymbol{s}) = Y(\boldsymbol{s}) + \epsilon(\boldsymbol{s}) \tag{1}$$

where $\epsilon(\boldsymbol{s})$ is a sequence of uncorrelated Gaussian random variables, each with mean 0 and variance σ^2_ϵ. The process $Y(\boldsymbol{s})$ corresponds to the true (latent) spatial process vector of interest for which we further assume the following decomposition:

$$Y(\boldsymbol{s}) = \mu(\boldsymbol{s}) + \eta(\boldsymbol{s}) \tag{2}$$

where, $\mu(\boldsymbol{s})$, represents a spatial mean component and, $\eta(\boldsymbol{s})$, is a zero mean spatially-dependent random process with covariance matrix $\boldsymbol{\Sigma}_\eta$. Usually, the mean, $\mu(\boldsymbol{s})$, is a parametrized function of spatial covariates, $X_j(\boldsymbol{s}),\ j = 1, \ldots, p$.

Predicting or interpolating the variable of interest, Y, at some unobserved location $\boldsymbol{s}_0$, it is of particular interest in spatial analysis. Some data sets, in fact, may have missing values at some sites and these missing values may be separated or clumped. While separated missing values may occur in case of instrument malfunctions, an example of clamped missing values, may be represented by passive satellite images due to cloud presence.

In practice, many different methods exist for spatial prediction, and the choice of a given method will depend on the specific characteristics of the data being analysed. Gaussian processes, neural networks, and deep learning models are all powerful tools for spatial interpolation, and can be used to capture complex spatial structures and dependencies that may be difficult to model with traditional methods, such as kriging. This paper provide a brief introduction on the use of low-rank model representations for using these methods in the context of spatial interpolation.

2. Gaussian Processes

A popular assumption for the noise-free process $Y(\boldsymbol{s})$ of Eq. (2) is that it can be interpreted as a Gaussian Process. From a practical perspective, finite dimensional realizations of a GP are simply multivariate Gaussian and we can thus assume that $\mathbf{Y} \sim N(\boldsymbol{\mu}, \boldsymbol{\Sigma}_\eta)$, where $\mathbf{Y} = \big(Y(\boldsymbol{s}_1), \ldots, Y(\boldsymbol{s}_n)\big)'$, $\boldsymbol{\mu} = \big(\mu(\boldsymbol{s}_1), \ldots, \mu(\boldsymbol{s}_n)\big)'$ and $\boldsymbol{\Sigma}_\eta$ depends on a parameter vector $\boldsymbol{\theta}$ which specifies the spatial covariance function. If the mean, $\mu(\boldsymbol{s})$, is taken to be a linear combination of covariates such that $\mu(\boldsymbol{s}) = \boldsymbol{x}(\boldsymbol{s})'\boldsymbol{\beta}$, where $\boldsymbol{x}(\boldsymbol{s}) = \big(1, x_1(\boldsymbol{s}), \ldots, x_p(\boldsymbol{s})\big)'$ and $\boldsymbol{\beta}$ are associated fixed effects, simple estimation of the parameters, $\boldsymbol{\beta}$ and $\boldsymbol{\theta}$, can be obtained by maximum likelihood and predictions at new locations simply reduces to computing the conditional expectation $\hat{Y}(\boldsymbol{s}_0) = E\big[Y(\boldsymbol{s}_0)|\mathbf{z}\big]$.

3. Multi-Layer neural networks

Neural networks (NN) can be used for a variety of tasks, including, for example, nonparametric regression. One advantage of NN in this framework, is that they can model non-linear relationships between the input and output variables, which can be difficult to capture with traditional regression methods. The regression function is of the form, $E\big[Z(\boldsymbol{s}_i)\big] = f\big(\widetilde{\mathbf{x}}(\boldsymbol{s}_i)\big)$, where $\widetilde{\mathbf{x}}(\boldsymbol{s}_i)$, is a suitable vector of covariates and $f(\cdot)$ is a non-linear function. The unknown non-linear regression function $f(\cdot)$, which describes how the inputs $\widetilde{\mathbf{x}}(\boldsymbol{s}_i)$ are translated into outputs $Z(\boldsymbol{s}_i)$, is learnt through the specification of multiple layers (i.e., multi-layer perceptrons, MLP) of interconnected processing nodes, or neurons, which include: an input layer, one or more hidden layers, and an output layer. Each neuron in the hidden layer receives inputs from the neurons in the previous layer and computes a weighted sum of the inputs, which is then passed through an activation function to produce the output. Formally, if L is the number of hidden layers in the model, and P_l is the number of hidden neurons for layer l, the steps of the network compute the following quantities:

$$\begin{aligned} \widetilde{\boldsymbol{x}}_l(\boldsymbol{s}_i) &= f_l\Big(\mathbf{b}_l + \mathbf{W}_l\, \widetilde{\boldsymbol{x}}_{l-1}(\boldsymbol{s}_i)\Big), \;\; l = 1, \ldots, L \\ E\big[Z(\boldsymbol{s}_i)\big] &= f_{L+1}\Big(b_{L+1} + \sum_{j=1}^{P_L} w_{L+1,j}\, \widetilde{x}_{L,j}(\boldsymbol{s}_i)\Big) \end{aligned} \tag{3}$$

where $\widetilde{\boldsymbol{x}}_0(\boldsymbol{s}_i) = \widetilde{\boldsymbol{x}}(\boldsymbol{s}_i)$, $\widetilde{\boldsymbol{x}}_l(\boldsymbol{s}_i)$ represents a P_l-dimensional vector of neuron values at layer l, $\mathbf{W}_l$ is a $(P_l \times P_{l-1})$ matrix of weights, $\mathbf{b}_l$ is a $(P_l \times 1)$ vector of intercepts, and $f_l(\cdot)$ is the activation function that accounts for non-linear relationships between the inputs and the outputs. The choice of the activation functions is made before the training, and the weight matrices are estimated during the training process. In any case, the final activation function f_{L+1} is chosen so as to match the support of $Z(\boldsymbol{s}_i)$ at the output layer. If $Z(\boldsymbol{s}_i)$ is real-valued, then f_{L+1} is typically the identity function. Parameter estimation in NN is done using back-propagation and, during the training, the weights and biases of the neurons are adjusted to minimize the error between the predicted output and the actual output. For classical

regression problems, the fit accuracy is usually measured by the mean squared error (MSE) between observed and predicted values.

4. Deep Gaussian Processes and low-rank models

The two paradigms reviewed in Sect. 2. and 3. are complimentary in their scope. The popularity of GP is owed to their simplicity and model interpretability. However, it is also known that they suffer from the following three limitations:

1. applying GPs and Kriging requires estimating the spatial covariance function, which is commonly assumed to be stationary;
2. the mean of the process, $\mu(\boldsymbol{s})$, very often relies on the strong assumption of a linear covariate effect;
3. GPs and Kriging can be computationally prohibitive for large spatial datasets, since they involve computing the inversion of $\boldsymbol{\Sigma}_\eta$, which may be large in many applications.

Given that spatial processes can exhibit non-Gaussian distributions, non-stationarity, and complex spatial patterns, many practitioners are turning to neural networks to address these limitations. However, while neural networks are capable of estimating arbitrary non-linear covariate effects, they assume that the data units are independent. To address these challenges, deep neural networks (DNNs) have received considerable attention in the context of geospatial data and interpolation (see (12) for a comprehensive review).

In particular, recent approaches based on neural networks to model spatial data often use spatial coordinates or some form of transformation, such as distances or basis functions, as additional covariates (see, for example, (3)). These methods thus incorporate all spatial information (covariates and space) directly into the mean.

To provide a link between this approach and Eq. (1) and (2), we note that the process $Z(\boldsymbol{s})$ has the following basis-function representations:

$$\begin{aligned} Z(\boldsymbol{s}) &= \boldsymbol{x}(\boldsymbol{s})'\,\boldsymbol{\beta} + \eta(\boldsymbol{s}) + \epsilon(\boldsymbol{s}), \\ &= \boldsymbol{x}(\boldsymbol{s})'\,\boldsymbol{\beta} + \sum_{j=1}^{q} \alpha_j\,\psi_j(\boldsymbol{s}) + \xi(\boldsymbol{s}) \\ &= \widetilde{\mathbf{x}}(\boldsymbol{s})'\,\boldsymbol{\gamma} + \xi(\boldsymbol{s}), \end{aligned} \tag{4}$$

where $\tilde{\mathbf{x}}(\boldsymbol{s}) = \big(\boldsymbol{x}(\boldsymbol{s})',\ \boldsymbol{\psi}(\boldsymbol{s})'\big)$ is a P-dimensional dimensional vector of covariates, $\boldsymbol{\psi}(\boldsymbol{s}_i)$ is a q-dimensional expansion vector that maps the low-dimensional latent process, $\boldsymbol{\alpha}$, to $\eta(\boldsymbol{s})$, $\boldsymbol{\gamma} = \big(\boldsymbol{\beta}', \boldsymbol{\alpha}'\big)'$, and the error term $\xi(\boldsymbol{s})$ is a stochastic process independent of the basis-function coefficients. The inclusion of $\xi(\boldsymbol{s})$ in Eq. (4) accounts for the error incurred by using only a finite number of basis functions. It preserves variability of $Z(\boldsymbol{s})$, and in that sense, Eq. (4) is a statistical model, not an approximation, of spatial variability.

The representation given in Eq. (4) can be obtained as a result of the Karhunen-Loéve (KL) theorem (1). Furthermore, the basis functions in Eq. (4) may be defined by truncations of a countable basis, or they may simply be functions thought to be important for representing the spatial variability. For example, basis functions can come in the form of splines (11), wavelets (10), bisquare functions (5), Wendland functions (9), and finite elements (7). Physical basis functions or the output of a numerical model, such as an atmospheric-transport model could also be used as basis functions.

The relationship between the GP and a NN can be seen by first noting that, in a single layer NN, assuming f_l is an identity function and no covariates $\boldsymbol{x}(\boldsymbol{s})$ are involved, $E\big[Z(\boldsymbol{s}_i)\big]$ results in a linear function of the basis functions $\psi_j(\boldsymbol{s})$ similarly to Eq. (4). Furthermore, upon the orthogonalisation of the set of basis functions, $\big(\widetilde{\mathbf{x}}_{L,j}(\boldsymbol{s}_1), \ldots, \widetilde{\mathbf{x}}_{L,j}(\boldsymbol{s}_n)\big)'$, $j = 1, \ldots, P_L$, Eq. (3) demonstrates that, for $P_L \to \infty$, an infinitely wide NN provides a representation of a GP. To this purpose, (8) and (6) establish that it is possible to fit a NN of infinite widths via Bayesian training using GP priors. Clearly, rather

than using infinitely wide NNs, an NN with large hidden layer widths and depths can be specified to approximate the process.

After selecting a family of basis functions, the training process of the neural network involves iteratively switching between feed-forward (obtaining the fits based on the current estimates of the weights) and back-propagation (updating the weights based on the current fits). In general, the NN can be trained over all the available sample though estimation can be expedited by splitting the data into smaller and disjoint mini-batches. After estimating the full set of parameters, say $\widehat{\boldsymbol{\Omega}}$, of the neural network, spatial prediction of the process at an unobserved location can be obtained by evaluating Eq. (3) at the desired site, denoted by $\boldsymbol{s}_0$.

5. Discussion

By drawing from recent literature on DNNs and GPs, we have briefly discussed a framework that uses low-rank model representation of a spatial process and basis functions as input variables in DNNs for modeling spatial dependence. This approach opens up avenues for exploring the potential of deep learning in spatial prediction. For future work, we plan to evaluate the effectiveness of neural networks for spatial prediction under different scenarios, including non-Gaussian and non-stationary processes, and to compare their performance with traditional prediction methods such as kriging. We will also investigate various choices of basis functions and show that, for certain options, specific forms of DeepKriging (3) can be obtained in both one- and two-dimensional settings. Additionally, we will explore methods for quantifying the uncertainty associated with predictions. Results from simulations as well as real environmental data, will be presented to demonstrate the effectiveness of the approach for spatial prediction.

Abstract

Random Forest (RF) is a Machine Learning algorithm, very popular in environmental applications thanks to its flexibility and predictive performances. Even if its working mechanism is simple and intelligible, RF is considered a *black box* model since it prevents grasping how predictors are combined to generate the response variable predictions. This lack of interpretability represents a limitation of RF, especially when some knowledge is required on the response-predictors relationship from the decision-making perspective. In this work, we aim to explain RF using a Post-Hoc approach, i.e. by extracting a compact and simple list of rules from an estimated RF focusing on a spatial regression context. By means of a spatial dataset, we compare the final sets of rules and discuss the predictive accuracies of the standard RF and its *gold standard* for the case of spatially correlated data.

Keywords: Explainable Machine Learning, inTrees, Post-hoc methods, Rule extraction, RF-GLS

1. Introduction

The Machine Learning (ML) era has given rise to complex and powerful methods that can process vast amounts of data and make predictions with remarkable accuracy. However, the inherent *black-box* nature of some of these techniques has raised concerns about their lack of interpretability. Often the term *interpretability* is used as a synonym for *explainability*, but actually they refer to two different concepts. According to Rudin *et al.* (11), interpretability is referred to models that are built to be interpretable, while explainability is obtained by applying further techniques to non-interpretable models in order to extract information. On the topic of explainable ML methods, the recent paper by Wikle *et al.* (14) is worth to be mentioned. In particular, the authors discuss the use of explainability techniques in spatial ML to understand the role of specific inputs in predicting environmental variables. Even if from a statistical point of view the gold standard would be to use interpretable ML methods, when this is not possible it is a good practice to try to extract information from non-interpretable ML methods that have proven good performance.

In this work, among ML techniques, we consider Random Forest which is well known for its high prediction accuracy. It is a non-parametric supervised algorithm that, thanks to its flexibility, can model complex non-linear relationships between the response variable (categorical or continuous) and the predictors (3). RF is defined as an ensemble model as the result of aggregating a set of decision trees. Each tree is the result of a recursive binary splitting process obtained using re-sampled data and a random

set of predictors evaluated at each node as splitting candidates. Given its adaptability, RF has also been widely applied in the spatial framework with different strategies to deal with the spatial autocorrelation of the data. Patelli *et al.* (10) have recently proposed a literature review and a novel taxonomy of the existing strategies adopted to adjust RF for spatially correlated data. In particular, the authors highlight that the most interesting strategy is the RF-GLS method proposed by Saha *et al.* (12), who extend the RF by estimating trees using generalized least squares (GLS). It was proven that RF-GLS outperforms the classical RF in the presence of spatial correlation, thus representing the gold standard to be used in the spatial framework.

In any case, spatially aware or not, RF remains a non-interpretable algorithm. However, it is possible to use specific methods to explain the RF resulting model, as described in the review by Haddouchi and Berrado (7). In particular, "Internal Processing" (IP) methods try to get "insights that are inherent to internal processing" providing a global overview of the model. "Post-Hoc" (PH) methods instead are based on RF post-processing, such as for example the "Rule Extraction" (RE) approaches (see e.g. inTrees (5), SIRUS (2), Node harvest (9) and RuleFit (6) among others). These methods aim to find a limited set of rules (each defined as the combination of predictors and split values) that is common to many trees in the RF and that allow representing the prediction mechanism of RF.

The main aim of this contribution is to verify if, for a spatial regression problem, there exist differences in the rules obtained by using - so far - the inTrees approach applied to two different cases: trees grown by RF-GLS and by a classical RF. We expect that taking or not into account the spatial correlation when implementing RF will have an impact also in its extracted rules. The analysis is carried out by using a dataset regarding daily meteorological records measured by 159 monitoring stations in Croatia. We present here preliminary results followed by a discussion on further steps.

2. Data and methods

The explainability of RF in the spatial framework is illustrated using meteorological daily data from the national network of 159 stations in Croatia for the year 2008, provided by the Croatian National Meteorological Service (available at `https://github.com/AleksandarSekulic/RFSI`). At this stage of the work, we have not considered the temporal dimension of the data confining the analysis to a single day: 14^{th} June 2008. The locations of the 151 stations working at this date are shown in Fig. 1. In particular, dots and crosses represent training and test data considered to implement the RF-GLS and RF algorithms. For this dataset, we randomly selected 90% of the data (i.e., 135 observations) for training the algorithms and used the remaining 10% of the data (i.e., 16 observations) for testing the algorithms. Croatia is a country located in southeastern Europe, bordering the Adriatic Sea. It has a diverse topography with flat plains in the east, a hilly central region, and mountainous terrain in the west. The response variable is the mean daily temperature[1] [`TEMP`], measured in degrees Celsius (°C). The minimum and maximum observed mean daily temperature values are 1.8°C and 21.5°C, respectively. The highest temperatures are recorded along the coast and at low altitudes. The variables used as predictors are latitude [`lat` (in meters)], longitude [`lon` (in meters)], distance-to-coastline [`HRdsea` (in km)], elevation [`HRDdem` (in meters)], wetness index [`HRtwi`], seasonal fluctuation [`ctd` (in days)], insolation (total incoming solar radiation) [`INSOL` (in Joules)], and Moderate Resolution Imaging Spectroradiometer land surface temperature [`MODIS.LST`] images. The dataset and predictors are detailed in (8) and references therein. In particular, this dataset was used by Sekulić *et al.* (13) to evaluate and compare the performance of a spatial interpolation method they proposed, i.e. the Random Forest Spatial Interpolation.

With the aim of obtaining simple, stable and accurate rules, we implemented the inTrees approach proposed by Deng (5) and implemented in the homonym `R` package `inTrees`[2]. The set of algorithms proposed in the work of Deng (5) can be applied to all tree ensemble methods to perform different tasks: extract, prune, select and summarize the rules. Each step is not mandatory, and the procedure can be tailored based on the specific explanatory necessity.

[1] On most meteorological stations `TEMP` is measured three times a day: at 7 am, 1 pm and 9 pm.

[2] `https://cran.r-project.org/web/packages/inTrees/index.html`

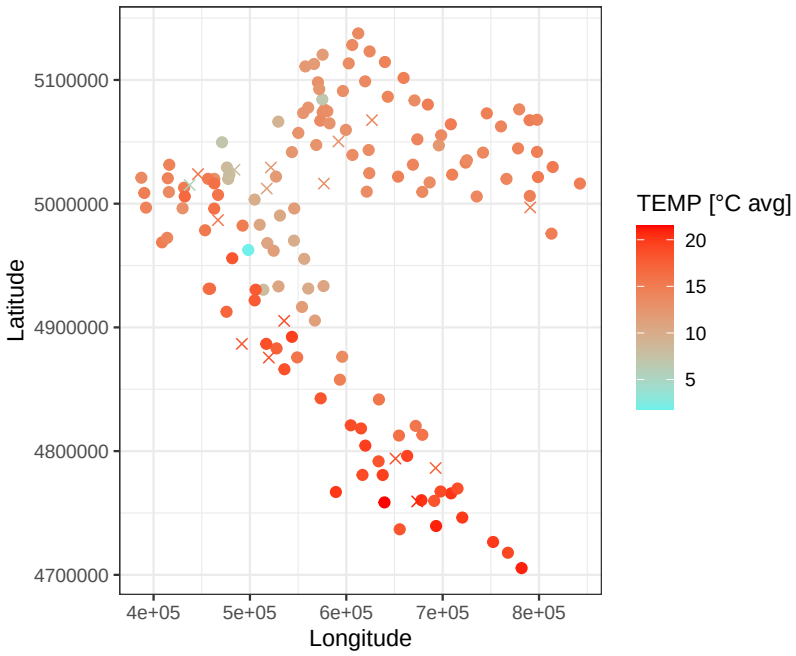

Figure 1: Mean daily temperature recorded on 2008-06-14 in 151 Croatian meteorological stations. Dots represent the mean daily temperature registered in the 135 training sites; crosses represent the mean daily temperature measured in the 16 test sites.

In order to extract and analyze rules by means of `inTrees`, the first step consists in running the chosen RF algorithm to have a collection of trees grown over a set of training data. Each tree results in the combination of all its splits, i.e. the conditions that permit splitting of the predictor space and getting predictions in the final regions. Then the obtained rules can be evaluated by using the relative "frequency" of occurrence, the prediction "error" and their "length" representing the rule complexity.

Using these metrics and considering opportune (decay) functions, the rules can be further simplified by pruning irrelevant predictor-split values. In order to have a compact rule set containing relevant and non-redundant rules, a complexity-guided condition selection method can be used, e.g. guided regularized Random Forest (GRRF) (4). In the end, the extracted rules can also be summarized by a rule-based learner that should be comparable in terms of prediction accuracy to the standard RF but more interpretable, named Simplified Tree Ensemble Learner (STEL). Note that in `inTrees` it is possible to build a STEL only for classification problems.

3. Preliminary empirical results

This section shows our preliminary results by applying the inTrees approach to extract insights from the RF-GLS and RF algorithms applied to the temperature spatial dataset.
We started by training the regression RF-GLS and RF on the same training set, by means of the R packages `randomForestGLS`[3] and `randomForest`[4], respectively. We used the same setting for the hyperparameters. In particular, we have set to 1000 the number of trees (`ntree` in `R`) and to 3 (one-third of the total number of predictors) the number of the variables randomly sampled as candidates at each split (`mtry` in `R`). For the RF-GLS, the covariance function used in modelling the spatial dependence structure among the observations was the default value, i.e. the exponential covariance function (`cov.mat` in `R`). Note that the coordinates [`lat`, `long`], measured in meters, have also been considered as predictors in both algorithms. In order to stabilize the forest structure, we followed the strategy pro-

[3] https://cran.r-project.org/web/packages/RandomForestsGLS/index.html
[4] https://cran.r-project.org/web/packages/randomForest/index.html

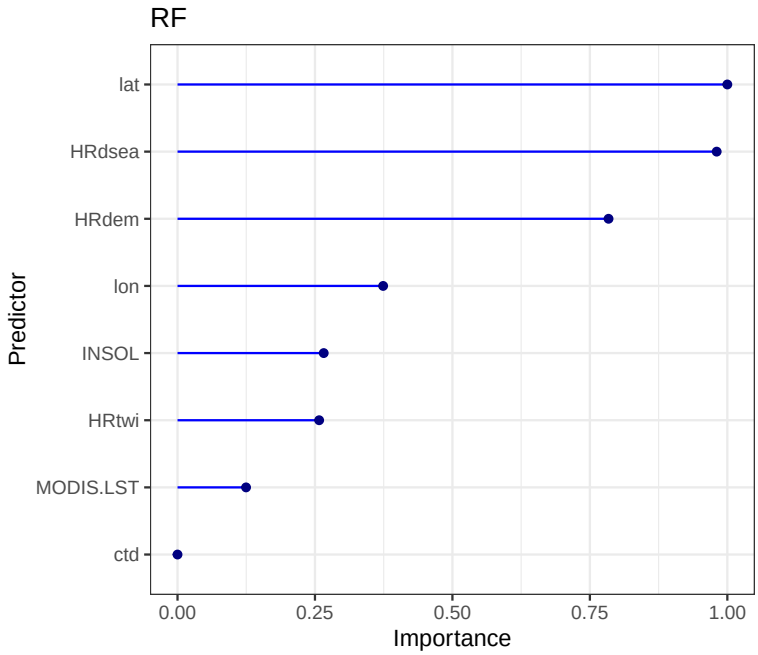

Figure 2: Variable importance plot for RF. The importance index is scaled to a maximum of 1.

posed in Bénard *et al.* (2) for rule generation consisting in restricting the node splits to the q-empirical quantiles of the predictors. This modification to Breiman's original regression tree algorithm is expected to have a small impact on predictive accuracy but is essential for stability.

Table 1 shows the test accuracy in terms of root mean square error and percentage of explained variance of the two algorithms when the node splits are restricted to the 10-empirical quantiles of the predictors. Different values of q will be considered in the next steps of the work. As expected, RF-GLS shows a better predictive performance than RF because it is able to capture the spatial autocorrelation of the response variable.

Table 1: Root Mean Square Error (RMSE) and percentage of explained variance (Var explained) values evaluated for the test dataset.

Algorithm	RMSE [°C]	Var explained [%]
RF-GLS	1.057	93.52
RF	1.357	89.32

Latitude, distance-to-coastline and DEM are the most important predictors for RF (see Fig. 2). This information is not reported for RF-GLS since the `R` package `randomForestGLS` does not provide the variable importance as output yet.

Given the two forests, we applied the inTrees approach described in Section 2. For both algorithms, RF-GLS and RF, we used the same setting for the tuning parameters of the `inTrees` functions. We extracted the rule conditions from the set of trees with a maximum length of 3 (`maxdepth` in `R`) from each tree. The distinct rule conditions extracted from the 1000 trees of RF-GLS and RF were 2,836 and 3,007, respectively. Then, we assigned the outcome values (mean of the response variable values of the training observations that satisfy the condition) [pred] to the conditions and measured the quality of the rules by "frequency" [freq], "error" [err], and "length" [len]. We pruned the extracted rules' irrelevant or redundant variable-value pairs considering the metric "error" and the "relative" decay function. With the irrelevant variable-value pairs being removed, the pruned rules have shorter conditions and a frequency that increases without an increase in error. Finally, we applied the complexity-guided regularized random forest (GRRF) to the set of distinct pruned rules in order to have two compact lists of stable rules (≤ 30)

able to explain the results of both algorithms. We grew 1000 trees, setting the importance threshold to 0.1 and using the default values for the other tuning parameters of the function `selectRuleRFF` in `R`. From a run of this function we obtained a list of 19 and 25 rules starting from the forests grown by the RF-GLS and RF algorithms, respectively. By applying both these lists of rules to test data we obtained a very good predictive performance: the percentage of variance explained was 92.01 and 90.17, respectively.

Table 2 and Table 3 show the two lists of the first ten rules output for the meteorological dataset. The scores [impRF] of the selected conditions are calculated by building an RF on the selected rules. In general, the two lists of selected rules have 17 rules in common. An example is represented by the first rule in Table 2 and Table 3. More specifically, the first rule in both lists shows that the interaction of a low latitude with a low elevation and a low distance to the coastline induces a higher mean daily temperature. The third rule in Table 2 (and then the fifth rule in Table 3) displays that the interaction of low longitude and a high elevation induces a mean daily temperature of about 9°C. This is composed of two conditions (lon<= 589199.5 & HRdem>317.40), and satisfied by the 14.8% of the observations in the training dataset and has an RMSE (the square root of "err") of about 2.2°C. One can notice that rule scores (importance values) and the rules metrics are not related. For instance, the fourth rule in Table 2 (and then the second rule in Table 3) has a larger frequency than the three most important ones.

Table 2: First ten rules extracted, measured, pruned and selected via GRRF, generated by RF-GLS. The rules are ordered by scores (importance value - ImpRF)

rule	len	freq	err	condition	pred	impRF
1	3	0.252	3.082	lat <= 4931735.37 & HRdem <= 609.20 & HRdsea <= 26.14	18.534	1
2	3	0.289	3.998	lon > 457787.2 & HRdem<=609.20 & HRdsea <= 26.14	18.160	0.893

4. Discussion and next steps

This work represents a first attempt to "open" an RF that is specifically designed for spatially dependent data, i.e. RF-GLS. This algorithm should be the gold standard in a spatial framework. We compared

the predictive performance and explainability of RF-GLS and RF applied to a Croatian meteorological dataset. Both algorithms have shown high and similar predictive performance in our application. A cross-validation procedure will be implemented to confirm this result. Among the different approaches existing in the literature to obtain explainability from RF, we focused on the rule extraction methods. In particular, we considered the approach proposed by Deng (5) applying the same constraints to the node splits proposed in Bénard *et al.* (2). We found two compact lists of rules with high predictive performance sharing a large number of rules in common. However, the shared rules have different scores (importance values) within their respective membership lists. As next step, we aim to tune the GRRF hyperparameters to reduce the number of rules in the two lists while maintaining their predictive performance. Moreover, we aim to set up a comparison study considering the main competitors of inTrees, i.e. SIRUS (2), Node harvest (9) and RuleFit (6). Unfortunately, the `R` functions implementing RF-GLS (`RFGLS_estimate_spatial` and `RFGLS_predict_spatial`) return objects that are not valid inputs for the `R` functions implementing the competitor rule extraction methods. This will require further investigation.

Abstract

Although literature on spatial point process models and associated techniques is now widely available, in problems related to multivariate settings and classification the methodology is scarce and far from being flexible enough. We here provide a mathematical framework for coupling neural network methods with the statistical analysis of point patterns with a focus on two problems. We first use deep convolutional neural networks and employ a Siamese framework to build a discriminant model for distinguishing structural differences between spatial point patterns. Then, we discuss an example of deep neural networks in the statistical analysis of highly multivariate spatial point patterns and provide a new strategy for building spatio-temporal point processes using variational autoencoder generative neural networks.

Keywords: Classification, Deep neural networks, Log-Gaussian Cox processes, Multi-layer perceptron, Siamese architecture, Spatial point processes

1. Introduction

Locations of trees in a forest stand, epicenters of earthquakes in a geographical region, or locations of crime incidents in a city are typical examples of spatial point pattern data. Many point process models, statistical inference approaches, and data analysis methods have been developed for spatial and spatio-temporal point patterns on different domains (12; 5; 13).

However, there is still room for substantial improvements and further developments in some areas of point pattern analysis. In particular, point process models and statistical methods for analyzing a set of spatial point patterns of $m \geq 2$ groups (populations, species, types, or other categorical characteristics), each observed at $T \geq 2$ different time instances on the same observation window are scarce. Although several multivariate point process models have already been developed (9; 15; 14; 2; 6), due to the curse of dimensionality, modeling and statistical analysis of highly multivariate point patterns observed at several time instances are both theoretically and computationally challenging.

In a related context within the analysis of spatial point patterns, it is important to distinguish between random and structural differences among observed point patterns from several populations. For example, analyzing the ecological distance or dissimilarity between species can reflect the effect of underlying processes on the spatial structure of ecological communities. Point pattern matching in pattern recognition and computer vision tasks also tries to quantify how one set of point patterns differs from another set of point patterns by considering isometric transformations and random noise or jittering of the position of points in each pattern (16; 1). Thus, detecting and quantifying relative similarities and

differences at large and small scales among partially observed point patterns provide an understanding of hidden differences in their corresponding populations. Moreover, such similarities and differences can be used to classify an unlabeled spatial point pattern into one of the populations.

Recent rapid developments in machine learning algorithms and methodologies have provided data analysis tools for various types of data (7). Because of the flexibility, generalization ability, and scalability of machine learning algorithms, they can be employed for statistical analysis of complex and highly multivariate data with spatial and temporal attributes (8). This makes spatial point processes and neural networks a convenient couple for statistical analysis of highly multivariate point patterns observed on several time instances. Consequently, more attention has recently been directed to merge machine learning algorithms in general, and deep neural networks in particular, into the statistical analysis of spatial point patterns.

Focusing on the modeling of the intensity functions of highly multivariate point processes, (17) used kernel density estimation and a variational autoencoder approach for analyzing the inhomogeneity in point patterns of location-based social networks. (4) provided a general framework for supervised statistical learning for point processes, and discussed cross-validation through independent thinning and the performance evaluation metrics in terms of bivariate innovations for spatial point patterns. (10) used deep convolutional neural networks and employ a Siamese framework to build a discriminant model for distinguishing structural differences between spatial point patterns. Recently, (11) provided a mathematical framework for coupling neural network methods with the statistical analysis of point patterns.

This short contribution summarises the ideas developed in these two previous papers (10; 11). On the one side, we use deep convolutional neural networks to extract features in a given spatial point pattern. Deep convolutional neural networks provide a flexible yet tractable family of transformations, are suitable for data with spatial correlations, and have been widely used in pattern recognition and image classification (8). We then use a Siamese framework of deep convolutional neural networks to construct a parametric discriminant model to distinguish structural differences in a set of spatial point patterns from several groups, each with a number of replicates. On the other side, we discuss an example of deep neural networks in the statistical analysis of highly multivariate spatial point patterns with the aim of providing a new strategy for building spatio-temporal point processes using variational autoencoder generative neural networks.

2. Statistical and neural network methodology

2.1 Dissimilarity and classification for spatial point patterns

Given two spatial point patterns, random similarities or differences between them provide no information about the underlying differences between their corresponding generative point processes, and only structural similarities or differences are of interest. To this end, major determinants of given point patterns, that include the most relevant information about the underlying point processes that have generated the observed point patterns, must be extracted by a suitable transformation. This transformation has to reflect appropriate large and small scale features and/or incorporate necessary first, second, and higher-order characteristics of a spatial point process and ignore less pronounced and redundant aspects. Such transformation is called feature extraction in machine learning and pattern recognition literature.

For a given pair of observed point patterns $\mathbf{x}, \mathbf{x}' \in \mathcal{X}$, with $\mathcal{X}$ denoting the space of all spatial point patterns on the observation window W, it is of interest to know whether $\mathbf{x}$ and $\mathbf{x}'$ are *structurally* different or if their differences are due to chance (random or unstructured differences). In fact, any difference between $\mathbf{x}$ and $\mathbf{x}'$ is due to pure chance if their corresponding point processes, X and X', are statistically indistinguishable; i.e., $\mathbb{P}_X = \mathbb{P}_{X'}$ or equivalently $f_X = f_{X'}$, with $\mathbb{P}$ being the probability distribution (or measure), and f the corresponding density function. Even in the case that $\mathbb{P}_X \neq \mathbb{P}_{X'}$ ($f_X \neq f_{X'}$), some of differences between $\mathbf{x}$ and $\mathbf{x}'$ are still due to chance, but it is expected to observe some further differences that reflect the structural differences between the probability distributions of X and X'. Thus, random similarities or differences between $\mathbf{x}$ and $\mathbf{x}'$ provide no information about the underlying differences between X and X', and we are only interested in structural similarities or

differences.

We can have dissimilarities by pattern or feature matching. A dissimilarity (distance) function $D : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ takes any pairs of point patterns $\mathbf{x}, \mathbf{x}' \in \mathcal{X}$ and quantifies the differences between them by a real number $D(\mathbf{x}, \mathbf{x}')$. For example, dissimilarity functions can be based on distances between quadrat counts or pairwise point-to-point distances between observed point patterns. A suitable dissimilarity function takes small values when $\mathbb{P}_X \approx \mathbb{P}_{X'}$, or equivalently $f_X \approx f_{X'}$, and large values when $\mathbb{P}_X$ and $\mathbb{P}_{X'}$, or f_X and $f_{X'}$ are very different. Thus, we want to extract only major determinants (called features) of $\mathbf{x}$ and $\mathbf{x}'$ that include most relevant information about $\mathbb{P}_X$ and $\mathbb{P}_{X'}$ and remove less pronounced and redundant aspects.

Let $G : \mathcal{X} \to \mathcal{F}$ be a transformation that maps any observed point pattern $\mathbf{x} \in \mathcal{X}$ into a point in the feature space $\mathcal{F}$, which is assumed to be a metric space with metric $D_{\mathcal{F}}$. Then, the dissimilarity function

$$D(\mathbf{x}, \mathbf{x}') = D_{\mathcal{F}}\left(G(\mathbf{x}), G(\mathbf{x}')\right) \tag{1}$$

captures and quantifies differences between any pair of point patterns $\mathbf{x}, \mathbf{x}' \in \mathcal{X}$ in terms of their extracted features by G (3). If G is selected such that it incorporates the most relevant information about $\mathbb{P}_X$, then Eq. (1) compares structural differences between $\mathbf{x}$ and $\mathbf{x}'$. The transformation $G(\mathbf{x})$ might be chosen to be any summary statistic of the observed point pattern $\mathbf{x}$ such as an estimate of the intensity function, pair correlation function, nearest neighbor distance distribution function, empty space function or J function.

To use convolutional neural networks (CNNs), the data are required to have a known grid-like topology. For the ease of representation, we consider the planar case $W \subset \mathbb{R}^2$ and partition the observation window W into a $d_1 \times d_2$ regular grid of cells $B_{ij}, i = 1, \ldots, d_1, j = 1, \ldots, d_2$. Then, any point pattern $\mathbf{x} \in \mathcal{X}$ can be discretized over partition cells by cell counts $x_{ij} = n(\mathbf{x} \cap B_{ij})$. The discretized point pattern $\tilde{\mathbf{x}} = [x_{ij}]$ is the input layer of the network and it can be thought of as an image, which consists of a two-dimensional grid of cell counts as pixel values. Feature maps are obtained by repeating the convolution and pooling layers a suitable number of times to obtain a final feature vector $\mathbf{G} = [g_{k'}]$, which contains all biases and weights of the layers. Note that the elements of $\mathbf{G}$ encompass more exhaustive information about $\mathbb{P}_X$ than elements of all previous layers.

Let $\boldsymbol{\vartheta}$ denote a parameter vector that contains all biases, kernels of convolution layers and weights and biases of the last fully connected layer. Then, given $\boldsymbol{\vartheta}$, the convolutional neural network is a very flexible transformation

$$G_{\boldsymbol{\vartheta}} : \mathbf{x} \mapsto \mathbf{G} \tag{2}$$

from the observation space $\mathcal{X}$ to the feature space $\mathcal{F} = [0, 1]^{\ell_L}$ that maps a discretized point pattern $\tilde{\mathbf{x}}$ to its corresponding final feature vector $\mathbf{G}$. Note that $\mathbf{x}$ is arbitrary and no assumption, such as homogeneity or isotropy, is made on the underlying generative point process of $\mathbf{x}$.

In our context, let $\mathcal{D} = \{\mathbf{x}^{(s,t)}, s = 1, \ldots, m, t = 1, \ldots, T\}$ be a set of spatial point patterns of $m \geq 2$ groups, each observed with $T \geq 4$ replicates on the same observation window W. A relevant research question here is how we can use the observed point patterns in $\mathcal{D}$ to discriminate differences between groups. It falls under the topic of discriminant analysis, which is concerned with the relationship between the grouping variable s of a point pattern $\mathbf{x} \in \mathcal{D}$ and its extracted features. And we use a Siamese framework (3) to construct a parametric discriminant model to distinguish differences between any pair of observed point patterns in $\mathcal{D}$ based on their extracted features.

2.2 Variational autoencoder generative neural networks for multivariate spatial point patterns

In this second part, we use generative neural networks within the context of point process methodology to provide a predictive statistical model in the context of log-Gaussian Cox processes. In particular, we discuss a framework to construct predictive models for multivariate (multi-type) spatial point patterns using multilayer perceptrons (also known as feedforward) neural networks to relate the spatial point patterns to a small set of latent random fields and obtain a generative variational autoencoder model. (15)

considered common and species-specific hidden Gaussian random fields to account for unobserved influential factors, and analyzed the environmental inhomogeneity and intra and inter-specific interactions of $m = 9$ species in only one temporal instant. We provide an extension of such multivariate framework to the spatio-temporal case by considering spatio-temporal independent zero mean and unit variance Gaussian random fields, accounting for species specific random effects and intra-species spatio-temporal correlations, together with inter-species spatio-temporal correlations with different scales. Parameter estimation is done through variational inference that approximates the corresponding posterior density. A variational distribution under the neutral hypothesis of no inter- and intra-specific interactions among species is used.

3. Data analysis of the Barro Colorado Island (BCI)

The paper is wrapped up with reporting several analysis carried out over BCI data. For the classification problem, we restrict our attention to the $m = 130$ most abundant species with 1808725 alive trees in $T = 8$ censuses, while we consider the $m = 100$ most abundant species in the BCI data with 1767880 trees in the 8 censuses to fit the multivariate spatio-temporal LGCP model. See complete details in (10; 11).

Abstract

Online shift detection in multivariate data with unknown parameter settings is quite challenging. In statistical process control and monitoring, various self-starting methods that have been proposed aim to overcome such issues. In high dimensions, any distributional assumption, with the most typical being that of normality, can be strict or even unrealistic, calling into question the efficient performance of any method. In this work, we propose a Nonparametric multivariate CUSUM-type control chart to detect translocations for the mean vector. The proposed methodology is adaptive, free from tuning parameters that need to be set by the user.

Keywords: Adaptive, CUSUM, Location shifts, Kernel Density Estimation, Self-Starting

1. Introduction

Multivariate detection schemes have been increasingly common in the last decades, as they allow monitoring a process by considering associations between the tested variables. The interest is placed on online monitoring procedures, as they can detect a disorder in real-time. A process is called In Control (IC) when it operates under such common causes of variation only. We refer to a process as Out Of Control (OOC) when special/assignable causes of variation are present. Statistical Process Control and Monitoring (SPC/M) is a set of powerful statistical methods that aim to detect early the presence of unusual observation/irregularities.

Several multivariate methods in SPC/M have been proposed for detecting a system disorder for a continuous monitoring process; an extensive literature review is provided in (1). In most of the methods, the standard setup requires a long training phase (phase I) under in control conditions for performing calibration before starting the testing (phase II). This requirement is restrictive when preliminary data are not available. Other limitations (especially for multivariate processes) are the requirement to define a set of tuning parameters or/and the parametric assumption, i.e., that the data follow a known distribution; for example see (5) or (2). Nonparametric methods have been introduced in the literature to relax the latter constraint. However, in many cases, they also have challenging issues when applied in practice due to, for example, not considering dependencies between variables (e.g., (4)) or requiring strict assumptions such as prior knowledge of both the IC and the OOC state; (7).

In this work, we focus on detecting location shifts in multivariate processes by proposing a nonparametric CUSUM-type chart. The proposed methodology is an online cumulative likelihood ratio test of two competing distributions, estimated through the Kernel Density Estimation (KDE) method. The use of KDE allows us to have the information for the entire IC distribution and not just one summary statistic, which is advantageous, especially for detection. Furthermore, the KDE-CUSUM is self-starting, as it can provide testing without the requirement of any lengthy historical dataset. The main contribution of the method is that it is adaptive, because it does not require any preliminary specification for the magnitude or the direction of a change.

The paper is organized as follows. In Section 2, we provide the theoretical background and the KDE-CUSUM derivation, while in Section 3, we discuss the stopping rule and the appropriate performance metrics. A short simulation study is presented in Section 4. Finally, Section 5. provides a short discussion, highlighting a few points that deserve further work.

2. Statistical modeling

An online change point model can be considered as sequential testing between two hypotheses (states); the IC state with distribution function F_0 against the OOC with distribution function F_1. Assuming that these distributions are known is strict and unrealistic, especially for multivariate processes. In practice, the pre-change density f_0 may be known under specific conditions, but it is highly restrictive to assume that the post-change density f_1 is known in advance. For this reason, we will adopt the nonparametric approach to estimate the unknown IC density via kernel smoothing.

In this setup, assume a random sample of multivariate data is obtained sequentially, and at time t we have $\boldsymbol{x}_{1:t} = (\boldsymbol{x}_1, \boldsymbol{x}_2, ..., \boldsymbol{x}_t)$. Each observation $\boldsymbol{x}_i$ is p-dimensional and specifically $\boldsymbol{x}_i = (x_{i,1}, ..., x_{i,p})$. The KDE at time t will be based on the previous data $\boldsymbol{x}_{1:(t-1)}$. We study the KDE in the context of a mean process change. The key idea for suitably expressing the OOC state is to shift the parameters of the IC state, estimating the potential translocation based on the most recent data points. Thus, the estimated OOC density will be a translocated version of the IC density. We test whether the observation $\boldsymbol{x}_t$ supports the IC state or the OOC state by considering the following ratio 1 with estimated densities $\hat{f}_0$ and $\hat{f}_1$, i.e.:

$$L_t = \frac{\hat{f}_1(\boldsymbol{x}_t|\boldsymbol{x}_{1:(t-1)})}{\hat{f}_0(\boldsymbol{x}_t|\boldsymbol{x}_{1:(t-1)})} = \frac{\sum_{i=1}^{\hat{\tau}-1} K_{\boldsymbol{H}}\left(\boldsymbol{x}_t - (\boldsymbol{x}_i + \boldsymbol{\delta}_{\hat{\tau}:(t-1)})\right)}{\sum_{i=1}^{\hat{\tau}-1} K_{\boldsymbol{H}}\left(\boldsymbol{x}_t - \boldsymbol{x}_i\right)}, \tag{1}$$

where $K_{\boldsymbol{H}}$ is the Normal kernel, the matrix $\boldsymbol{H}$ is the bandwidth, a smoothing parameter, whose choice is discussed in more detail below, while $\hat{\tau}$ and $\boldsymbol{\delta}_{\hat{\tau}:(t-1)}$ represent the estimation for the change point and the shift respectively for which we will provide details next. As the estimated densities $\hat{f}_0$ and $\hat{f}_1$ play the role of predictive distributions, as they are sequentially updated based on the previous data. Using predictive distributions allows the estimates to be sequentially updated without wasting the IC information the test data can provide, rather than using distributions with estimated and fixed parameters

from a calibration (training) phase.

As the goal is to create a memory-based control chart based on $\log L_t$, the cumulative statistic at time t is given by the following expression:

$$S_t = \max\{0, S_{t-1} + \log L_t\}, \tag{2}$$

where $S_0 = 0$. For more details on deriving the recursive formula, see (12).

As both the states and the change point are unknown, we do not provide any test for the first three observations obtained, but we "sacrifice" them to obtain rough representatives of them, initiating the chart. Precisely, we set $\hat{\tau} = 3$, $\boldsymbol{\delta}_{3:3} = \boldsymbol{x}_3$ and $S_{1:3} = 0$, and the control chart can provide online testing starting from the fourth data point, i.e., the next observable. After this, the estimate $\hat{\tau}$ follows from an inherent property of CUSUM. Specifically, the log-ratio provides evidence in favor of the denominator (IC state) when it is negative, while when it is positive supports the nominator (OOC state). At the same time, the zero truncation in 2 fades away the memory in favor of the IC state. The first observation for which the cumulative statistic is greater than 0 denotes the start of the persistent change. Taking this into account, we conclude that the first OOC observation is $\hat{\tau} = \max\{t : S_t = 0\}$. Regarding the shift $\boldsymbol{\delta}_{\hat{\tau}:(t-1)}$, it is the difference between the post-change and the pre-change mean vectors, i.e.:

$$\boldsymbol{\delta}_{\hat{\tau}:(t-1)} = \sum_{j=\hat{\tau}}^{t-1} \boldsymbol{x}_j/(t-\tau) - \sum_{j=1}^{\hat{\tau}-1} \boldsymbol{x}_j/(\tau-1). \tag{3}$$

In this way, we split the data before and after the estimated change point, avoiding the involvement of the contaminated data in the calculation of the IC estimates. The benefit of this formulation is twofold. On the one hand, the control chart is adaptive to successfully detect either small or large shifts, being free from tuning parameters. On the other hand, it is directional invariant as it can detect a location shift in any direction. Turning now to the bandwidth $\boldsymbol{H}$, which is thoroughly discussed in the literature (for example, see (3)), it should be carefully chosen to avoid a degeneracy or oversmoothing for the density estimation. We suggest the use of the unconstrained bandwidth introduced by (11), which minimizes the Asymptotic Mean Integrated Squared Error (AMISE) for the Normal kernel, and it is given by:

$$\hat{\boldsymbol{H}} = \hat{\boldsymbol{\Sigma}}_{1:(\hat{\tau}-1)} \left(\frac{4}{(p+2)\cdot(\hat{\tau}-1)} \right)^{2/(p+4)}, \tag{4}$$

where $\hat{\boldsymbol{\Sigma}}_{1:(\hat{\tau}-1)}$ is the sample covariance matrix of the p-dimensional data $\boldsymbol{x}_{1:(\hat{\tau}-1)}$.

It is worth noting that locally adaptive bandwidths have also been proposed and discussed in the literature. Apart from the fixed bandwidths, adaptive choices have also been proposed and discussed in the literature. For further information see (9) and (10). In any case, since our primary goal is detection and not estimation, the choice of $\boldsymbol{H}$ is not crucial as long as it is chosen in a reasonable way.

3. Stopping time and performance metrics

KDE-CUSUM is a sequential hypothesis testing procedure where two competing states are compared via the log-ratio of their kernel-estimated multivariate densities within a memory-based control scheme. The goal is to detect a transition from the IC to the OOC state as soon as possible while keeping the number of false alarms at a low predetermined level. In this spirit, we define the stopping time T by:

$$T = \inf\{t : S_t \geq h\}, \tag{5}$$

i.e., it is the first time that the cumulative statistic S_t exceeds a threshold h, which is determined by a pre-specified false alarms tolerance.

An important aspect is the evaluation of the proposed method via appropriate metrics. Regarding the IC performance, we suggest using the IC Average Run Length (ARL_0) for the decision limit h

derivation, as described in (8). ARL_0 corresponds to the average number of consecutive IC observations obtained sequentially until the first false alarm is raised. Regarding the OOC detection, an appropriate performance metric should consider the location of τ. Thus, we adopt the framework of (6), estimating the Conditional Expected Delay (CED), which is given by:

$$CED(\tau) = E_\tau(T - \tau + 1 | T \geq \tau) = \frac{E_\tau((T - \tau + 1)^+)}{P(T \geq \tau)}, \tag{6}$$

where $(T - \tau + 1)^+ = \max\{0, T - \tau + 1\}$. $CED(\tau)$ is the expected delay of an alarm after the change point occurs.

4. Short Simulation study

In this section we provide a brief simulation study, comparing the performance of the proposed KDE-CUSUM against the distribution free EWMA (DFEWMA, (4)). As IC distribution we consider a two-dimensional ($p = 2$) Normal with mean zero vector and a covariance matrix $\boldsymbol{C}$ with $c_{k,l} = 0.6^{|k-l|}$. Simulating 1,000 IC sequences, we derive the decision limits (for KDE this is h) setting $ARL_0 = 100$. Regarding the OOC scenarios, we will examine the performance in detecting several persistent shifts, setting two change point locations $\tau \in \{51, 101\}$. Regarding the DFEWMA, we set the smoothing parameter $\lambda = 0.1$ and the weight parameter $w = 29$ based on the authors' recommendations. The simulated results are given in Table 1. As can be seen, KDE-CUSUM detects a change faster in almost all cases establishing its good diagnostic ability. The only setting where DFEWMA performs better corresponds to the case of shift $(1, 1)$. This is because DFEWMA does not consider correlations between variables, and its statistic is based only on ranks. So in this specific case, with a small positive and simultaneous shift in the variables, it is favored in terms of detection. On the other hand, KDE-CUSUM performs better in all other cases and maintains its good diagnostic ability for changes in all directions.

Table 1: The simulated results

$\boldsymbol{\mu}_{OOC}$	$\tau = 51$		$\tau = 101$	
	KDE-CUSUM $CED(\tau)$	**DFEWMA** $CED(\tau)$	**KDE-CUSUM** $CED(\tau)$	**DFEWMA** $CED(\tau)$
$(1, 1)$	10.259	**6.660**	8.874	**6.559**
$(2, 2)$	**3.057**	4.118	**2.930**	4.116
$(1, 0)$	**7.645**	11.440	**6.763**	10.876

$(1, -1)$	**3.107**	6.173	**3.041**	6.012

5. Discussion and Future Work

In this work, we develop a methodological framework to efficiently detect changes in multidimensional processes, while relaxing the strict assumption of a known distribution. Precisely, we developed a multivariate nonparametric CUSUM focusing on detecting shifts of the mean vector. The adaptability of the proposed methodology allows the detection of systematic changes (small or large) in any direction, as well as being free of tuning parameters, which is important in high dimensions where intuition may not

be available. At the same time, the density estimation via kernels allows us to consider the associations between the variables and, generally, the data structure, which is crucial for detection performance. Furthermore, the method does not require a lengthy historical dataset to estimate the IC state; it can provide effective testing for mean vector shifts after a few dozen IC data while updating the estimates using the current process data.

Despite the promising results obtained with the proposed method, this is still work in progress. In the following steps, we will extend the research on the most appropriate bandwidth choice while considering the performance and addressing the computational cost in higher dimensions. Furthermore, we will extend the detection scheme for the case of changes in the covariance matrix, while demonstrating its performance in practical applications with real data.

An Approach for Profile Monitoring via Mixture Regression Models

Davide Forcina, Antonio Lepore, and Biagio Palumbo

Abstract

Profile monitoring of quality characteristics can be improved by suitably modeling the influence of concurrent process variables, aka covariates, through a functional linear model (FLM). However, in many applications, a single FLM is not sufficient to capture the complexity of the relationship between the quality characteristic and the covariates. To address this issue, a new profile monitoring control chart is presented to let the regression structure vary across groups of subjects when the covariates are available in functional or scalar form.

Keywords: Statistical Process Control, Profile Monitoring, Multiple Functional Linear Models

1. Introduction

Statistical process control (SPC) plays a crucial role in quickly detecting special causes of variation acting on a process, which is then said to be out of control (OC). Otherwise, the process is said to be in control (IC). The quality characteristic of interest in modern industrial processes is often represented by functional data or profiles (17), due to the complex and high-dimensional formats of data gathered in modern industrial applications. The Industry 4.0 framework is in fact reshaping manufacturing processes and data acquisition systems to increase the complexity and the variety of the available signals and measurements.

Traditional SPC approaches extract scalar features from each profile and apply classical techniques for multivariate data (15). However, this feature extraction is subjective and may compress useful information. Consequently, there is a growing interest in profile monitoring, which aims to monitor a process when the quality characteristic is best characterized by one or multiple profiles (16). Many real industrial processes exhibit more than one IC pattern due to multiple operating conditions, challenging the traditional assumption of a single IC state. This data multimodality may get standard approaches ineffective in effectively describing and monitoring the process. Grasso et al. (8) proposed a method based on curve classification to assess the mode to which the data belong, along with a control charting scheme that handles functional data for each detected mode. However, this method is not designed to account for any covariate information that may influence the quality characteristic being monitored.

In the context of unimodal SPC, extreme realizations of covariates can lead to the incorrect judgment of the process OC state for the quality characteristic. Conversely, situations may arise where non-extreme covariate values result in wrongly assessing the process state as IC.

To address these issues, the functional regression control chart (FRCC) has been proposed (1) to adjust the monitoring of a functional quality characteristic by incorporating the influence of multiple functional covariates through a suitable functional linear model (FLM). However, the FRCC assumes a

single linear relationship between the functional response and covariates, which may not hold when the subjects come from an inhomogeneous population consisting of several homogeneous subpopulations or clusters.

Classical finite mixtures of regression models have been useful for modeling such heterogeneity when the predictor variables and responses are scalars (5; 11). Extensions of these models to the functional case have been presented in the literature (21; 3; 22; 19; 6). However, none of these works has applied the models in a profile monitoring context. Furthermore, the functional mixture regression (FMR) approach is conceptually different from existing curve-based clustering methods used in the design phase of the multimode process monitoring framework. While the latter methods focus on clustering the functions themselves, the former focuses on detecting the possible existence of different regression structures.

To fill this literature gap, we propose a functional mixture regression control chart, hereinafter referred to as FMixture, for the monitoring of profiles adjusted by the influence of functional covariates through a finite mixture of FLMs. We evaluate the performance of the proposed control chart in identifying anomalies in the quality characteristic through a Monte Carlo simulation study. Finally, we demonstrate the flexibility of the proposed control chart in handling FLMs with different types of responses and/or predictors by presenting a real-case study in the monitoring of a resistance spot welding (RSW) process in the automotive industry through dynamic resistance curve (DRC) observations at given electrode wear described through scalar covariates.

2. The Proposed Control Chart

The proposed FMixture control chart can be considered as a general framework for multimode profile monitoring, where different modes are characterized by their own relationship between the predictors and the response. The following FLM for the k-th cluster is used to model the relationship between the standardized functional response $Y(t)$ and the multivariate functional covariates $X(s)$

$$Y(t) = \beta_{0k}(t) + \int_{\mathscr{S}} (\beta_k(s,t))^T X(s) ds + \varepsilon(t), \quad t \in \mathscr{T}, k = 1, \ldots, K, \tag{1}$$

where $\beta_k = (\beta_{k1}, \ldots, \beta_{kp})$ is k-th component-specific regression coefficient vector, β_{0k} and ε are k-th component-specific functional intercept and the functional error term, respectively. The random error function is independent of X, it has $\mathrm{E}(\varepsilon) = 0$ and $\mathrm{var}(\varepsilon) = \nu_\varepsilon^2$. In order to deal with the infinite dimensionality of the data, the truncated multivariate functional principal component or Karhunen-Loève decomposition (2; 9) is performed on the standardized functions, where the number of retained functional principal components is chosen in order to guarantee a minimum fraction of variance explained (FVE). Then, functional parameters are projected onto the truncated space spanned by the retained eigenfunctions, which allows applying existing methods from the classical finite mixture models literature (13).

In particular, given N independent realizations (X_i, Y_i) of (X, Y), $i = 1, \ldots, N$, a mixture regression model in the functional principal component scores of Y_i and X_i is specified, with multivariate Gaussian distributions as mixture components, where π_k the probability of each observation belonging to the k-th cluster. The estimation of the parameters can be performed by maximizing the log-likelihood function through the expectation-maximization (EM) algorithm (4; 14) and, finally, any departure of the estimated in-control (IC) distribution is monitored through a monitoring scheme inspired by (20) and (18), based on a likelihood ratio test statistic.

3. Simulation Study

The performance of the FMixture control chart is evaluated through an extensive Monte Carlo simulation study. The functional response has been generated to mimic the shape of DRCs shown in the real-case study in Section 4. through three FLMs ($K = 3$) with a common functional intercept term β_{0k} and different regression coefficient functions β_k.

The aim of the simulation is to assess the FMixture control chart performance in identifying any departure from the in-control mixture distribution in the presence of shifts in the intercept function $\beta_{0k}(t)$

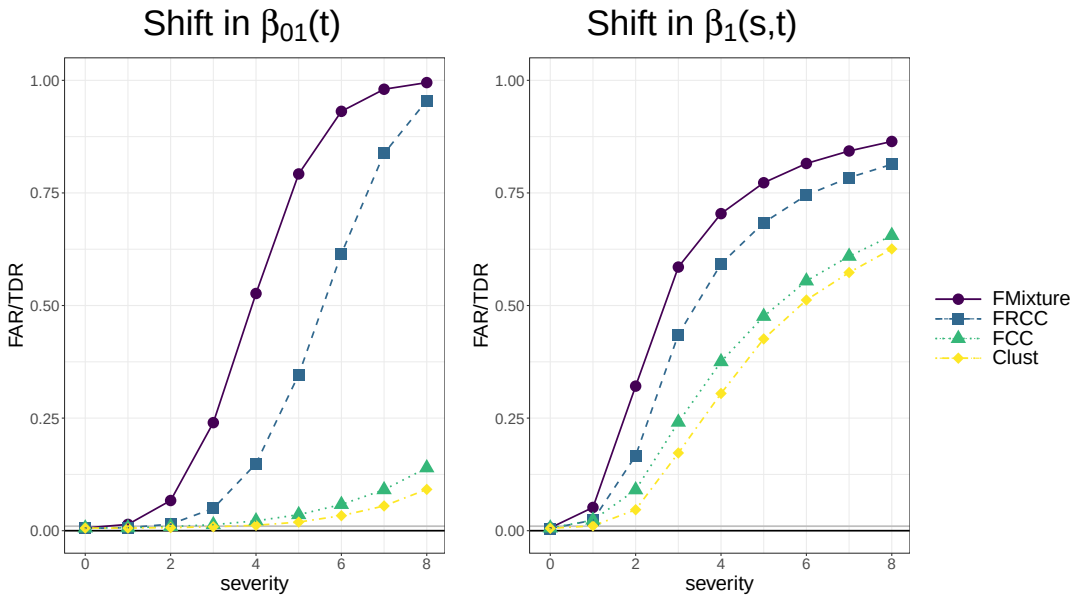

Figure 1: Mean FAR (Severity = 0) or TDR achieved in Phase II by the FMixture control chart, FRCC, FCC, and Clust for each shift case (shift in intercept $\beta_{01}(t)$, shift in the regression coefficient function $\beta_1(s,t)$ as a function of the severity level.

and in the regression coefficient function $\beta_k(s,t)$. Several scenarios are investigated, however, for brevity, in this paper we show a scenario that is able to demonstrate the behavior of the proposed FMixture control chart relative to its competitors. It consists in the presence of three clusters but the shifts occur only in the first one, whereas the remaining are IC. The FMixture control chart is compared to three different profile monitoring methods: (a) the functional regression control chart (FRCC) of (1); (b) monitoring the coefficients coming from the functional principal component decomposition of the standardized response Y via Hotelling's T^2 and SPE control charts - hereinafter referred to as functional control chart (FCC) - and, inspired from (10) and (8); (c) clustering, then FCC applied on each cluster - hereinafter referred to as Clust. Eight severity levels are explored and for each combination of shift case and severity levels, 100 simulation runs were performed. The control chart performance is evaluated by means of the mean true detection rate (TDR) and the mean false alarm rate (FAR), which are estimated as the average proportion, over the simulation runs, of points that fall outside the control limits, whilst the process is, respectively, OC or IC.

Simulation results are shown in Figure 1, where the mean FAR and TDR as a function of the severity level for each shift case is displayed. The FMixture control chart outperforms all the competing methods, in particular, the gain in efficiency is more evident where a shift in the functional intercept $\beta_{01}(t)$ is present.

4. Real-Case Study

To show the practical applicability of the FMixture control chart in handling diverse regression structures, we present a real-case study in the automotive industry. This study focuses on monitoring the quality of the RSW process, crucial for ensuring the integrity of welded joints (12). The data analyzed were provided by Centro Ricerche Fiat (Italy) and were collected during lab tests conducted at the Mirafiori Factory on a car body. During the RSW process, joints are formed by applying pressure to the weld area using two copper electrodes. By applying a voltage to these electrodes, a current flows through the material, raising the metal temperature at the faying surfaces of the workpieces until they reach the melting point. The mechanical pressure exerted by the electrodes then joins the metal sheets, creating what is known as the weld nugget. In the RSW process, expulsion refers to the molten metals that are expelled at the faying surface or the workpiece/electrode interface. This is a common phenomenon that can lead

to a significant decrease in resistance in the DRCs (Dynamic Resistance Curves). While it is crucial to avoid expulsion as it can compromise joint quality, it has been observed that most of the detected defective spots in the joints, as revealed by downstream ultrasonic inspections, did not exhibit expulsion. Therefore, expulsion is considered an IC (in-control) pattern. Furthermore, the behavior of the DRCs is also influenced by the wear of the electrode material and geometry. As the upper limit for both variables is set to prevent defective joints, this information can be incorporated into the monitoring process.

To this aim, a total of 1802 DRCs, which correspond to the same spot weld location, are considered for Phase I, while 1500 OC profile patterns are used in Phase II to compare the online monitoring performance of the FMixture control chart with that of the competing methods. The proposed control chart is implemented as in Section 2, where 901 Phase I observations, which are randomly selected without replacement, form the training set and the remaining 901 the tuning set. Accounting for at least the 95% of the total variance explained, five components are chosen and two mutually exclusive groups with different regression structures are suggested by BIC. In Phase II, the FMixture control chart signals 70.3% of the observations as OC. Finally, the proposed method is compared with the competing methods presented in Section 3. through the estimated TDR, denoted as $\widehat{TDR}$, on the Phase II sample. Moreover, to quantify the uncertainty of $\widehat{TDR}$, a bootstrap analysis (7) is performed to build confidence. The FMixture control chart achieves $\widehat{TDR} = 0.70$, with a confidence interval $[0.68, 0.72]$, FRCC achieves $\widehat{TDR} = 0.57$, with a confidence interval $[0.55, 0.60]$, FCC achieves $\widehat{TDR} = 0.57$, with a confidence interval $[0.55, 0.60]$, while Clust achieves $\widehat{TDR} = 0.57$, with a confidence interval $[0.55, 0.60]$. Therefore, the FMixture control chart outperforms all the competing methods since, differently from FRCC and Clust, it takes into account the variability explained by the covariates and the heterogeneous structure of the population simultaneously, then the proposed method is the best to promptly identify OC conditions in the considered RSW process.

5. Conclusions

In this paper, we propose a new framework for the statistical process monitoring of a functional quality characteristic in the presence of functional/scalar covariates modeled by different functional linear models. To evaluate the performance of the proposed FMixture control chart, an extensive Monte Carlo simulation is conducted in the function-on-function case. The results are compared with three existing control charts from the literature. The findings demonstrate that the FMixture control chart outperforms the competitor control charts in detecting deviations from the mixture distribution. The superiority of the proposed control chart is observed in OC scenarios that involve a shift in the intercept alone and the regression coefficient functions. Furthermore, we illustrate the practical applicability of the proposed method through a real-case study in the automotive industry. The study focuses on monitoring the quality of a resistance spot welding process using observations of the dynamic resistance curve at given scalar covariates representing electrode wear.

Anomaly Detection in Circular Data

Houyem Demni[a] and Giovanni C. Porzio[a]

[a]Department of Economics and Law, University of Cassino and Southern Lazio;
houyem.demni@unicas.it, porzio@unicas.it

Abstract

Circular data arise as directions, rotations, axes, clock, or calendar measurements. Applications are found in industry, envirometrics, Earth sciences and many other fields. Detecting outliers is an important problem that has been studied in several research areas. In this study, an outlier identification procedure for circular data is suggested. The proposed method is based on robust estimates of distribution parameters on the circle and it is illustrated through two real data examples.

Keywords: angles, directions, Ko estimator, outliers, robust statistics.

1. Introduction

A circular observation lies on the circumference of the unit circle and it can be described in polar coordinates by an angle $\phi \in [-\pi, \pi)$ or $[0, 2\pi)$ measured in a specified direction from a specified origin, as well as in Cartesian coordinates through the vector $x = (\cos\phi, \sin\phi)^T$ for which $||x|| = 1$. Circular data arise in many fields such as in Earth sciences (5), biology (20), bioinformatics (16) and also in industry (11). Books covering many aspects of circular data are available within the literature (15; 23).

When dealing with circular data, as with any kind of data analysis, outlying observations or anomalies may influence the main findings and conclusions. They can also reveal unexpected patterns in the data.

Outliers can be defined as observations that are different from the majority. These outlying observations may occur due to copying or recording errors, they could have been recorded under exceptional circumstances, or they simply come from another population.

Detecting these anomalous cases can be thus essential. However, numerous difficulties can arise while performing this task. In practice, as it will be discussed shortly, we found that the available techniques may be not as effective as they should be. Particularly, outliers may not be detected, a notorious effect called masking, or some good observations might be flagged as outliers (which is known as the swamping effect). To avoid these effects, a potentially useful approach is to rely on robust statistical procedures, and this work is aimed at investigating this perspective.

The paper is organized as follows. Section 2. provides a review on outlier detection techniques on the circle, while Section 3. describes the robust anomaly detection technique. Finally, in Section 4, two real data examples are used in order to illustrate the proposed methodology.

2. Outlier Detection on the Circle

Within the literature, several tools have been considered to detect outliers in circular data. One option is to detect outliers by deletion. That is, one or more points are deleted, the analysis is performed without

them, the deleted points are then somehow compared with the obtained results. Within this context, many techniques have been made available. For instance, a statistic that identifies an observation as an outlier if it appears as the most influential observation on the mean resultant length has been proposed (14). Four tests of discordancy for outlier detection have been described and compared in (6). These techniques can be only used for small sample sizes and to detect a single outlier. A discussion on outlier detection on the circle has been also provided in textbooks (7; 15) where the proposal of (6; 14) has been considered.

An outlier detection rule based on the locally most powerful invariant statistic and the likelihood ratio test has been introduced in (21) under the assumption that the data follow a von Mises distribution. They compared their proposed method with the ones in (6; 14). However, their method relies on assuming that the concentration parameter is known.

Unfortunately, outlier detection techniques by deletion suffer from the masking effect. That is, an outlier is undetected because of the presence of another adjacent anomalous observation.

More recently, a series of new statistical tests for anomaly detection in circular data, based on a circular distance (3; 12), the sums of these distances (2) and on the spacings theory (17) have been introduced and compared with existing techniques. Nevertheless, each of these techniques has some limits. The procedures in (2; 3) are able to detect only single outliers, while the cutoff value for the one in (12; 17) is obtained through simulations under a specific data model. Additionally, the detection rule in (17) imposes that multiple outliers are well separated from the rest of the data.

Other authors discussed how to identify outliers in multivariate directional settings (i.e., when data lie on a sphere or on a torus) (1; 8; 24). Although these methodologies can be adapted to the circular case, no specific study is available along this direction.

Alternatively, robust statistical techniques can be used. However, this concept have been only considered in (4) or within the context of circular regression (19). In (4), the weighted likelihood and minimum disparity methods are extended to the circular case under the von Mises distribution assumption. Their proposal is rather complex to be applied and it strongly depends on the choice of a bandwidth and of a certain α parameter.

3. Robust Anomaly Detection

Anomaly detection is a task strongly related to the idea of robust statistics. Outliers can be detected by fitting the majority of the data and flagging as potential outliers the observations that deviate from it (22).

Robust procedures assume that the majority of the data (that are supposed to be clean) follows a specific probability distribution (9). For instance, for data on a line, the data are assumed to follow the Normal probability density function with unknown mean and standard deviation. Under this assumption, the location and dispersion parameters of the distribution are estimated in a robust way, and a cutoff threshold is identified in order to recognize and discard potential outliers. As cutoff, the quantile of the assumed distribution is typically considered.

For Normal data, thus, an observation x_i will be flagged as outlier if

$$\frac{x_i - \hat{\mu}}{\hat{\sigma}} < \Phi^{-1}(1 - \alpha/2),$$

where $\hat{\mu}$ and $\hat{\sigma}$ are some robust estimates of the corresponding parameters, and Φ is the standard Normal cumulative distribution function (cdf).

Within the circular domain, we apply this same procedure and we assume data come from the von Mises distribution. The von Mises distribution is the most used distribution to model circular data, and its circular density is given by:

$$h(\phi; \mu, \kappa) := \frac{1}{2\pi I_0(\kappa)} \exp(\kappa \cos(\phi - \mu)), \tag{1}$$

with I_0 the modified Bessel function of the first kind and of order 0, and where μ is a location parameter and $\kappa \geq 0$ is the concentration parameter. For $\kappa = 0$, the distribution reduces to the uniform distribution

on the circle. When $\kappa > 0$, the distribution is symmetric around μ, which is both the directional mean and median of the distribution.

In our setting, we also assume $\kappa > 0$. This is because (a) under uniformity on the circle it would be odd to find points that "deviate from the majority of the data", and (b) in such a case the parameter μ is undefined.

Under this model, robust anomaly detection will be performed by first robustly estimating μ and κ. Then, the (shortest arc) distance of each observed angle ϕ_i from the estimated μ will be computed, and then compared with a cutoff value $c_\alpha(\kappa), \alpha > 0$. The value of α will be set by the analyst, keeping in mind that it represents the expected proportion of the points that will be flagged as outliers while actually they are not.

The cutoff value $c_\alpha(\kappa)$ will be the $1 - \alpha/2$ quantile direction of a von Mises distribution centered in $\mu = 0$. It will be thus obtained by solving the equation: $\int_0^{c_\alpha(\kappa)} \frac{1}{2\pi I_0(\kappa)} \exp(\kappa \cos(\phi))d\phi = (1 - \alpha/2)$.

Hence, in practice, a circular observation ϕ_i will be flagged as potential outlier/anomalous data if

$$d(\phi_i, \hat{\mu}) > c_\alpha(\hat{\kappa}), \tag{2}$$

where $d(\phi_i, \phi_j) := \pi - |\pi - |\phi_i - \phi_j||$ is the length of the shortest arc joining ϕ_i with ϕ_j.

Robust estimators of μ and κ must be adopted in Equation 2 in order to get an effective anomaly detection rule. This will guarantee protection against the masking effect, while the level of swapping will be controlled by the chosen value of α.

Within this work, as robust estimators of μ and κ, we suggest to use the Fisher circular median and the simple concentration estimator discussed in (10), respectively. The first is defined as the point minimizing the shortest arc distances of the sampled observations from it. That is, let $C = \{\phi_1, .., \phi_i, .., \phi_n\}$ be a circular data set. Its Fisher median is given by:

$$\hat{\mu} := \arg\min_{\eta \in \mathcal{S}} \sum_{i=1}^{n} d(\phi_i, \eta)). \tag{3}$$

The robust estimator of the concentration parameter described in (10) is instead given by

$$\hat{\kappa} = (\Phi^{-1}(0.75)/CMAD(C))^2, \tag{4}$$

where $CMAD(C)$ is the circular median absolute deviation of the set C, this latter being the median of the shortest arc distances of the observed values ϕ_i from $\hat{\mu}$.

At the end, as a peculiar property of data on the circle, we note that the minimization problem in Equation 3 can result in a disconnected set of values (if the set is connected, the median will be given by its central point). Should this unlikely event occur, a different robust estimator of the location parameter μ must be adopted (e.g. the circular trimmed mean estimator).

4. Illustrative Examples

For illustrative purposes, the anomaly detection procedure proposed in Section 3. is here applied to two real data sets. The first is the well-known Sardinian sea stars while the second is related to an industrial application, and it considers some wind directions.

4.1 Sea stars

The Sea stars data was provided by (7) and it is available within the library *circular* in *R*. It refers to the resultant directions in degrees moved by 22 Sardinian sea stars over a period of 11 days after their displacement from their natural habitat. We transform the given angles from degrees to radians, and we consider that 0 radians is the North pole and the rotation is clockwise.

The data are plotted in Figure 1. According to (7), the 13th and 14th observations (2.565 and 5.201 radians) are outliers. In fact, these values emerge as far-out values with respect to the the majority of the

data. The sample circular median of the data is $\hat{\mu} = 0.040$ radians and it is shown by the black arrow in Figure 1 (left and right panels) while the corresponding estimator of the concentration parameter $\hat{\kappa} = 6.942$. Then, we compute the cutoff threshold at a level $\alpha = 0.01$ (which turns out to be equal to 0.936 radians), and the shortest arc distances between each data point and the circular median. By comparing the computed distances with the threshold, observations 13 and 14 are flagged as outliers (Figure 1, right panel, highlighted in red).

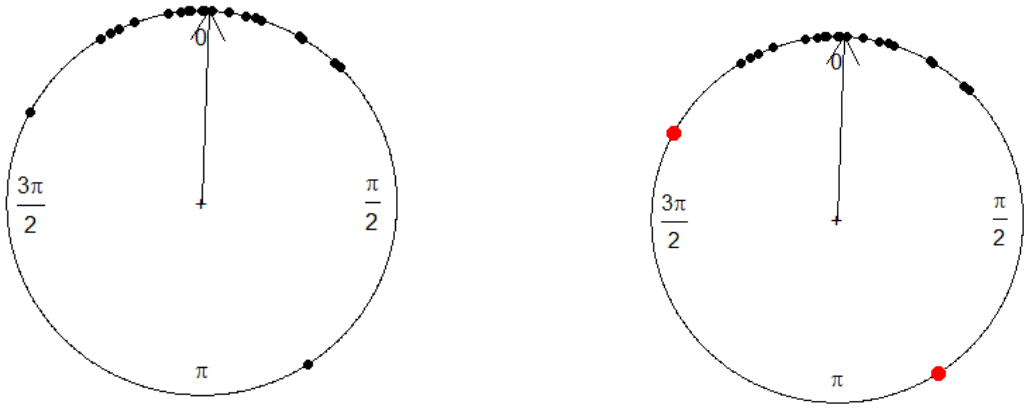

Figure 1: Resultant directions moved by Sardinian sea stars over a period of 11 days after displacement from their natural habitat. Raw data circular plots: the black arrow shows the sample circular median direction (left), outliers are flagged in red (right).

4.2 Wind directions

The modeling and the monitoring of wind directions play an important role in the industry of wind power generation (18). The data comes from the recording of wind directions from the meteorological station at "Col de la Roa" in the Italian Alps via data-logger every 15 minutes. Daily recorded wind directions between 3:00 am and 4:00 am inclusive from January 29, 2001 to March 31, 2001 are considered. Accordingly, there are five directions recorded every day leading to a total of 310 measurements (in radians). The data are also available within the *R* package *circular*.

These wind directions have a sample circular median $\hat{\mu} = 0.165$ radians and an estimate of the concentration $\hat{\kappa} = 3.848$. The associated cutoff value at $\alpha = 0.01$ is given by 1.351 radians. The wind directions are depicted in Figure 2 (left panel) and their circular median is drawn by the black arrow. By evaluating the shortest arc distances between each point and the median, and comparing them to the threshold, outliers are flagged (Figure 2, right panel). We found sub-populations of outliers located around the East-Southeast, Southeast, South and West directions.

The same data example was considered in (4), where the presence of sub-populations of outliers located around the East-Southeast, Southeast and South directions was visually inferred by means of a non parametric density estimator.

Acknowledgments This work has been partially funded by the BiBiNet project (grant H35F21000430002) within the POR-Lazio FESR 2014-2020.

Abstract

Ensemble methods, such as Bagging, Boosting or Random Forests, often enhance the prediction performance of single learners on both classification and regression tasks. In the context of regression, we propose a gradient boosting-based algorithm incorporating a diversity term with the aim of constructing different learners that enrich the ensemble while achieving a trade-off of some individual optimality for global enhancement. We present a simple convergence result ensuring that the associated optimization strategy reaches the global optimum. In the experiments, we consider a variety of different base learners with increasing complexity: stumps, CART trees, Purely Random Forests and Breiman's Random Forests. Finally, we consider simulated and benchmark datasets and a real-world electricity demand dataset to show, by means of numerical experiments, the suitability of our procedure by examining the behaviour not only of the final or the aggregated predictor but also of the whole generated sequence.

Keywords: Diversity, Boosting, Tree-based methods, Regression

1. Introduction

The practical interest of using ensemble methods has been highlighted in several works. Ensemble methods, such as Bagging, Boosting or Random Forests, often enhance the prediction performance of single learners on both classification and regression tasks.

Aggregation estimation as well as sequential prediction provide natural frameworks for studying ensemble methods and for adapting such strategies to time series data. Sequential prediction focuses on how to combine by weighting a given set of individual experts while aggregation is mainly interested in how to generate individual experts to improve prediction performance.

2. Boosting diversity

A key quantity for analysing ensemble strategies is to introduce the concept of diversity (see [2]). Considering a linear combination of individual predictors, the squared error of the mixture can be decomposed as the sum of the weighted average error of the predictors minus a positive diversity term.

We propose, in the regression context, a gradient boosting-based algorithm by incorporating in the classical Boosting with the l2 loss (see [3]) a diversity term to guide the gradient boosting iterations. The idea is to trade off some individual optimality for global enhancement. The improvement is obtained with progressively generated predictors by boosting diversity.

We establish a new algorithm, Boosting Diversity (BoDi), which takes diversity into account at each step. The goal is to focus on the intermediate learners and on the ensemble at the same time to enrich prediction. The BoDi algorithm is implemented in the homonymous R package (see [4]).

3. A convergence result

Verifying the hypotheses of a theorem from [2] a convergence result is given ensuring that the associated optimisation strategy reaches the global optimum.

4. Experimental results

In the experiments, we consider a variety of different base learners with increasing complexity: stumps, CART trees, Purely Random Forests and Breiman's Random Forests.

We consider simulated and benchmark datasets and a real-world electricity demand dataset to show, by means of numerical experiments, the suitability of our procedure by examining the behaviour not only of the final or the aggregated predictor but also of the whole generated sequence.

5. Conclusions

In this study, we propose a new boosting algorithm for regression problems based on the diversity formula. This method constructs a base learner at each step improving the diversity term of the diversity formula and then tries to reduce the mean square error.

Our initial experiments on simulated data and tree-based base learners confirm the potential of themethod when the base learner is rich enough to generate diversity (Random Forests and Purely Random Forests). This could be considered as a surprise, even if combining Random Forests and Boosting is a way to improve initial Random Forests.

How ENBIS has contributed to the UK Universities Research Excellence Framework

Shirley Coleman [a]

[a] NU Solve, School of Mathematics, Statistics and Physics, Newcastle University, UK;
shirley.coleman@newcastle.ac.uk

Abstract

Universities should be Centres of Excellence in Research, Learning and Fellowship in Society. As publicly funded institutions it is not surprising that periodically Universities are asked to demonstrate how they are having a positive impact on Society. Research Excellence Framework assessments were carried out in the UK in 2014 and 2021 and on each occasion, academic departments were required to submit a specified number of impact case studies. Impact case studies present an opportunity to showcase the wide range of benefits that statistical thinking can bring. They are coincident with the culture of ENBIS, the European Network of Business and Industrial Statistics, and the benefit of belonging to such a network is evident in all aspects of impact work. The talk will consider the concept of Excellence Frameworks and present an example from the 2021 Research Excellence Framework. The benefits of ENBIS involvement will be demonstrated in all aspects of the impact case study ensuring a successful outcome.

Keywords: societal benefit, continuous improvement, open data, data science, impact case studies, Industry 4.0, monetising data

1. Introduction

Universities in the UK are publicly funded institutions and it is not surprising that periodically they are asked to demonstrate their worth. Assessment is carried out with regards to teaching and learning, research and knowledge exchange. In the most recent Research Excellence Framework (REF) assessments in 2014 and 2021, academic departments were required to submit a specified number of impact case studies from each department.

Impact case studies are extremely well suited to applied statisticians and are highly relevant to the culture of ENBIS, the European Network of Business and Industrial Statistics. They represent an opportunity to showcase the wide range of benefits that statistical thinking can bring. One aspect of impact is in the monetising of data. This focuses on making the absolute best of the effort that goes into collecting data in all parts of a process or operation. With Industry 4.0 thinking prevalent in most companies and the wide availability of sensors plus the expectation of a digital profile the world is awash with data.[7] Making sense of this data and using it to understand and continuously improve the quality and efficiency of output makes sound sense both from a financial and a sustainable environmental point of view. [1].

The next section gives an overview of Excellence Frameworks and the REF in particular. In section 3 an impact case study from 2021 is described highlighting the value to the author of being part of ENBIS. Finally, section 4 gives plans for future contributions and concluding remarks.

2. Excellence Frameworks

Excellence Framework assessments are carried out with regards to teaching and learning, research and knowledge exchange. These all aim to help Universities improve but can understandably cause anxiety when staff feel they are being judged. They fear the implications could range from negative press and league table scores to censure and reduction in public funding, even though this is not (usually) the case. In theory, the concept is to help the Universities in their continuous improvement.

2.1 Knowledge Exchange Framework

The Knowledge Exchange Framework (KEF) shows the underlying supportive rationale. Universities are required to contribute data on a number of dimensions over a number of years. The aggregated scores are then compared with "like" Universities to give insight and to encourage a positive attitude to change. The KEF website https://kef.ac.uk/dashboard gives output from the KEF which is open access and appealing for users to explore.

2.2 Research Excellence Framework

The Research Excellence Framework (REF) is interesting because as well as an appraisal of research output in terms of academic papers in highly regarded journals, there is also a requirement to present impact case studies.

Impact case studies are based on the following outputs:

1. A narrative about research on a theme which can extend back up to 20 years
2. Supporting academic publications in relevant journals with at least a 2* ranking
3. Evidence demonstrating impact on society

Academic departments are allocated to an appropriate Unit of Assessment (UoA) depending on their specialty. There must be one impact case study for every 7-10 academic staff members. Before each REF there is considerable uncertainty as to what is expected and what will be judged well. After each REF the case studies are all made available on a Government website and can be freely scrutinised for future ideas. Here we consider UoA 10 which is for Mathematics and Statistics.

2.2.1 Research theme

The long time scale for the research theme is helpful to show how the work progressed and to allow older academic papers to be included. The evidence for the impact, however, has to be in the last 5 years

2.2.2 Academic publications

There must be at least 3 or 4 respectable academic publications on the theme in journals associated with the UoA. At least one author must have been a member of the department at the time of the publication. It can be difficult to publish in high ranking subject specific journals when the research is applied and often straddles several areas of interest.

2.2.3 Societal impacts

Impacts can be in terms of creating new jobs or increasing sales, exports, profits or investments, developing intellectual property or implementing new products. In all cases the impacts must be accompanied by evidence and be corroborated by business or partners external to the academic department.

2.3 Continuation from 2014 to 2021 Research Excellence Framework

The dates of each REF are not pre-set and guidelines can change between REFs. However the concept was similar from 2014 to 2021 and it was permitted to present a continuation of a previous impact case study provided there was substantial progression.

3. Example of Impact Case Study from 2021 REF

The impact case study presented in this section is of particular interest as it drew significantly on the ENBIS network which facilitated the opportunities that were fundamental to the work.

3.1 Research theme

An impact case study entitled "Faster Fault Tracking for National Grid Gas", [2] was successfully reported in REF 2014. Research in statistical applications in gas and other utilities continued and formed part of the subsequent REF 2021 impact case study entitled "Statistics-based Data Analytics for Industry - A Focus on Small and Medium Enterprises"[5].

The focus on SMEs was very much influenced by extensive European funding achieved in conjunction with pro-ENBIS, the EC Framework 5 Thematic Network funding obtained by ENBIS President Dave Stewardson for the newly formed ENBIS.

3.2 Academic papers

The academic publications supporting the impact case study included early work with Stewardson who was a founder member of ENBIS and principal investigator of pro-ENBIS [9]. The concept of using open data integrated with company internal data was initiated by involvement with ENBES, the European Network for Business Establishment Statistics and ICOTS, the International Conference on Teaching Statistics which were ENBIS partners. [3, 4]. A pivotal paper was written by a team of ENBIS members.[6]. Publications on data science were written in collaboration with Italian ENBIS members [10] and as a result of involvement in a European Conference of Mathematics in Industry with a Hungarian ENBIS member [4].

The papers provided an opportunity to report on the results of Knowledge Transfer Partnerships (KTPs) funded by Innovate UK. Seven two-year KTPs were won by the author in open competition between 2014 and 2021 due in part to the impressive benefits of being an active ENBIS member with access to experts from all parts of Europe and the opportunity to participate in external examining, research workshops, conferences and publishing. [8].

3.3 Societal impact

Societal impact was shown by a combination of testimonials and evidence from reports. For example, the impact case study references: "The testimonial from the Technical Director of Advanced Engineering Solutions (AES). *Provides evidence of the financial impact and global reach of the research.*"

The KTPs were particularly valuable in providing evidence of the benefits of the partnership corroborated by the business partner. This evidence forms part of the obligatory completion of the final report pending payment of the final installment of the Innovate UK funding to the business partner. Impacts from one KTP were included in the impact case study as follows:
The research work has led to the following benefits since 2016:

- an increase in annual sales turnover of £4M;
- an increase in annual exports of £4M;
- an increase in annual profit of approximately £1M;
- the creation of 5 new jobs within the business;
- an investment of greater than £1M in new software and hardware implementation and support.

These are clearly valuable impacts and contributed to the impact case study being suitably highly rated in the REF.

4. Concluding Remarks

Excellence frameworks fit well with the ENBIS philosphy. In particular as regards the Research Excellence Framework but also whenever an international flavour showing reach is helpful in obtaining research funding. The ENBIS website states that it is "a platform connecting individuals and organisations, interested in theoretical developments and practical applications in the field of business and industrial

statistics".The interaction that such a platform facilitates is clearly invaluable for opening minds to research ideas and statistical possibilities. International collaboration leads to exchange of work and study and boosts the global recognition of members' Universities, companies and Institutions, as well as staff esteem.

It is interesting that most impact case studies in the Mathematics and Statistics Unit of Assessment arise from statistical applications rather than pure or applied mathematics. This is probably due to the explosion of interest in data science that is driving businesses to seek out academic partnerships to explore new capabilities. It also reinforces the importance of the work of ENBIS and shows the value of a network where statisticians can share ideas and develop their research.

Acknowledgments The author is indebted to the camaraderie of the ENBIS community and the valuable skills, knowledge and experience of the members met and worked with over the years.

Maintenance of degrading systems by dynamic programming or reinforcement learning

Antonio Pievatolo

National Research Council, Institute for Applied Mathematics and Information Technologies
"E: Magenes" (CNR IMATI), Via A. Corti 12, 20133 Milano, Italy;
antonio.pievatolo@mi.imati.cnr.it

Abstract

We examine some contributions from the literature, that, taken together, indicate how many system maintenance problems can be framed as Markov Decision Processes and therefore solved by using dynamic programming or reinforcement learning, according to the degree of available information on the system degradation process and the nature of the state and action spaces. Following this approach, is it possible to avoid ad hoc solutions and formulate the problem in a unifying framework.

Keywords: maintenance, reinforcement learning, degradation models

1. Introduction

Dynamic programming (DP) and reinforcement learning (RL) guarantee an exact or approximate solution to sequential decision problems. Many maintenance problems are naturally sequential. For example, for preventive maintenance, one has to schedule a series of repair or inspection times using a priori information on system degradation (including that given by a model); for condition-based or predictive maintenance, information on the current degradation state of the system is used to choose the next times for inspection or repair. In both cases, every decision brings an immediate reward (positive or negative), such as the intervention cost, the cost of possible failures until the next inspection or repair time, etc., and a future reward determined by future decisions, depending on the system state determined by the first decision.

This description is well represented by the Bellman equation for the value function (see [1])

$$v_\pi(s) = \mathbb{E}\left[R(s,a) + \gamma v_\pi(s')\right] \tag{1}$$

where π is a function from the state space of the system to the action (or decision) space, which defines a (deterministic) policy for action selection; v_π is the expected return obtained by following policy π when the current state is s; $R(s,a)$ is the immediate reward obtained from the selection of action $a = \pi(s)$; s' is the state resulting from a and the system degradation model; $\gamma \in (0,1)$ is a discount factor. The expectation on the right-hand-side is taken with respect to the conditional distribution of s' and $R(s,a)$ given s, thus indicating that we are working under a Markov process assumption, since we do not consider other previous state values. It is easy to imagine that the future degradation of a system will depend on its present degradation level but not on the previous ones, thus justifying the Markov assumption.

The Bellman equations can be derived by logical reasoning, as in the original Bellman paper [2], or by mathematics [1], starting from the formal definition of the value function

$$v_\pi(s_t) = \mathbb{E}\left[\sum_{k=0}^{\infty} \gamma^k R(s_{t+k}, a_{t+k}) \mid s_t\right] \tag{2}$$

and under the Markov decision process assumptions. The best maintenance strategy is the one corresponding to the policy π which maximizes $v_\pi(s)$ for every state s, so it is clear that, as long as the consequences of the maintenance strategies are correctly represented by v_π, a DP or RL approach are the correct way to obtain the best strategy. The Bellman equations are in fact at the basis of the DP or RL methods to compute or approximate v_π.

In the following take some example from the literature to illustate this approach. In Section 2. we consider preventive maintenance, followed by condition-based and predictive maintenance in Section 3. A discussion on future work in Section 4. concludes this paper. Whenever methods or terminology from the DP or RL areas are encountered, we refer the reader to the fundamental book by Sutton and Barto [1].

2. Preventive maintenance

An interesting example of DP applied to preventive maintenance is given by [3], Chapt. 5, where the mission time of a system is T and m maintenance points have to be optimally placed. A nonhomogeneous Poisson process with increasing intensity $\lambda(t)$ describes events (called initial failures) that eventually will bring the system to a terminal failure after a random waiting time X with distribution F. The repair cost of a repair after terminal failure is 1, whereas the cost of a preventive maintenance is $c < 1$ and its effect is to remove initial failures, but without changing the system degradation state. The process of terminal failures is a nonhomogeneous Poisson process with cumulative intensity function $\Lambda_F(t) = \int_0^t \lambda(y)F(t-y)dy$. With m maintenance points, the expected repair and maintenance cost over the mission time, i.e., our value function, is

$$m \times c + \mathbb{E}\sum_{k=1}^{m+1} N(t_{k-1}, t_k) = m \times c + \sum_{k=1}^{m+1} \int_{t_{k-1}}^{t_k} \lambda(x)F(t_k - x)dx \tag{3}$$

where $t_0 = 0 < t_1 < \ldots < t_m \leq T = t_{m+1}$ are the maintenance points and $N(t_{k-1}, t_k)$ is the (random) number of terminal failures occurring in the interval (t_{k-1}, t_k).

Letting $N(x, T; n)$ denote the number of terminal failures when x is a maintenance point and n further maintenance points are optimally located between x and T, the best values of $t_1, \ldots, t_m$ can be found sequentially by backward dynamic programming via the following set of equations

$$\begin{aligned}
N(x,T;1) &= \max_{t_m} \mathbb{E}\left\{N(x,t_m) + N(t_m,T;0)\right\} && k = m-1 \\
N(x,T;2) &= \max_{t_{m-1}} \mathbb{E}\left\{N(x,t_{m-1}) + N(t_{m-1},T;1)\right\} && k = m-2 \\
\vdots &= \vdots && \vdots \\
N(x,T;m-1) &= \max_{t_2} \mathbb{E}\left\{N(x,t_2) + N(t_2,T;m-2)\right\} && k = 1 \\
N(x,T;m) &= \max_{t_1} \mathbb{E}\left\{N(x,t_1) + N(t_1,T;m-1)\right\} && k = 0
\end{aligned}$$

which allows for the recovery of optimal maintenance points as t_1^* from $N(0,T;m)$, then t_2^* from $N(t_1^*,T;m-1)$, etc. Finally, the best value of m is the one which minimizes $N(0,T;m)$. For the given cost criterion this policy cannot be improved upon, because the optimum is found in the entire action space. Other policies, such as the trivial policy of equispaced maintenance times, are necessarily suboptimal.

3. Condition-based or predictive maintenance

[4] consider a process X_t with independent increments (such as the gamma or the inverse Gaussian processes) as a model of system degradation. The degradation state of the system is only observed at inspection points: at every such point a maintenance decision (among wait, if $X_t < M$, preventive replacement, if $M \leq X_t < L$, corrective replacement, if $X_t \geq L$) is made and the next inspection point is chosen as the quantile of order p of the remaining useful life (RUL) distribution. This criterion is called a parameterized policy. After replacement the process regenerates itself, forming a sequence of renewal cycles. The cost associated with an interval $[0, t)$ is given as

$$C(t) = C_I N_I(t) + C_p N_p(t) + C_c N_c(t) + C_d d(t) \tag{4}$$

where the cost coefficients are the cost of inspections, of preventive maintenance, of corrective maintenance, and the unit cost of downtime, respectively. Then the N functions are the number of inspections, of preventive and corrective replacement, respectively. Finally $d(t)$ is the downtime in $[0, t)$, that is, the time between every failure in the interval and the subsequent inspection. By the properties of the renewal processes, the long term average cost $\mathbb{E}C(t)/t$ converges to $\mathbb{E}[C(S_1)]/\mathbb{E}(S_1)$, as $t \to \infty$, where S_1 is the length of a renewal cycle. This cost is to be minimized with respect to global parameters M and p.

The maintenance problem across one renewal cycle corresponds with an episodic task in an MDP framework, which is one where a task terminates because the system reaches a set of terminal states, represented in this case by $X_t > M$. We do not write down the formal representation of the decision problem, but it should be clear that the decision and the transition to the next state at each inspection time only depend on the current degradation level of the system. Therefore one can search for the optimal (M, p) by RL using a policy gradient method for episodic tasks.

[5] consider a problem very similar to that examined by [4], with these differences: degradation follows a Wiener process with drift, but the degradation levels are discretized, the system has a fixed mission time, inspections are made at given regular intervals, and there is no preventive maintenance threshold, therefore a preventive replacement decision can be made at any inspection time. Then, the best policy is chosen among the finite set of functions that map degradation levels to actions, by solving a discrete optimization problem. The authors explicitly consider an RL framework for their problem and solve it by temporal-difference learning.

4. Discussion

We have agued that MDPs can be used to represent common maintenance problems, thus opening the door to a DP or RL approach to their solution. In particular, the availability of RL tools to address large state and action spaces provides a motivation for further investigation in this direction. Future work will include the identification of classes of maintenance problems that are wide enough to justify this effort, and also, inspired by [6] and [7], the examination of a special feature of many maintenance problems, which is the passage of the system through regenerative states (such as renewals), in particular how this feature affects the formulation of the RL approach and the design of optimization algorithms.

Environmental Exposures and Under-5 Mortality in India: A Survival Analysis of DHS Data

Vinod Joseph Kannankeril Joseph

INTRODUCTION

Climate change is expected to increase the frequency and intensity of environmental extremes, leading to significant public health concerns in the coming years. Most low- and middle-income countries are located in relatively environmentally challenged regions compared to developed countries. However, child growth faltering and mortality in developing countries are invariably attributed to poor nutrition, infection and poverty. Despite the scale-up of nutrition, water, and sanitation interventions and widespread reductions in diarrhoea and all-cause mortality over the past decades, child growth faltering remains a major source of morbidity and mortality in Sub-Saharan Africa and Asia. Globally, nutrition-related factors contribute to approximately 45% of under-five deaths, with Sub-Saharan Africa and Central and Southern Asia accounting for over 80% of under-five deaths, despite only accounting for 52% of the global under-five population. Furthermore, five countries, including Nigeria, the Democratic Republic of the Congo, Ethiopia, India, and Pakistan, account for half of all under-five deaths in 2019.

There has been increasing interest in assessing the impact of rising environmental risk factors on children's health and survival as climate change continues. Despite the demonstrated implications of environmental exposures, early life growth's possible effects have been rarely studied. . In the Indian context, previous studies have largely focused on child, maternal, and household-level risk factors of infant and child survival while ignoring the potential effect of environment and geographic space. Additionally, little has been done to investigate how under-five mortality is associated with socio-demographic and environmental aspects that affect child survival.

Identifying prevalent environmental hazards in different settings where children live is crucial for developing setting-based interventions. Understanding the threats that environmental hazards pose to human health can help mitigate risks and increase preparedness. Thus, this study aims to investigate the associations between environmental exposures and under-five mortality in India. By filling this knowledge gap, this study will help elucidate the effects of environmental exposures on child survival in the country. This study aims to explore the linkages between environmental exposures and under-five mortality in India.

METHODOLOGY

Data source

The data for this study was obtained from the National Family Health Survey (NFHS)-4, which is the Indian version of the Demographic and Health Surveys, conducted in a representative sample of households across India. The study also utilized data on air pollution, obtained from The Air Quality Life Index (AQLI) initiative by the Energy Policy Institute at the University of Chicago (EPIC), which uses satellite-derived PM2.5 raw data from the Atmospheric Composition Analysis Group at Dalhousie University at a high resolution of 10km x 10km. In addition, data on drought-prone areas in the year 2015 was obtained from the Ministry of Agriculture and Farmers Welfare, Government of India, and the Mahalanobis National Crop Forecast Centre (MNCFC) in New Delhi.

Statistical Analysis

To investigate the association between environmental and socio-demographic factors and under-five mortality in India, we employed Kaplan-Meier survival plots, log-rank test (Mantel test), and Cox proportional hazard model. The synthetic cohort component approach was used to calculate death rates. The Kaplan-Meier estimator is a non-parametric statistic that estimates the survival function from lifetime data. It is the simplest way of computing survival over time despite all these difficulties associated with subjects or situations. For each time interval, survival probability is calculated as the number of subjects surviving divided by the number of patients at risk. Kaplan-Meier survival plots are useful for graphical comparison of potential differences. The log-rank test is used to test the null hypothesis that the survival distribution is the same in two or more groups. The test compares the number of observed events to the number of expected events (based on Kaplan-Meier curves) at all points where the events occur. The numerical value of the test statistic is compared to the chi-square distribution with degrees of freedom that are equal to the number of groups being compared minus one. To estimate the hazard ratios (HRs) with their 95% confidence intervals (CIs) for under-five mortality, we used Cox proportional hazard regression. Adjusted hazard ratios for under-five death were calculated for the total sample, adjusting for each independent variable.

RESULTS

The results of the log-rank test, mortality rates, and hazard ratios indicate the influence of environmental factors on child survival (Table 1). The under-five mortality rate was 59.09 deaths per thousand live births in air polluted areas, compared to 38.27 deaths per thousand

live births in non-air polluted areas, with a gap of 20.82 deaths per thousand live births. In drought-prone areas, the under-five mortality rate was 53.87 deaths per thousand live births compared to 46.63 deaths per thousand live births in non-drought prone areas, with a gap of 7.2 deaths per thousand live births. The national under-five mortality rate was 49.75 deaths per thousand live births.

The log-rank test statistics for air pollution and drought were 344.27 and 83.54, respectively, with p-values less than .001 for all environmental factors, indicating a significant difference in survival experience between groups. The hazard ratios showed that children living in air polluted areas had a 1.09 times higher risk of under-five death compared to those in non-air polluted areas, while children living in drought-prone areas had a 1.055 times higher risk of under-five death compared to those in non-drought prone areas. Figure 1 presents the Kaplan-Meier survival plots comparing child survival across the different environmental exposures.

CONCLUSIONS

The results of this study demonstrate the significant influence of environmental and socio-demographic factors on under-five mortality and child survival in India. It is crucial to recognize these threats and work collaboratively to mitigate the risks and be prepared. To improve people's health, a multi-sectoral, holistic approach is necessary, integrating efforts inside and outside healthcare systems. The high levels of air pollution in India require effective policies and regulation for environmental resource management. Cross-border strategies are necessary to address the issue of pollution.

A quarter of the global disease burden can be prevented by reducing environmental and social risk factors. Understanding these threats can help us work together to mitigate the risks and be prepared, particularly in the context of anthropogenic climate change. Creating healthier environments will not only benefit health and the quality of life but also reduce the burden on the healthcare system. A sustainable approach in this regard may help countries achieve the goals set out in the 2030 Agenda for Sustainable Development. This study highlights the urgent need to improve our understanding of the relationship between environmental risk factors and human health, especially at this crucial time.

The impact of temperature on expressed sentiment by migration status: evidence from geo-located Twitter data"

Risto Conte Keivabu

Laboratory of Digital and Computational Demography, Max Planck Institute for Demographic Research, 18057 Rostock, Germany

Jisu Kim

Laboratory of Digital and Computational Demography, Max Planck Institute for Demographic Research, 18057 Rostock, Germany

Abstract

The escalating prevalence of extreme temperatures due to climate change is expected to impact various aspects of human life, with mental health being a critical component that has implications for overall well-being. In this study, we aim to contribute to the growing body of research examining the connection between temperature and expressed sentiment. Our analysis utilizes geo-referenced text data from Twitter users, combined with comprehensive meteorological information, to assess the effects of temperature on individuals. Our sample comprises 1,839 Twitter users based in the United States, including 979 natives and 860 migrants, who tweeted between 2012 and 2019. We combine the users' locations with finely-tuned meteorological data provided by Gridmet. Our findings reveal that both cold and hot days contribute to a decline in positive sentiment and an increase in negative sentiment among users. Interestingly, we do not detect any significant differences in the impact of heat or cold on native users compared to migrants. However, we do observe variations in impact of heat and cold within the migrant group, depending on the length of their stay in the United States. In conclusion, leveraging individual-level geo-referenced textual data offers valuable insights into the effects of extreme temperatures on people's mental states and the heterogenous impact in the population. Furthermore, it sheds light on how the anticipated rise in future temperatures could influence multiple dimensions of human well-being.

Introduction

In recent years, the impact of climate change and heat exposure on human behavior and wellbeing has become even more critical (Adger et al., 2022; Vargas et al., 2023). Recent studies documented temperature to affect several domains of human activity such as productivity (Cai et al., 2018), cognitive abilities (Chang & Kajackaite, 2019), test scores (Park et al., 2020), mental health (Mullins & White, 2019), time use (Graff Zivin & Neidell, 2014), reproductive behavior (Hajdu & Hajdu, 2019; Wilde et al., 2017), decision making (Almås et al., 2019; Heyes & Saberian, 2019) and leisure activities (Fan et al., 2023). Moreover, increasingly researchers have inquired the impact of climate on human activities leveraging new sources of data.

Recently, studies have combined novel digital data with meteorological information to provide additional evidence on the effect of temperature on human online behavior and expressed sentiment. For example, studies investigated how climate affects expressed sentiment of Twitter and Facebook users in the United States (Baylis et al., 2018) and Weibo users in China (Wang et al., 2020) finding a decrease in positive sentiment and an increase in negative sentiment with exposure to extreme heat and cold. Additionally, an increase in hate speech with exposure to hot and cold days has been documented in a large sample of tweets in the United States (Stechemesser et al., 2022). Nevertheless, a gap in these studies is represented by the use of aggregate level data and a lack of insights on the heterogenous impacts of climatic variables on the online population residing within the same location.

In this article, we contribute to the growing literature interested in the impact of extreme temperature on online behavior exploring how migration status stratifies the impact of temperature on Twitter users. For this purpose, we leverage a unique dataset of geolocated tweets of individual users located in the United States that provides information on migration background (Kim et al., 2023). We combine this dataset with meteorological variables at the date in which the users have tweeted to estimate the impact of extreme temperatures on their sentiment. The analysis of a heterogeneous impact of extreme temperature by migration background could offer insights on adaptation to the local weather. For example, studies on the association between temperature and mortality found variation in adaptation to heat and cold based at different latitudes and climatic zones (de Freitas & Grigorieva, 2015; Medina-Ramón & Schwartz, 2007). Additionally, studies documented differences in human thermal perception that depend on physiological and psychological adaptations (Schweiker et al., 2018). On one hand, migrants could be less adapted then natives to the new climatic context to which they relocate and weather could be considered as an additional cost to their migration experience. On the other hand, having less experience with the local meteorological phenomena might refrain them from perceiving temperatures out of the local averages as unusual and feel concerned about it.

Followingly, we describe the data and methods used in the analysis, we present preliminary results and conclude with a discussion of the findings.

Data and methods

Data

In the analysis, we rely on two main datasets. First, we collect data on tweets from a sample of Twitter users using the Twitter API. The sample is comprised of 979 native and 860 migrant users for which we have tweets collected between 2012 and 2019 comprising a total of 505,157 tweets. The migrant sample is defined as those users that: "have tweeted at least one geo-tagged tweet per month in one country (home country) for 12 consecutive months and one geo-tagged tweet per month for 12 consecutive months in another (destination) country". Moreover, the sample of native and migrants have been selected matching them on variables such as: number of followers, friends, tweets, account age, age, and gender. Also, we use the modal location of the tweets of each individual to allocate the city of residence to the users.

We connect the individual user location with daily meteorological information provided by GRIDmet. GRIDmet is a highly reliable source of meteorological data for the contiguous United States with a resolution of 4km and available from 1979 to 2023 (Abatzoglou, 2013). For our purpose, we collected the daily meteorological values at the grid cell at the center of the city in which the Twitter user is residing. The meteorological values we collected are maximum temperature, wind speed, shortwave downwelling radiation, humidity and precipitation.

Variables

Our outcome variables are measures of positive and negative sentiment expressed in the tweets. We used the RoBERTa algorithm on the textual data from the tweets to compute measures of positive and negative in the tweets (Liu et al., 2019). However, we disregarded tweets that contain only urls or emojis and translate non-English text to English. Alternative methods to compute sentiment exist but for the purpose of our textual data, RoBERTa has been shown to provide more robust estimates (Liu et al., 2019).

Our main exposure variable is maximum temperature. We measure maximum temperature on the day of the tweet using binary variables for the daily temperature range with intervals of 3°C ranging from < -6°C to > 33°C. The binary variables are preferred to a continuous measure of temperature to capture a non-linear association between temperature and sentiment as shown in previous studies (Wang et al., 2020).

Also, we collect additional meteorological information provided by Gridmet as precipitation, wind speed, shortwave downwelling radiation and humidity.

Method

$$1) \quad Y_{iutc} = TEMP_{tc}^{j} + X_{tc} + \delta_{mc} + \upsilon_{d} + \mu_{i} + \varepsilon_{iutc}$$

In the equation, Y_{iut} denotes the outcomes, positive and negative sentiment score, measured for tweet *i* of user *u* at date *t* in city *c*. The temperature exposure is captured by TEMP composed by the categories j described above and measured at date *t* and city *c*. The temperature range 3 to 24°C is considered as the comfort zone and excluded from the analysis. We capture the causal effect of temperature on sentiment using a set of widely used fixed effects(Heyes & Saberian, 2019). Most importantly, we use user level fixed effects $\mu_{i.}$ that allows us to capture the within user variation determined by a day in a specific temperature bin on sentiment relative to a day in the comfort zone. Also, we include month-by-city fixed effects δ_{mc} to account for city specific seasonal differences and day of week fixed effects υ_{d} to rule out that our results are biased by possible differences in users sentiment within the week such as the Monday effect (K. Kim & Ryu, 2022). Also, we added a vector X of time-varying meteorological and individual level control variables captured at date t in city *c*. The meteorological control variables that we include are precipitation, wind speed, humidity and solar radiation for which we use continuous values. Standard errors are clustered based on the month-by-city unit of analysis to account for spatial and temporal autocorrelation[1].

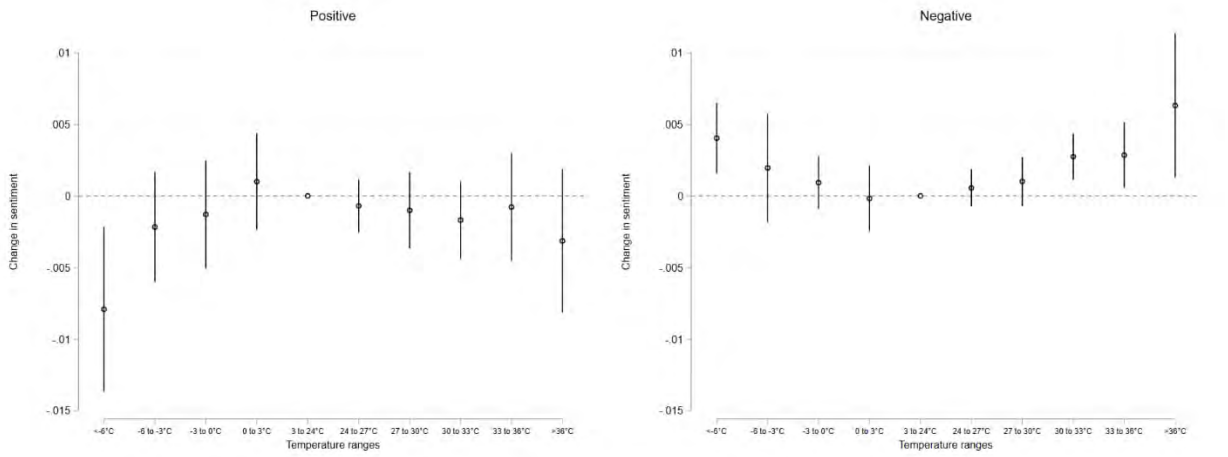
Also, we explore a stratified impact of temperature in our population. First, we inquire heterogeneity in the impact of temperature between our sample of natives and migrants adding a running separate analysis based on our dummy identifier (0=Natives, 1=Migrants). Secondly, we stratify the analysis within the migrant population based on their length of stay in the United States. More precisely, we use a binary to divide migrants in two groups i.e.: those that resided more than 24 months in the US and those that resided less than 24 months[2].

Preliminary results

In Figure 1, we present results on the impact of maximum temperature on positive and negative sentiment. We observe the relationship to be an inverted U-curve for positive sentiment and a U curve for negative sentiment. Respectively, extreme cold temperatures show to reduce positive sentiment with an increased effect size recorded at the coldest temperature bin (<-6°C). For hot temperatures(>36°C) we find a decrease in positive sentiment but the effects are not statistically significant at the 95% level. For negative sentiment, we observe a similar increase with hot and cold temperatures and a similar effect size at both extremes.

[1] Our estimates are robust to alternative clustering of standard errors.
[2] The choice of such threshold is based on the mean months of permanence in the sample of migrants that is 24 months.

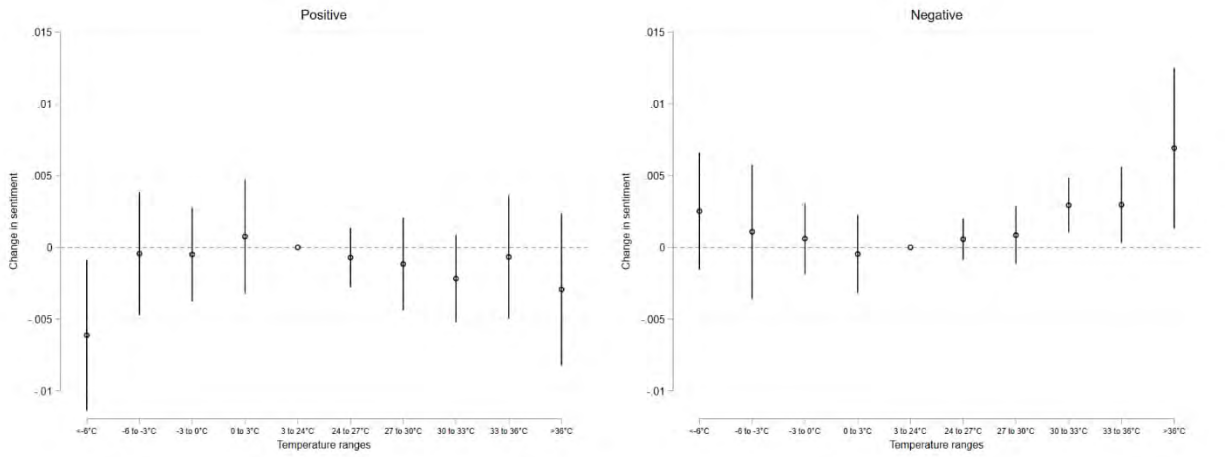
Figure 1. Maximum temperature impact on positive and negative sentiment



Note: in the figure we present results based on the equation 1 with 95% confidence intervals. On the left panel are presented results for positive sentiment and negative sentiment on the right.

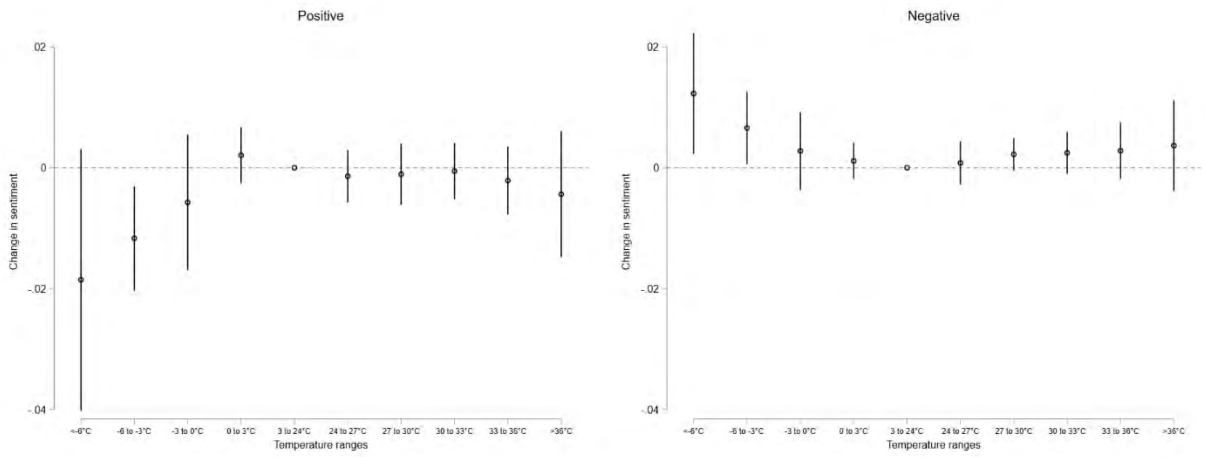
In Figure 2 and 3, we explore heterogenous effects of temperature on sentiment by migration background. However, we do not observe any significant differences between the two groups as the coefficients for natives in Figure 2 and migrants in figure 3 have similar effect sizes and the confidence intervals are overlapping.

Figure 2. Impact of temperature on native users



Note: in the figure we present results based on the equation 1 for the native sample. Coefficients with 95% confidence intervals. On the left panel are presented results for positive sentiment and negative sentiment on the right.

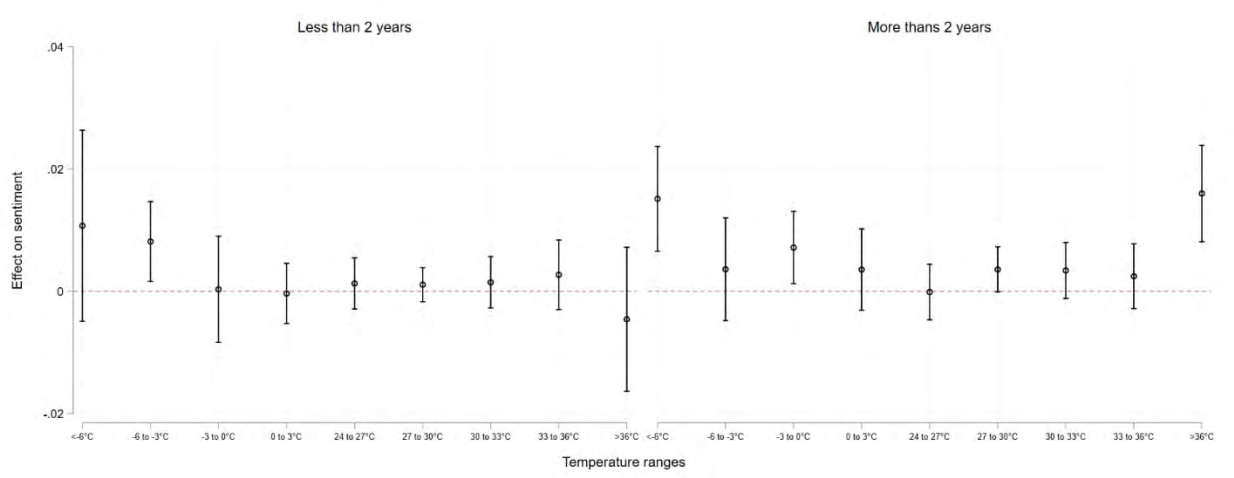
Figure 3. Impact of temperature on migrant user sentiment



Note: in the figure we present results based on the equation 1 and for the migrant sample. Coefficients with 95% confidence intervals. On the left panel are presented results for positive sentiment and negative sentiment on the right.

Despite not finding any differences in the impact of temperature between natives and migrants we could observe some variation within migrants. In Figure 4, we observe a larger increase in negative sentiment with heat (>36°C) and cold(<6°C) for migrants that resided in the location for more than 2 years compared to those that resided less than 2 years. Possibly, the results could suggest migrants that resided for longer in the location to be more concerned about unusual weather events.

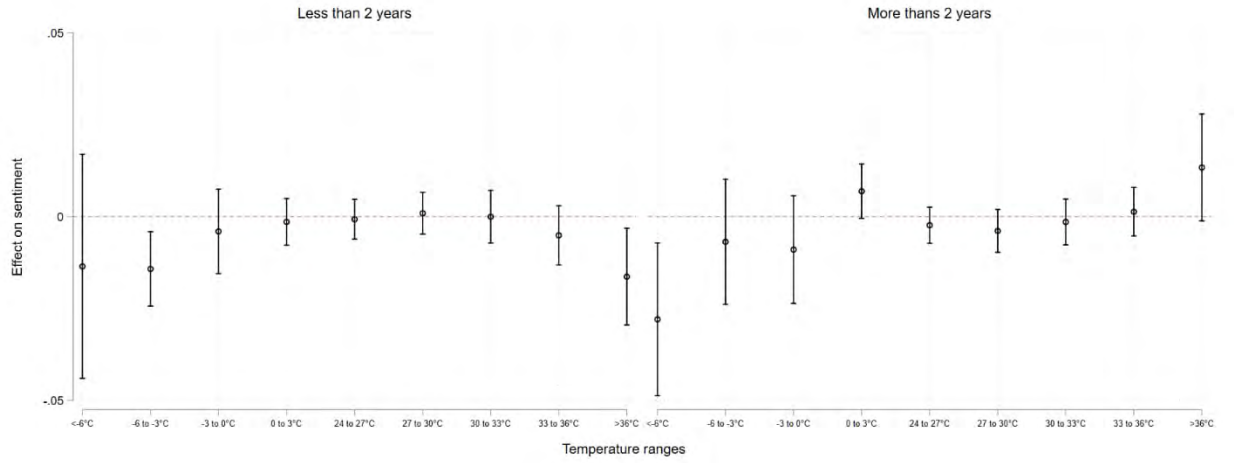
Figure 4. Impact of temperature on negative sentiment of migrants by permanence time



Note: in the figure we present results based on the equation 1 for the sample of migrants and an interaction with a dummy variable differentiating individuals that have been in the location for more than two years (0-1). With 95% confidence intervals.

Conversely, we observe in Figure 5 migrants that have resided less than two years in the location to experience a larger decrease in positive sentiment in their tweets when exposed to heat (>36°C). Possibly, the results could suggest a higher impact of such weather events on their mood.

Figure 5. Impact of temperature on positive sentiment of migrants by permanence time



Note: in the figure we present results based on the equation 1 for the sample of migrants and an interaction with a dummy variable differentiating individuals that have been in the location for more than two years (0-1). With 95% confidence intervals.

Discussion and conclusion

In this article, we have analyzed the impact of temperature on the expressed sentiment of a sample of Twitter users residing in the United States. We provided three main findings. Extreme cold and heat reduce positive sentiment and increase negative sentiment of Twitter users as found in previous research (Baylis et al., 2018; Wang et al., 2020). Secondly, we did not observe any substantive differences in the impact of heat on cold between native and migrants. Finally, we found differences in the impact of temperature within migrants depending on their length of stay in the United States. Interestingly, we observe a larger increase of negative sentiment with heat and cold exposure for migrants that have resided in the location for more than two years suggesting a higher concern to the temperature extremes. Conversely, migrants that have recently relocated to the US experience a larger decrease in positive sentiment when exposed to heat that could be related to their higher sensitivity to such weather extremes.

Our study has three main limitations. First, a problem we share with existing studies is that we cannot infer how expressed sentiment online affects behavior or mental health offline. Secondly, the findings should be carefully generalized to other populations, as our sample of Twitter users is not representative of the U.S. general population or of other Twitter users. Nevertheless, its strength is the availability of information on individual's country of origin. Thirdly, we are not able to differentiate if the tweets contain negative or positive information related to the weather, climate change or to user specific state of mind. However, previous research has shown results to be robust when excluding weather specific tweets from the analysis of temperature effect on expressed sentiment of individuals(Baylis et al., 2018).

In following analysis, we will explore additional heterogeneities in the sample of migrants. For example, differences could exist between migrants depending on their country of origin and their location of relocation in the United States.

In conclusion, new geotagged digital data sources combined with meteorological data allow to explore the impact of temperature extreme on populations for which currently there is small evidence of a stratified effect.

andrea.ongaro@unimib.it

Abstract

The prevalence of human microbiome data in biomedical research has increased due to the association observed between microbiome composition and several diseases. The Dirichlet-multinomial distribution is frequently used to analyze this type of data, but it often fails to adequately model real microbiome datasets due to the restrictive parameterization imposed on its covariance matrix. This work proposes a novel distribution to be considered in microbiome data analysis, which can be used to define an alternative regression model for multivariate count data (e.g., microbiome data). The new distribution is a structured finite mixture model with Dirichlet-multinomial components. We show how this mixture model can enhance microbiome data analysis by clustering patients into "enterotypes", a classification based on the taxa composition of gut microbiota. Finally, we consider an application based on a real gut microbiome dataset.

Keywords: Bayesian inference, Count data, Discrete simplex, Mixture model, Multivariate regression

1. Introduction

The set of genes associated with the microbiota (i.e., bacteria, viruses, and unicellular eukaryotes living in the human body) is usually referred to as the human microbiome (1; 6). The relationship between human beings and microbiota is generally mutually beneficial, but changes in the gut microbiome can be negatively associated with health outcomes, such as diabetes, cardiovascular disease, obesity, autoimmune disease, and anxiety (4; 10; 12). However, the attention that microbiome research is experiencing is not solely due to the above-mentioned medical associations, but also to remarkable improvements in DNA sequencing technology, making microbiome data easier to be collected.

The Dirichlet-multinomial (DM) distribution is commonly used for analyzing microbiome data (3; 14). The DM, by assuming that the probability vector underlying a multinomial distribution follows a Dirichlet distribution, enriches the analysis of microbiome datasets by allowing for overdispersion. Nonetheless, its covariance structure still results too rigid, making the DM inadequate for modeling real microbiome datasets and hindering the description of co-occurrence and co-exclusion relationships between microbial taxa. This study proposes a new distribution generalizing the DM, the extended flexible Dirichlet-multinomial (EFDM), and a regression model based on it. The EFDM provides a better fit to real microbiome data while still allowing for a clear interpretation of its parameters. As a finite mixture model with DM components, the EFDM can account for latent groups in the data, enabling the identification of clusters sharing similar microbiota compositions.

2. Statistical models for microbiome data

Given a specific biological sample, microbiome data represent its composition in terms of D bacterial taxa. More formally, we can define a microbiome dataset as a collection of D-dimensional vectors $\{\mathbf{Y}_1, \mathbf{Y}_2, \ldots, \mathbf{Y}_N\}$, where the r-th element Y_{ir} of $\mathbf{Y}_i$ counts the number of occurrences of taxon r in the i-th sample, $i = 1, \ldots, N$ and $r = 1, \ldots, D$. Since the i-th sample contains a total number n_i of bacteria, microbiome observations satisfy $\sum_{r=1}^{D} Y_{ir} = n_i$. From a statistical point of view, this implies that the support of $\mathbf{Y}_i$ is the D-part discrete simplex $\mathcal{S}_{n_i}^{D} = \left\{\mathbf{y} = (y_1, \ldots, y_D)^\intercal : y_r \in \{0, 1, \ldots, n_i\}, \sum_{r=1}^{D} y_r = n_i\right\}$.

2.1 Distributions on the discrete simplex

The DM is a widespread generalization of the multinomial distribution that can be obtained by taking advantage of a compound approach (7). More specifically, one can assume that $\mathbf{Y}|\mathbf{\Pi} = \boldsymbol{\pi} \sim \text{Multinomial}(n, \boldsymbol{\pi})$ and that $\mathbf{\Pi} \in \mathcal{S}^D = \{\boldsymbol{\pi} = (\pi_1, \ldots, \pi_D)^\intercal : \pi_r > 0, \sum_{r=1}^{D} \pi_r = 1\}$ (i.e., the D-part continuous simplex) follows a mean-precision parameterized Dirichlet distribution:

$$f_{\text{Dir}}(\boldsymbol{\pi}; \boldsymbol{\mu}, \alpha^+) = \frac{\Gamma(\alpha^+)}{\prod_{r=1}^{D} \Gamma(\alpha^+ \mu_r)} \prod_{r=1}^{D} \pi_r^{(\alpha^+ \mu_r)-1},$$

where $\boldsymbol{\mu} = \mathbb{E}[\mathbf{\Pi}] \in \mathcal{S}^D$, and $\alpha^+ > 0$ is a precision parameter. Within this framework, $\mathbf{Y}$ is marginally distributed as a DM, with probability mass function (p.m.f.)

$$f_{\text{DM}}(\mathbf{y}; n, \boldsymbol{\mu}, \alpha^+) = \frac{n!\Gamma(\alpha^+)}{\Gamma(\alpha^+ + n)} \prod_{r=1}^{D} \frac{\Gamma(\alpha^+ \mu_r + y_r)}{(y_r!)\Gamma(\alpha^+ \mu_r)}.$$

The mean vector of a DM distribution is $\mathbb{E}[\mathbf{Y}] = n\boldsymbol{\mu}$, so the parameter $\boldsymbol{\mu} = \mathbb{E}[\mathbf{Y}]/n$ can be thought of as a (scaled) mean vector. Moreover, its covariance matrix is

$$\mathbb{V}[\mathbf{Y}] = n\mathbf{M}\left[1 + \frac{n-1}{\alpha^+ + 1}\right], \tag{1}$$

where $\mathbf{M} = (\text{Diag}(\boldsymbol{\mu}) - \boldsymbol{\mu}\boldsymbol{\mu}^\intercal)$ coincides with the multinomial covariance matrix by considering $\boldsymbol{\mu} = \boldsymbol{\pi}$. On the one hand, Equation (1) highlights how the additional parameter α^+ allows increased flexibility in the variability structure with respect to the standard multinomial distribution. On the other hand, it is clear that the DM enriches the multinomial by adding just a single parameter (namely α^+) in the modelization of the covariance matrix, which may not be enough, especially with a large value of D.

We propose to take advantage of an alternative sound distribution defined on $\mathcal{S}^D$, namely the extended flexible Dirichlet (EFD, (9)). The EFD distribution can be defined as a structured finite mixture with Dirichlet components, entailing some constraints among the components' parameters to ensure the identifiability of the model.

Thanks to its mixture structure, the probability density function (p.d.f.) of an EFD-distributed random vector can be expressed as

$$f_{\text{EFD}}(\boldsymbol{\pi}; \boldsymbol{\mu}, \alpha^+, \mathbf{p}, \mathbf{w}) = \sum_{j=1}^{D} p_j f_{\text{Dir}}\left(\boldsymbol{\pi}; \boldsymbol{\lambda}_j, \frac{\alpha^+}{1 - w_r}\right), \tag{2}$$

where $\boldsymbol{\lambda}_j$ is the j-th component-specific mean vector defined by

$$\boldsymbol{\lambda}_j = \frac{1 - w_r}{1 - \mathbf{p} \cdot \mathbf{w}^\intercal}(\boldsymbol{\mu} - \mathbf{p} \circ \mathbf{w}) + w_r \mathbf{e}_j, \tag{3}$$

$\boldsymbol{\mu} \in \mathcal{S}^D$ is the overall mean vector of $\mathbf{\Pi}$, α^+ is a real positive value, $\mathbf{p} \in \mathcal{S}^D$ is the vector of mixing weights, $\mathbf{e}_j$ is a vector with all elements equal to zero except for the j-th which is equal to one, and

$\mathbf{w} = (w_1, \ldots, w_D)^\intercal$ is a D-dimensional vector whose r-th element lies in the $\left(0, \min\left\{1, \frac{\mu_r}{p_r}\right\}\right)$ interval and controls the distance among the components' barycenters (9). Here, $(\mathbf{a} \circ \mathbf{b})$ denotes the Hadamard (i.e., element-wise) product between vectors $\mathbf{a}$ and $\mathbf{b}$.

If the parameter $\mathbf{\Pi}$ of the multinomial is supposed to be EFD distributed, an alternative discrete distribution for count vectors is defined, namely the extended flexible Dirichlet-multinomial (EFDM). The p.m.f. of the EFDM can be expressed as

$$f_{\text{EFDM}}(\mathbf{y}; n, \boldsymbol{\mu}, \alpha^+, \mathbf{p}, \mathbf{w}) = \sum_{j=1}^{D} p_j f_{\text{DM}}\left(\mathbf{y}; n, \boldsymbol{\lambda}_j, \frac{\alpha^+}{1 - w_r}\right), \tag{4}$$

where $\boldsymbol{\lambda}_j$ is defined as in Equation (3). It is interesting to note that when $\mathbf{p} = \boldsymbol{\mu}$ and $w_r = 1/(\alpha^+ + 1)$ for every $r = 1, \ldots, D$, then the DM distribution is recovered. Thus, the EFDM is a generalization of the DM distribution, including it as inner point.

Equation (4) shows that the EFDM is a finite mixture with DM components displaying a precise form for their (scaled) mean vectors $\boldsymbol{\lambda}_j$, $j = 1, \ldots, D$. Thanks to the properties of a finite mixture model, the overall EFDM mean vector can be expressed as:

$$\mathbb{E}[\mathbf{Y}] = n \sum_{r=1}^{D} p_r \boldsymbol{\lambda}_r. \tag{5}$$

It is possible to show that the EFDM covariance matrix is characterized by $2D - 1$ additional parameters with respect to the DM, namely $D - 1$ distinct elements in the vector of mixing weights $\mathbf{p}$, and the D elements in the vector $\mathbf{w}$. This is the key element explaining the better ability of the EFDM in modeling a wide range of scenarios.

In Figure 1, the p.m.f. of the DM and EFDM distributions are compared through a discrete ternary diagram. In this example, $D = 3$ is selected and a clear bimodality of the EFDM can be noted. Indeed, even if the EFDM considers three non-empty components, its p.m.f. shows only two distinct modes due to two small values in $\mathbf{w}$, placing the second and the third clusters close to each other.

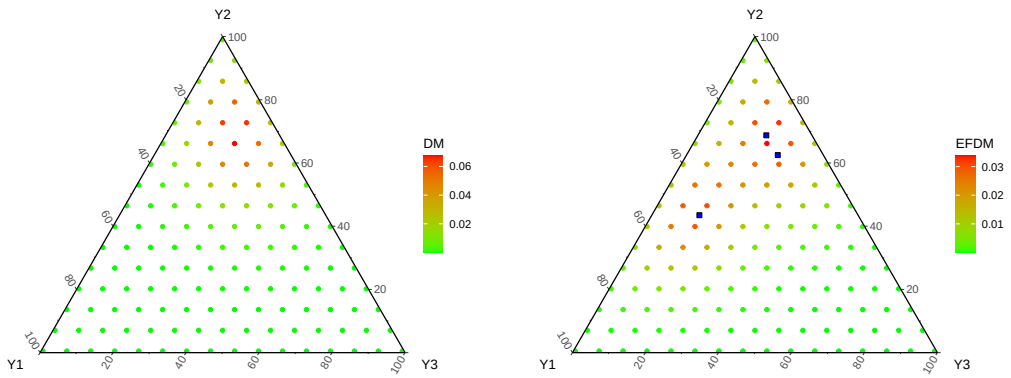

Figure 1: Probability mass function of the DM (left panel) and the EFDM (right panel) distributions with $n = 15$, $\boldsymbol{\mu}_{DM} = (0.13, 0.67, 0.2)^\intercal$, $\boldsymbol{\mu}_{EFDM} = (0.28, 0.54, 0.18)^\intercal$, $\alpha^+ = 150$, $\mathbf{w} = (0.348, 0.063, 0.063)^\intercal$, and $\mathbf{p} = (0.5, 0.25, 0.25)^\intercal$. Blue squares represent the component specific barycenters $\boldsymbol{\lambda}_1$, $\boldsymbol{\lambda}_2$, and $\boldsymbol{\lambda}_3$.

3. Regression models for microbiome data

To perform a regression analysis on a microbiome dataset, we start by considering a set of independent multivariate responses $\mathbf{Y} = \{Y_1, \ldots, Y_N\}$ collected on N subjects. Each response $\mathbf{Y}_i$ records the count (i.e., the frequency) of D possible taxa among n_i trials, so that the elements of $\mathbf{Y}_i$ sum to n_i. Furthermore, the i-th subject is associated with a $(K+1)$-dimensional vector of covariates $\mathbf{x}_i$. A parameterization of the EFDM model that is useful for regression analysis involves the parameters $\boldsymbol{\mu}, \mathbf{p}, \alpha^+, \tilde{\mathbf{w}} = (\tilde{w}_1, \ldots, \tilde{w}_D)^\intercal$, where

$$\tilde{w_r} = \frac{w_r}{\min\left\{1, \frac{\mu_r}{p_r}\right\}} \in (0, 1) \tag{6}$$

is a normalized version of w_r.

Two regression models can be defined: the EFDM regression (EFDMReg) and the DM regression (DMReg). EFDMReg assumes that each $\mathbf{Y}_i$ follows an EFDM$(n_i, \boldsymbol{\mu}_i, \alpha^+, \mathbf{p}, \tilde{\mathbf{w}})$ distribution, while DMReg assumes a DM$(n_i, \boldsymbol{\mu}_i, \alpha^+)$ distribution. In both models, by following a GLM-type approach (5), we can link the parameter $\boldsymbol{\mu}_i$ to the linear predictor by taking advantage of a proper link function, such as the multinomial logit link function:

$$g(\mu_{ir}) = \log\left(\frac{\mu_{ir}}{\mu_{iD}}\right) = \mathbf{x}_i^\intercal \boldsymbol{\beta}_r, \qquad r = 1, \ldots, D-1, \tag{7}$$

where $\boldsymbol{\beta}_r = (\beta_{r0}, \beta_{r1}, \ldots, \beta_{rK})^\intercal$ is a vector of regression coefficients for the r-th element of $\boldsymbol{\mu}_i$. The last taxon has been conventionally chosen as the baseline category, thus $\boldsymbol{\beta}_D = \mathbf{0}$, but any other taxa could have been selected as the baseline.

We shall adopt a Bayesian approach to inference, therefore a prior distribution for all parameters is needed. The parameterization of EFDMReg based on $\boldsymbol{\mu}, \mathbf{p}, \alpha^+$, and $\tilde{\mathbf{w}}$ defines a variation-independent parameter space, which allows assuming prior independence. As a consequence, we can elicit a prior distribution for each parameter separately. We prefer to adopt a weakly informative prior for each parameter, to induce minimum impact on the posterior distribution. In the following, we consider:

- $\boldsymbol{\beta}_r \sim N_{K+1}(\mathbf{0}, \Sigma)$, where $\mathbf{0}$ is the $(K+1)$-vector with zero elements, and Σ is a diagonal matrix with 'large' variance values;
- $\alpha^+ \sim Gamma(kg, g)$ for small values of the rate parameter g so to induce a large variability around the prior mean k;
- $\tilde{w}_r \sim Unif(0, 1)$, $r = 1, \ldots, D$;
- a uniform prior on the simplex for $\mathbf{p}$.

Inferential issues are dealt with by the Hamiltonian Monte Carlo (HMC) algorithm (8), which is a popular generalization of the Metropolis-Hastings. More specifically, the Stan modeling language (11) allows the implementation of an HMC method to obtain a simulated sample from the posterior distribution. To compare the fit of the models, we use the Watanabe-Akaike information criterion (WAIC) (13; 15), a Bayesian criterion that balances goodness-of-fit and model complexity. Models with lower WAIC values generally provide a better fit to the dataset.

4. An application to gut microbiome data

In this section, we show the results of the DMReg and EFDMReg models in a real-case scenario. In particular, we applied the DM and EFDM regression models to a microbiome dataset that was previously analyzed by Wu et al. (16) and Xia et al. (17). The dataset consisted of gut microbiome data from $N = 98$ healthy volunteers, with the counts of $D = 3$ bacterial genera (*Bacteroides*, *Prevotella*, and *Ruminococcus*) recorded. Arumugam et al. (2) used these bacteria to define three groups they called "enterotypes", which can provide information about the human body's ability to produce vitamins. Wu et al. conducted a cluster analysis on these data by using the partitioning around medoids (PAM) approach

and identified two of the three enterotypes defined by Arumugam et al, namely enterotypes 1 and 2. Moreover, these two clusters are characterized by different frequencies: 86 out of the 98 samples were allocated to the first enterotype, whereas only 12 samples were clustered into enterotype 2. This is due to the small number of subjects with a high abundance of Prevotella (i.e., only 36 samples showed a Prevotella count greater than 0).

In addition to bacterial data, we considered $K = 9$ covariates representing information on micronutrients in the habitual long-term diet, which were collected by using a food frequency questionnaire. These additional covariates were selected by Xia et al. using an l_1 penalized logistic normal multinomial regression approach. Table 1 shows the posterior mean and 90% credible set of each parameter involved in the DMReg and EFDMReg models. While the significant covariates are the same across the models, the EFDMReg model has a lower WAIC, indicating a better fit. This is due to the additional set of parameters involved in the mixture structure.

Table 1: Posterior mean and 95% CS for the parameters of the DMReg and EFDMReg models. Regression coefficients in bold are related to 90% CS's not containing the zero value.

		DMReg		EFDMReg	
		Post. Mean	90% CS	Post. Mean	90% CS

The mixture structure of the EFDMReg model can be utilized to cluster observations into groups through a model-based approach. Specifically, each observation can be allocated to the mixture component that most likely generated it. The mixing weight estimates (0.714, 0.210, and 0.076) from Table 1 confirm the presence of two out of the three enterotypes defined by Arumugam et al. To illustrate the benefits of the EFDMReg model in microbiome data analysis, we compared the clustering profile

Table 2: Confusion matrix for clustering based on the EFDMReg model compared to the PAM algorithm.

		EFDMReg	
		1	2
PAM	1	78	8
	2	2	10

obtained by the EFDMReg model and the one obtained with the PAM approach used by Wu et al. Table 2 summarizes this comparison in a confusion matrix, which shows that the clustering generated by the EFDMReg model highly agrees with the one obtained by the PAM algorithm (i.e., for 91.7% of the observations). This percentage is obtained using the covariates selected by Xia et al. in a logistic normal multinomial regression model context. Clearly, the results could be improved by developing an ad hoc variable selection procedure for the EFDMReg model. In conclusion, the EFDM distribution and the EFDMReg model are new statistical tools to be used in the analysis of microbiome data (as well as any other kind of multivariate count data). The main gain of the EFDMReg, as well as the better fit than the standard DMReg model, lies in its ability to jointly perform regression and clustering observations into some biological-relevant groups.

Abstract

The Italian Thyroid Cancer Observatory foundation maintains a database including all records on patients with confirmed diagnosis of thyroid cancer reported by several specialized centers in the country. One of the objectives of this project is to monitor the evolution over time of the response to treatment, which is a synthesis of serum values and ultrasound imaging, measured over an ordinal 4-point scale. The response to treatment is measured at 12 months, 3 and 5 years since the initial treatment; patients may underwent additional treatments, between measurement occasions, which may alter the initial risk composition. Our analysis focuses on modelling the response at 12 months as a function of baseline risk classification, clinical and surgical information. Further, we aim at exploring the transition between response categories when we consider the 12 months and 3 years measurements, since these may be affected by additional treatments occurred in the meanwhile.

Keywords: ordinal probit, multilevel study, unobserved heterogneity

1. The case study

The Italian Thyroid Cancer Observatory (ITCO) collects real-world practice data on patients with histologically confirmed diagnoses of differentiated, medullary, poorly differentiated or anaplastic, thyroid cancer. Data collection is performed via a web-based database made available since 2013 by the Thyroid Cancer Center at Sapienza University of Rome (the network's Coordinating Center). It has then been expanded to include data from several other centers in the country. It now includes more than 10,000 prospectively collected cases, registered at the time of primary treatment in one of the reporting ITCO centers. If the patient underwent surgery elsewhere, he/she is included when starting the follow-up in the reporting center (if within 12 months after primary treatment). Each record includes information on patient demographics and biometrics, diagnosis, pathology, surgical and radioactive iodine treatments, and information recorded at periodic follow-up examinations. For the purposes of this study, we focus on cases that match the following inclusion criteria:

1. histological diagnosis of differentiated thyroid cancer, including papillary, follicular, and poorly differentiated tumors;
2. registration in the ITCO database before February 1, 2023;
3. presence of clinical evaluation between 6 and 18 months after the primary treatment, when the response to the initial treatment is assessed.

Exclusion criteria are:

1. histological diagnosis of non-invasive follicular thyroid neoplasms with papillary-like nuclear features, unknown malignant potential tumors, medullary, or anaplastic thyroid cancer;
2. lack of complete information on the initial treatment or pathology.

For each case, several information are available, ranging from initial surgical treatment procedure, cervical lymph node dissection, radioactive iodine remnant ablation. The risk category was estimated by the study team according to the 2009 American Thyroid Association (ATA) guidelines (4), as modified by the 2015 release (6). The classification is based on data recorded at the time of initial treatment with a few exceptions in the presence of specific surgical or radioiodine remnant ablation (RRA) treatments, and for aggressive papillary thyorid carcinomas PTCs. The response to the initial treatment is calculated based on available clinical evaluation performed at 12 months (range 6-18 moths) since the initial treatment. It is an ordinal response with 4 categories, as described in the following, based on the evidence obtained from neck ultrasound [US] in all patients, and radioiodine scintigraphy in selected cases. Further information for defining the response is derived from basal/stimulated serum thyroglobulin (Tg) and anti-Tg antibody (TgAb) levels. Guidelines come from ATA when looking at patients undergoing thyroidectomy and RRA, and from the European Society for Medical Oncology (ESMO) as for the others. Ultrasound imaging was considered as indicative of an evidence of a disease in the presence of high suspicion lymph nodes, according to the European Thyroid Association guidelines stratification (7), while low suspicion lymph nodes were grouped in nonspecific findings (8).

2. The statistical model

Our purpose is to model the response to treatment at 12 months Y_{ij}, for patient $i = 1, \dots, n_j$, followed by center $j = 1, \dots, m$. Since the response is ordinal with $G = 4$ categories, we use an underlying random variable approach, see eg (3) for a thorough review. This dates back at least to the 50s, see e.g. (2) or (11) for early developments. The idea is that the *observed response* comes out of the discretization of an underlying latent variable Y_{ij}^* described by the following linear regression model

$$Y_{ij}^* = \sum_{l=1}^{q} z_{ijl}\beta_l + u_j + \varepsilon_{ij} = \mathbf{z}_{ij}'\boldsymbol{\beta} + u_j + \varepsilon_{ij},$$

where $z(\mathbf{x}_{ij}) = \mathbf{z}_{ij}$ is a q-dimensional design vector based on the p-dimensional vector of individual features $\mathbf{x}_{ij}$, $i = 1, \dots, n_j$, $j = 1, \dots, m$. Given the hierarchical structure of the available data, with patients nested within treatment centers, a mixed effect specification is used. That is, each center is associated to a specific intercept u_j, $j = 1, \dots, m$. The usual assumption of conditional independence holds; further assumptions entail independence of u_j and ε_{ij}, $i = 1, \dots, n_j$, $j = 1, \dots, m$, and *weak* exogeneity of the design vector with respect to the errors terms. Let us consider a set of strictly increasing thresholds, $-\infty = \alpha_0 < \alpha_1 \cdots < \alpha_{G-1} < \alpha_G = +\infty$; the underlying response variable (URV) approach is based on the assumption that $Y_{ij} = g$ if and only if $\alpha_{g-1} \leq Y_{ij}^* < \alpha_g$, $g = 1, \dots, G$. So that

$$\begin{aligned} \Pr\left(Y_{ij} \leq g \mid u_j, \mathbf{x}_{ij}\right) &= \Pr\left(Y_{ij}^* < \alpha_g \mid u_j, \mathbf{x}_{ij}\right) = \Pr\left(\mathbf{z}_{ij}'\boldsymbol{\beta} + u_j + \varepsilon_{ij} < \alpha_g \mid u_j, \mathbf{x}_{ij}\right) = \\ &= \Pr\left(\varepsilon_{ij} < \alpha_g - u_j - \mathbf{z}_{ij}'\boldsymbol{\beta} \mid u_j, \mathbf{x}_{ij}\right) = F_{\varepsilon|u,x}\left(\alpha_g - u_j - \mathbf{z}_{ij}'\boldsymbol{\beta}\right). \end{aligned}$$

The choice of non-decreasing thresholds α_g, $g = 1, \dots, G$, and a constant parameter vector $\boldsymbol{\beta}$ are useful to ensure non-decreasing values for the cdf of the error term. Different choices for the cdf $F_{\varepsilon|u,x}$ may lead to different models for the ordered response; among these, we may recall the *cumulative* probit and logit models. Denoting by $\boldsymbol{\alpha} = (\alpha_1, \dots, \alpha_{G-1})'$ the vector of thresholds for the URV specification and according to all the hypotheses above, we may define the log-likelihood function as follows:

$$\ell\left(\boldsymbol{\alpha}, \boldsymbol{\beta}, \phi\right) = \prod_{j=1}^{m} \int_{\mathcal{U}} f_{Y|X,U}\left(\mathbf{y}_j \mid \mathbf{Z}_j, u_j\right) f_{U|X}\left(u_j \mid \mathbf{Z}_j\right) \mathrm{d}u_j,$$

where

$$u_j \overset{iid}{\sim} f_U\left(\cdot \mid \phi\right), \quad j = 1, \ldots, m,$$

and

$$f_{Y|X,U}\left(\mathbf{y}_j \mid \mathbf{Z}_j, u_j\right) = \prod_{i=1}^{n_j} \prod_{g=1}^{G} \theta_{ijg}^{d_{ijg}}.$$

Here, the parameter θ_{ijg} is defined as

$$\theta_{ijg} = \Pr(Y_{ij} = g \mid u_j, \mathbf{x}_{ij}) = \Pr(Y_{ij} \leq g \mid u_j, \mathbf{x}_{ij}) - \Pr(Y_{ij} \leq g - 1 \mid u_j, \mathbf{x}_{ij}),$$

while d_{ijg} takes unit value if and only if $Y_{ij} = G$; that is, $d_{ijg} = \mathbf{1}(Y_{ij} = G)$, with $\mathbf{1}(\cdot)$ being the indicator function. The interested reader may refer to (1) for a comprehensive review of models for clustered ordinal responses. For a parametric assumption on the distribution of center-specific intercepts u_j, $j = 1, \ldots, m$, we may consider approximation techniques based on Gaussian quadrature and its extensions, see (9), (10). As it can be noticed, the distribution of the center-specific intercepts u_j, $j = 1, \ldots, m$, in the previous integral is conditional on the observed covariates, and this helps take into account potential dependence between center-specific observed and unobserved features. To handle this dependence, we approximate $f_{U|X}(\cdot \mid \cdot)$ by a discrete distribution specified on a finite set of locations $\{\zeta_1, \ldots, \zeta_K\}$ with associated masses given by $\pi(\zeta_k \mid \mathbf{X}_j)$, leading to the following log-likelihood function

$$\ell\left(\boldsymbol{\alpha}, \boldsymbol{\beta}, \phi\right) = \prod_{j=1}^{m} \sum_{k=1}^{K} f_{Y|X,U}\left(\mathbf{y}_j \mid \mathbf{Z}_j, u_j = \zeta_k\right) \pi\left(\zeta_k \mid \mathbf{X}_j\right),$$

where

$$\pi\left(\zeta_k \mid \mathbf{X}_j\right) \propto \exp\left[\mathbf{w}(\mathbf{X}_j)'\boldsymbol{\gamma}\right]$$

and $\mathbf{w}(\mathbf{X}_j)$ is an appropriate design vector that describes the dependence of u_j on $\mathbf{X}_j$, $j = 1, \ldots, m$, as in *concomitant variable* models, see (5).

3. Data analysis plan

After about 12 months since the initial treatment, the distribution of the $n = 5,840$ patients that satisfy the inclusion criteria by the surgical approach is as follows:

Table 1: Distribution of the response at 12 months by surgical approach

	Surgical approach		
Response	TT	nTT	LT
1	196	4	2
2	329	16	9
3	2285	88	5
4	2583	105	218
Total	5393	213	234

The response is classified as

1 *structural incomplete*: chemical and imaging evidence of the disease;
2 *biochemical incomplete*: chemical values above the threshold, without clear imaging evidence;
3 *indeterminate*: chemical values below the threshold, but above zero, no clear imaging evidence;
4 *excellent*: no chemical or imaging evidence.

In addition to the surgical approach (total thyroidectomy - TT, near total thyroidectomy -nTT, thyroid lobectomy -LT), we use info on patients' demographic (age and sex), clinical (ATA risk category, histology, tumor size, radioiodine remnant ablation, etc.) and surgical features (central, lateral neck dissection, number of lymph nodes metastatic and removed,etc.).

As it can be noticed from the table above, the response is excellent in the majority of the cases, but still it remains indeterminate in quite a large portion of the sample. This poses relevant clinical questions about treatment effectiveness and the reasons for indeterminacy; clinicians therefore suggested the need to extend the follow-up window to include visits up to, at least, three years since the initial treatment.

We therefore analyzed the transitions from the state (the response values) observed at 12 months and at three years since the initial treatment. The aim is that of verifying whether indeterminacy decreases with time and, if so, if this may be affected by additional treatments underwent between the two periodic follow-up visits. For this purpose, we restrict our attention to cases classified as indeterminate at 12 months since the initial treatment, and analyze whether further empirical evidence registered in that occasion (eg suspicious residual tissue in thyroid bed found by neck US) and additional treatments (in particular RRA) may help explain the transition to the state observed at 3 years since initial treatment.

Abstract

Graphical lasso methods are not invariant to scalar multiplication of the variables. On the other hand, Gaussian graphical models are invariant to scalar multiplication, and thus it is common practice to apply graphical lasso after the observed variables are standardized to unit sample variances. We consider the symmetric graphical lasso method for learning Gaussian graphical models for paired data and show that this family of models is not invariant to scalar multiplication of the variables, but that in the special case where homologous variables have equal variances it still makes sense to standardise the variables. We then carry out an empirical analysis to assess the impact of standardization on the symmetric graphical lasso method.

Keywords: brain network, fMRI data, Gaussian graphical model, penalized likelihood method.

1. Introduction

Let Y_V be a multivariate Gaussian random vector whose entries are indexed by a finite set $V = \{1, \ldots, p\}$, and let $G = (V, E)$ be an undirected graph with vertex set V and edge set E, where an edge is an unordered pair $\{i, j\} \in E$ of distinct vertices. In a Gaussian graphical model (GGM) every vertex of G is associated with a variable in Y_V, and the distribution of Y_V is said to be Markov with respect to G if every missing edge between two vertices implies that the corresponding variables are conditionally independent given the remaining variables. If we denote by $\Sigma = (\sigma_{ij})_{i,j \in V}$ and $\Sigma^{-1} = \Theta = (\theta_{ij})_{i,j \in V}$ the covariance and the concentration matrix of Y_V, respectively, then in a GGM it holds that for every missing edge of the graph, i.e. $\{i, j\} \notin E$ with $i \neq j$, the corresponding entry of the concentration matrix is equal to zero, $\theta_{ij} = \theta_{ji} = 0$; we refer to (4) for a comprehensive account on GGMs.

GGMs have become a popular tool in applications involving the joint learning of multiple networks, that is in the case where the observations come from two or more groups sharing the same variables, and it is expected that there are similarities between the networks associated with groups. In this context, the literature has mostly focused on the case where the groups are independent so that every network is a distinct unit, disconnected from the other networks (7), and only more recently on the case where groups are not independent (8; 9; 5; 6). More specifically, (5) and (6) considered the case of paired data, where there are exactly two dependent groups. Paired data commonly arise in paired design studies, where each subject is measured under two different conditions, or time points, as well as in matched observational studies.

In the pair data framework, Y_V is partitioned into two subvectors $Y_L = (Y_L, Y_R)^\top$ where $L = \{1, \ldots, p/2\}$ and $R = \{p/2+1, \ldots, p\}$ and every variable in Y_L has an homologous variable in Y_R. We set $i' = i+p/2$ and assume, without loss of generality, that Y_i is paired with $Y_{i'}$. Interest is for similarities between the edge structure of the two subnetworks of Y_L and Y_R, but also on similarities between the parameter values of the two groups. Hence, (5) considered GGMs with additional restrictions of the form

$$\theta_{ij} = \theta_{i'j'} \quad \text{for some} \quad i, j \in L. \tag{1}$$

We remark that GGMs with equality restrictions on the concentration values were introduced by (3) with the name of RCON models, and thus, formally, the constrains in (1) identify a subfamily of RCON models. (5) approached the problem of learning the model from data by implementing a penalized likelihood method, which they called the *symmetric graphical lasso* (SGL), that comprises two penalty terms: a graphical lasso penalty (2, section 9.3) to induce sparsity in the graph structure, and then a fused lasso penalty to induce the equalities (1).

One fundamental issue in the application of graphical lasso methods is that they are not invariant to scalar multiplications of the variables, and for this reason it is common practice to standardise the data to have unit sample variances; see, among others, (2, p. 8). It is not clear, however, as this preliminary step may affect the result of the analysis when a symmetric graphical lasso is applied and in this paper we investigate this problem.

2. Normalization in paired data problems

We first approach the problem by considering the simplifying assumption that the variances of the variables in Y_V are known. Formally, we assume that $\Delta = \mathrm{diag}(\Sigma)$ is known and set $Z_V = \Delta^{-\frac{1}{2}} Y_V$ so that $\mathrm{var}(Z_V) = \Delta^{-\frac{1}{2}} \Sigma \Delta^{-\frac{1}{2}}$ coincides with the correlation matrix of Y_V. Accordingly, the concentration matrix of Z_V is given by $\mathrm{var}(Z_V)^{-1} = \Delta^{\frac{1}{2}} \Theta \Delta^{\frac{1}{2}} = (\theta_{ij}\sqrt{\sigma_{ii}\sigma_{jj}})_{ij \in V}$ so that one can see that

$$\theta_{ij} = 0 \quad \text{if and only if} \quad \theta_{ij}\sqrt{\sigma_{ii}\sigma_{jj}} = 0. \tag{2}$$

Because the missing edges of G are given by the zero pattern of Θ, then it follows immediately from (2) that the distributions of Y_V and that of Z_V belong to the same GGM. It is straightforward that the same is true when Δ is any diagonal matrix with positive entries and this shows that GGMs are invariant with respect to scalar multiplication of the variables. Different is the case where we are interested in equality restrictions because

$$\theta_{ij} = \theta_{i'j'} \quad \text{does not imply} \quad \theta_{ij}\sqrt{\sigma_{ii}\sigma_{jj}} = \theta_{i'j'}\sqrt{\sigma_{i'i'}\sigma_{j'j'}},$$

and this shows that RCON models are not invariant with respect to the scalar multiplication of the variables, in the sense that the distributions of Y_V and Z_V do not generally belong to the same RCON model defined by the restrictions in (1). We can conclude that standardisation is a problematic step in the application of the symmetric graphical lasso method because it does not maintain the equality constraints of the process generating the original data.

A feature of paired data is that for every $i \in L$ the variables Y_i and $Y_{i'}$ are homologous and, thus, it is somehow natural to consider the specific case where their variances are equal. Indeed, if we assume that $\sigma_{ii} = \sigma_{i'i'}$ for every $i \in L$ then it is straightforward to see that $\theta_{ij} = \theta_{i'j'}$ if and only if $\theta_{ij}\sqrt{\sigma_{ii}\sigma_{jj}} = \theta_{i'j'}\sqrt{\sigma_{i'i'}\sigma_{j'j'}}$ and therefore, in this case, as far as the equality restrictions in (1) are concerned, the distributions of Y_V and Z_V belong to the same RCON model.

We turn now to the case where the entries of Δ are not known and a random samples of n i.i.d. observations from $Y_V \sim N(0, \Sigma)$ is available. Then, the normalization step is commonly carried out by replacing Δ with $\mathrm{diag}(S)$, where $S = (s_{ij})_{ij \in V}$ is the sample covariance matrix. Recall that in GGMs it holds that $\hat{\sigma}_{ii} = s_{ii}$ is the m.l.e. of σ_{ii}, for every $i \in V$. On the other hand, we have seen above that for the family of RCON models of interest it makes sense to standardise the variables only when homologous variables have equal variances, and in this case the m.l.e. of the variances can be computed

as $\hat{\sigma}_{ii} = \hat{\sigma}_{i'i'} = (s_{ii} + s_{i'i'})/2$, for every $i \in L$. This suggests that in RCON models for paired data we have three possible options: no standardization (NS); classical standardization (CS), where we use a rescaling matrix with sample variances s_{ii} on the diagonal; equal variances standardization (EVS), where we compute the m.l.e. of the variances under the assumption that $\sigma_{ii} = \sigma_{i'i'}$, and plug them into the computation of the rescaling matrix.

3. Empirical analysis on fMRI brain data

Although the application of graphical lasso to standardised data has become common practice, little is known about the impact of this operation on the result of the analysis, with the relevant exception of (1) where it is shown that the standardisation of the variables may have a strong effect on the result of inference with the graphical lasso. In this section, we consider RCON models for paired data and carry out an empirical analysis to assess the effect of standardisation on the result of the SGL method. We base our analysis on a set of real data so as to assess the impact of this rescaling in a relevant area of application. More specifically, we consider neuroimaging data previously analysed in (5). The data set we consider refer to $n = 404$ observations from $p = 70$ regions of the human brain, spatially paired regions from the left hemisphere (Y_i with $i = 1, \ldots, 35$) and the right hemisphere ($Y_{i'}$ with $i' = 36, \ldots, 70$).

We have shown in Section 2. that in paired data problems it makes sense to standardise the variables only if the assumption of equal variances is satisfied and that, in this case, different types of standardisation are possible. We apply the SGL method to the residuals from a parametric filter on the original time series. These can be assumed to be i.i.d. realizations from a $p-$dimensional multivariate Gaussian distribution with zero mean vector and covariance matrix Σ. The covariance matrix is unknown and it is reasonable to assume all variables to be measured on the same scale, with equal variances, due to how the signals are recorded, pre-processed and then filter for temporal correlations. In this way, when applied to these data, the three different standardisation methods, i.e. (NS), (CS) and (EVS), should not affect or impact the results obtained by using the SGL method to estimate the concentration matrix from the data.

We have therefore a framework that allows us to quantify the effect of standardisation by comparing the models obtained from the application of the SGL method after the three different standardisation methods have been applied. Furthermore, in order to assess the uncertainty of the estimated effects, a subsampling procedure is implemented, as follows. From the original 404×70 data matrix we generate $B = 10$ subsamples by randomly sampling the observations into batches of size $\tilde{n} = 100$. For each of these 10 subsamples, as a first step we compute the sample covariance matrix S. Secondly, we rescale S via one of the three standardisation methods. In each subsample $b = 1, \ldots, B$, for each of the three options we fit the SGL model: the output of the algorithm is an estimated concentration matrix $\hat{\Theta}$ and the associated graph $\hat{G}$ and equalities in the concentration values.

We inspect the obtained graphs to understand the effect of the three approaches for standardization. In particular, we summarize how much these graphs are similar to each other, for all possible pairs of comparisons: $\{\hat{G}_{\text{NS}}, \hat{G}_{\text{CS}}\}$, $\{\hat{G}_{\text{NS}}, \hat{G}_{\text{EVS}}\}$, and $\{\hat{G}_{\text{CS}}, \hat{G}_{\text{EVS}}\}$. To quantify the similarity we use two different metrics: the F1 score, that is the harmonic mean of precision (fraction of true positives among predicted positives) and recall (fraction of true positives over the actual positives); and the Matthews Correlation Coefficient (MCC), which is the analogous of a correlation coefficient for binary classifiers. The F1 score ranges from 0 to 1 and higher values are associated with better matching between the two objects; the MCC varies from -1 to +1, with larger values (irrespective of the sign) characterizing situations where the two graphs agree on the structure identified. The two metrics are computed twice: (i) in terms of edge structure, that is considering how many edges are common to the two solutions compared; (ii) in terms of symmetric concentrations, which refers to the common equality constraints identified by the two fitted models being compared. We report a summary of the results for the analysed data in Table 1.

Considering first the edge structure, the average value of F1 is higher when comparing CS and EVS than the average values computed by juxtaposing each of the two options for standardization to NS. This means that the effect itself of rescaling - either assuming equal variances for all variables

Table 1: Average (*standard deviation*) F1 scores, in percentage, and MCCs across the 10 random subsamples; `NS`: no standardization; `CS`: classical standardization; `EVS`: equal variances standardization.

Compared methods	Edge structure		Symm. concentrations	
	F1 score	MCC	F1 score	MCC
NS - CS	54.05 (*2.73*)	+0.51 (*0.05*)	62.51 (*3.58*)	+0.62 (*0.04*)
NS - EVS	51.52 (*5.34*)	+0.49 (*0.04*)	39.82 (*20.29*)	+0.49 (*0.12*)
CS - EVS	70.87 (*7.72*)	+0.67 (*0.11*)	56.70 (*27.82*)	+0.66 (*0.17*)

(`CS`) or assuming paired equalities (`EVS`) - produces two graphs similar to one another, and both these graphs appears to be less comparable with the one obtained without applying any rescaling at all. The insight is corroborated also by the computed average MCC values. A similar argument can be made with respect to the symmetries on the concentration matrices obtained by the SGL in each of the three scaling options: all average value of F1 are below 70%, with the similarity measure showing high variability when considering the comparisons that involve the EVS option. Some evidence of differences in the symmetries identified by the SGL for the three scaling methods is found also in the computed average MCC values.

We want to highlight that, although we expect data in this specific application to be observed on the same scale, the impact of the standardization is relevant on the recovered graphs, suggesting that either the assumption of equal variances is not met or the chosen option for rescaling actually matters. Moreover, even the comparison with the highest similarity (`CS` and `EVS`, with an average F1 score of 70.87%) points out there is still some effect of the choice of standardization method on the symmetric graphical lasso procedure, which deserves further investigation.

4. Discussion

In this short manuscript we tackled the often overlooked issue of rescaling data as a preliminary step to applying a graphical lasso procedure and, in particular, the SGL algorithm. We used fMRI data as an example of a setting where it is reasonable to assume variables to be measured on the same scale. We quantified the (dis)similarity of the recovered graphs, in terms of edge structure and symmetric concentrations, obtained by employing each rescaling option available and we observed a lack of robustness of the estimates to the approach adopted for standardizing.

We consider the problem of rescaling worthy of further considerations, and a potential venue for future research in order to understand the plausibility of equal variances assumption, and what is the effect of the rescaling when that assumption is not valid.

Abstract

The transition to more environmentally sustainable production processes and managerial practices is an increasingly important topic. Many industries need to undergo radical change to meet environmental sustainability requirements; the tourism industry is no exception. In this respect, a particular aspect that needs further attention is the relationship between airport performances and investments in environmental sustainability policies. This work represents a first attempt to provide empirical evidences about this relationship. Through the application of a non-parametrical method, we first assess the efficiency of the Italian airports' industry. Secondly, we investigated the relationship between airports' performance and management commitment toward the ecological transition using a Tobit regression model. The results show that airports' adherence to formal multi-year ecological transition programs has a positive and consistent impact on their performance.

Keywords: Environmental sustainability, DEA, Air transport sector, Tobit Regression.

1. Introduction

Today, the airport network of a country is considered a strategic asset for governments. Moreover, airports are the main engine of the tourist sector and several studies have shown their significant contribution to the economic development of the regions that host them (5; 6). The economic boost is due to the airport activities, which manifest themselves by reducing unemployment, increasing income per capita, enhancing productivity, favoring greater investment and trade as well as greater social and cultural development (18; 22; 24). Moreover, the performances of airports are a topic of interest for a vast array of stakeholders, including airlines, governments, passengers, and the residents of the served areas (9; 22). Another topic of growing importance is sustainability, intended as the societal goal to reduce human impact on the environment. In particular, the attention to transition management (i.e., the set of processes through which certain aspects of society change significantly over a short time horizon) to push sustainable growth is increasing sharply (21). In the airport sector, Airport Carbon Accreditation (ACA) is currently the only globally institutionally recognized certification for reducing the carbon footprint. This measure was launched in 2008 by Airport Council International (ACI), through 6 certification steps: "Mapping", "Reduction", "Optimization", "Neutrality", "Transformation" and "Transition". A fundamental prerequisite for accessing this program is the accomplishment, by an accredited institution, of compliance with ISO14064 (Greenhouse Gas Accounting). By reaching the latest level of accreditation (Transition), the airport proves to be in line with the 2015 Paris Agreement, that is, to actively

contribute to limiting the global average temperature rise to 1.5 °C and no more than 2 °C compared to preindustrial levels. Several works have been proposed to evaluate the performances of the airports (8). However, few have been interested in the environmental performances (16), while the relationship between efficiency and environmental sustainability is still an unexplored topic. The aim of this work is to study the relationship between the performance in terms of efficiency of airports and the investments towards the adoption of more sustainable practices. To achieve this goal, a two-step analysis was conducted on a dataset of Italian airports: first, we estimated the efficiency frontier through the Data Envelopment Analysis (DEA) approach. Subsequently, through a Tobit regression model, we investigated whether a relationship between efficiency and environmental sustainability exists. This was possible through the creation of a proxy variable that could assess which airports are further ahead in investments aimed at sustainability.

2. Literature review

Firms' efficiency, as well as the efficiency of the production process, are concepts widely studied in the transport sector, the agro-food sector, the large-scale retail trade, telecommunications, and the banking sector. The literature of benchmarking is mainly divided in two streams. One, focused on the use of parametric models, such as the stochastic frontier analysis (e.g., (1; 27)), where it is necessary to establish a priori a functional form for the relationship between input, output, and inefficiency. Notwithstanding, another research flow is involved in the adoption of nonparametric models for the study of the frontier, such as Data Envelopment Analysis (DEA) modeling (e.g., (4; 8; 19; 20)). DEA is a method that arises from the seminal work of (15) and (17), who were the first to try to measure the efficiency of a sample of production units, the so-called decision-making units (DMUs). This method, through a linear programming procedure, provides an efficiency score for each DMU with a limited number of necessary assumptions. It is based on an optimization function that defines weights to be attributed to the combination of inputs and outputs of each DMU such as to maximize the outputs (setting the level of inputs) or minimize the inputs satisfying at least a given level of output (hereinafter output-oriented and input-oriented DEA models). Furthermore, the DEA modeling framework can be divided according to the assumptions on the returns to scale. The model assuming constant returns to scale was developed by (12), while (7) added an assumption about the concavity of the frontier, allowing for variable returns to scale. The main difference between the two models lies in the definition of efficiency; in the Charnes model (henceforth CCR-I), the computed efficiency score is the overall efficiency of the DMU (i.e., OTE), taking into account both technical efficiency (i.e., the ability to produce a desired output using the minimum possible input) and allocative efficiency (i.e., the ability to use inputs optimally, choosing the most efficient combination of inputs). In the Banker's model (BCC-I), the score measures only the technical efficiency of the production unit, ignoring allocative efficiency (i.e., PTE). The DEA has been widely employed in the investigation of airport efficiency since the seminal work of (19). Some researchers, for example, (26), and (2), studied the efficiency of airports through an input oriented DEA (DEA-I), arguing that the main output, passenger traffic, was a phenomenon beyond managerial control, and therefore a difficult to maneuver lever. Others (e.g., (11; 19; 23)) have adopted an output-oriented DEA (DEA-O), assuming that most of the equipment for airport operation has the nature of fixed assets, therefore beyond the control of management (at least in the short run).

In the literature about the air transport sector, DEA models have been used in a two-step analysis, in the first step, the DEA is used to estimate the efficiency frontier, while in the second step regression models are used to explain the efficiency itself. A useful tool for estimating a linear relationship when the dependent variable is simultaneously censored on the left or on the right is the Tobit regression model (28). In practice, Tobin's model modifies the likelihood function in order to take into account the non-equiprobability in sampling for each observation depending on whether the latent dependent variable has fallen above or below the threshold determined by the censorship. In this way, it is possible to further discriminate the phenomena that influence the performances of the airports. Concerning the variables to be included in the models, several evidences have been highlighted in literature, such as for example the ownership of the airports (25), their sizes (11), the internationality of airport traffic (13) the location of the

airports (29) and their belonging to a group (3). However, the relationship between airport performance and environmental sustainability seems to remain particularly unexplored.

3. Data description

The dataset used in the present study reports information on almost all Italian airports (30 units) in 2019. The sample covers over 99% of all passengers transiting through Italian airports in the year, so it reports information very close to that of the real population. The data were collected merging various sources: economic and financial information from the AIDA platform, data on passengers, movements of aircraft and goods from the Italian Statistical Institute (ISTAT) archives; data on the runways, internal equipment, and size from the National Air Transport Authority (ENAC); and, finally, some variables have been constructed by the authors, as explained in the following. We computed both the variable returns to scale input-oriented model BCC-I (7), and the constant returns to scale input-oriented model, CCR-I (12) with 4 inputs (EMPLOYEES, CHINDESKS, RUNWAYMT, PRODCOSTS) and 4 outputs (TOTPAX, GOODS, TOTPLANES and TOTREVENUES). To ensure the discriminatory power of the DEA in this analysis, we followed the criteria suggested in the literature on the relationship between the number of DMUs, and inputs and outputs (e.g., (14)). Our model respects both the $N_{DMU_s} \geq 3 \times (inputs + outputs)$ rule, and the $N_{DMU_s} \geq (inputs \times outputs)$ rule. The variable EMPLOYEES contains the total number of employees, CHINDESKS reports the number of check-in desks available in the terminal, RUNWAYMT the runway meters, PRODCOSTS the total production costs (thousands / EUR), TOTPAX (%), GOODS (%), TOTPLANES (%), contain information on the total number of airports' passengers, goods and airplanes managed as percentage of the total in Italy in the year 2019, TOTREVENUES indicates revenues totals (thousands/EUR) for the year studied, and SURFACE describes the total surface of the airport (m^2).

4. Results

In table 1 we report the results of the DEA. The DEA models suggest that 6 out of 30 airports are globally efficient (OTE = 1), while 12 out of 30 reach the purely technical efficiency frontier (PTE = 1). The average efficiency of Italian airports is relatively high. Indeed, the average efficiency exceeds 79% considering the OTE and is even higher for the PTE (87.9%). Following these results, we can see how Italian airports are well managed on average. By comparing the scores arising from the 2 models, we can discriminate between the relative inefficiency of the DMUs due to the management of operations (PTE) and the inefficiency due to its scale (SE). 6 out of 30 airports exhibit constant returns to scale and are efficient, suggesting that they are in their optimal production condition. However, the remaining DMUs operate under increasing returns, indicating that many airports could experience a more than proportional increase in performance from the increase in their production size. In order to investigate the relationship between performance and environmental sustainability, we constructed a variable able to capture the commitment toward the ecological transition shown by the management. Exploiting the 6 ACA certification steps, the variable SUSTAINABILITY was designed to assume values between 0 and 7. Level 0 includes all airports that do not currently exhibit any commitment towards sustainability that is higher than the duties established by Italian law. Level 1 includes all the companies that have publicly declared (through the website) a real commitment (e.g., reclamation investments in the area surrounding the airport, efficient water management, installation of solar panels), but which have not been admitted to in the ACA program. Scores from 2 to 7 are attributed to all companies that adhere to the ACA program based on the certification level reached by the airport (e.g., score 2 = "mapping", score 3 = "reduction", score 3 = "optimization", etc).

In table 2 we exhibit the results for the Tobit regressions (we report the marginal effects). The management's adoption of policies aimed at environmental sustainability has a positive impact on the performance of the airport. Further, the coefficient shows a positive sign, and the likelihood ratio test (LT) confirms the significance of the estimate, rejecting the null hypothesis that the SUSTAINABILITY

effect on the efficiency scores is equal to 0. This is an important result and, to our knowledge, the first in identifying a clear impact of sustainable choices on airport performance. Both DEA models adopted for the study are input-oriented. The positive effect of an airport's admission to the ACA program could suggest that the improved efficiency is linked to an internal efficiency process (e.g., mapping excess CO2 emissions). If we consider the impact of sustainability on purely technical efficiency (BCC-I), the effect seems to be amplified, confirming an improvement in purely operational management. The EBITDA margin has a positive, statistically significant coefficient and with a considerable magnitude. This implies that the Italian airports, which transform a notable part of the sales volume into profits, are more efficient. The variables LCC and GROUP are not significant, suggesting that the airlines business model does not affect airports' efficiency and that independent airports or airports belonging to a group have, on average, similar performances. The same could be said for OWNERSHIP. Our results suggest that there is no evidence from data that private owned airports outperform public ones or vice-versa. The coefficient of LOGAREAPAX is significant but with the opposite sign considering the overall efficiency (which seems to benefit from more spaces dedicated to passengers), and purely technical efficiency. This may suggest that space management is crucial for the airport. Increasing the available space can lead to

the installation of more sale points and attractions for the passengers, and this can lead an airport to an overall efficiency resulting from the generated higher revenues. However, more space can also lead to potential threats in the operational management of resources.

5. Concluding Remarks

The present work constitutes an attempt to understand the relationship between airports efficiency and environmental sustainability. Specifically, the effect of airports joining programs aimed at reducing environmental impacts on overall efficiency and pure technical efficiency has been deepened through a DEA model and a Tobit regression analysis. Our results suggest that there is a statistically significant and positive association between Italian airport efficiency and environmental sustainability. In fact, according to our model, airport efficiency increases as management's commitment to sustainable policies grows. In particular, we assessed sustainability by discriminating between airports that do not show any declared commitment to ecological transition practices exceeding the obligations imposed by national law, and airports that adhere to the ACA program. This constitutes an important result, as it demonstrates that the time is now ripe for managers to include environmental performance improvement policies in their strategic choices, particularly in the airport sector.

Sustainability: still an undefined concept for Italians

Raffaele Angelone[a], Andrea Marletta[a]

[a]University of Milano-Bicocca: raffaele.angelone@unimib.it, Andrea.marletta@unimib.it

Abstract

During recent years, the concept of sustainability has been spread like one of the most cited and interesting trend topics giving a lot of definitions and good practices to perceive it. One of the aspects less frequently faced is the perception of sustainability for the population and the companies. In this paper, this issue has been analysed using results from a survey in which a sample of 1,000 respondents answered to the perception of sustainability for Italian companies. Since items in the questionnaire also asked for the behaviour of the respondent regards to the company declaring to be sustainable in terms of preferences and availability to spend, it is possible to identify different behaviours from the respondents. From a methodological point of view, these behaviours have been achieved creating some decision trees where each node represents a different group of respondents.

Keywords: Sustainability, sample survey, decision trees

1. Introduction

The theme of sustainability is actual and attractive for researchers and many contributions in terms of papers and projects have been published about it. From a statistical point of view, this has been translated in the research of some indicators able to give a clear and quantitative definition of sustainability [1]. In this way, the publication of the sustainable development goals (SDGs) in 2015 was a referring point on the path of sustainable development [7]. From an economic point of view, this concept is normally associated with the concept of circular economy and with the development of policies intent on reduce the wastefulness of resources [6]. In most cases, people associated the definition of sustainability only to issues related to the environment citing the R's concept: Reduce, Reuse and Recycle [4] but there are other fields in which this concept has been spread very quickly as the tourism sustainability or sustainability in medicine [2,5].

In this paper, the attention is focused in the perception of citizens towards the sustainability and the concrete actions conducted by the companies to achieve the sustainable development goals in Italy. This objective was achieved asking the population how much they are informed about sustainability, SDGs and how much they are available to pay to choose a sustainable company respect to one not sustainable. To realize this, a survey has been conducted on 1,000 respondents and the aim of the survey is to measure the population's knowledge of the 2030 Agenda, its objectives, and the level of perception of companies' actions in this area.

The analysis starts by describing the attitudes and behaviours of the investigated population regarding sustainability and then identifies the different approaches to the topic and defines groups of respondents characterised by them. To achieve this objective the decision tree technique has been applied. The use of this technique allows detecting the most discriminant variables leading to the creation of the nodes representing the groups.

The paper is structured as follows: after the introduction, a second section is dedicated to the methodologies used to answer the research objectives. A third section will show the description of the dataset and some preliminary results. Finally, some conclusions will follow.

2. Decision trees for sustainability behaviours

The construction of decision trees belongs to the family of classification models. It classifies cases into groups or predicts values of a dependent (target) variable based on values of independent (predictor) variables. The procedure provides validation tools for exploratory and confirmatory classification analysis. One of the most used scopes of decision trees is for segmentation, that is to say, to identify persons who are likely to be members of a particular group. In this context, each group correspond to a different behaviour towards the sustainability. Differently from other classification methods, as for example, the cluster analysis, the decision trees also propose a flow that leading to the creation of a group. In a questionnaire, this method could start from a question that is more discriminant and it makes a first classification based on that question. Secondly, the first partition is split into new nodes based on the second more discriminant question and so on.

Even if this method is immediate in presence of quantitative variables, it is possible to draw decision trees also using normal or ordinal data. In this case, since the items are in a 4-point or 5-point scale, the use of this technique is justified.

For the analysis, the growing technique, that is to say the decisional rule used to obtain the nodes was the CHAID (Chi-squared Automatic Interaction Detection) method. At each step, CHAID chooses the independent (predictor) variable that has the strongest interaction with the dependent variable. Categories of each predictor are merged if they are not significantly different with respect to the dependent variable [3].

Once obtained the nodes from the tree, a more in-depth analysis of socio demographic characteristics could provide a more complete picture of respondents and help in better understanding their attitude towards sustainability

3. Application and results

Data have been collected through a survey by Demoskopea, an Italian marketing research company. The study was carried out on a quota sample of 1,000 cases representative of the Italian adult population (18-64 years) broken down by age, gender, geographical area and town size. The respondents, after being drawn from a panel of individuals collected to be representative of Italian population, received an e-mail with an invitation and a link to participate in the study. The 10-minute questionnaire was administered in CAWI (Computer-Assisted-Web-Interviewing) mode. Before identifying the behaviours respect to sustainability, some general considerations about the perception of sustainability of the respondents could be drawn. The study reveals a limited knowledge of the 2030 Agenda and its contents by the Italian population; in fact, only 28% of those interviewed claim to know the agenda and its objectives. The youngest segments of population are the most aware (See Figure 1).

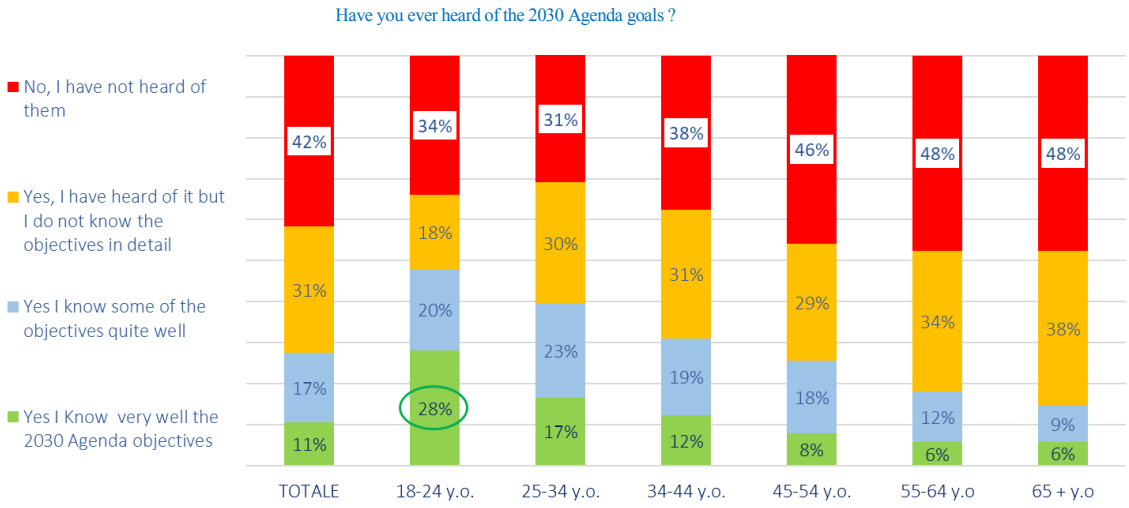

Figure 1: General perception of Sustainability for Italian population (Total Sample n.=1.000)

The concept of sustainability and its content are not well defined for a large part of the Italian population. The topic is mostly reduced to the topics most discussed in the public debate such as climate awareness and the need to use renewable energy sources.

The very young (18-24 years) tend to have a vision linked to more specific topics such as waste management, ensuring the well-being of the population, and a return to organic farming (See Table 1). The column percentages have been computed only considering answers given by respondents in that age interval.

	TOTAL	18-24 y.o	25-34 y.o.	35-44 y.o.	45-54 y.o.	55-64 y.0	65+ y.o
Being climate and environmentally conscious	45%	36%	48%	41%	46%	46%	47%
Making greater use of renewable energy	44%	42%	46%	38%	41%	52%	45%
Adjusting resource consumption to planet production	32%	28%	32%	33%	29%	34%	36%
Increasing separate waste collection	26%	32%	28%	25%	26%	25%	26%
Using ecological means for mobility in cities	25%	28%	23%	23%	26%	29%	24%
Meeting current needs without compromising the future	20%	18%	15%	20%	22%	18%	29%
Preferring purchases of zero-km products	19%	16%	16%	21%	19%	20%	18%
Aiming at people's wellbeing	14%	18%	16%	12%	13%	15%	13%
Promoting organic farming	12%	20%	15%	14%	9%	9%	12%
Becoming Carbon Neutral	11%	13%	14%	15%	10%	8%	7%
Ensuring job protection	10%	10%	8%	9%	13%	9%	8%
Ensuring public health care for all	9%	14%	5%	7%	11%	8%	16%
Combating illegal work and exploitation	7%	4%	6%	7%	8%	10%	7%
Citizenship income for those in real need	5%	6%	6%	6%	5%	5%	2%
Respect for differences in gender/sexual orientation	4%	4%	5%	6%	5%	2%	4%

Table 1: Associated concepts with sustainability for Italian population for age (Total Sample n.=1.000)

As well as the general perception, perceptions of the role played by companies in the field of sustainability were also. Italians in principle show a broad openness in supporting the efforts of companies in the field of sustainability (75% of the population) and believe that these efforts can have a positive influence on consumer choices (56%). The youngest seems to be more willing to recognize the impact of companies' commitment (See Figure 2).

To what extent will the concrete commitment of companies to achieving the sustainability goals of the 2030 Agenda influence future consumer choices?

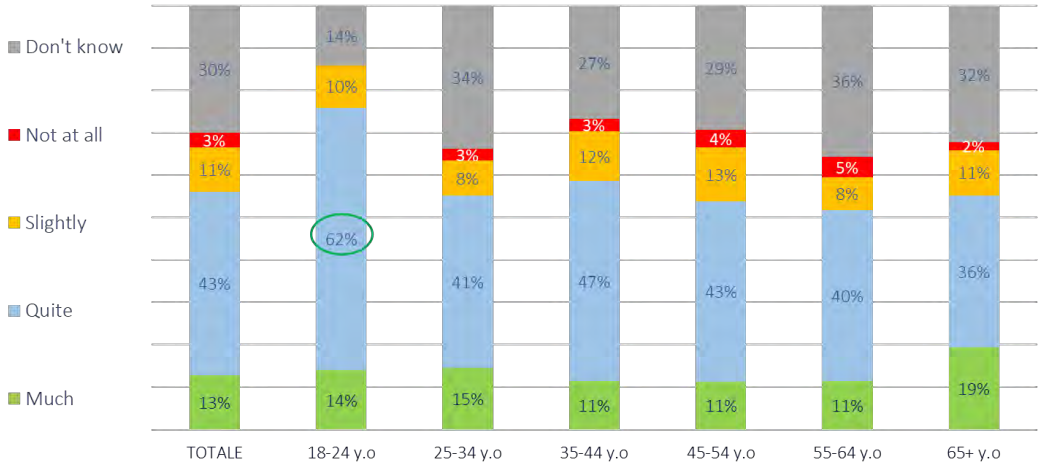

Figure 2: Influence of companies' commitment in sustainability on future consume choice. (Total Sample n.=1.000)

However, there is little awareness and limited recognition of companies' commitment to sustainability among respondents. Only 36% of respondents think that companies are committing to concrete actions for sustainability; 32% think they are not committing enough, and the remaining 32% have no idea about this. Looking at the different sectors, food and retail companies are perceived as more active.

Two reasons seem to explain the low recognition of companies' efforts: on the one hand, the difficulty of identifying and defining the objectives, the concrete actions that companies should take makes it difficult for people to recognise and evaluate them. As the matter of facts, Italians have no clarity on where companies should put their effort. As an answer to the question, they propose a long list of priorities on top of which we have the clean energy and the well-being for everybody (See Figure 3).

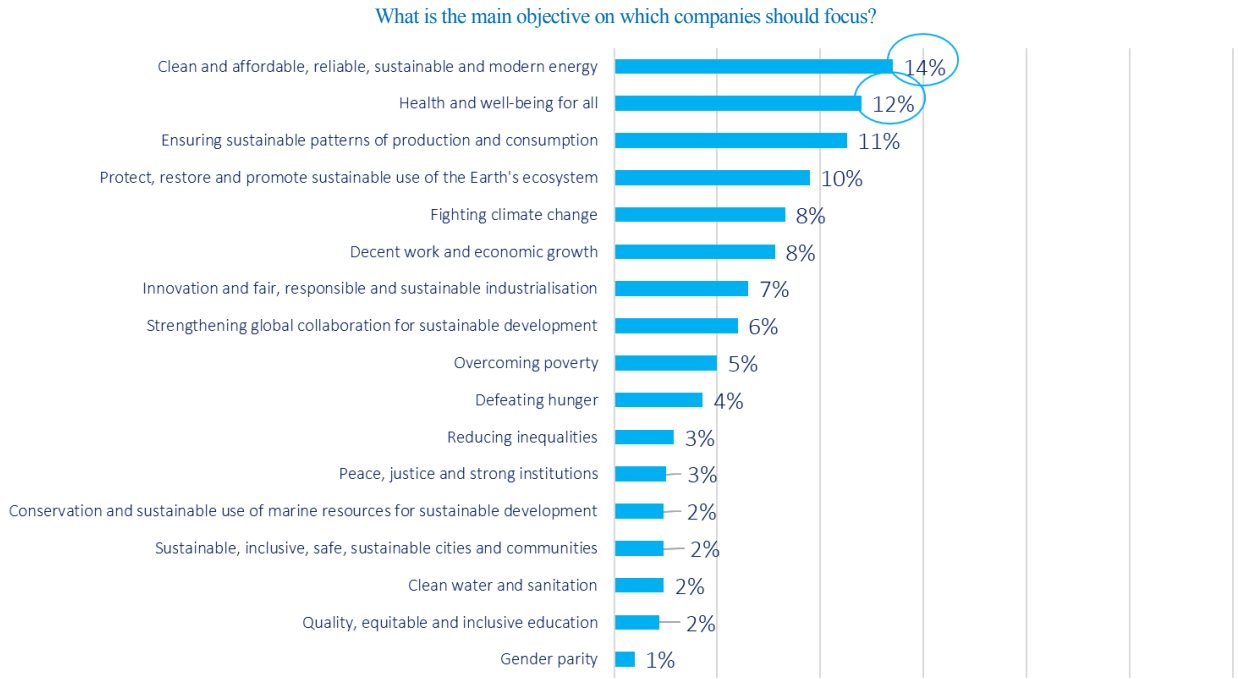

Figure 3: Objectives for company in sustainability for Italian population (Total Sample n.=1.000)

On the other hand, there is a low level of trust in companies and their commitment to sustainable development. Only 29% of respondents say they believe in the declared commitment of companies. In this context, external certification plays a very important role in influencing people's choice for most of the population.

The proposed decision tree has been selected among the trees with a dependent variable derived from an item of the questionnaire considered as a proxy of the overall low level of consciousness of Italian population, as shown in Figure 4. It starts considering as dependent variable: the question related to the population awareness about the efforts made by companies about sustainability ("How much are the Italian companies making an effort for sustainability with investments tangible actions and focused ventures"? 5-point scale).

To explain above result the following were considered as independent variables:

1. How much could the tangible responsibility of Italian companies for SDGs influence the consumers' future choices (5-point scale)?
2. Have you ever heard about SDGs (4-point scale)?
3. Have you even chosen a product or a service because the company is involved in sustainable development projects (Yes/No)?
4. How much are you available to spend more for products and services of a company involved in sustainable development (6-point scale)?

Among considered independent variables, only the first two showed a strong discriminating power. The other two items did not enter in the tree denoting their low discriminant power.

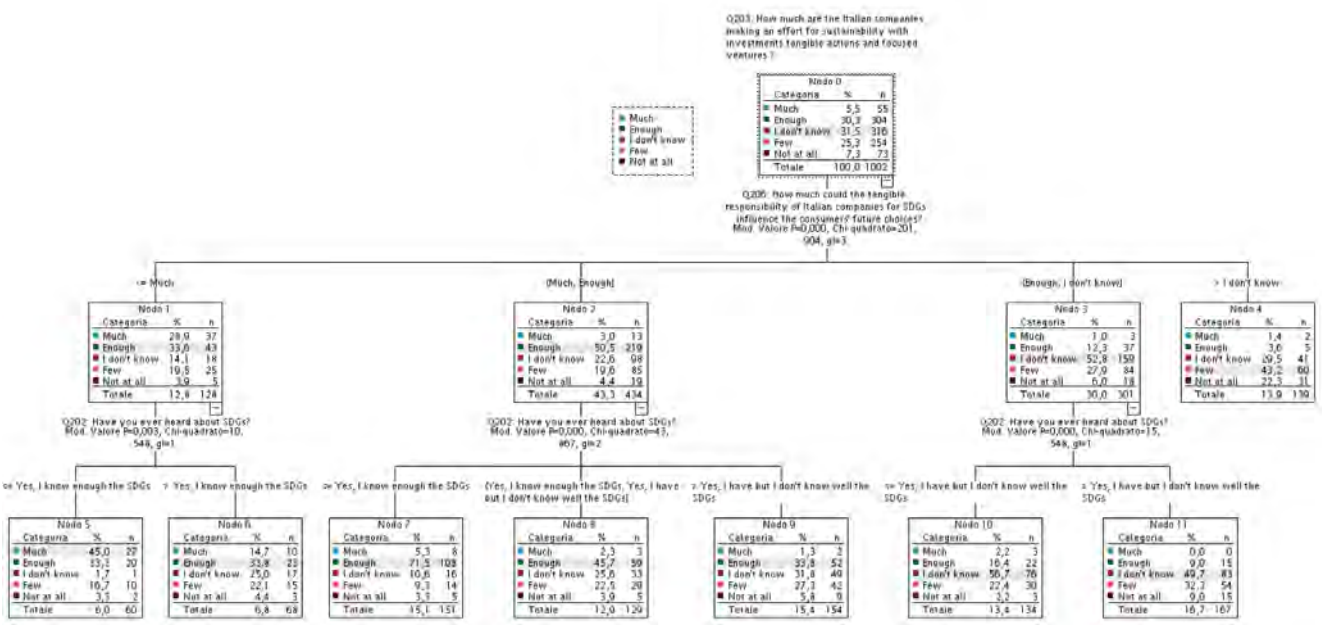

Figure 4 Decision tree about Population perception of companies' efforts in the field of sustainability (Total Sample n.=1.000)

The proposed tree in Figure 4 produces 8 nodes representing 4 basic attitudes that differ in their level of knowledge of the SDGs. The first node is composed by 139 respondents (14% of total population) and represents a group of people completely **not involved in sustainability**. They are not aware of the companies effort and they declare that companies efforts on sustainability will not have an impact on consumers choice. The second group of nodes (two nodes) is composed by 138 (14%) respondents who believe that **sustainability efforts of companies will have a strong impact on people choice** These are mostly people who are well informed about corporate sustainability efforts. The two nodes differ for the level of SGD awareness: high for node 2 (60 resp.); low/none for node 3 (68 resp.). The third group of nodes (3 nodes) represents the majority of the sample 434 respondents (43%). These are people who are convinced that **sustainability companies efforts will have a some kind of effect** on people choice. They have a fair knowledge of companies efforts. Difference in SDG awareness is generating three nodes: node 4 (151 resp.) high; node 5 (129 resp.) limited; node 6 (154 resp.) low/ none. The last group of nodes (2 nodes) is composed by 301 respondents (30%) who **have no idea about the effect** on people choice. They don't know about actions taken by companies in the field of sustainability. As for the other groups the two nodes differ for the SDG consciousness: node 7 (134 resp.) high; node 8 low/none.

4. Conclusions

From the descriptive analysis of the data two main general findings that characterise the attitude of Italians are clear: (1) an unclear perception of the concept of sustainability and SGD by respondents; (2) a limited knowledge of the efforts made by companies in the field of sustainability.

The decision trees have been used as an exploratory approach to identify and measure the different approaches/ attitudes towards the sustainability present among Italians. The exercise helped in identifying two strong discriminant variables ("Perceived impact of company efforts on consumer choice" and "SDGs awareness") that defined 8 different nodes. Next steps would be to better define the 8 nodes characteristics analysing their socio demographic characteristics, their perception and attitudes towards sustainability.

Quasi-experimental evidence on COVID-19 lockdown effects on Italian household food shopping basket composition and its sustainability

Beatrice Biondi[a] and Mario Mazzocchi[a]

[a]University of Bologna - Dept. of Statistical Sciences;

b.biondi@unibo.it; m.mazzocchi@unibo.it;

Abstract

Movement restrictions imposed by governments in response to the COVID-19 pandemic have helped controlling the spread of the disease, but they have also impacted lifestyles, such as dietary habits and food choices. In this study, we explore the effect of the first lockdown period and its aftermath on food and drink purchases, with a particular focus on the overall changes in healthiness and sustainability of dietary choices. We estimate a panel difference-in-differences model on weekly purchases from household scanner data, over a period of two years. We found a large increase in consumption of unhealthy, comfort food and drinks such as ice creams, sweet spreads and beer. Despite the relative change in composition of the food basket, the associated greenhouse gas emission levels are substantially unchanged.

Keywords: Household scanner data, Panel difference-in-differences, COVID-19, food consumption

1. Introduction

The spread of COVID-19 disease has impacted people lives all over the world in many different ways. During forced lockdowns, the containment measures in place (e.g. stay at home restrictions, schools and workplaces closure and restaurants closure) changed the lifestyle of an entire population. Among other behaviours, dietary habits and food and drink consumption had to adjust to the new situation. The change in food consumption behaviours is mainly due to substitution for out-of-home consumption, stockpiling and hoarding behaviour, increased time availability for meal preparation, and psychological coping mechanisms potentially leading to an increase in comfort food consumption (1; 3).

The aim of the present study is therefore to explore how restrictions against COVID-19 spread affected food and drink at-home consumption, focusing on the first lockdown and the first post-pandemic unrestricted period. We consider the quantity consumed of some unhealthy foods and placebo goods, and analyse the overall (food basket) greenhouse gas emission (GHGEs) levels, and how they changed with respect to the pre-pandemic status quo.

2. Methods

2.1 DATA

Our data consist in household-scanner recorded purchases of all food and drink purchases made by a representative sample of households in Italy over a period of two years, 2019 and 2020, provided by The Nielsen Company (Italy). The sample includes more than nine thousands unique households; each household in the Nielsen panel records all food and drink purchases brought home through an hand-held scanner and answers a questionnaire about socio-demographic characteristics once a year.
The dataset contains aggregated weekly purchases for all food and drink product categories. Each row in the dataset contains information about amount (in kg or litres), expenditure in Euros, number of items purchased. Prices were obtained by averaging household unit values (i.e. ratios between expenditures and volumes) by region and week, under the standard assumption that consumers within the same area and in the same time period face the same prices.

Data on food and drink purchased quantities were translated into GHG emissions based on conversion factors as provided in (2): they account for all the production phases, from field to farm gate, transport, processing, packaging, storage and supermarket operations. We first aggregated the 66 product-specific emission factors over our ECOICOP classification (19 food categories), and then calculate the total kg of carbon dioxide equivalent (CO_2e) GHGEs from food and drink purchases, per household per week.

2.2 MODEL

We compare food purchases in different periods of 2019 and 2020 by means of a Difference-in-Differences panel regression. The baseline period considers the pre-pandemic months (essentially January and mid-February), the lockdown period goes from March to mid-May, and the post-lockdown considers the period from mid-May until the end of September. The remaining period of the year is not considered because of its smaller informative power – being far away from the lockdown – and because of confounding effects related to new types of restrictions enacted.

Let's consider a generic output Y, and observations on the purchases of n-th household in week t:

$$Y_{nt} = \alpha_n + \mathbf{X}\beta + \gamma Year_{2020} + \delta_1 D_1 + \delta_2 D_2 + \zeta_1 D_1 Year_{2020} + \zeta_2 D_2 Year_{2020} + \varepsilon_{nt} \qquad (1)$$

where the vector $\mathbf{X}$ includes possible controls, $Year_{2020}$ is a dummy variable that equals one in the year 2020, D_1 is the dummy for the lockdown period, and D_2 is the dummy for the post-lockdown period, a_n are household fixed effects, ε_{nt} is the random component. We estimate several models, with different dependent variables and covariates:

- A set of I regressions are estimated on disaggregated product categories, and consider *scaled* volumes, $Volume\_s_{int}$, for the i-th product purchased by the n-th household in week t [1]. The vector $\mathbf{X}$ includes the average regional weekly price for individual products, P_{irt}.
- Other models are estimated on aggregated data, for the n-th household in week t, the dependent variables considered are: $Volume_{nt}$, Exp_{nt}, UV_{nt}, which include total food quantity, total expenditure and aggregated unit value, respectively.
- The final set of estimated regressions is on emissions: $Emiss_{nt}$ is the weekly household GHGEs from food and drink purchases, and $Emiss\_kg_{nt}$ considers the emissions per kg of purchased food. Here, we control for household-specific weekly aggregated unit values, UV_{nt}

[1] Since food products are very different in terms of average weekly purchased volumes, and rarely comparable in their unit of measure, we obtain comparable amounts by rescaling the volume variable as follows: $Volume\_s_{int} = Volume_{int}/Volume_{i,baseline2019}$, where i indicates the good, n refers to the household and t to the specific week; $Volume_{i,baseline2019}$ equals the average volume for product i in the period between 31 December and 17 February 2019.

We are particularly interested in coefficients ζ_1 and ζ_2 in (1), the DiD coefficients for the lockdown and post-lockdown periods: they measure the differential level of Y in 2020 in each period, i.e. ζ_1 and ζ_2 represent the lockdown and post-lockdown impact on Y, respectively.

3. Results and Discussion

Table 1 reports estimates of the relative changes in purchased quantities for a selection of food products. Hence, the coefficient reflects the change in purchased quantities with respect to the corresponding period of 2019. Considering the lockdown period, base ingredients (mainly flour, sugar and pastry ingredients) experienced the highest rise in consumption, confirming a shift towards home-made preparation. An increase in comfort food consumption is also observed, namely ice creams, beer, sweet spreads (jams, chocolate spreads and honey). Animal products, like pork meat and cheese, show relatively larger increases than other food groups, such as vegetables and pasta. Fish products purchases did not change during the lockdown period, whereas prepared dishes and festivity foods and wines decreased significantly. In the post-lockdown period, most variations became smaller, but still significantly higher than their baseline. Products like ice creams, for which out-of-home consumption is especially relevant, experience a significant decrease in purchases during the post-lockdown period, when restrictions were lifted.

Then, we translate the changes in purchases of the 19 food and drink categories into aggregate outcomes and their greenhouse gas emissions. Table 2 reports the results: estimates show a significant change in total purchased volumes during lockdown (more than 5 kg of food per household per week) and weekly household expenditure (around €12 per household per week). On average, there was a shift towards cheaper products, as the average unit value fell by €0.4 per kg. In terms of emissions, the larger amount of purchases during the lockdown period resulted in larger total emissions (nearly 40% more than the average emission levels in 2019). However, when controlling for the increased purchased volumes, no significant change in emission levels is observed. During the post-lockdown period, food purchases and expenditure remained slightly higher than their counterfactual level. Again, the impact in terms of GHGEs is merely related to the higher volumes, and emissions per kg of purchase foods were basically unchanged.

4. Conclusion

We exploit the detailed information available from Nielsen household scanner data to estimate the impact of COVID-19 restrictions on food purchases and their greenhouse gas emissions using a Difference-in-Difference model.

The lockdown period is associated, as expected, with higher amounts of purchased foods for home consumption, hence higher emissions. However, we find no evidence that the relative sustainability of food purchases has worsened. Similar findings emerge from the post-lockdown period, but to a much lower extent.

Path analysis in Ising models: an application to cyber-security risk assessment

Monia Lupparelli and Giovanni M. Marchetti

Abstract

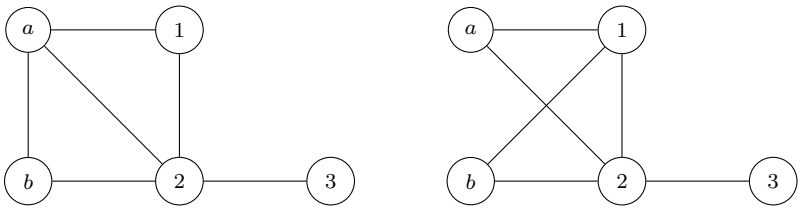
We propose a method for path analysis in undirected graph models for binary variables to quantify the strength of association in multiple paths joining a pair of vertices in the underlying graph. With special focus on Ising models, we provide a decomposition of a marginal pairwise parameter into the sum of measures uniquely associated to the edge set of the paths linking the related couple of vertices. The work has been stimulated by a collaboration with a consultant company working in cyber-security risk assessment in industrial Operational Technology systems.

Keywords: Industrial network, Odds-ratio, Risk mitigation, Undirected graph.

1. Introduction

Ising models, introduced by Ernst Ising in 1925 to represent the joint distribution of magnetic solid materials in a lattice, are increasingly used to study independence relationships between atomic variables which can assume "active" or "not active" status (Ising , 1925) . Variables are represented by the vertices of an undirected graph where a missing edge between two vertices corresponds to a conditional independence assumption for the related pair of variables. Ising models represent a special exception of hierarchical log-linear models with zero interaction parameters of order higher than two, and a set of odds-ratio parameters measure the association detected by the edges of the underlying graph. In ferromagnetism, modelling the transition of the variable status is a relevant aspect of interest and, nowadays, the same principle is borrowed to explore the relationships in a set of homologous binary variables which may show a synchronized behaviour, as symptoms or risk factors; see Kruis and Maris (2013) and Marsman et al. (2018). Recently, Ising models have been also employed to study the propagation of risk events in catastrophic systems and, in particular, in operational technology (OT) systems where studying and monitoring the spread of cyber-attacks is an aspect of primary interest (Denuit and Robert , 2022).

The set of paths joining a pair of vertices provides a full picture of the dependence between the related couple of variables and our opinion is that studying the relationships across multiple paths may provide insight to quantify the propagation of the variable status in Ising models. Despite path analysis has been introduced and is traditionally employed to study causal relationships in directed acyclic graphs (Wright , 1921), we acknowledge that the analysis of paths can be relevant in multivariate settings regardless the type of graphs and the causal interpretation of the associations. Path analysis in Gaussian undirected graph models has been introduced only more recently by Jones and West (2014) and some years later developed by Roverato and Castelo (2020). These Authors exploit the functional relationship between the variance-covariance and the precision matrices to derive a mapping interpretable in terms of path analysis. Path analysis in discrete undirected graphs seems to be barely studied.



(a) (b)

Figure 1: Ising graphical models for the random vector $X_V = \{X_a, X_b, X_1, X_2, X_3\}$; variables X_a, X_b represent the pair of interest for the analysis of paths.

We propose a decomposition of the pairwise probability related to a couple of vertices into the sum of measures based on products of odds-ratios directly associated to the edge sets of multiple paths. In turns, this decomposition represents an alternative path-based mapping between the mean and the canonical parameters in Ising models. This approach represents a first attempt to study the status propagation in Ising models and in related fields of application.

2. The Ising model

Consider a finite set V, and let $X_V = \{X_j\}_{j \in V}$ be a vector of random binary variables with levels $i \in \mathcal{I}_V$, where $\mathcal{I}_V = \{0,1\}^{|V|}$ is a $2^{|V|}$ probability table. Let $\pi = (\pi_D)_{D \subseteq V}$ be the probability parameter for the joint distribution of X_V, where $\pi_D = P(X_D = 1_D, X_{V \setminus D} = 0_{V \setminus D})$ is the probability of the event associated to the cell i_D of $\mathcal{I}_V$, with $D \subseteq V$. If X_V follows a multivariate Bernoulli distribution $P(X_V; \pi)$, $\log \psi = (\log \psi_D)_{D \subseteq V}$ is the log-linear canonical parameter in the exponential family theory. The mapping between the probability and canonical parameter is based on the Möbius transformation,

$$\log \psi_D = \sum_{D' \subseteq D} (-1)^{|D \setminus D'|} \log \pi_{D'}, \qquad \log \pi_D = \sum_{D' \subseteq D} \log \psi_{D'}, \qquad D \subseteq V. \tag{1}$$

For any $j \in V$, the parameter ψ_j is the odd for the variable X_j, for any $j, k \in V$, the parameter ψ_{jk} is the odds-ratio for the variables X_j, X_k, both computed in the table $\mathcal{I}_V$. Given the product $\Psi = \prod_{D \subseteq V} \psi_D$, let Ψ_D be any sub-product including only log-linear terms ψ_E with $E \subseteq D$, for any $D \subseteq V$. The mean parameters for the joint distribution of X_V are defined by the vector $\mu = (\mu_D)_{D \subseteq V}$, where $\mu_D = P(X_D = 1_D)$ is the probability of the realization of the event i_D in the marginal table $\mathcal{I}_D = \{0,1\}^{|D|}$, with $D \subseteq V$. For any pair D, E of disjoined subsets of V, consider the conditional probability

$$\pi_{D|E} = P(X_D = 1_D, X_{V \setminus D \cup E} = 0_{V \setminus D \cup E} | X_E = 1_E), \qquad D, E \subseteq V,\ D \cap E = \emptyset,$$

that the event i_D realises in the slice of the table $\mathcal{I}_V$ defined by $i_E \in \mathcal{I}_E$.

In graphical models, a random vector X_V is associated to a graph, in particular we consider an undirected graph $\mathcal{G} = (V, \mathcal{E})$, where V is a set of vertices/nodes and $\mathcal{E}$ is a set of pairs of vertices; if the couple $\{j, k\} \in \mathcal{E}$, the vertices j and k of the graph are joined by an undirected edge; see Figure 1. The Ising model is an independence model for the vector X_V over an undirected graph $\mathcal{G} = (V, \mathcal{E})$ (Ising , 1925). A pair of variables associates to vertices not joined by an edge are assumed to be independent given the status of other variables. A formal definition of an Ising model follows.

Definition 1. *Given a random vector X_V of binary variables associated to an undirected graph $\mathcal{G} = (V, \mathcal{E})$, the Ising model is the family of Ising probability distributions $P_{\mathcal{G}}(X_V; \psi)$ where $\log(\psi_{jk}) = 0$ for every pair $\{j, k\} \notin \mathcal{E}$. The probability parameters are*

$$\pi_D \propto \left\{ \prod_{j \in D} \psi_j^{x_j} \times \prod_{j,k \in D : \{j,k\} \in \mathcal{E}} \psi_{jk}^{x_j x_k} \right\}, \qquad x_j, x_k \in \{0,1\}, \quad D \subseteq V. \tag{2}$$

An aspect of primary interest in Ising models is studying the transition of the active status through the edge set of the graph and the status propagation between two vertices reasonably runs through the set of paths connecting them. A path δ is defined by an ordered sequence $(j, k, \ldots, z)$ of distinct vertices, with $j, k, \ldots, z \in V$, such that any couple of adjacent vertices in the sequence is joined by an edge in $\mathcal{G}$. Repetition of vertices is not allowed in this definition of paths. Let Δ_{ab} be the set of all paths with endpoints $a, b \in V$ where the generic element of the set is a path $\delta = (\delta_1, \ldots, \delta_m)$ with $\{\delta_j, \delta_{j+1}\} \in \mathcal{E}$, for any couple of adjacent vertices in δ. The set of paths joining vertices a and b for the graph in Figure 1(a) is $\{(a, b), (a, 1, 2, b), (a, 2, b)\}$. A path is said to be active when all variables along the path show the active status. The transition of the variable status realises through active paths.

This work aims to provide a decomposition of the probability μ_{ab} associated to vertices $a, b \in V$ with the intent to give insight on the strength association driving the transition of the variable status across paths. This decomposition is founded on the following lemma (Lupparelli and Marchetti , 2023).

Lemma 1. *Let $P_{\mathcal{G}}(X_V; \psi)$ be an Ising model. The marginal probability μ_{ab} is equivalent to*

$$\mu_{ab} = \frac{\sum_{\delta \in \Delta_{ab}} \pi_{\delta ab}}{\sum_{\delta \in \Delta_{ab}} \pi_{\delta|ab}}, \tag{3}$$

where Δ_{ab} is the set of paths joining the pair $a, b \in V$ of vertices.

Equation (3) does not completely addresses our scope since probability $\pi_{\delta ab}$ is not uniquely related to an active path $\delta \in \Delta_{ab}$, e.g., paths $(a, 1, 2, b)$ and $(a, 2, 1, b)$ in Figure 1(b) have the same probability π_{12ab} to be active, despite they consider different sets of edges and different pairwise associations. Also, the probability $\pi_{\delta|ab}$ is a non-trivial function of ψ used to model the presence of edges in Ising models.

3. Logistic regression models for events in collapsed tables

A logistic regression approach is proposed to parametrise the probability $\pi_{\delta|ab}$ of a baseline event in the conditional distribution of $X_{V\setminus ab}|\{X_a, X_b\}$.

Definition 2. *Given the set X_V of variables associated to an undirected graph $\mathcal{G} = (V, \mathcal{E})$, for any $\delta \in \Delta_{ab}$ with $a, b \in V$, let Y_δ be a binary variable which takes level 1 if the event associated to the baseline cell $i_\delta \in \mathcal{I}_{V\setminus ab}$ realises, and 0 otherwise.*

Any $\delta \in \Delta_{ab}$ induces the partition $\{X_a, X_b, X_\delta, X_{\setminus\delta}\}$ of the random variables in X_V. The variable Y_δ is defined by collpasing the marginal table $\mathcal{I}_{V\setminus ab}$ with respect to the baseline cell related to the event $\{X_\delta = 1_\delta, X_{\setminus\delta} = 0_{\setminus\delta}\}$:

$$Y_\delta = 1 \quad \text{if } \{X_\delta = 1_\delta, X_{\setminus\delta} = 0_{\setminus\delta}\}, \quad \text{and} \quad Y_\delta = 0 \quad \text{otherwise.}$$

Each path $\delta \in \Delta_{ab}$ defines a probability table $\mathcal{I}_K$, with $K = \{\delta, a, b\}$, for a vector of three binary variables $X_K = (Y_\delta, X_a, X_b)$ following a trivariate Bernoulli distribution with probability parameter $\pi^\delta = (\pi^\delta_E)_{E \subseteq K}$ where

$$\pi^\delta_E = \pi_E, \qquad \delta \in E \subseteq K, \tag{4}$$

$$\pi^\delta_E = \sum_{E' \subseteq V\setminus ab : E' \neq \delta} \pi_{EE'}, \qquad \delta \notin E \subseteq K. \tag{5}$$

The log-linear parameter is $\log \theta^\delta = (\log \theta^\delta_E)_{E \subseteq K}$ with $\log \theta^\delta_E = \sum_{E' \subseteq E} (-1)^{|E \setminus E'|} \log \pi^\delta_{E'}$, for each $E \subseteq K$. We consider a logistic parameterisation for the conditional distribution of $Y_\delta|\{X_a, X_b\}$ to study the relationship between θ^δ and ψ parameters. For any $\delta \in \Delta_{ab}$, we have

$$\log \frac{P(Y_\delta = 1|X_a = 1, X_b = 1)}{1 - P(Y_\delta = 1|X_a = 1, X_b = 1)} = \beta_\delta + \beta_{\delta a} X_a + \beta_{\delta b} X_b + \beta_{\delta ab} X_a X_b, \quad \delta \in \Delta_{ab}. \tag{6}$$

The regression coefficients in equation (6) are function of parameter ψ (Lupparelli and Marchetti , 2023).

Theorem 1. *Let $P_{\mathcal{G}}(X_V;\psi)$ be an Ising model. For any $\delta \in \Delta_{ab}$ with $a,b \in V$, consider the set $\{Y_\delta, X_a, X_b\}$ of binary variables and the logistic regression parameters in equation (6) for the conditional distribution of $Y_\delta|\{X_a, X_b\}$. The following equivalences hold:*

$$\beta_{\delta E} \quad = \quad \log\left(\frac{\prod_{j,k\in\delta}\psi_{Ejk}}{\theta^{\delta}_{E}}\right), \qquad E \subseteq \{a,b\}. \tag{7}$$

4. The path-based decomposition

Exploiting the results of Theorem 1 and of Lemma 1, a path-based decomposition of the marginal probability μ_{ab} is derived for any $a,b \in V$ (Lupparelli and Marchetti , 2023).

Theorem 2. *Let $P_{\mathcal{G}}(X_V;\psi)$ be an Ising model. Given the set Δ_{ab} of paths joining the pair $a,b \in V$ of vertices,*

$$\mu_{ab} = \sum_{\delta\in\Delta_{ab}} \omega_\delta \frac{\Psi_{\delta ab\setminus\omega_\delta}}{1^T\pi(\Delta_{ab})}, \tag{8}$$

where

$$\omega_\delta = \psi_{a\delta_1}\psi_{\delta_1\delta_2}\ldots\psi_{\delta_m b}, \qquad \delta \in \Delta_{ab}, \tag{9}$$

$\Psi_{\delta ab\setminus\omega_\delta}$ is the sub-product of parameter ψ_{jk}, $j,k \in \delta ab$ with entries omitted in ω_δ, and $\pi(\Delta_{ab})$ is a column vector with generic element

$$\frac{\Psi_{\delta ab}}{\Psi_{\delta ab} + \Theta^{\delta}_{ab}}, \qquad \delta \in \Delta_{ab},$$

with $\Theta^{\delta}_{ab} = \prod_{E\subseteq ab}\theta^{\delta}_{E}$.

For any $\delta \in \Delta_{ab}$, the decomposition in equation (8) includes the measure ω_δ which is an interpretable parameter of multivariate dependence able to quantify the intensity of the propagation of the variable status since it is a product of the odds ratios associated to the edge set of the path. The term $\Psi_{\delta ab\setminus\omega_\delta}$ represents the residual strength of association to compute the joint probability of the active path event, but it does not directly influence the transition of the variable status along the path. Finally, $1^T\pi(\Delta_{ab})$ is a normalizing measure given by the sum over all paths $\delta \in \Delta_{ab}$ of the probability $\pi_{\delta|ab}$ that X_a and X_b are active only because of variables of a specific path δ are active. It is worth noticing that the decomposition of Theorem 2 can be also generalised to pairwise measures of association, e.g., the marginal odds-ratio or the dependence ratio, if the intent is to disentangle the marginal dependence across multiple paths.

5. An application

Inspired by the recent stream of the literature on attack graphs and on Ising models for cyber-security analysis (Denuit and Robert , 2022), the proposed method for path analysis is illustrated through an application for industrial networks with the focus on cyber-security in operational technology (OT) systems. In this context, vertices of a graph are used to represent industrial assets (e.g., servers, firewalls, computers, devise) corresponding to atomic variables which become active when they receive an attack and not active otherwise. The graph skeleton is a priori defined depending on the connections/interactions between items. A basic assumption in OT systems is that a cyber attack can run only through the paths of the graph. As an illustrative example, consider the graph in Figure 2 better discussed in Lupparelli and Marchetti (2023). For any pair of vertices $\{j,k\} \notin \mathcal{E}$, the probability of X_j to be attacked/non-attacked is independent of the probability of X_k to be attacked/non-attacked, given the status of their neighbors. An Ising model is assumed with the following log-linear parameters $\log\psi$ properly assigned on the basis

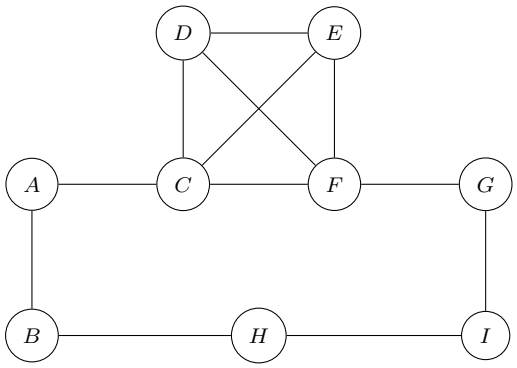


Figure 2: Ising model for a cyber-security case-study

of reasonings supported by the expertise of collaborators working in cyber-security field:

$$\begin{array}{c} A \\ B \\ C \\ D \\ E \\ F \\ G \\ H \\ I \end{array} \begin{pmatrix} 0.1 & 0.2 & 0.8 & 0 & 0 & 0 & 0 & 0 & 0 \\ . & 0.3 & 0 & 0 & 0 & 0 & 0 & 0.8 & 0 \\ . & . & -0.2 & 0.4 & 0.6 & 0.9 & 0 & 0 & 0 \\ . & . & . & 0.1 & 0.3 & 0.2 & 0 & 0 & 0 \\ . & . & . & . & 0.1 & 0.5 & 0 & 0 & 0 \\ . & . & . & . & . & 0.2 & 0.7 & 0 & 0 \\ . & . & . & . & . & . & -0.6 & 0 & 0.8 \\ . & . & . & . & . & . & . & 0.1 & 0.9 \\ . & . & . & . & . & . & . & . & 0.2 \end{pmatrix}.$$

the elements in the main diagonal represent the propensity of each item to be attacked depending on its vulnerabilities; the off-diagonal terms are related to the graph edges and reveal the risk of a local attack propagation which depends on the intensity and on the type of interaction between the items, on their own vulnerabilities and of their neighbours.

Suppose that item B received an attack which spread to item F. We are interested in measuring the propagation risk of this attack over all paths starting from B to F. The same reasoning holds for an attack going from F to B. The path-based decomposition of the probability μ_{BF} provides insights to assess and to mitigate, at the same time, the risk of the attack propagation. Under the Ising model, $\mu_{BF} = 0.64$. Table 1 includes the list of six paths running between vertices B and F with the related risk measures ω_δ of attack propagation computed using the decomposition in Theorem 2. Path (6) has the highest risk since it includes edges with high scores showing great interconnections between vertices. The table includes the conditional probability $\pi^*_{\delta|BF}$, normalized over all the possible paths, that, since B, F have beed attacked, the attack propagation occurred through path $\delta \in \Delta_{BF}$; paths (1) and (3) show the highest probability. Notice that paths (1) and (3), sharing the same vertices with different orderings, have the same probability $\pi^*_{\delta|BF}$ but different propagation risks ω_δ; conversely, paths (3) and (4) have the

Path	size	ω_δ	$\psi_{\delta_1\delta_2}$	$\psi_{\delta_2\delta_3}$	$\psi_{\delta_3\delta_4}$	$\psi_{\delta_4\delta_5}$	$\psi_{\delta_5\delta_6}$	$\pi^*_{\delta\|BF}$
(1) (B, A, C, D, E, F)	6	9.03	1.22	2.23	1.49	1.35	1.65	0.33
(2) (B, A, C, D, F)	5	4.95	1.22	2.23	1.49	1.22	-	0.07
(3) (B, A, C, E, D, F)	6	8.17	1.22	2.23	1.82	1.35	1.22	0.33
(4) (B, A, C, E, F)	5	8.17	1.22	2.23	1.82	1.65	-	0.12
(5) (B, A, C, F)	4	6.69	1.22	2.23	2.46	-	-	0.04
(6) (B, H, I, G, F)	5	24.54	2.23	2.46	2.23	2.01	-	0.11

Table 1: Path-based analysis for attack propagation risks in a cyber-security case-study

same risks, since they show similar intensity of interconnection along the path, but different probabilities. A naive risk assessment for the network system focused on the pair of items B and F could be obtained by averaging the propagation risk ω_δ with the probabilities $\pi^*_{\delta|BF}$ over all the paths, i.e,

$$R_{BF} = \sum_{\delta \in \Delta_{BF}} \omega_\delta \times \pi^*_{\delta|BF} = 9.95.$$

We also explore the effect of risk mitigation in the network structure. Suppose that we are able to protect both the item B and the interconnection represented by the edge $H - I$ such that the parameters become $\log \psi_B = -0.1$ and $\log \psi_{HI} = 0.3$, respectively. Then, the propagation risks for paths (1)-(5) are unchanged since the edge $H - I$ appears only in the last path where the risk reduces from 24.54 to 13.46. Similarly, the normalized probabilities of paths (1)-(5) slightly change, whereas the conditional probability that path (6) is active goes from 11% to 6%. The naive risk assessment becomes $R_{BF} = 8.49$. Another possible action could be devoted to protecting the interconnection represented by the edge $A-C$ which is crucial for five paths. If the log-linear parameter can be reduced to $\log \psi_{AC} = 0.4$, then the propagation risks ω_δ for paths (1)-(5) reduce to 6.04, 3.32, 5.47, 5.47 and 4.48, respectively. The related conditional probabilities slightly decreases with the exception of the last one that increases from 11% to 16%. The overall risk is almost the same, i.e. $R_{BF} = 8.43$. In this setting, the mitigation of the pairwise parameters related to the edges provides a reduction of the risk propagation parameter ω_δ; however this action might not reduce the overall risk which also depends on main effect parameters revealing the propensity of each item to be attacked/non-attacked.

6. Conclusion

Cyber-security risk assessment rises serious challenges for future research developments involving also computer science expertises. The industrial network is typically huge and not sparse, then any methodology needs to be scalable and able to handle very large tables. From this side, the proposed decompositions directly work on the rectangular log-linear parameter space, rather than on the probability space, and this represents a technical gain since log-linear parameters are variation independent. A relevant issue consists in the assignment of model parameters that should be dynamically learned and inferred from the activity of the network which rapidly and continuously changes over the time, as well as the vulnerability of vertices and of their interactions.

Enhancing Markowitz model: inspection of correlations and tail covariances

Gloria Polinesi[a]

[a]Department of Economics and Social Sciences - Universitá Politecnica delle Marche;
g.polinesi@staff.univpm.it

Abstract

Information contained in the correlation matrix of the financial products plays a crucial in order to construct portfolios as well as the tail effects of asset returns.

Structure hidden in the correlation matrix can be revealed appealing to hierarchcal clustering algorithms and spectral methods individually, or through a combination of them. Furthermore, covariance as a mesure of portfolio risk does not distinguish downside from upside risk. .

The work shows the state of the art of asset allocation models which enhances Markowitz portfolios focusing on Minimum Spanning Tree and Random Matrix Theory used to extract information from correlations and on different measures of portfolio risk accounting for asymmetry in the risk.

Keywords: Financial time series, correlation matrices, tail dependence, cluster analysis, random matrix theory, asset allocation.

1. Introduction

Time series are one of the many instruments to represent data and this type of data is present in a variety of fields, from brain activity to financial area.

Looking for similarities between time series requires peculiar techniques due to their nature. Clustering algorithms, spectral methods and correlation based graph allow leading information from the structural organization of correlation matrix of the return time series whereas correlation matrices could be represented as complete graphs where the notion of hierarchy lacks [7]. The key role of information contained in correlation matrix of financial asset returns and the asymmetry in the portfolio risk - difference between downside and upside risk- is crucial in order to construct portfolios taylor made for investors.

The aim of the work is to show the state of the art of asset allocation models which enhances Markowitz portfolios focusing on the combination of hierachical clustering and spectral methods, i.e, Random Matrix Theory (RMT), used to extract information from correlations; and on different measures of portfolio risk accounting for asymmetry in the assets distribution.

The literature relative to clustering algorithms on correlation matrices of stock returns time series is very amply and it stems from the seminal paper of [19]. Specifically, this author investigates the correlation coefficient matrix to detect the hierarchical organization present inside the stock market: distance matrix based on correlation matrix is used to determine the Minimal Spanning Tree (MST) connecting the N stocks. With only a few exceptions Mantegna shows that groups are homogeneous with respect to industry and often also subindustry sectors,

meaning that stocks belonging to the same sector or subsector are driven by the same economic factors.

The work of [34] shows how a MST calculated on a correlation matrix "filtered" from random noise through the RMT approach can improve the performance of the optimal portfolios. Similar papers, based on the applications of RMT to asset management, are [16], [31], [32], [5].

[11] extend the application of the RMT approach in [34] to Exchange Traded Fund returns (ETFs) but including a third dimension of risk, the network centrality, into the Markowitz objective function.

Furthermore, [21] provide a measure of systemic vulnerability of portfolio due to the asset centrality by combining in the Markowitz model tha classical covariance and the left-tail covariance. This new measure of portfolio risk overcome the drowbacks of the covariance which does not take into account asimmetry in the risk. Other works as [18] and [13] overcome the limitation of covariance since they are able to capture the downside risk through quantile-based measures.

The remainder of this paper is organized as follows. Sect. 2. introduces hierarchical clustering algorithms and extensions to "filter" correlation matrix of financial assets. Sect. 3. describes asimmetry measures of portfolio risk . Sect. 4. is devoted to portfolio optimization strategies. Finally, Sect. 5. draws some conclusions.

2. Methods for filtering correlation matrices

This Sect. describes hierarchical and not hierarichical methods used for filtering correlation matrices of return time series. These techniques reduce the number of parameters cleaning "measurement noise" due to the finite length of time series.

Mantegna's first work dates back to the 1999 and this author investigates the correlation matrix to detect the hierarchical organization of stocks in financial market. In a ultrametric space, the MST connecting stocks reveals a topological arrangement of financial market. Indeed, MST, defined as the minimum structure in terms of sum of distances between nodes, groups stocks homogeneous with respect to the economic sector of underlying companies.

Following this stream of literature, [35] confirm that nodes share information according to the communities they belong to whose are organized in a nested structure and hierarchical clustering algorithms allow to detect this complex structure.

[33] also qualify the minimal spanning tree as the corresponding representation of a fully-connected system (network) where sparseness replaces completeness in a proper way.

Steps in order to draw MST can be summarized as follow, starting from the correlation matrix of the time series of N asset returns, computed as difference of the logarithm of prices in the time horizon T [1].

$$r_i(t) = logP_i(t) - logP_i(t-1) \tag{1}$$

The elements of correlation matrix for each pair of assers

$$c_{ij} = \frac{E(r_i r_j) - E(r_i)E(r_j)}{\sigma_i \sigma_j} \tag{2}$$

converted in distance elements:

$$d_{ij} = \sqrt{2 - 2c_{ij}} \tag{3}$$

MST is drawn from the distance matrix in Eq. (3), which allows to shrink links connecting financial products from $\frac{N(N-1)}{2}$ (total number of parameters in the distance matrix) to $N-1$. In general, MST is able to detect the hierarchical organization in sectors and subsectors of stocks, but it is known in literature that result changes if frequency of data changes. [3] demonstrate

[1] Price observations can be daily, weekly, monthly or yearly.

that decreasing the time horizon (i.e. from daily to intraday frequency) correlation between pairs of stocks decreases by affecting the hierarchical organization: minimal spanning tree moves from a clustered and structured set to a simpler set.

Random matrix theory (RMT) represents the main non-hierarchical approach in order to investigate the structure of the financial correlations. The first results in the financial context can be found in [10], [15] and [28]. Specifically, RMT compares eigenvalues, $\lambda_k < \lambda_{k+1}$, of an empirical correlation matrix (Eq. 1) to eigenvalues of a random Wishart matrix $\mathbf{R} = \frac{1}{T}AA^T$. The $\mathbf{A}$ contains N time series of length T whose elements are independent, identically distributed random variables with zero mean and variance $\sigma^2 = 1$.
The random correlation matrix of this set of variables in the limit $T \to \infty$ is the identity matrix, when T is finite, the correlation matrix is in generally different from the identity matrix.
The theory of random matrices shows that in the limit $N \to \infty$ and $T \to \infty$ with a fixed ratio $Q = \frac{T}{N} \geq 1$ and $\sigma^2 = 1$, the eigenvalue spectral density is given by:

$$f(\lambda) = \frac{T}{2\pi} \frac{\sqrt{(\lambda_+ - \lambda)(\lambda - \lambda_-)}}{\lambda} \tag{4}$$

where $\lambda_\pm = 1 + \frac{1}{Q} \pm 2\sqrt{\frac{1}{Q}}$. Information can be extract from eigenvalues that are higher then λ_+ (deviating eigenvalues) and it involves correlations between assets belonging to the same industry or geographical area; while, the "bulk" of eigenvalues agree with RMT reveals the random correlations [29].

Authors use RMT to filter correlation matrix and then construct MST because, in order to extract the structure hidden in large correlation matrices, trees are easier to interpret with respect to the inspection of large matrices [6]. By using this procedure, [23] obtain a clusterization per strategies of the Hedge Funds returns, according to the definition of strategies provided by [17].

3. Asimmetry measures of portfolio risk

The mean variance approach proposed by [22] to measure portfolio risk does not account for asymmetry in the risk. This is due to the fact that covariance is a measure of portfolio risk based on moments and, as consequence, does not distinguish downside from upside risk.

The quantile-based tail measures — value-at-risk (Var), expected shortfall (ES), extreme downside correlations (EDC) and p-tail risk (see, for example [18], [13]) — overcome the limitation of covariance in that they are able to capture the downside risk. However, their main drawback is that they are rather insensitive to the shape of the tail distribution since they strongly depend on the a priori choice of the confidence level and/or quantiles, thereby accounting mainly for the frequency of the realizations - not their values - [14].

In contrast to quantile-based approaches, the extreme downside hedge (EDH) of [13] is estimated by regressing asset returns on some measure of market tail risk. The latter, however, suffers from the above-mentioned drawback. Nevertheless, this approach is an attempt to use the values of asset returns to measure the tail risk.

Moreover, [21] propose a new variability measure for left-hand tail risk that overcomes the mentioned drawback based on the stratification procedure by [20]. This measure has the advantage that it is defined endogenously, without any a priori choice, and it captures risk from the asset volatility and co-movements as well as from the left-hand tail distribution of the asset returns, while preserving an elementary expression. In detail, the procedure in [20] can be adapted to the gross returns to identify a new informative set of parameters for each asset time series. This informative set is used to define the left-tail-covariance-like matrix via the cosine similarity and the new variability measure of portfolio risk obtained as a convex combination between classical portfolio variance and the left-tail-covariance.

4. Portfolio optimization strategies

Recent literature on financial time series has investigated techniques to exploit clustering information for developing a new approach to portfolio selection (see, among others, [30], [24], [25], [4], and [36]).

The idea underlying this approach is to substitute the original correlation matrix of the classical Markowitz model with an ultrametric correlation-based clustering matrix with the twofold objective of filtering the correlation matrix and improve the portfolio robustness to measurement noise.

The use of "improved covariance" matrix estimators as an alternative to the sample estimator is considered an important approach for enhancing portfolio optimization [26]. Indeed, most of the portfolio strategies alternative to the Markowitz model are based on RMT filtering procedure and ultrametric matrices associated to the hierarchical clustering algorithms applied to the empirical correlation matrices.

[29] use the filtering correlation matrix resulting from random matrix approach in the minimum variance model proposed by Markowitz showing that for these portfolios the realized risk is more closer to the predicted one. Moreover, [6] demonstrate that RMT is found to greatly reduce the difference between the predicted and realized risk of a portfolio, leading to an improved risk profile for a fund of hedge funds.

[34] construct portfolio by solving Markowitz solution but cleaning correlation matrix of stock returns through random matrix approach, single linkage and average linkage. Clustering algorithms combined with RMT filtering procedure improve the reliability of the Markowitz portfolio in terms of the ratio between predicted and realized risk. Also [35] prove that using the empirical correlation matrix leads to a dramatic underestimation of the real risk. In fact, they demonstrate that the risk of the optimized portfolio obtained using a "filtered" correlation matrix is more stable, although the real risk is always larger than the predicted one.

[11] describe how the use of filtered covariance matrices (through RMT and MST) and the dimension of systemic risk represented by eigenvector centrality between assets in the original Markowitz solution is outperformed in terms of standard portfolio performance measures.

Previous works consider Pearson correlation coefficient, other researches focus their attention on different correlations. For example, [2] apply an active portfolio management framework where interconnectedness between assets are based on mutual information measure, [8] and [9] propose to group time series of returns according to assets behaviour in tail (loss events) and then construct portfolios in order to manage risk during crisis scenario. [12] pick satellite (or pheripheral) assets according to their Adaptive Lasso Quantile Regression (ALQR) coefficients, that provide the information concerning the dependence between core portfolio and satellites at different tail events.

The recent study by [27] reveals that for a realistic stress test, special attention should be given to tail risk in individual returns and also tail correlations. In this context, the work of [21] interpretates the portfolio risk obtained by combining classical and left-tail covariances as the weighted average of the centralities of a suitably defined node weighted network [1].

5. Conclusion

The work shows the state of the art of asset allocation models which enhances Markowitz portfolios focusing on Minimum Spanning Tree and Random Matrix Theory used to extract information from correlations and on different measures of portfolio risk accounting for asymmetry in the risk.

These tools employed in the asset allocation models allow higher performing investments in terms of risk by enhancing the classical mean-variance portfolio model.

Filtering techniques combined with hierarchical clustering algoritms and tail movements of assets are tailored to manage risk of portfolio decreasing exposure to systemic vulnerability of

the financial products.

Abstract

Interest in the well-being measurement is constantly increasing worldwide. In addition to objective measures, interest often regards the degree to which people are satisfied with their economic conditions and a joint subjective and objective perspective to analyze the economic well-being is adopted. Data for statistical analysis is often available from different samples, with each sample containing measurements on only some of the variables of interest. In this context, statistical matching appears as a very useful technique.

In this paper the statistical matching between variables measuring the objective and the subjective economic well-being, available in different samples, is performed and its uncertainty is evaluated.

Keywords: statistical matching, economic well-being, likelihood ridge, uncertainty

1. Introduction

Interest in the well-being measurement is constantly increasing worldwide in order to reduce social inequalities and to improve people's quality of life [12]. In addition to objective measures, interest often regards the degree to which people are satisfied with their economic conditions and a joint subjective and objective perspective to analyze the economic well-being is adopted. Household income is generally used as proxy for objective economic well-being as well as what people think about their economic situation is used as measure of subjective economic well-being.

In Italy, reliable information on households income is provided by EU Statistics on Income and Living Conditions (EU-SILC, for short). On the other hand information on subjective concepts such as emotional well-being, social participation and trust in institutions, complementary to EU-SILC are provided by Aspect of Daily Life survey (ADL, for short). Both surveys are carried out by ISTAT.

This constitutes a serious problem since joint information on objective and subjective economic well-being are used by policy makers for analyzing the impact of policy strategies. In this context, statistical matching appears as a very useful technique for the integration of multiple independent sources referring to the same, not overlapping, target population, as an alternative to implementing new surveys or the extension of the questionnaires of existing one.

In this paper the approach proposed in [3] to deal with the statistical matching is applied. The paper is organized as follows. In Sect. 2, the statistical matching problem for categorical variables and the concept of uncertainty are briefly recalled. Furthermore, the reduction of uncertainty by means of auxiliary information is discussed. In Sect. 3, such a methodology is applied to EU-SILC and ADL datasets.

2. Uncertainty in statistical matching for categorical data

Suppose A and B are two independent samples of n_A and n_B independent and identically distributed records from the same joint probability mass function (*pmf*) $p(x, y, z; \boldsymbol{\theta})$ referring to the categorical variables (X, Y, Z) with I, J, and K categories, respectively. In sample A, we only observe X and Y, in sample B we only have observations of X and Z. The common variable X is called matching variable.

At a *micro* level, the aim is to reconstruct a complete synthetic dataset with joint observations on all the variables of interest. At a *macro* level, the aim is the estimation of the joint *pmf* $p(x, y, z; \boldsymbol{\theta})$, see [4]. Because of the lack of joint information on all the three variables, $p(x, y, z; \boldsymbol{\theta})$ is not directly identifiable, unless under strong assumptions, which are generally hard to confirm.

Alternative approaches have been proposed in the literature to overcome the *identification problem*. The first approach assumes the conditional independence assumption between Y and Z given X (CIA) [9]. A second approach assumes the existence of external information regarding the statistical relationship between Y and Z, *i.e.*, a third sample C in which (X, Y, Z) has been observed [11] or proxy variables for Y, Z as in [13]. A third approach consists in analyzing the uncertainty regarding $p(x, y, z; \boldsymbol{\theta})$. Under this approach, several alternative models for the joint distribution of (X, Y, Z), compatible with the distributions of (X, Y) and (X, Z) in the samples A and B are considered.

In a parametric setting, the consequence of the identification problem is that only ranges of values containing all the pointwise estimates obtainable by each model compatible with the available sample information can be detected. Intervals defined by these ranges are known in the literature as *uncertainty intervals*, see [8; 10; 3]. Uncertainty in a nonparametric setting is analyzed in [1]. In [6] statistical matching under informative sampling designs is investigated. Finally, in [7] statistical matching under non-ignorable sampling and nonresponse is discussed.

When the variables of interest are categorical, uncertainty is dealt with in [3], where parameters uncertainty is estimated according to the maximum likelihood principle under the multinomial assumption of the joint pmf of (X, Y, Z). Notice that, if we perfectly know $P(X = i, Y = j) = \theta^*_{ij.}$ and $P(X = i, Z = k) = \theta^*_{i.k}$ for $i = 1, \ldots, I$, $j = 1, \ldots, J$, and $k = 1, \ldots, K$, the parameter $\boldsymbol{\theta}^* = \{\theta_{ijk}\}$ lies in the following reduced parameter space

$$\Theta_{SM} = \left\{ \sum_k \theta_{ijk} = \theta^*_{ij.}, \sum_j \theta_{ijk} = \theta^*_{i.k}, \theta_{ijk} \geq 0, \sum_{ijk} \theta_{ijk} = 1 \right\}. \tag{1}$$

The parameter estimate which maximizes the likelihood function is not unique and the set of plausible maximum likelihood estimates for (1), is called *likelihood ridge*. It is defined as

$$\widehat{\Theta}_{SM} = \left\{ \sum_k \theta_{ijk} = \widehat{\theta}_{ij.}, \sum_j \theta_{ijk} = \widehat{\theta}_{i.k}, \theta_{ijk} \geq 0, \sum_{ijk} \theta_{ijk} = 1 \right\}, \tag{2}$$

where

$$\widehat{\theta}_{ij.} = \frac{n^A_{ij.}}{n^A_{i..}} \frac{n^A_{i..} + n^B_{i..}}{n_A + n_B}, \quad \widehat{\theta}_{i.k} = \frac{n^B_{i.k}}{n^B_{i..}} \frac{n^A_{i..} + n^B_{i..}}{n_A + n_B}, \tag{3}$$

and $n^A_{ij.}$ denotes the number of observations in sample A with $(X = i, Y = j)$. Similar definitions hold for the remaining quantities in (3). All the distributions in the likelihood ridge are equally informative, given the data.

Uncertainty measures can be defined by analyzing the characteristics of the parameter space $\widehat{\Theta}_{SM}$. Since each parameter θ_{ijk} lies in an interval $\theta^L_{ijk} \leq \theta_{ikk} \leq \theta^U_{ijk}$ whose upper and lower bounds can not be generally expressed in closed form, we use as uncertainty measure (UM) for each θ_{ijk} the interval length, that is $UM(\theta_{ijk}) = [\theta^U_{ijk} - \theta^L_{ijk}]$. Then, an overall uncertainty measure, proposed in [10], can be defined as follows

$$UM(\boldsymbol{\theta}) = \frac{\sum_{ijk}(\theta^U_{ijk} - \theta^L_{ijk})}{M} \tag{4}$$

where M is the number of uncertain parameters. In this context, extra-sample information (constraints) leading to a restriction of the parameter space Θ_{SM} to a subspace $\Omega \subset \Theta_{SM}$ can be very useful for reducing the overall uncertainty. Clearly, the more informative is the constraint, the greater is the reduction in uncertainty (4).

In Sect. 3, the likelihood ridge is analyzed under two scenarios: (i) without constraints, referring to the estimation of the unconstrained parameter space Θ_{SM} (unconstrained scenario); (ii) under constraints defined as structural zero, referring to the estimation of the constrained parameter space Ω (constrained scenario).

3. Application to EU-SILC and ADL

ADL multi-purpose survey belongs to the National Statistical Plan and is carried out annually by ISTAT. It collects information on the daily life of both individuals and households covering different social aspects referring to the individual's quality of life, the degree of satisfaction with one's living conditions, the economic situation. Subjective motivations and opinions contribute, together with objective information on social life, health, work, and lifestyles to define social information. For the 2019 edition, the sample consists of 19536 households. EU-SILC survey's main objective is to provide data on income, poverty, social exclusion, and living conditions. For the 2019 edition, the sample consists of about 22000 households. In this application we consider the following variables:

1. Y =*Total Disposable Household Income*, henceforth *Income*, discretized in four ordinal categories : 1 [0, €16100); 2 [€16100, €25400); 3 [€25400, €40800); 4 [€40.800, ∞). The categorization is based on the quartiles.
2. Z =*Satisfaction with the economic situation over the past 12 months*, henceforth *Sitec*, based on an ordinal four-point scale assigning 1 to *very much*; 2 to *quite a lot*; 3 to *a little*; 4 to *not at all*.

With regard to the matching variables the literature highlights two main criteria for their selection. First of all, there must be both homogeneity in their statistical content and similarity in the distributions of the variables across the two surveys. Secondly, the variables must be significant in explaining variations in the target variables.

In the application, the variables *Household size* (*Ncomp*), *Geographical area of residence* (*Area*) and *Occupational status* (*Condlav*), have been considered as possible matching variables and have been harmonized across the two datasets. The Hellinger distance is equal to 7%, 9% and 10% for *Ncomp*, *Area* and *Condlav*, respectively. Furthermore, all the variables are statistically significant in explaining variations in both Y and Z. Then, X = *Ncomp* is chosen as matching variable.
The exploration of the likelihood ridge, for the unconstrained and constrained scenario, has been done by using EM algorithm considering 100000 random starting points, see [3]. The restricted parameter space is defined by imposing the following structural zeros in the contingency table: $\theta_{i,1,1} = \theta_{i,1,2} = \theta_{i,4,3} = \theta_{i,4,4} = 0 \; for \; i = 1, \ldots, 4$; *i.e* we impose that a households with income below the first quartile cannot express an high or quite high degree of satisfaction with their economic resources, as well as households with income greater or equal to the last quartile cannot be totally or partially dissatisfied.

Table 1 shows the simulation extremes of the likelihood ridge $[\theta^L_{ijk}, \theta^U_{ijk}]$ in 100000 runs of EM for both scenarios, the average values $\bar{\hat{\theta}}_{ijk}$ over the 100000 estimates and the uncertainty measure $UM(\theta_{ijk})$. Finally, last column reports the estimate under the CIA assumption ($\hat{\theta}^{CIA}_{ijk}$).

The main finding in Table 1 refers to the reduction of ranges for some of the estimated probabilities when auxiliary information is introduced (see columns 7 and 11). In some cases, the introduction of structural zeros is so informative that EM algorithm converges to a single estimate. Notice that, a reduction in the range can correspond to a higher concentration of its density. For instance, the density of θ_{122} (cell 6) approximated with the frequency distribution of the 100000 simulations, is reported in Fig 1 for the unconstrained (histogram on the left) and the constrained scenario (histogram on the right). As expected, the latter distribution is more concentrated, due to the extra-sample information. The overall uncertainty (4) is 0.036 under the unconstrained scenario. It reduces to 0.021 where structural zero are introduced.

Table 1: Range of probability estimates $[\theta^L_{ijk}, \theta^U_{ijk}]$, mean values $\overline{\hat{\theta}}_{ijk}$ and uncertainty measure $UM(\theta_{ijk})$ over 100000 runs of EM under the unconstrained scenario and the constrained scenario. The last column refers to CIA estimate ($\hat{\theta}^{CIA}_{ijk}$)

	Variables			Unconstrained Likelihood ridge				Constrained Likelihood ridge				CIA

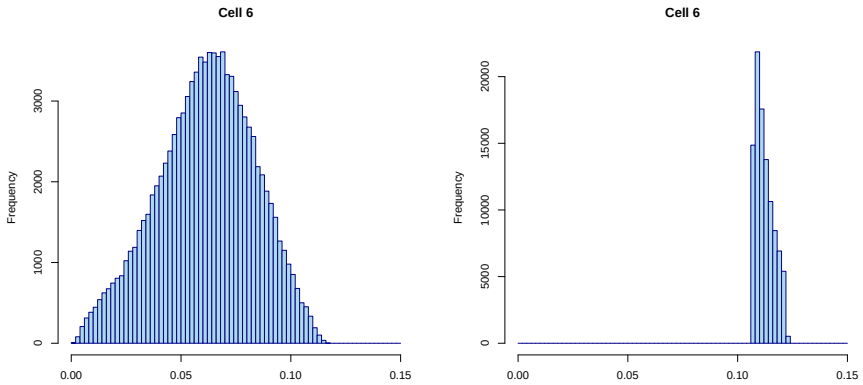

Figure 1: Likelihood ridge for cell 6 for scenario 1 (histogram on the left) and scenario 2 (histogram on the right).

Finally, the Goodman-Kruskal (Gamma) association index is computed over the 100000 estimated contingency tables under scenario 2. The histogram of the Gamma sample distribution has been reported in Fig. 2, from which it can be argued that there is a strong positive association between income and self-assessment of economic status. The negative sign is due to the reverse order of the categories of the *Sitec* variable with respect to the concept of satisfaction.

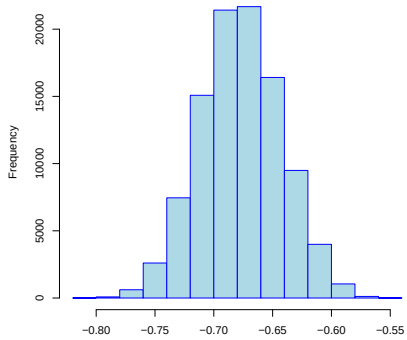

Figure 2: The values of Goodman-Kruskal Gamma association index over 100000 replications under scenario 2

With regard to the *micro* approach, by choosing a plausible joint *pmf* from the likelihood ridge, is possible to reconstruct a synthetic data set in which all variables of interest are observed. Further developments of the present work will focus on statistical matching in a multivariate context to pursue the goal of identifying the overall determinants of economic well-being. This can be achieved by embedding the methodological framework of Bayesian networks in the statistical matching as proposed in [2; 5].

Abstract

An understanding of the relationship between traffic and pollution is crucial to enable policy makers and planners to manage the effects of pollution in urban areas. Typically air pollution modelling uses expensive, intensive monitoring, but in this article we explore the potential of using readily available surrogates for traffic conditions from crowd-sourced data. We design a travel delay metric to compare traffic flow estimates from a gold-standard automatic number-plate recognition (ANPR) survey in Bath, UK to data from the Google Maps traffic API. We observe very good agreement between the ANPR-based and Google-based delay ratios with two caveats: 1) we observe some evidence that the Google-based measures have a slight time delay and 2) Google-based measures are subject to truncation in low-traffic settings compared to ANPR-based delay measures.

Keywords: air pollution, traffic modelling, ANPR, Google Maps

1. Introduction

Air pollution accounted for 6.4 million deaths in 2015 with more than half (4.2 million) caused by poor ambient air quality (1). These deaths, attributed to diseases such as cancer and cardiovascular diseases, are associated with pollutants such as carbon monoxide (CO), nitrogen dioxide (NO_2) and other nitrogen oxides (NO_x), as well as fine particulate matter (PM 2.5). Traffic is a major source of pollution in cities, along side other sources such as industry and household heating emissions. A recent report by the UK Department of Transportation on the contribution from different sources of pollution found that transport is responsible for a third of NO_x emissions in the UK, with cars and taxis having the greatest share (2).

An understanding of the relationship between traffic and pollution is crucial to enable policymakers and planners to try to control the effects of pollution in urban areas. This understanding is usually obtained by modelling the emissions of traffic and the resulting pollution. The results of the modelling are then used by local governments in urban areas to develop regional policies based on measures such as restricting certain classes of vehicles from a city centre to reduce pollution concentrations. However, the data required for accurate models needs to be very comprehensive, requiring information on factors such as fleet age, typical average speeds, road classification and engine types as well as a detailed understanding of traffic conditions, especially congestion. Typically, this requires intensive on-the-ground monitoring, which is financially impractical for resource-constrained small local authorities.

The objective of the research we present here is to explore the potential of using readily available surrogates for traffic conditions from crowd-sourced data from mobile devices in place of expensive,

intensive monitoring. We compare the readily available data against an intensive survey over a two week period in the City of Bath, United Kingdom and find generally good agreement between the two. We also demonstrate the correlation of our novel metric with measured road-side air pollution levels.

2. Comparisons of Traffic Measures

In this section, we introduce two types of data collected during the survey period. Then we will define the concept of a 'delay ratio' and describe how we calculate this metric for our two data sources. Finally, we explore the relationships between these two measures.

2.1 Data Sources

Data on traffic levels is available at varying cost and resolution. Some sources of data give the flow of traffic in terms of average vehicle speeds at a point or along a segment or route; whereas, others consist of vehicle counts, which can be converted into either volume of cars passing a sensor in a given time window or speeds along a route if pairs of vehicle observations are combined, which requires recognising and recording the individual vehicles.

Data at the individual vehicle level can be collected by various methods, most often either human surveys or Automatic Number Plate Recognition (ANPR) cameras. The data from ANPR cameras can be cross referenced against a database of vehicles and their engine specifications to get detailed information about which vehicles passed which cameras at any given time, alongside the pollutants they are expected to emit. However, such methods are expensive and thus limited in their spatial density as well as the time for which they can be installed.

The Bath and Northeast Somerset Council carried out ANPR monitoring in the first two weeks of November 2017 to inform decision making about which vehicle types to charge in a Clean Air Zone later introduced in 2021. Cameras at 40 sites covering the main entry and exit points to the city were used to understand traffic patterns. The city publicly released anonymised versions of the ANPR data, with unique vehicle IDs replacing number plates. Observations of unique vehicle IDs at sequential cameras were then used to calculate journey times along selected origin-destination (OD) routes. Because vehicles are not continually observed, we cannot determine whether the journey between two cameras was direct or involved a stop off (e.g., at a petrol station or school). To focus on plausibly direct journeys, we exclude very long journey times (30 minutes in the examples below).

Crowd-sourced data from mobile devices in vehicles themselves are a promising alternative source of traffic data. These sources include commercial data from GPS navigation devices installed in vehicles (5), ride share taxi movement data (6), and Google's Traffic API (3). Google provide their Google Distance Matrix API to access their traffic data, which is based on the movements of all Android phones where the users have not disabled such access to their personal movements. Requests for live travel time data from Google's API between a selected OD pair can be made using various programming interfaces, including libraries in JavaScript and Python, and gives a proxy for vehicle flow rather than absolute counts. While this aggregate information contains no data about vehicle fleet composition, it is easily accessible, requires no installation of physical infrastructure and can be used instantly at any given location.

2.2 Defining a metric to compare ANPR and Google Maps

To compare the ANPR and Google data, we defined a new proxy for congestion called the *delay ratio*. While the ANPR can be used to measure both traffic volume and traffic flow speed between OD pairs, the Google data can only measure traffic flow. Although the Google data cannot be used to measure congestion directly, we can use increased journey times as a proxy for congestion.

We define the delay ratio, D, as the ratio of the travel time in a 15-minute window to the typical travel time on an OD route. This is a dimensionless measure where $D = 1$ means the journey times in the 15-minute window are typical, and proportional increases indicate delayed journeys and congestion.

For example, a value of $D = 1.2$ means the journey between specified end points takes 20% longer than expected. For the ANPR data, we assign each journey to a 15 minute interval based on the time the vehicle was recorded at the end of the route. We take the median journey time for each interval within the 15 minute window as the 'typical' travel time. This is then re-scaled by the median travel time over the whole two-week period to construct a delay index. For the analysis in this paper, we exclude 15 minute windows where fewer than 10 vehicles were observed. The travel times from Google were obtained by querying the API every 15 minutes. Compared to the ANPR data, we cannot know as precisely what the 15 minute travel time represents, and as we will see later, there are likely some important differences in terms of lags in Google's estimates of travel time in a given window.

3. Comparisons of delay metrics

To compare the delay metrics, we used data from a three mile route between two major roundabouts in Bath, shown in Figure 1.

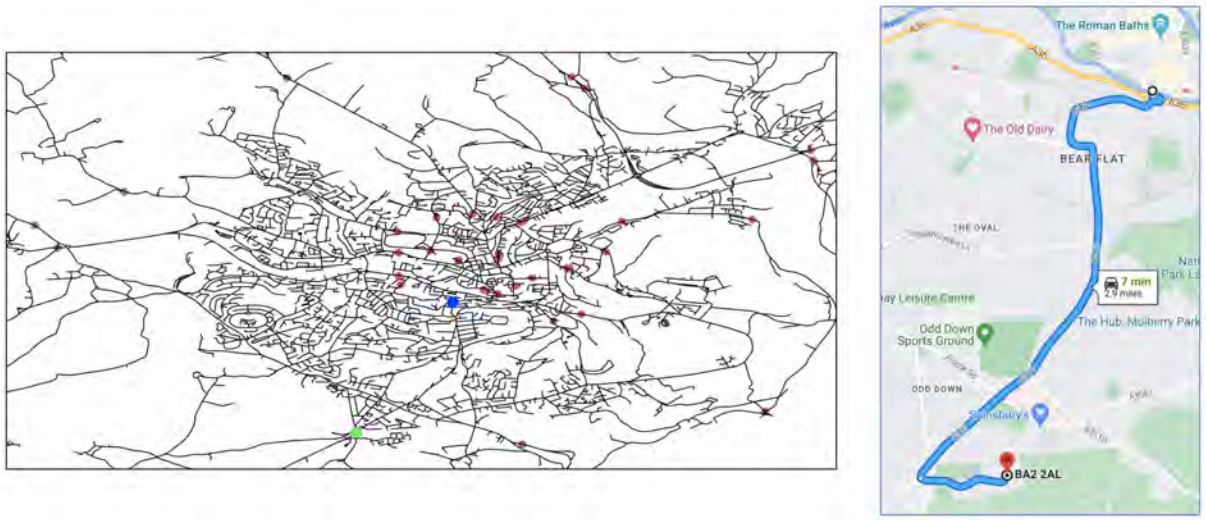

Figure 1: The left hand panel shows the major roads in Bath with the coloured dots indicating the camera locations in the ANPR survey. The blue and green dots are the locations of the cameras at the origin and destination, respectively, of the route studied in this section. The right hand panel shows the journey in Google Maps.

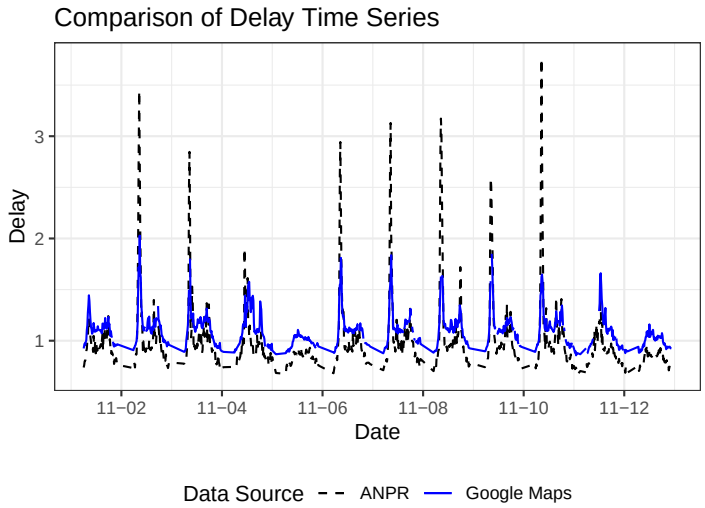
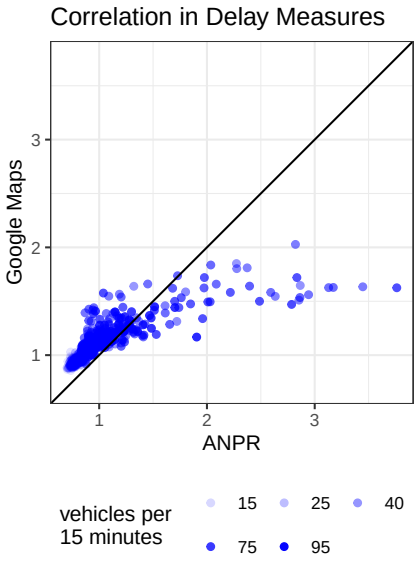
Exploratory analysis of the two types of delay metrics shown in Figure 2 indicates generally good agreement between the delay metrics defined by the two data sources. However, both the time series (Figure 2a) and the scatter plot (Figure 2b) show that the the ANPR-based measure of delay have larger extremes than the Google-based measure of delay. We note that the observations of extreme delays in the ANPR data cannot be explained by low traffic volumes in the corresponding time windows. Instead, we hypothesise that the Google Maps travel times are smoothed in some fashion that moderates extreme values. During light traffic conditions, when travel times are *below* the typical values, there is also a discrepancy between the two metrics, with Google-based values again being modulated towards 1, but this discrepancy is arguably less relevant to pollution modelling.

Figure 2a also indicates a small phase shift in the delay measurements, with the peaks in the Google Maps-based delay metric occurring just after the ANPR-based peak. We verified this by calculating the cross correlation function between the two time series across lags of up to 5 time windows (75 minutes). We found that the ANPR-based delay metric at time t is most strongly correlated with the Google-baed delay metic at time $t + 1$ (i.e., the subsequent 15 minute interval). One potential explanation is that there is a gap between when users transmitting their location data to Google experience traffic congestion and when Google updates the estimated travel times for a user about to start the same journey.



(a) Comparison of delays metrics over 15 minute windows.



(b) Scatter plot of delay metrics.

Figure 2: Visual comparisons of delay metrics. In the right hand plot, the level of transparency indicates the number of vehicles that contributed to the ANPR delay calculations for a given 15 minute time window.

4. Relationships to Pollution

To explore the relationship between our proposed Google-based delay metric and air pollution, we queried journey times over short segments near four permanent air pollution monitoring stations over a period of several weeks in Autumn 2018 to Spring 2019. Figure 3 shows the delay ratio as defined above for east-bound traffic on the London Road, which is traffic entering the city, and nitrogen dioxide measurements from a road-side station that is part of the UK Department for Environment Food & Rural Affairs' Automatic Urban and Rural Network of air pollution monitoring stations.

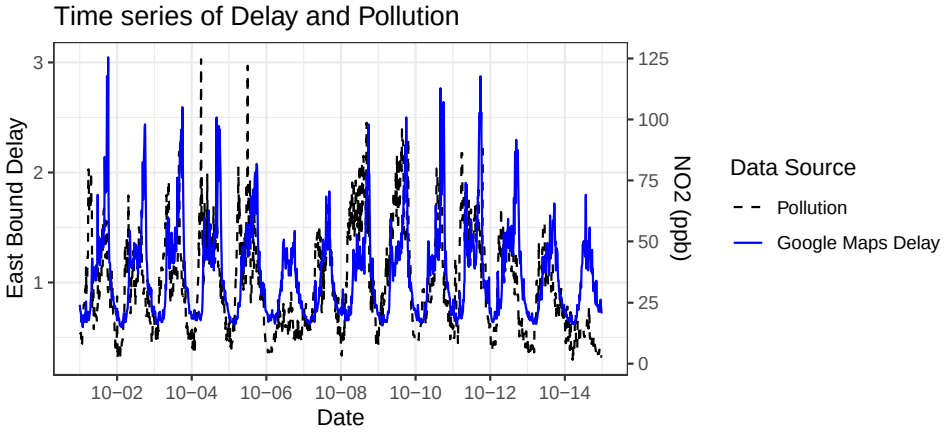


Figure 3: Comparison of the time series of Google Maps-based delay in East Bound traffic and NO_2 on the London Road in Bath in October 2018.

Figure 3 shows the comparison of delay and pollution for two weeks of data in October 2018. While there are some clear correlations between the traffic flow as measured by Google Maps and NO_2 levels, we again see that the two quantities are out of phase, with the peak in delays often counterintuitively coming after the peak in pollution. We also see some cases (e.g., October 6) where there is very weak

correlation between traffic flow and pollution levels. This behaviour is expected because many other environmental conditions, particularly wind speed and direction, will determine road-side pollution levels in a particular location alongside the amount of pollution being generated by traffic. State-of-the art air quality models would include emissions from traffic within physically motivated chemical transport models that describe the dispersion of pollutants over time as well as the advection of gasses and particles by the wind (4).

5. Conclusions

Overall, we observe very good agreement between the ANPR-based and Google-based delay ratios with two caveats: 1) we saw that the Google-based measures have a slight time delay compared and 2) Google-based measures are subject to truncation in low-traffic settings, leading under-estimates compared to ANPR-based delay ratios. Furthermore, we demonstrated that the Google-based measures show a strong association with a key pollutants in Bath, although the lagging issue persists. Taken together, these results indicate that crowd-sourced traffic flow data could be used a cheap yet effective proxy for intensive traffic monitoring in real-time air pollution modelling.

Abstract

Holothurians are marine invertebrates that produce ecosystem services increasing the local productivity of benthic communities, by e.g. releasing trapped nutrients, reducing stratification and increasing nutrification of sediments. In this work, we propose a point-process model that aims at better understanding the species distribution accounting for the effects of some ecological covariates.

Keywords: Point process, Bayesian inference, Sampling effort

1. Introduction

Holothurians, commonly known as sea cucumbers, are benthic marine invertebrates belonging to the Phylum Echinodermata, Class Holothurioidea, represented by more than 1500 species worldwide constituting globally one of the most common organisms associated with soft bottoms [11]. Also, among temperate waters they play a key role as bioturbators, in fact, Holothurians offer ecosystem services that increase local productivity. Bioturbation of sediments by Holothurians releases nutrients trapped in the sediments to benthic ecosystems [11]. When Holothurians occur with high densities, they can reduce microalgal production and enhance the availability of nutrients, such as ammonium, increasing the gross productivity of benthic communities. Sediment digestion by Holothurians may be responsible for up to 50% of the dissolution of calcium carbonate in reef systems [9]. Holothurian bioturbation also reduces stratification and nutrification of sediments and can directly increase oxygen levels in the sediment [9]. The digestion of carbonate sands and metabolic activity of Holothurians are also a cause of turnover of inorganic carbon. The ecological role of Holothurians as bioturbators is thus pivotal in facilitating the availability of nutrients and oxygen for other organisms in both tropical and temperate waters [5].

Local fisheries exploit the species inhabiting coral reefs in tropical and subtropical regions, and their high value in Asian markets has encouraged global overfishing and associated declines. In response to the market demand, the fishery of sea cucumbers has shifted to new target species as the Mediterranean ones [13]. The current lack of information about the sea cucumbers' population dynamics, habitat use, and spatial ecology can lead to inadequate management [7].

Using underwater photogrammetry-based imagery (i.e., High spatial resolution ∼0.5 cm/pixel orthophotomosaics and Digital Surface Models), data on the presence, and relative coordinates, of Holothurians were collected in 5 temporal windows. We envision these data as a realization of a log-Gaussian Cox process, which is estimated under a Bayesian framework using the Integrated nested Laplace approximations (INLA) [8], implemented in the INLA software [2], available at `www.r-inla.org`. We propose 4 different models. In the first two, only the locations of Holothurians are modeled: while the first model assumes that there is a log-Gaussian process for each time-window, in the second the log-Gaussian process is shared. In the last two models we assume that Holothurians can be hidden by the presence of Posidonia oceanica meadows. Then the presence of Posidonia oceanica is described as a spatial process used as a predictor in the log-Gaussian Cox models introduced above, in a similar way as in the preferential sampling approach [1].

In what follows, we show some preliminary results that highlight the role of the natural Posidonia oceanica meadow and of some environmental covariates in the spatial distribution of the Holothurians.

2. Structure-from-Motion photogrammetry data and image processing

The recent widespread of Structure from Motion (SfM) photogrammetry for marine research [6] provides new tools and approaches to accurately map the distribution and behavior of many organisms in shallow aquatic environments including Holothurians that typically have high contrast against pale sandy sediments. Structure from Motion (SfM) photogrammetry allows extracting a plethora of fine-scale variables of benthic habitats by analyzing 3D digital models of the underwater environment, directly derived from overlapping two-dimensional camera images taken from different points of view [10]. SfM-derived ortho-mosaics can be analyzed in several ways, providing an excellent tool for accurate measurements that are difficult or even impossible to get in situ with traditional methods. They can provide also valuable information for fine-scale assessment and monitoring of benthic communities[12]. Some attempts have been carried out to map Holothurians in the tropical reef by using aerial imagery acquired by lightweight Unmanned Aerial Systems [13]. However, underwater photogrammetry-based imagery has never been used to assess Holothurians abundance and density among Mediterranean waters. In this study, to accurately map the seabed and the presence of two species of sea cucumbers (Holothuria tubulosa and H. poli) we used ultra-fine scale orthophoto mosaics derived by SfM processing according to the methodology proposed by [12].

Fieldwork was carried out in 5 temporal windows (seasons) on the east side of Giglio Island (central Tyrrhenian Sea, Italy), inside one of the four restoration sites located in the shipyard areas identified after the Costa Concordia shipwrecking. At the end of the wreck removal operations (July 2014) and after the seabed cleaning phase (April 2018), the natural environmental conditions were restored, ensuring the suitability of the area for transplant. Indeed, since 2019 transplanting operation has begun inside the shipyard area by using iron stakes to install into the dead matte bed detached fragments of P. oceanica. The area displayed a mosaic of habitat, including hard and soft bottom communities as well as natural (high-density meadow) and transplanted (low-density meadow) as P. oceanica beds. A diver propulsion vehicle equipped with spirit level, compass, depth gauge and a GoPro Hero10 Black action camera was used for image acquisition. Approximately 6000 still images were acquired by pointing the camera down towards the substrate at a near-nadir position, 4 m above the seabed, ensuring a resolution useful for micro-scale assessments.

Image processing was carried out through the 3D reconstruction software Agisoft Metashape v 1.6.2 (Agisoft LLC, Russia) generating digital surface models (DSMs) and orthophoto mosaics. ArcGIS 10.6 was used to manually digitize each visible Holothurian in the orthomosaic at each sampling event (seasons). As many as 984, 1478, 938, 769 and 668 sea cucumbers were respectively detected for each of the 5 seasons. DSMs implemented in the Spatial analyst extensions were used to estimate other seabed features such as slope, aspect, vector ruggedness (VRM) and rugosity. An object image analyses (OBIA) approach was adopted to speed up the classification of the orthophoto mosaics, leading to the definition of five cover classes: sandy bottoms, hard bottoms covered by photophilic algae, Posidonia oceanica, dead 'matte' of Posidonia oceanica and transplanted Posidonia oceanica.

3. Log-Gaussian Cox process models for the presence of Holothurians

Let $\mathbf{X}_t$ be a point process on the space $\mathcal{S} \in \mathbb{R}^2$ at times $t \in \{1, 2, 3, 4, 5\}$, and $\mathbf{x}_t = (\mathbf{x}_{1,t}, \ldots, \mathbf{x}_{n_t,t})'$ be its realization, where $\mathbf{x}_{i,t} = (x_{i,1,t}, x_{i,2,t})'$ represents the presence of an Holothurian and its location. The idea is to model $\mathbf{X}_t$ as a log-Gaussian Cox process, with the following intensity function (letting $\mathbf{x}_{i,t} = \mathbf{x}$ for convenience):

$$\log \lambda_t(\mathbf{x}) = \beta_{0,t} + \mathbf{z}_t(\mathbf{x})\boldsymbol{\beta} + w_t(\mathbf{x}) \tag{1}$$

where $\beta_{0,t}$ is a time-specific intercept, $\mathbf{z}_t(\mathbf{x})$ is a vector of possibly time-dependent covariates, while the regressors $\boldsymbol{\beta}$ are the same for all t. The component $w_t(\mathbf{x})$ is the realization of a time-specific second-order stationary Gaussian process $W_t(\mathbf{x})$ with mean 0 and covariance function $C(h; \boldsymbol{\theta})$.

As an alternative model, we assume that the data at different time points share the same Gaussian process, possibly rescaled, hence

$$\begin{aligned} \log \lambda_1(\mathbf{x}) &= \beta_{0,1} + \mathbf{z}_1(\mathbf{x})\boldsymbol{\beta} + w_1(\mathbf{x}) \qquad \text{if } t = 1 \\ \log \lambda_t(\mathbf{x}) &= \beta_{0,t} + \mathbf{z}_t(\mathbf{x})\boldsymbol{\beta} + \delta_t w_1(\mathbf{x}) \qquad \text{if } t > 1 \end{aligned} \tag{2}$$

As a third type of model we implemented a modified version of the preferential sampling [1]. The idea is that the ability to observe the presence of Holothurians highly depends on the concentration of P. oceanica in the area. For this reason, letting $y(\mathbf{x})$ be the logistic transformation of the fractional P. oceanica coverage, we extend the first model assuming the following:

$$\begin{aligned} y(\mathbf{x}) &= \gamma_0 + \gamma_1 x_1 + \gamma_2 x_2 + \rho v(\mathbf{x}) + \epsilon(\mathbf{x}) \\ \log \lambda_t(\mathbf{x}) &= \beta_{0,t} + \mathbf{z}_t(\mathbf{x})\boldsymbol{\beta} + w_t(\mathbf{x}) + v(\mathbf{x}) \end{aligned} \tag{3}$$

where $v(\mathbf{x})$ is a realization of a Gaussian process independent of $W_t(\mathbf{x})$ and $\epsilon(\mathbf{x})$ is an i.i.d. Gaussian nugget effect. The same idea is used to extend the second modeling approach, thus obtaining:

$$\begin{aligned} y(\mathbf{x}) &= \gamma_0 + \gamma_1 x_1 + \gamma_2 x_2 + \rho v(\mathbf{x}) + \epsilon(\mathbf{x}) \\ \log \lambda_1(\mathbf{x}) &= \beta_{0,1} + \mathbf{z}_1(\mathbf{x})\boldsymbol{\beta} + w_1(\mathbf{x}) + v(\mathbf{x}) \qquad \text{if } t = 1 \\ \log \lambda_t(\mathbf{x}) &= \beta_{0,t} + \mathbf{z}_t(\mathbf{x})\boldsymbol{\beta} + \delta_t w_1(\mathbf{x}) + v(\mathbf{x}) \qquad \text{if } t > 1 \end{aligned} \tag{4}$$

Notice that models in (3), and (4) merge raster data for P. oceanica coverage with point data for Holoturian locations. This is possible since INLA allows to map data with different spatial support to a common estimation mesh by defining suitable projection matrices, thus avoiding the so-called change of support problem (COSP) [3].

4. Application

In this section, we show some preliminary results. In all models, we use as covariates the two spatial coordinates, the water temperature and the sea bottom rugosity, hence we have:

$$\mathbf{z}_t(\mathbf{x}) = (x_1, x_2, z_{\text{temp},t}(\mathbf{x}), z_{\text{rug}}(\mathbf{x}))'.$$

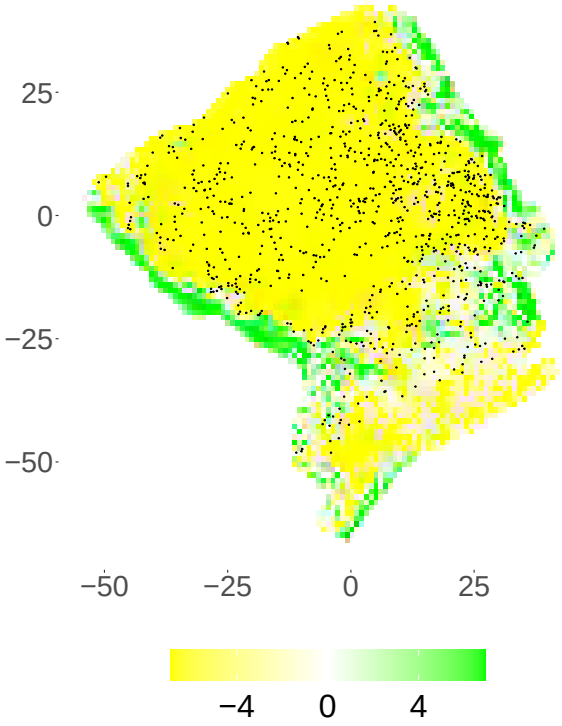

Figure 1: Graphical representation of the logistic transformation of the fractional P. oceanica coverage ($y(\mathbf{x})$). Dots correspond to the locations of holothurian at $t = 1$. Values below zero are depicted using a yellow gradient, while values above zero are illustrated using a green gradient.

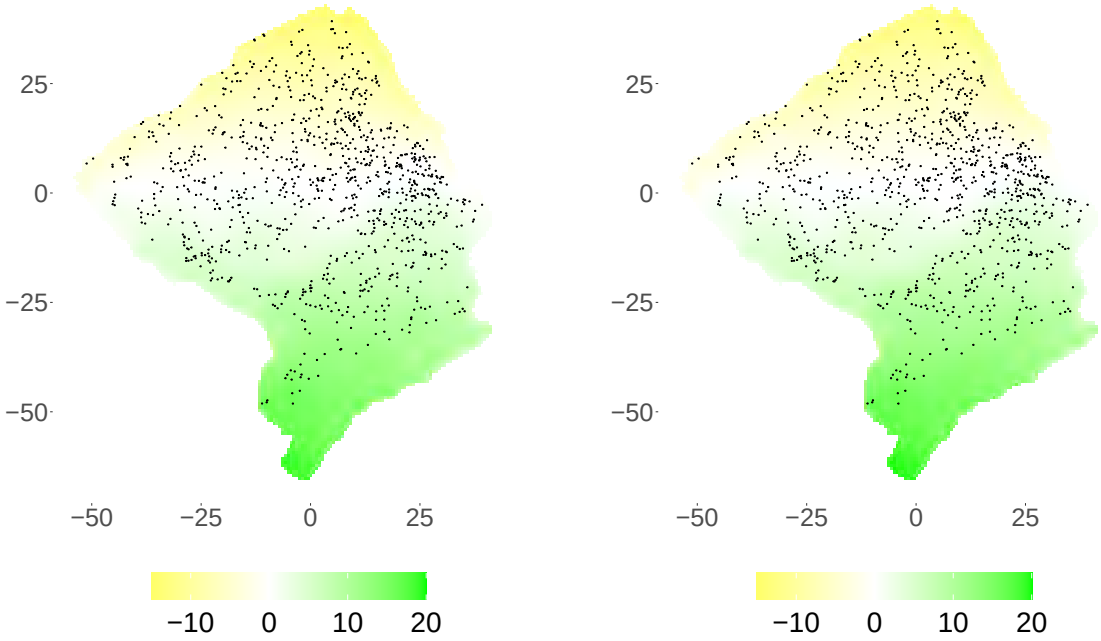
		γ_1	γ_2	ρ
M3	Post. Mean	0.002	-0.004	0.928
	95% CI	(0.001, 0.002)	(-0.004, -0.003)	(0.359, 1.440)
M4	Post. Mean	0.002	-0.004	0.994
	95% CI	(0.001, 0.002)	(-0.004, -0.003)	(0.390, 1.597)

Table 2: $y(\mathbf{x})$ - Posterior means and 95% credible intervals of the regression parameters γ_1 and γ_2 and of the interaction parameter ρ.

To differentiate between the results of the four approaches, we indicate as M1, M2, M3, and M4 the models given by equations (1), (2), (3), and (4), respectively. The water temperature and the sea bottom rugosity were chosen as an example, but the appropriate selection of the available explanatory variables will contribute to an extended version of this work. Figure 1 shows evidence of an inverse relation between the recorded presence of Holothurians and the concentration of natural P. oceanica meadow that can hide the presence of Holothurians.

The INLA R package was used to estimate the four models and to obtain the WAIC [4]. It should be noted that the WAIC can't be used to compare models M1 and M2 with M3 and M4, since they consider different variables. Tables 1 and 2 contain the posterior means and 95% credible intervals of the regressive parameters in $\boldsymbol{\beta}$, γ_1 and γ_2 and of the interaction parameter ρ. Figure 2 shows the maps of the estimated shared spatial component $v(\mathbf{x})$ for models M3 and M4.

By analyzing the models output, there is evidence pointing toward models M2 and M4 being a better description of the data with respect to M1 and M3, which consider different Gaussian processes for every time point t. This is shown by the posterior estimates of the regressive parameters in Table 1 being quite similar across models and the posterior estimates of δ_t's in M2 and M4 being very close to the value 1 for all values of t. Moreover, WAIC values (not reported) are more favorable to model M2 than to M1 and to



(a) M3 (b) M4

Figure 2: Graphical representation of the estimated shared spatial component $v(\mathbf{x})$ for models M3 (left) and M4 (right). The color graduation is the same across the two pictures. Values below zero are depicted using a yellow gradient, while values above zero are illustrated using a green gradient. Dots correspond to the locations of holothurian at $t = 1$.

model M4 than to M3. It should be noted that, even though EDA shows an apparent inverse relationship between the presence of Holothurians and the concentration of P. oceanica, the positive estimated value of the coefficient ρ implies a direct relationship between the two, meaning more Holothurians with more P. oceanica. This pushes toward the expected conclusion that P. oceanica meadows tend to hide the presence of Holothurians in the pictures, thus inducing a form of preferential sampling [1]. Moreover, the range of variation of the estimated shared spatial component $v(\mathbf{x})$ is much higher than the one of the residual spatial variation $w_t(\mathbf{x})$ across the four models for all values of t. Given that δ_t's have posterior estimates close to 1, this proves that $v(\mathbf{x})$ is more relevant than w_t in explaining the spatial variation of the presence of sea cucumbers.

5. Conclusion

The preliminary results of this work show evidence that the proportion of Posidonia is relevant information to be used to describe the presence of Holothurians by a preferential sampling approach. In the future, we will enrich the model by using the Holothurians size as a mark, hence defining a marked point-process, and we will also investigate if and how the mark is affected by the Posidonia. We will also investigate how the other available covariates can be used to explain the presence of Holothurians and if their spatial distribution can be described by a point-process with clustering structure.

Abstract

Recently climate change has contributed to the decline in forest health, and yearly European forest health monitoring data are increasingly being used to investigate the effects of climate change on forests in order to decide on forest management strategies for mitigation. Forests in Germany have been badly affected and climate change now appears to be the major cause of defoliation (Eickenscheidt et al., 2019; Augustin et al., 2009). Thus, large scale forest conversions to more mixed forests with drought and heat resistant species are planned in some areas of Germany. This talk will cover the statistical aspects of a modelling project which has been informing decisions regarding this future forest conversion. Model selection is a challenge because of spatial confounding and the large number of correlated time varying environmental predictors. In addition there are computational challenges due to the large number of parameters and large sample sizes. A generalized additive mixed model is used for estimating spatio-temporal trends of defoliation, an indicator for tree health. Defoliation is modelled as a function of site characteristics (topography, soil and climate) with the aim of identifying the main factors associated with tree damage. The minimal model contains a space-time smoother and an AR1 process for temporal correlation. To eliminate predictors with negligible effects in the remaining set of predictors we use stability selection. Variable selection using integrated backward selection is carried out repeatedly with resampled data yielding selection inclusion frequencies. The final set of predictors are the predictors with selection inclusion frequencies above a certain threshold.

Keywords: forest health, spatio-temporal model, generalised additive mixed model, stability selection, integrated backward selection

1. Introduction

Recently climate change has contributed to the decline in forest health, and yearly European forest health monitoring data are increasingly being used to investigate the effects of climate change on forests in order to decide on forest management strategies for mitigation. Forests in Germany have been badly affected and climate change now appears to be the major cause of defoliation (Eickenscheidt et al., 2019; Augustin et al., 2009). There is a strong association between drought stress and defoliation (an indicator

of tree vitality) of the main species. Thus, large scale forest conversions to more mixed forests with drought and heat resistant species are planned in some areas of Germany.

Here we model forest health data from the Terrestrial Crown Condition Inventory (TCCI), a forest health monitoring survey which has been carried out yearly in the forests of Baden-Württemberg, Germany since 1983. Forests in this area have been badly affected by climate change: In 2019 46% of the forest area in Baden-Württemberg was considered to be significantly damaged: that is trees had more than 60% defoliation in the crown. In particular tree species that were previously thought to be climate-resilient were also badly affected by heat, drought and storms in recent years. The available predictor variables cover different aspects contributing to forest damage with site characteristics (topography, soil, competition) contributing to pre-disposition. The primary damaging factors are effects of climate change (drought, heat, late frost) and secondary damaging factors (pathogens, insects). These factors interact with each other.

The aim of the modelling is to identify the main factors associated with tree damage. The results will help to formulate hypothesis regarding the causes of damage and identify areas which are still suitable for the main species. A generalized additive mixed model is used for estimating spatio-temporal trends of defoliation, an indicator for tree health. Defoliation is modelled as a function of site characteristics (topography, soil and climate) with the aim of identifying the main factors associated with tree damage.

Model selection is a challenge because of the large number of correlated time varying environmental predictors with non-linear effects of many predictors due to there often being an optimal range for a variable. For example, there is an optimal range of Julian day of budburst, and budburst below or above this range is associated with increased defoliation. In addition we have spatial confounding. This happens when spatial regression models use spatial random effects or smooths to account for residual spatial correlation in the response variable and result in fitted values that are smoothed across the spatial domain of the data (Dupont et al., 2022). This can lead to unrealiable effect as collinearity between covariates and spatial effects can lead to significant bias. In addition there are computational challenges due to the large number of parameters and large sample sizes. We use a pragmatic approach to address these challenges in the context of our complex modelling task.

2. Data

We model forest health data from the Terrestrial Crown Condition Inventory (TCCI), a forest health monitoring survey which has been carried out yearly in the forests of Baden-Württemberg since 1983. The survey is in alignment with the International Co-operative Programme on Assessment and Monitoring of Air Pollution Effects on Forests and thus uses the same survey protocol (Eichhorn et al., 2017). The TCCI includes sampling points from the large-scale monitoring programme (level I) and longterm intensive monitoring areas (level II). The background and description of these two parts of the survey is given in Damman et al. (2001); de Vries et al. (2003) and Eichhorn et al. (2017). The level I data are essentially yearly repeated measures on a regular spatial grid with different subsets of locations missing, depending on the year resulting in sampling points on either a 4×4, 8×8 or 16×16 km grid. At each sampling grid point 24 sample trees with minimum height of 60 cm and a dominant and subdominant position within the forest stand are randomly selected using a protocol ensuring good spatial coverage within a 50 m radius. The trees are permanently marked and re-assessed during subsequent surveys. Trees that are removed are replaced by newly sampled trees. The level II sampling areas are of size 0.25 ha, predominantly in monoculture stands representing typical forest landscapes with the main species spruce, beech, fir, pine or oak. Only stands with trees of age 60 years or older were selected and all trees are permanently marked. Here we combine the level I (88 % of trees) and II (12% of trees) of the years 1991 to 2020 data for our analysis and this results in around 800 sampling grid points. The number of observations range between 1915 and 5320 for the different species.

Percentage of crown defoliation is recorded in both surveys and is the variable we are interested in modelling. This is recorded by eye for individual trees in 5% intervals. Defoliation is a good measure of tree vitality and health and has been heavily affected by climate change. Defoliation values in this survey range from 0% to 100% (see Figure 1). The main species (Norway spruce, beech, fir, pine and

oak) differ in their root system. These differences mean that the tree species are affected differently by climate change. In addition coniferous trees carry needles from the previous 7 years and this implies different levels of autocorrelation in time for coniferous and deciduous trees. So it makes sense to run separate model by species. Each observation records the average defoliation for the survey location by species.

As 24 trees are surveyed at each location, we model the yearly mean defoliation of the respective species of trees at each survey location. This is appropriate because we are interested in mean defoliation, the forest is heavily managed and at any location trees will be of the same age. There were more than 70 predictor variables available which have been selected due to a possible relationship to defoliation. Predictor variables include climate variables, deposition of pollutants (e.g. deposition of nitatrate), soil characteristics (e.g. coarse soil content), topography (e.g. topographic position and wetness index) , site characteristics (e.g. geology, slope direction) and stand charactersitics (e.g. mean age).

The average defoliation rate over the whole period was 0.25 (Figure 1).

3. Spatio-temporal model for defoliation

We model mean defoliation $\bar{y}_{it}$ of trees by species per location i and year t using an (generalised) additive mixed model (GAMM) (Eickenscheidt et al., 2019; Augustin et al., 2009).

$$\begin{aligned}\mathbb{E}(\bar{y}_{it}) &= f_1(\texttt{north}_i, \texttt{east}_i, \texttt{year}_t) + f_2(\texttt{stand age}_{it}) + \sum\nolimits_k f_k(x_{ik}) + \sum\nolimits_l f_l(z_{il}(t)) \\ &= \mathbf{X}_{it}\boldsymbol{\beta} \\ \bar{y}_{it} &= \mathbb{E}(\bar{y}_{it}) + \epsilon_{it}\end{aligned}$$

with $\boldsymbol{\epsilon}_i \sim N(\mathbf{0}, \boldsymbol{\Lambda}_i)$ where the covariance matrix $\boldsymbol{\Lambda}_i$ is within location i based on an AR1 process. The number of trees $\texttt{nobs}_{it}$, on which the mean defoliation $\bar{y}_{it}$ is based on, is used as a weight. The non-linear function $f_1(.)$ is a three dimensional tensor product smooth interaction with separate penalties for space and time using a thin-plate spline basis for space and a cubic regression spline basis for time. The tensor product set up results in separate smoothing parameters for space and time making it scale invariant (see Wood (2017) section 5.6 for details). The x_{ik} are stationary predictor variables and the $z_{il}(t)$ are time varying predictor variables. The smooth functions f_k and f_l for these are set up using cubic regression spline bases except for factor variables were we use a basis with a ridge penalty (i.e. the identity matrix). The ridge penalty is equivalent to an assumption that the coefficients are i.i.d. normal random effects. To simplify notation we let $\mathbf{X}_{it}$ be the combined model matrix row for location i at time t, covariates for linear and random effects, basis functions evaluated at observations it for covariates with smooth effects. The parameter vector $\boldsymbol{\beta}$ contains all coefficients for $\mathbf{X}_{it}$.

Note that we use a normal distribution with the identity link here. The response variable is an average of proportions and due to the central limit theorem we can expect the normal distribution to fit. It would also be possible to use a logit link in order to bound the fitted values between 0 and 1, but because we are mainly interested in the selected variables we are using the identity link for simplicity. If we were analysing the individual proportions rather than their mean, the quasibinomial family or beta distribution would be a possible choice. These options are all implemented in the `bam` and `gam` functions of the R package `mgcv` (Wood, 2017). To control smoothness and due to the random effect the penalized version of the log likelihood $l = \log L$, is optimised to find $\boldsymbol{\beta}$ given the penalty parameters λ_j, so

$$\hat{\boldsymbol{\beta}} = \underset{\beta}{\operatorname{argmin}} - l(\boldsymbol{\beta}) + \frac{1}{2}\sum\nolimits_j \lambda_j \boldsymbol{\beta}^{\mathrm{T}} \mathbf{S}_j \boldsymbol{\beta} \tag{1}$$

The $\mathbf{S}_j$ is the penality matrix for smooth terms or random effect j and $\boldsymbol{\beta}^{\mathrm{T}}\mathbf{S}_j\boldsymbol{\beta}$ measures for each smooth term how rough the smooth function is. For example in the case of a cubic regression spline it is the integrated squared second derivative of the smooth function.

For estimating the smoothing parameters the fact that the model can be seen as a Bayesian model is exploited. This means the choice of smooth with a given type of penalty can be translated into a prior

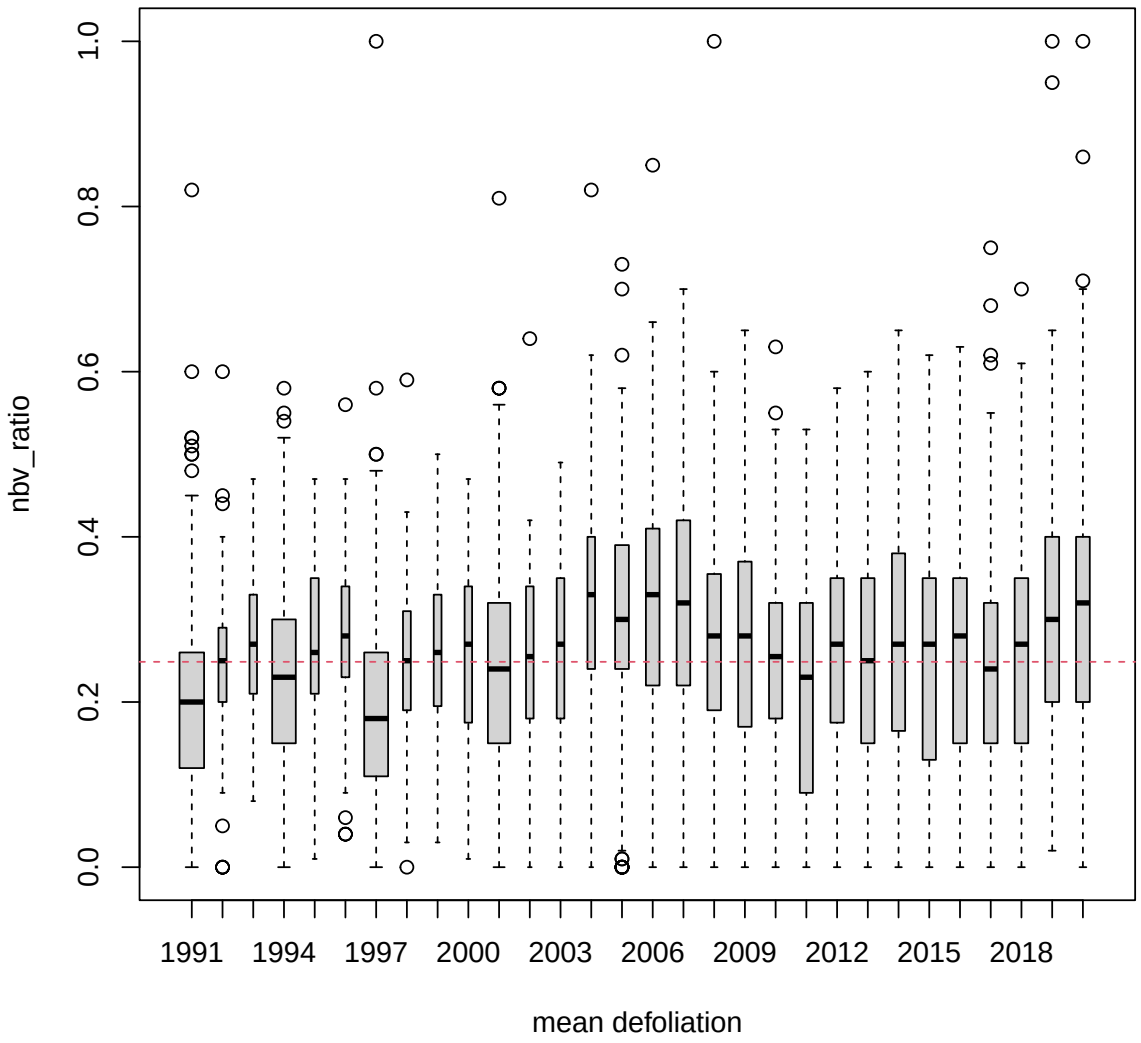

Figure 1: Boxplot of yearly mean defoliation of Norway Spruce over time. Shown are the yearly mean defoliation values averaged over all spruce trees observed at a sampling point. The red dashed line shows the overall mean defoliation. The box widths are proportional to the square-roots of the number of observations in the years (633, 69, 59, 584, 67, 65, 600, 64, 63, 59, 525, 60, 61, 60, 199, 195, 193, 192, 189, 182, 179, 184, 188, 183, 185, 199, 197, 194, 203, 197).

$\boldsymbol{\beta} \sim N(\mathbf{0}, \mathbf{S}_\lambda^-)$ with $\mathbf{S}_\lambda = \sum_j \lambda_j \mathbf{S}_j$. Note that $\mathbf{S}_\lambda$ contains penalties relating to the smooth effects and the random effects. The $\mathbf{S}_j$ for the random effect $\mathbf{b}$ is $\mathbf{I}$ and the respective λ_j is σ^{-2}. It follows that $\hat{\boldsymbol{\beta}}$ in (1) is the maximum a posteriori estimate. $\mathbf{S}_\lambda^-$ is an appropriate pseudo inverse. In this context smooths can be seen as latent Gaussian random fields and hence in terms of estimation we don't need to differentiate between random effects and smooths (see e.g. Kimeldorf and Wahba (1971); Silverman (1985)). Also for $n \to \infty$ and the number of parameters $p = o(n^{1/3})$ the posterior is (see e.g. Wood et al. (2017) section 6.10 for details)

$$\boldsymbol{\beta}|\mathbf{y}, \boldsymbol{\lambda} \sim N(\hat{\boldsymbol{\beta}}, (\mathbf{X}^{\boldsymbol{\mathcal{T}}}\mathbf{X} + \mathbf{S}_\lambda)^{-1}) \tag{2}$$

Using the above we can estimate $\boldsymbol{\lambda}$ to maximize the marginal likelihood

$$f(\mathbf{y}|\boldsymbol{\lambda}) = f(\mathbf{y}, \hat{\boldsymbol{\beta}}|\boldsymbol{\lambda})/f(\hat{\boldsymbol{\beta}}|\mathbf{y}, \boldsymbol{\lambda}) = L(\hat{\boldsymbol{\beta}})f(\hat{\boldsymbol{\beta}}|\boldsymbol{\lambda})/f(\hat{\boldsymbol{\beta}}|\mathbf{y}, \boldsymbol{\lambda})$$

This method can be parallelised, and made very efficient by marginal discretization of covariates (or exploiting natural discretization), thereby mitigating the $O(np^2)$ cost (Wood, 2011; Wood et al., 2017). Due to the large number of parameters and large sample sizes we use this efficient estimation implemented in the function `bam` in the R package `mgcv` in R (Wood, 2017).

Model selection

As the 80 predictors contain variables which are measuring similar characteristics, we initially exclude redundant variables in discussion with experts. Then in a second step if pairs of variables have a strong association and are proxies of each other we ideally take the variable with less missing values and/or the variable which is more useful in terms of identifying causes of tree damage and predictor value ranges for critical conditions. The minimum model includes the space-time smooth and AR1 process for temporal correlation as it is likeley that this will lead to smaller bias in estimates of effects of variables of interest (Dupont et al., 2022) because (a) the model without the space-time smooth (and AR1) is misspecified and hence inference is not going to be correct and (b) important predictors we don't have, e.g. deposition, will be explained (at least partially) by the space-time smooth.

Because conventional backward selection would be rather slow for the number of predictors we use integrated backward selection with extra penalties (Marra and Wood, 2011). This method adds a penalty to the coefficients of each smooth penalizing the null space (the null space is the linear part in a one dimensional smooth) of its smooth so that they can in principle be penalized out of the model. This is done by replacing the zero eigenvalues corresponding to the linear part by ones in the eigendecomposition of the penalty matrix $\mathbf{S}_j$ and this makes the penalty corresponding to the linear part similar to a ridge penalty. Then we exclude the predictors which are below a threshold in terms of effective degrees of freedom (edf). An edf below 1 means that a penality has been also applied to the null space, i.e. linear, part of the smooth. This works for any smooth (also two-dimensional smooth for interactions).

To eliminate predictors with negligible effects resampling methods (bootstrap) are used. Variable selection is carried out repeatedly with resampled data yielding selection inclusion frequencies. Final model selection is carried out with a subset of predictors with selection inclusion frequencies $> 30\%$. The advantage of this approach is that we reduce the number of predictors and deal with correlated predictors in an automatic fashion. See Augustin et al. (2005); Holländer et al. (2006); Meinshausen and Bühlmann (2010).

4. Results

Preliminary results show that the variable selection has resulted in reducing the set of 70+ predictors, yielding (mostly) plausible sets of predictors for the different species. Shown in Table 1 are predictors selected in any of the models for spruce, beech, pine and oak. In the talk we will show more results mainly backing up the hypothesis that indeed the effects of climate change such as increased temperatures and dry conditions are contributing to forest damage.

Abstract

Since the international flow of students across countries has increased over the years, it is crucial to analyze the flows to understand the main characteristics of student mobility trajectories involved in both Erasmus and Erasmus+ programs. In this manuscript, we use data from the European Union Open Data Portal and focus on gender inequalities in STEM (Science, Technology, Engineering, and Mathematics) scientific fields. Specifically, using a network analysis approach, we aim to determine whether any differences exist in international students' mobility according to gender and between STEM and non-STEM fields. In general, the results revealed that male STEM students are more inclined towards Erasmus mobility than female students. Specifically, we identified Scandinavian countries as the most significant importers of STEM Erasmus mobility students.

Keywords: student mobility, weighted network, gender gap, stem and no-stem, inequalities

1. Introduction

Internationalization is becoming an increasingly important topic for all higher education institutions, and the European Commission is providing new projects and programs to promote and encourage the internationalization of citizens, organizations, and universities.

In fact, the international flow of university students across countries has been increasing all around the world for several years. A general idea about the magnitude of incoming and outgoing students by country is possible to get from the website of the Institute of Statistics of UNESCO. [1]

Many European initiatives for learning and teaching mobility have been promoted to enhance personal development and increase cooperation between educational institutions. The most well-known program is the European Region Action Scheme for the Mobility of University Students (Erasmus), which aims to encourage and support academic mobility for students, professors, and academic staff in higher education within EU countries.

The number of participants in Key Action 1, *Learning Mobility of Individuals*, has increased from 3,000 participants in 1987 to 272,497 in 2013–2014, with approximately 954,000 individual mobility contracts concluded in 2020 under the Erasmus+ program 2014–2020 [2].

Exploring inequalities in international student mobility can be a complex and multi-faceted task that requires careful consideration of various factors such as socioeconomic background, nationality, gender,

[1]For details see http://uis.unesco.org/en/uis-studentfow.
[2]https://data.europa.eu/doi/10.2766/36418

language proficiency, and cultural capital. Over the years, several studies have been conducted to study international students' mobility, drawing trajectories and analyzing the influence of some factors on the decision to study abroad.

An interesting field of research deals with analyzing and capturing the structural features and patterns of student mobility across countries. Since international student mobility can be seen as a network of exchanges between higher education institutions (where the nodes are the universities/countries involved in the exchanges, and the links are the number of students going abroad for an exchange visit), the concept of networks can be easily applied in this context.

Several papers that used the social network analysis approach to understand the students' flows between countries have been published over the years. These papers aimed at i) detecting the presence of attractive countries by nodal centrality and authority scores (5); ii) identifying which countries can be called feeder and storer actors, i.e. good importers and good exporters (2; 12; 14); iii) revealing the presence of a core-periphery structure through block–modeling approach and clustering relational data (3; 14); iii) exploring the topology of the student mobility network by taking into account the exponential degree distribution and well–known network configurations (10); iv) identifying dense groups in the giant component using community detection algorithms (16); iv) assessing the determinants of student mobility patterns to test for the presence of homophily effects (17); and v) capturing the structural features and the patterns of student mobility across different countries by analyzing the factors pulling and pushing students to complete their higher education abroad (2).

Moreover, the gender gap in international students' mobility has been investigated by (8; 4) for emphasizing the presence of a denser network of connections involving females or engineering backgrounds, while the differences in the flows by disability, gender, and fields of study classified in stem and no-stem courses have been analyzed by (9).

In this manuscript, we focused on gender inequalities in STEM (Science, Technology, Engineering, and Mathematics) scientific fields. We postulate the following research question: "What are the gender-based inequalities in international students' mobility in STEM fields on the country level?"

2. Methodology

Methods of descriptive statistical analysis are supported using network analysis techniques. In this sense, we can define in a natural way a directed network with nodes representing countries in the Erasmus mobility network and directed edges by determined by the number of student mobilities among countries in the STEM fields.

Mathematically, weighted directed graph $\mathcal{G}$ is represented as $\mathcal{G}(\mathcal{C}, \mathcal{E}, \mathcal{W})$, where $\mathcal{C}$ represents the set of countries involved in the Erasmus program, $\mathcal{E} \subseteq \mathcal{C} \times \mathcal{C}$ is the set of edges given by the presence of students within STEM fields moving from one country to another, and $\mathcal{W}$ is the set of weights.

For any edge, (c_i, c_j) in $\mathcal{E}$, the weight w_{ij} is the number of students within STEM fields moving from country c_i to the country c_j, where c_i and c_j are elements of $\mathcal{C}$. Therefore, the number of students involved in each exchange defines the edge weights in $\mathcal{W}$.

The population, and consequently the number of students, in countries involved in the Erasmus program, varies greatly, from the smallest country, Liechtenstein, to the largest, Germany. For this reason, the normalization of student mobilities between two countries (edge weights) was considered. Not only sending country as considered in previous studies on similar topic, e.g. (17), but also receiving country impact the number of students mobilities between two countries. Therefore, each weight was divided by a square root of a product of enrolled students among adjacent countries (for each country a mean value of enrolled students was calculated in the analyzed period). This is actually normalisation by geometric mean of number of students in adjacent countries and similar approach was used by (3; 5).

In order to identify the most important exporters and importers of students in STEM fields, hubs and authorities algorithm (11) was applied on two normalized networks, female and male student mobility networks of STEM fields.

3. Data

Data on international student flows among Erasmus and Erasmus+ countries are freely accessible and downloadable from the official EC website on Erasmus-Statistics.[3] The data cover the academic years from 2007–08 to 2013–14 and from 2014–2015 to 2018–2019, for Erasmus and for Erasmus+, respectively.

Given that some changes occur in the student mobility scheme between Erasmus and Erasmus+ programs, the datasets have been compared by checking the variables, in order to make them comparable. Since the datasets for Erasmus+ also contain information for all mobility participants (students and staff: study exchanges and work placements for students, and teaching assignments and staff training), we discard the data related to traineeships and staff mobility, focusing the analysis on the student mobility for studies abroad.

Table 1 shows the trend in student mobility for studies (SMS) in both programs, according to gender and stem courses. It is particularly evident that there is an upward trend in SMS for both programs. Moreover, the proportion of females and stem courses is constant over the years.

Table 1: Distribution of student mobility in Erasmus and Erasmus+ programs

Erasmus				
Academic Year	Total no.	SMS	% Female	% Stem
2007–2008	182,697	162,694	61.15	12.55
2008–2009	198,523	168,193	60.63	13.91
2009–2010	213,266	177,705	60.86	10.80
2010–2011	231,408	190,495	60.86	11.00
2011–2012	252,827	204,744	60.61	12.79
2012–2013	268,143	212,522	60.64	13.12
2013–2014	272,497	212,208	60.22	13.11
Erasmus +				
Academic Year	Total no.	SMS	% Female	% Stem
2014–2015	299,319	221,583	59.37	12.24
2015–2016	300,018	215,828	60.22	12.77
2016–2017	325,755	236,892	60.08	13.03
2017–2018	340,100	244,320	59.89	13.44
2018–2019	351,682	248,165	60.43	13.85
2019–2020	328,739	250,890	60.26	14.16

From Table 2, we can observe that the mobility ratio for non-STEM and STEM students differs between male and female groups. Every fifth male student on Erasmus mobility is from a STEM field, which is more than twice the proportion compared to the female group.

Table 2: Contingency table of Erasmus student mobility regarding gender and (non)STEM fields

	STEM		
Gender	Yes	No	Total
Female	129,303 (08.21%)	1,445,381 (91.79%)	1,574,684 (100.00%)
Male	206,074 (20.08%)	820,444 (79.92%)	1,026,518 (100.00%)
Total	335,377 (12.89%)	2,265,825 (87.11%)	2,601,202 (100.00%)

Before merging the datasets, a preliminary analysis is performed to check whether the labels differ from one dataset to another and convert all codes of the field of education (ISCED6 1997–2011–2013) into the more recent classification.

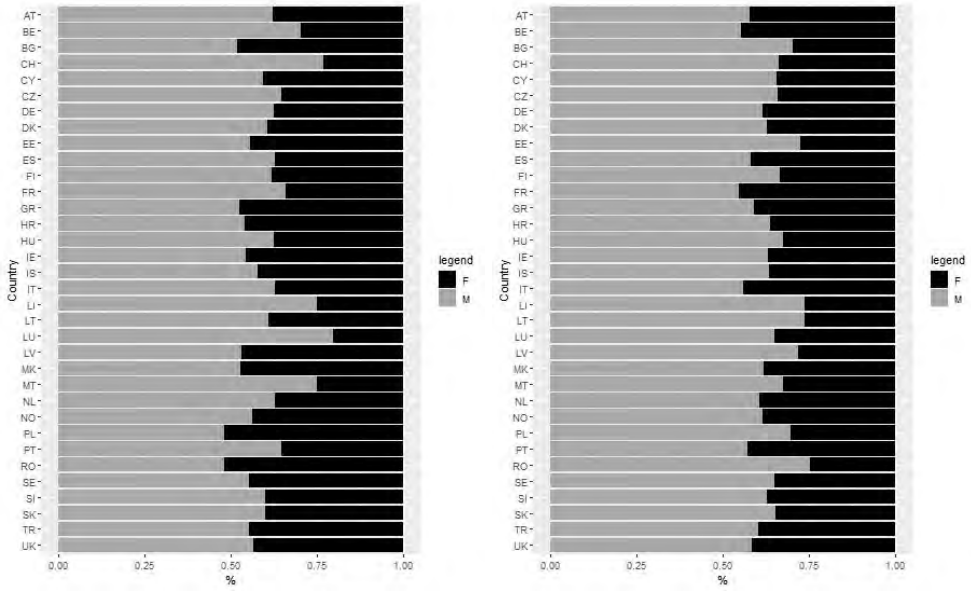
4. Main results and discussion

The distribution of Erasmus and Eramsus+ flow by gender is shown in Figure 1 for outgoing (a) and incoming (b) students, where only the STEM courses are considered. For almost all countries, the percentage of males is higher than that of females. In a few countries, the percentage of men and women is substantially equal.



(a) Outgoing students (b) Incoming students

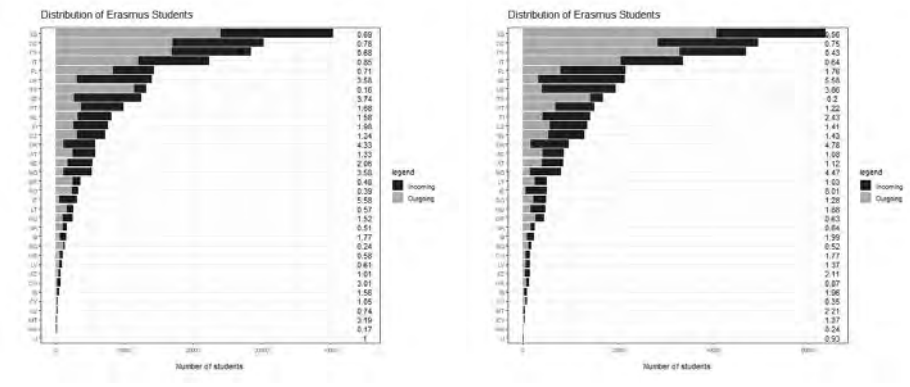
Figure 1: The distribution of Erasmus and Erasmus+ students (outgoing and incoming) for STEM courses and between males and females for all countries

Figure 2 shows the distribution of Erasmus and Erasmus+ students by country over the twelve academic years for STEM courses, distinguished by gender. Spain, Germany, France, and Italy are very attractive for STEM being the top destinations for both incoming and outgoing students. Spain in particular has the highest number of students in terms of both incoming and outgoing exchanges. Germany and France rank second and third for incoming and outgoing students. Italy is in fourth place for both incoming and outgoing students. This is true for both females (Figure 2 a) and males (Figure 2 b).

In addition, Figure 2 reports the ratio of incoming to outgoing students for females (a) and males (b), which has a similar role to the coverage ratio used in trade networks to analyze the trade balance of foreign countries. Values greater than one indicate the attractiveness of countries with more incoming compared to outgoing students. The Scandinavian countries (Sweden, Norway, and Denmark) present the highest ratio values, while the United Kingdom appears to be the most attractive. Spain, France, Germany, and Italy seem to be slightly more export-oriented.

We applied the hubs and authorities algorithm on normalized networks to ensure comparability among countries in terms of their size and the number of students. When comparing hub (authority) scores between countries, the further away they are from the coordinate origin, the stronger their hub (authority) score tends to be. Moreover, countries located above the dashed line demonstrate a higher hub (authority) value for male STEM students, while those located below the dashed line exhibit a higher hub (authority) value for female STEM students.

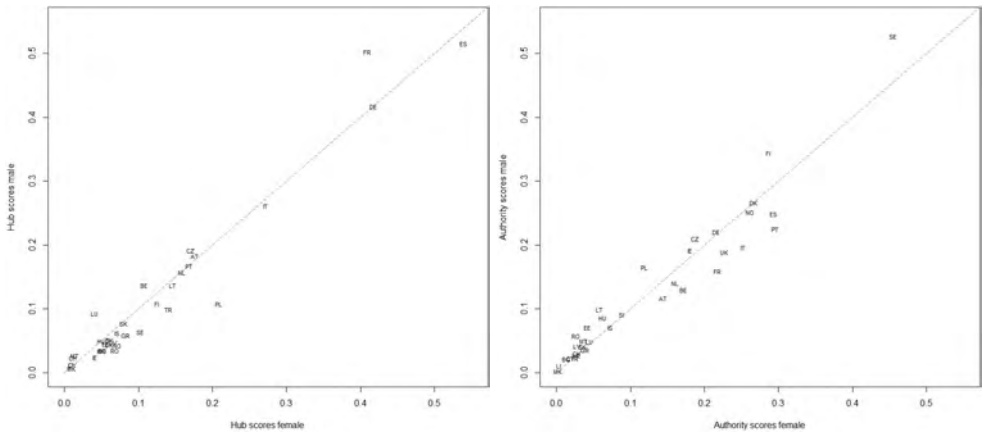
In Figure 3 a) hub scores of female STEM students is compared with their male counterparts. The most active exporters of STEM students are Spain, France, Germany, and Italy which coincides with results of whole Erasmus student mobility (5). The highest difference in favor of male STEM students is observed for France, while Spain is slightly favoring female STEM students. Among other, not-so-active exporters, the results of Poland and Turkey are also in the favor of female STEM students.



(a) Female students in STEM courses (b) Male students in STEM courses

Figure 2: The distribution of Erasmus and Erasmus+ students (incoming and outgoing) for all countries. The ratio between incoming and outgoing students is shown at the end of each bar.

Completely different results are obtained for authority scores in Figure 3 b), measuring the import of STEM students. The most active countries are from Scandinavia, with Sweden dominating, followed by Finland, Denmark, and Norway. The latter two are on the same level as Spain and Portugal. On one hand, male STEM students are more commonly visiting Sweden and Finland, on the other hand, female STEM students find Spain and Portugal more popular.



(a) Hub scores (b) Authority scores

Figure 3: Hubs and Authorities results compared between female and male Erasmus students per countries

5. Conclusion

Differences in Erasmus student mobility among STEM students with respect to gender have been observed. In relative terms, male STEM students are more inclined towards Erasmus mobility than their female counterparts. Results of descriptive statistics were further supported by hubs and authorities algorithm which takes into account also the relative importance of countries in terms of sending and receiving Erasmus students.

Countries with well-established traditions in Erasmus student mobility also happen to be the largest exporters of STEM students. However, Scandinavian countries are more attractive to STEM mobility students as they import a relatively larger number of such students. Sweden and Finland tend to import

more male STEM students, while Mediterranean countries such as Spain, Portugal, and Italy tend to be more attractive to female STEM students. With regard to exporting, France is dominated by male Erasmus STEM students.

In the future, we can compare the distributions of female and male students across different STEM fields. An obvious extension would be to analyze student mobility at the institutional level and identify the most active educational institutions in terms of student mobility. Additionally, identifying factors that contribute to gender-based inequalities would be a challenging task.

Abstract

This paper explores the impact of territorial location and socioeconomic factors on student mobility and educational inequalities in the transition from high school to university in Sicily, a region characterized by low tertiary enrollment rates and high early school leaving rates. The study uses a propensity score analysis, based on generalized boosted models (GBM), to isolate the territory effect on university enrollment choices while controlling for student sociodemographic characteristics and high school outcomes. The results of the study provide insights into the complex interplay between territory, socioeconomic factors, and student mobility in determining educational inequalities.

Keywords: educational inequalities, student mobility, propensity score, continuation ratio model

1. Introduction

Education is a complex system that is influenced by a multitude of factors, including socioeconomic status, family background, students' careers, and territorial location, among others. It is challenging to isolate the impact of each individual factor on educational outcomes, as these factors are often interrelated and can interact in complex ways. Primarily, most research focuses on inequalities related to the social origin of the students, widely recognised as the main factor contributing to educational inequalities (1). Further research has addressed the problem of inequalities related to gender, territory, and ethnic background (8). Despite the detection of a decline of inequality in educational opportunities in several countries, in Italy inequalities in the chances of earning a university degree have increased over time among all social classes (12). In Italy, the well-known economic gap between the Center-North and South of the country has been identified as one of the main causes behind the exacerbation of education inequalities across the country (3). This disparity is reflected mostly in *student mobility* i.e., the decision to leave the region of residence for study-related reasons, especially in the transition from high school to university. Italian student mobility is characterised by twofold vertical mobility: geographical – observed from the southern regions to the northern ones – and social – in terms of improvement of employment and lifestyle (13). Thus, student mobility from the South to the North is now considered a mechanism for maintaining the established regional imbalances (10). Studies on Italian domestic students' mobility (2) and graduates' mobility (7) confirm that this is not only a matter of temporary mobility but "Mezzogiorno" is experiencing a proper "brain drain" to the Center-North of Italy. Furthermore, the unidirectional mobility flows, from the South towards the Center-North of the country (4), primarily target students with the highest academic results and socioeconomic status (5).
The current work investigates the transition from high school to university focusing on territorial inequalities. The geographical location can be an unfair source of inequality in access to university, however,

focusing only on geography may leave the influence of socio-economic factors in relation to gender, experiences at home, and parental background unexplored. This paper tries to single out the contribution of the territory and socioeconomic status on inequality in the transition school-university. In detail, the focus is on Sicilian high school students, a region characterised by low tertiary enrolment rates and high early school leaving rates. In this crucial transition, students can follow three different paths: not enrolling at university, enrolling at university in the region they live, or moving to another region. The aim is to investigate the presence of intrinsic territorial effects on university enrolment choices controlling for student sociodemographic characteristics and high school outcomes associated with his/her choice. To isolate the territory effect we carry out a propensity score analysis in which we aim to balance the gender, socioeconomic status, mathematics test score and the high school track of clusters of Sicilian municipalities. Most studies that use propensity scores to control for imbalances compare just two treatment groups of interest (e.g., treatment and control). Nonetheless, several papers have shown that propensity score methods can be extended to the multiple-treatment case (6). In this work we use generalized boosted models (GBM) that uses an iterative procedure generating a large number of regression trees to find the propensity score model that leads to the best balance between treated and control groups. Here, the balance is the similarity between different groups based on their propensity score weighted distributions of pretreatment covariates. The inverse of the propensity score estimates are then used as weights of a continuation ratio multinomial model that describes the probability of not enrolling *vs* the probability of being enrolled and the probability of being enrolled in a university outside the region of residence *vs* the probability of being enrolled in the region of residence.

The paper is organised as follows: in Section 2, we illustrate the data and some descriptive statistics; in Section 3, we illustrate statistical methods that were employed to analyse students choices; in Section 4, we present the results; finally, in Section 5, the conclusions are reported.

2. Data and preliminary analysis

The empirical analysis reported in this work relies upon a linkage of micro-data coming from two administrative archives: the *Istituto nazionale per la valutazione del sistema educativo di istruzione e di formazione* (INVALSI) and the *Anagrafe Nazionale Studenti* (ANS)[1]. Both archives collect information at the student level from all Italian education institutions. INVALSI carries out national large-scale standardized tests to evaluate the overall quality of the educational system for each different type of school. INVALSI tests are administered annually to students at four levels of education, aiming to evaluate mathematical and Italian language skills and, English reading and listening skills. Moreover, INVALSI collects information about high-school students' profiles such as their socio-economic status (SES), family background, and geographical origin. ANS collects longitudinal information on the academic careers of all the students enrolled in any Italian university since 2008; more specifically, socio-demographic information about all the students and their educational achievements from high school to the master's degree. In this work, we select the 2018/19 cohort of Sicilian high school graduates.

In Table 1, we consider four distinct factors, usually taken into account when studying university attendance and performance: the SES (measured according to INVALSI and PISA criteria, standardized and centred to the Italian average (9)), the maths test score (administered and evaluated by INVALSI), the gender and the percentage of students attending a "liceo". It is known that students that attend "Liceo Scientifico" and "Liceo Classico", often referred as generalist high schools, are self-selected according to their perceived "ability" and/or availability of family financial resources (3).
The results highlight significant cluster differences regarding the transition to university: in 2019, the 44.1% of high school the graduates' population do not enrol at university, but this percentage ranges between 31.2% of Alcamo and 57.8% of Gela; the 16% of Sicilian students decide to move to another region for university enrolment: this rate ranges between 8.6% of Bagheria and 61.5% of Ragusa. It

[1]Data–drawn from the Italian "Anagrafe Nazionale della Formazione Superiore"–has been processed according to the research project "From high school to the job market: analysis of the university careers and the university North-South mobility" carried out by the University of Palermo (head of the research program), the Italian "Ministero Università e Ricerca", and INVALSI.

is interesting to highlight that Gela is characterised by the lowest mean SES and scores in INVALSI maths tests, factors that could in part explain the scarce university enrolment rate. The clusters with a university, namely Palermo, Messina, Catania, and Enna, and some neighbour clusters, show a lower percentage of movers and a lower SES. For many other clusters, a low SES is not always matched by a low percentage of movers or vice versa. For instance, Trapani and Ragusa have similar SES to Palermo but, at the same time, a significantly higher percentage of movers. The analysis provides a first evidence of the relationship between student characteristics, previous educational outcomes and their enrolment choices in line with (14): higher SES and attending a "liceo" correspond to higher enrolment rates; at the same time, lower scores in maths tests seem to be associated with higher university non-enrolment rates.

Table 1: Sociodemographic, high school performance, and university attendance of Sicilian students by the cluster of residence.

Cluster	$\frac{NotEnrolled}{Graduates}$	$\frac{Movers}{Enrolled}$	**Maths score (sd)**	**SES (sd)**	**% Liceo**	**% F**	**n**
ACIREALE	38,1	10,9	197,45 (34,51)	-0,10 (1,04)	46,0	56,0	252

3. Methods

In this section, a brief overview of the methods used for the analysis is presented. The approach can be summarized in three fundamental steps: *i*) cluster construction, *ii*) balancing procedure and *iii*) weighted regression model. The cluster construction, explained in (11), is based on the idea that students inside the same area of origin can directly communicate and eventually trigger a mechanism of mobility towards an out-of-Sicily university. Following this idea, we constructed 27 clusters aggregating several municipalities around a hub municipality (a municipality home to at least one secondary school with at least 200 students). Such clusters work as a compromise between the size of municipalities and provinces: municipalities are too small to capture mobility phenomena and provinces are too large and heterogeneous in terms of mobility.

The balancing procedure is based on propensity score analysis for multiple treatments. In this paper,

we use the generalized boosted models (GBM) approach, proposed in (6), and hereby briefly summarized. Let M denote the number of treatments being studied with $M = 27$ representing the number of Sicilian clusters. Let $\mathbf{X}$ denote the matrix of K observed pretreatment covariates (in our case, gender, maths test scores, SES, and high school track). Create dummy indicators, $T_i(t)$ that is, $T_i = t$ if individual i, was observed under treatment t, where $t = 1, \ldots, M$, and $i = 1, \ldots, n$. Fit separate GBMs to each dummy treatment indicator and obtain the estimated propensity score for the given treatment; GBM uses a piecewise constant model, made up of multiple simple regression trees, to predict binary outcomes. The fitting process starts with one tree and adds trees iteratively, where each new tree is chosen for its ability to best fit the residuals from the previous iteration. The predictions from each tree are adjusted for smoothness and better fit. The algorithm may overfit the data if too many trees are added, so a stopping criterion, such as out-of-sample error or imbalance on covariates, is used to select the final number of trees. Fitting GBM one treatment at a time produces, for individuals assigned to that particular treatment group, propensity scores and corresponding inverse probability of treatment weights, which balance the pretreatment characteristics between the group and the entire population. Critically, for each treatment indicator, the estimated propensity score, $p_t(X_i)$, computed from the iteration of the GBM fit, yields the 'best balance' (standardized mean difference (SMD)) between units with T_i $(T_i(t) = 1)$ and the pooled sample from all treatments.

Finally, we use the inverse of the propensity score estimates as weights in a continuation ratio logit model. This model estimates the odds of being in a certain category relative to the odds of being in that category or beyond. In terms of probability, this model estimates the probability of being in a category, given that an individual has been in that category or beyond. The continuation ratio (CR) model is a suitable option for the process behind the enrolment choice of the student: the first step is "do I continue to university?", so we consider the ratio (1), while the second step is "do I enroll at university outside Sicily or in Sicily?", so we consider the ratio (2). In particular, we are interested in estimating $\frac{P(Y=Not\_Enrolled)}{P(Y=Enrolled)+P(Y=Not\_Enrolled)}$ where $Enrolled = Enrolled\_Stayer \cup Enrolled\_Mover$, and $\frac{P(Y=Enrolled\_Mover)}{P(Y=Enrolled\_Mover)+P(Y=Enrolled\_Stayer)}$.

4. Results

In this section, we report the balancing procedure (Table 2) and the weighted continuation ratio model (Table 3 and Figure 1). In Table 2, we report the percentage of significant differences observed in the one-to-one cluster comparisons before and after the weighting procedure. The procedure provides an almost perfect balance of the Sicilian clusters. In Table 3, the parameters of the continuation ratio

Table 2: Maximum SMD, minimum p-value, and the number of significant differences observed in the one-to-one cluster comparisons before and after the balancing procedure.

	Before				After			
Variable	**Max SMD**	**Min pvalue**	**Not Signif.**	**Signif.**	**Max SMD**	**Min pvalue**	**Not Signif.**	**Signif.**
Student SES	0,59	0,00	165	186	0,17	0,18	351	0
Gender	0,36	0,00	233	118	0,14	0,13	351	0
INVALSI maths score	0,76	0,00	116	235	0,21	0,03	349	2
High school track:								
Hum/Sci Liceo	0,60	0,00	154	197	0,20	0,04	350	1

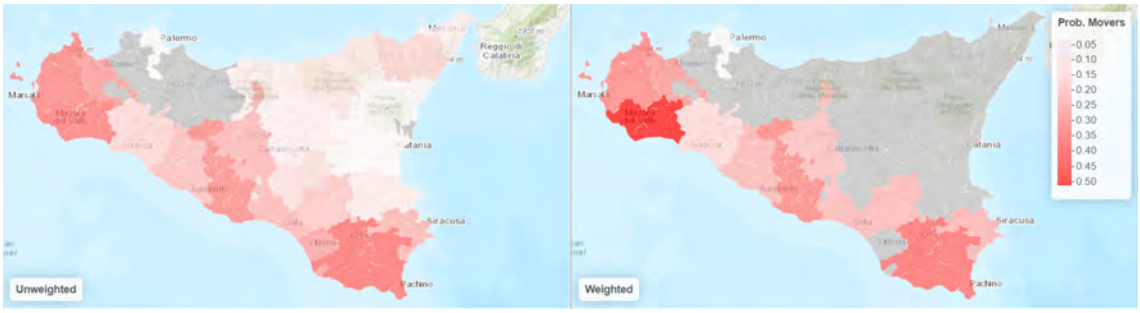
the weighting procedure for the non-enrolment at the university and the enrolment in another region. We consider the Palermo cluster as the reference category. The idea is that if there is a significant difference with Palermo, after the weighting procedure, is likely due to unobserved territorial characteristics. The probabilities of not enrolling at university are reported in Figure 1 (a). It appears clear that, before the matching procedure, there are relevant differences among the clusters. The eastern clusters have a higher probability of not enrolling at university than Palermo, with a unique exception represented by Canicattì, which shows a slightly lower probability. However, after removing the imbalance in the treatment variables, all the differences with Palermo are no more significant. This result is evidence of the role of the considered factors in the choice to engage in tertiary education. The probabilities of moving to

(a)



(b)

Figure 1: Predicted probabilities of not enrolling at university (a) and of moving to another region (b) before and after the weighting procedure.

another region are reported in Figure 1 (b). Before the weighting procedure, the region seems to split into two parts: students from the southern coast are more likely to leave Sicily, especially those coming from Ragusa, Trapani and Castelvetrano. On the other hand, the other clusters are less affected by student mobility but the difference with Palermo is significant. The scenario drastically changes after the weighting procedure: the students coming from the southern coast are still likelier to enrol at a university in another region, and these probabilities have further increased. Conversely, the differences observed between Palermo and the other clusters are no more significant.

5. Conclusions

In conclusion, the current work aimed to investigate the transition from high school to university in Sicily, focusing on territorial inequalities. First, we used a propensity score analysis based on generalized boosted models to control for the effects of different student characteristics and high school outcomes on university enrollment choices. The propensity score procedure provided an almost perfect balance of the Sicilian clusters. Then, we used weighted continuation ratio models to estimate the cluster differences in terms of the probabilities of not enrolling at a university and enrolling at a university located in another region. The results indicated that the non-enrollment at the university is primarily influenced by the socioeconomic student characteristics and high school outcomes rather than the territory (Figure 1 (a)); the enrolment in another region, especially in the southern part of the region, has deeper territorial roots that after the balancing procedure become even stronger (Figure 1 (b)). Overall, the study highlights the importance of considering the interplay between territory and economic variables in explaining inequalities in the transition from high school to university.

Challenges on Ethics, and Privacy in AI Applications to Fintech

Catarina Silva, Joana Matos Dias, and Bernardete Ribeiro

University of Coimbra

Abstract

AI in Fintech presents several ethical and privacy challenges. One of the main concerns is the potential for algorithmic bias, where machine learning models may unintentionally perpetuate existing discrimination, such as by considering factors like race, gender, or age. Another issue is the difficulty in interpreting the decision-making process of these models, which can create accountability issues and distrust in financial institutions. Additionally, there are concerns about data privacy and security, as large amounts of sensitive financial data are being used to train and validate these models. In this paper we analyse what has been the dynamics of the research community in addressing these concerns. A preliminary bibliometric analysis is done, considering publications within the last 10 years. It is possible to conclude that many of these aspects are still not considered by most publications, and no significant researchers' networks exist that could leverage research in this area.

Keywords: Ethics, Privacy, AI, Fintech.

1. Introduction

Nowadays, the issues of explainability and accountability of artificial intelligence algorithms are at the forefront of discussions. These concerns are particularly critical in the financial sector, where decisions based on AI outputs can have significant impacts on the lives of individuals and society as a whole. Numerous questions have been raised regarding this topic that merit the attention of the scientific community, namely (see Figure 1):

- **Governance**: Who should be accountable for the development and maintenance of AI models used for decision making? Who is responsible for evaluating and ensuring the quality of these models?
- **Policy development**: Who is responsible for creating policies and guidelines for the use of AI? How can the perspectives of different stakeholders be incorporated? Who are these stakeholders?
- **Cultural acceptance**: What steps are necessary to foster trust in AI models? How can concerns about societal impacts, such as job displacement, be addressed? How can inertia towards technological and cultural shifts be overcome?
- **Risk assessment**: How can risks associated with AI model building and use be measured, defined, and mitigated? How can we prevent fraud, manipulation, and cybercrime? How should national and international legislation address the risks and consequences of biased or misapplied AI models?

Figure 1: AI in Fintech Challenges

- **Model selection**: What criteria should be used to select AI models for different situations, given inherent conflicts between criteria such as accuracy and explainability?
- **Process and technology**: What platforms and technologies should be used for AI models? What process adjustments are necessary to fully leverage the benefits of AI?

2. Preliminary bibliometric analysis

To evaluate the progress in research on the aforementioned topics, we propose conducting a bibliometric analysis, which will be detailed in the following sections.

2.1 Bibliometric search

We considered all journal and conference papers published from 2017 to the end of February 2023, indexed in Scopus. Additionally, the search considered the following constraints:

- TITLE (finance OR fintech)
  AND TITLE ((artificial AND intelligence) OR (machine AND learning))
  AND TITLE (ethics OR privacy OR explainability OR transparency))

- KEY (finance OR fintech)
  AND KEY ((artificial AND intelligence) OR (machine AND learning))
  AND KEY (ethics OR privacy OR explainability OR transparency)))

- LIMIT-TO (DOCTYPE , ”ar”) OR LIMIT-TO (DOCTYPE , ”cp”))

This means that we have selected all publications that have, either in the title or in the keywords, the words ”finance” or ”fintech” and refer to AI or ML approaches. The title or keywords must explicitly consider one of these subjects: ethics, privacy, explainability or transparency.

The search considered the following query string:

```
( (TITLE ( finance OR fintech ) AND TITLE ( ( artificial AND
intelligence ) OR ( machine AND learning ) ) AND TITLE ( ethics OR
privacy OR explainability OR transparency) ) OR (KEY ( finance OR
fintech ) AND KEY ( ( artificial AND intelligence ) OR ( machine
AND learning ) ) AND KEY ( ethics OR privacy OR explainability OR
```

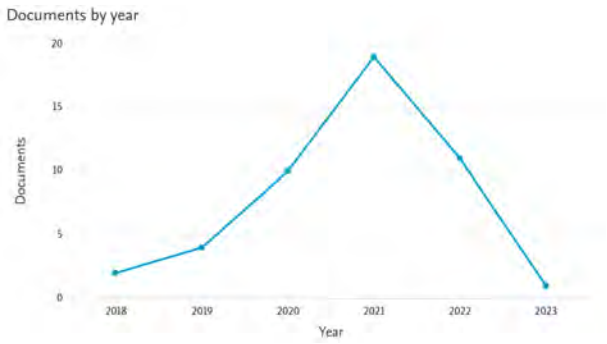

Figure 2: Documents per year (Source: Scopus)

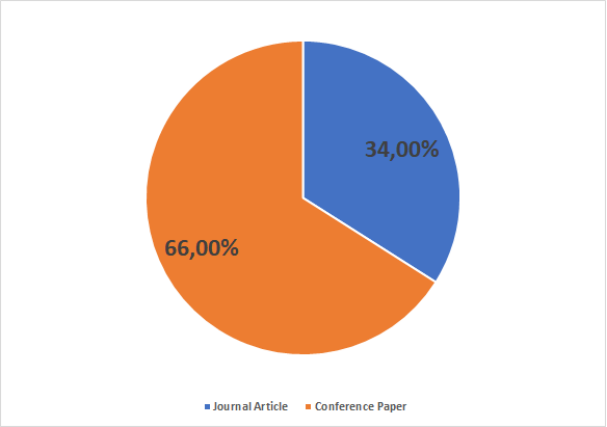

Figure 3: Publication Media (Source: Scopus)

```
transparency) ) ) AND ( LIMIT-TO ( DOCTYPE , "ar" ) OR LIMIT-TO (
DOCTYPE , "cp" ) ) AND ( LIMIT-TO ( PUBYEAR , 2017 ) OR LIMIT-TO (
PUBYEAR , 2018 ) OR LIMIT-TO ( PUBYEAR , 2019 ) OR LIMIT-TO ( PUBYEAR
, 2020 ) OR LIMIT-TO ( PUBYEAR , 2021 ) OR LIMIT-TO ( PUBYEAR , 2022
) OR LIMIT-TO ( PUBYEAR , 2023 ) )
```

Only 47 publications[1] were found that comply with this query, distributed per year as depicted in Figure 2. If the search is extended to also include the abstract, then this number increases to 264 publications. This is an interesting observation on its own: it can lead us to conclude that the ethical questions are not the central part or concern in many of these works, but they are somehow being taken into account in the research made. In this preliminary analysis, only the small set of 47 manuscripts will be considered. The enlarged dataset will be studied in future works. We have read the abstract of all the 47 papers, to assure that each one should be considered for further analysis. All of them were considered, even though some of them considered fintech alongside other AI applications. It is interesting to note that the year where more publications can be found is 2021. Most manuscripts have been published in conference proceedings, as depicted in Figure 3, which would be expected in a relatively recent area of research.

2.2 Authors network

There are a total of 146 authors associated with these manuscripts. On average, each author has participated in one manuscript only. China is the country with more contributions (15 in total). Looking at the

[1]The reference list of the publications considered can be found in https://drive.google.com/file/d/1q9dnzoR6otsiLrBuTZNHlDHz1VT_eqgv/view?usp=share_link

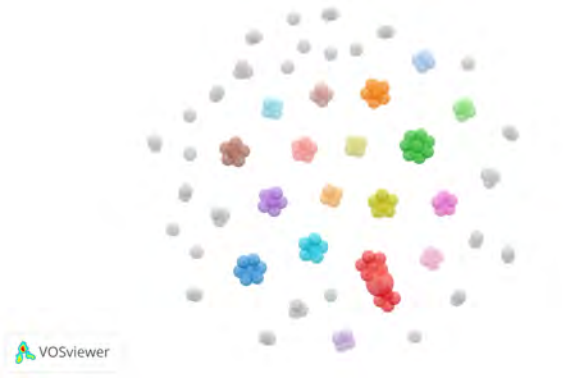

Figure 4: Authors' network (Source: Scopus)

set of authors, it can be seen that there are still no networking taking place: the coauthors of each article are not connected to other authors. So it seems that each research team is still working on its own, and no cooperation is in place in terms of published research. This can be visualized in Figure 4, when it is clear that there are no really connections among others associated with different manuscripts.

2.3 Keywords network

Figure 5 depicts the keywords network, where different colours represent different keyword clusters. This image considers keywords that were present at least 3 times (from the set of 578 different keywords associated with this publication set). There are four clusters that represent the most frequently used keywords. The red cluster considers manuscripts that are not addressing any particular problem, but rather consider in more general terms the use of AI and ML in finance, expliciting the ethic dimension of these works. The yellow cluster considers works dedicated to financial products (like cryptocurrencies), being also concerned with data security and protection. The green cluster is composed by keywords associated with financial services and the corresponding risk assessment and management. The blue cluster is linked with model development (learning algorithms, privacy by design). It is interesting to realize that, although ethics and data protection are presented (due to the query done to retrieve the chosen manuscripts), there are important keywords that are missing, related with legal regulation, explainability, accountability, for instance.

3. Conclusions

Although an increased concern with ethical questions is clearly emerging in the scientific community considering the application of AI in critical contexts, like finance, the number of manuscripts that consider, in its core, fintech and ethics, explainability, accountability are still scarce.

The recent proposals by the European Union, namely the Digital Services Act that aims at defining a common set of rules, obligations, and accountability across EU to provide all types of digital services, while ensuring a high level of protection to all users [2]. In this proposal, financial applications are considered high-risk applications subject to strict obligations before they can be put on the market[3]:

- adequate risk assessment and mitigation systems;
- high quality of the datasets feeding the system to minimise risks and discriminatory outcomes;

[2] https://commission.europa.eu/strategy-and-policy/priorities-2019-2024/europe-fit-digital-age/digital-services-act-ensuring-safe-and-accountable-online-enviro en

[3] https://digital-strategy.ec.europa.eu/en/policies/regulatory-framework-ai

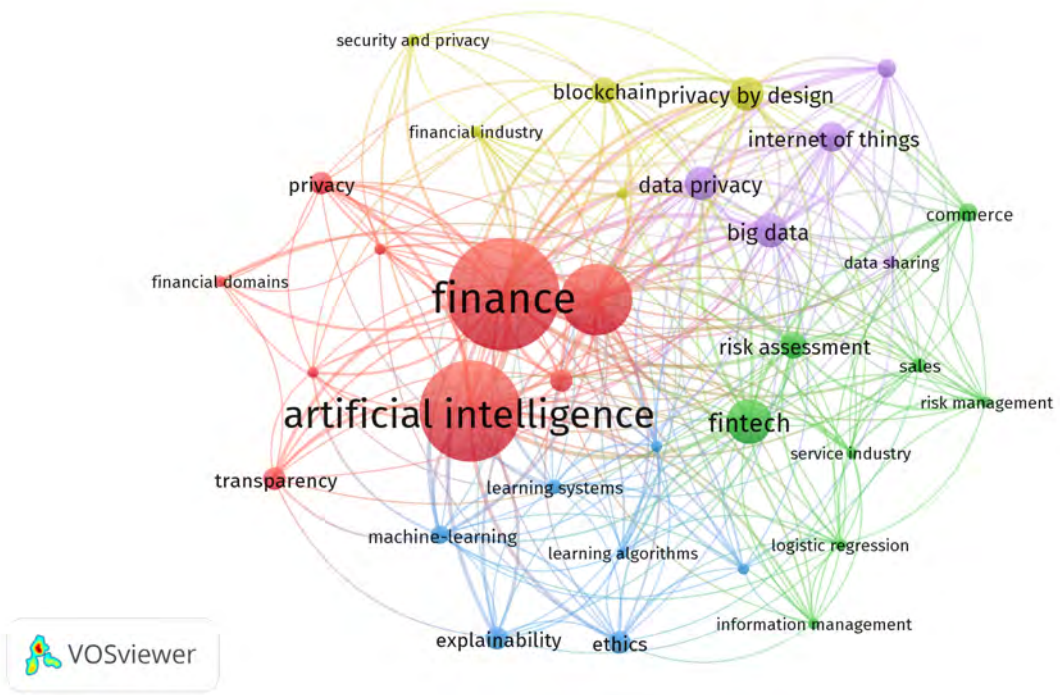

Figure 5: Publication Media (Source: Scopus)

- logging of activity to ensure traceability of results; detailed documentation providing all information necessary on the system and its purpose for authorities to assess its compliance;
- clear and adequate information to the user;
- appropriate human oversight measures to minimise risk;
- high level of robustness, security and accuracy.

In this work we can conclude that it seems that there is a literature gap in what concerns the connection between law and AI, since no manuscripts are clearly concerned with algorithm development and application evolving alongside specific legislation creation and adoption. AI developers and researchers should be working together with regulators.

Uncertainty & fairness metrics

Anna Gottard[a]

[a]Dipartimento di Statistica, Informatica, Applicazioni "G. Parenti"
Florence Center of Data Science - University of Florence; anna.gottard@unifi.it

Abstract

Nowadays, many decisions are made taking as suggestion predictive models based on observed data. Even if the learning process is fair and not malicious, predictive models may systematically discriminate against certain groups of people. The resulting decisions will be unfair. Fairness-aware statistical machine learning investigates how to create discrimination-free predictive models. We discuss the various source of unfairness as solutions to unfairness cannot be separated from its source. We provide a way to distinguish the lack of fairness due to the data generating process/sample from that induced by the predictive algorithm. In addition, we provide some simple strategies to evaluate uncertainty in fairness metrics for the large sample case. An illustrative example on synthetic data from a specific data generating process provides insights into the CART algorithm behaviour.

Keywords: Fairness, Predictive modeling, Statistical machine learning, Uncertainty

1. Introduction

Decisions that affect individuals increasingly rely on statistical machine learning procedures. Algorithms support criminal justice decisions, credit banking, hiring practices, and personalized medicine. Fairness in machine learning has become a critical issue as the growing use of automated decision-making procedures has highlighted the potential for bias and discrimination. The definition of fairness is not univocal and depends on context. See, among many, (11), (12), (13) and (15) for detailed reviews on fairness.

Fairness is generally defined as the absence of discrimination in the outcome of an automated decision-making system. This includes discrimination against individuals or groups based on sensitive or protected characteristics, such as race, gender, or age, as well as discrimination against individuals or groups due to their socioeconomic status, or other factors.

We can distinguish three main situations that result in a lack of fairness.

1. *Algorithm bias*, when the algorithm induces bias about sensitive attributes,
2. *Sampling bias*, when the data set is biased as a result of an unfair selection mechanism,
3. *Population bias*, when Nature is unfair.

While these situations may occur simultaneously, each recalls a specific definition of fairness and requires unique solutions. It is crucial to recognize these possible sources of unfairness and take steps to mitigate them when building and deploying statistical machine learning algorithms.

The first source of unfairness considered is algorithmic bias. This type of bias arises when a model is developed to make predictions based on certain features or variables that are not directly relevant and result in discrimination against certain groups or individuals. For instance, if a model is designed to make predictions based on an individual's race or gender, it could lead to the unjust treatment of particular groups.

The second source of unfairness arises when the data used to train the model is not representative of the population for which the model is intended. This can occur due to selection effects, such as when data are predominantly drawn from a particular demographic group or race, leading to biased and unfair treatment of under-represented groups or individuals. Machine learning algorithms assume that data are an *iid* sample representative of the population and are thus unsuitable for handling selection effect. Additionally, a dataset can be discriminative because it is drawn from a population affected by population bias. This brings us to the third source of bias.

The third situation is particularly intriguing, because it involves unfairness and discrimination in the population itself. If Nature is unfair, every random sample drawn from the population of interest will be unfair. Addressing fairness issues in this type of situation requires the algorithm to move away from the true data generating process and produce predictions for a better world, intentionally biased to counter the effects of Nature's unfairness. This can be achieved by adjusting the dataset or modifying the loss function of the predictive algorithm. Some authors treat fairness issues as a problem of imbalanced data, as discussed in (7).

Consider, for instance, tree-based regression and classification algorithms, a popular class of predictive models known for their simplicity and ability to handle both nonlinear and interaction effects. The most widely used algorithm is the Classification and Regression Tree (CART) algorithm (4). Despite not having the highest predictive performance, CART is valued for its transparency and ease of interpretation. However, fairness can be problematic in classification trees that use greedy search. Not only can CART amplify bias present in the dataset or population, but it can also introduce unfairness in predictions. According to (9), tree-based algorithms that use greedy search tend to rely on background variables, typically including sensitive attributes, while ignoring some variables that directly affect the response. This issue is propagated to ensemble methods based on CART.

The purpose of this paper is two-fold. The first objective is to contribute to the ongoing effort of quantifying uncertainty in fairness metrics. We propose a straightforward method for assessing the level of uncertainty in fairness metrics. Prior research studies, such as (10) and (6), have observed that fairness metrics tend to exhibit inconsistency when applied to different train-test splits of the data. We argue that these metrics should be viewed as estimates of the *true* metric value, and that sample variability can be accounted for using simple statistical procedures. At this aim, confidence intervals can be computed for the true level of fairness measured with a given metric. The importance of confidence intervals for fairness metrics has been also highlighted by (3). The second objective is to provide a procedure to identify the source of unfairness by comparing simple intervals of fairness metrics that can be easily computed on subsets of the observed sample. In particular, we will examine the metric of statistical parity, which measures the difference in proportion of positive outcomes between different groups. By comparing the confidence intervals of this metric across training and test data, we can gain insights into the factors that contribute to unfairness. The approach presented in this paper can be easily implemented in a wide range of contexts, making it a valuable tool for researchers and practitioners alike.

The remainder of this paper is organized as follows. Section 2. discusses statistical parity as a fairness metric and its estimator. Section 3. provides two confidence intervals for evaluating the uncertainty of such a metric as well as a statistical procedure for comparing unfairness. A synthetic data example is included. Finally, concluding remarks are provided in Section 4.

2. A measures of fairness: statistical parity

Consider a set of explanatory variables $\boldsymbol{X} = (X_1, \ldots, X_p)$, and a response Y that, for simplicity, we assume to be binary, $\mathcal{Y} = \{0, 1\}$. Suppose we are given a random sample $\mathcal{D} = \{(\mathbf{X}_i, Y_i)\}_{i=1}^n$ of units independently drawn from a distribution F_{XY} having domain $\mathcal{X} \times \mathcal{Y}$.

A *classifier* h can be formally defined as a mapping function $h : \mathcal{X} \to \mathcal{Y}$, that assigns a class label $y \in \mathcal{Y}$ to a given set of values $\boldsymbol{x} \in \mathcal{X}$. The mapping function $h(\boldsymbol{X})$ is learned by minimizing a loss function that is typically a function of the classification risk, or *error rate*, $R(Y, h(\boldsymbol{X})) := \mathbb{P}(Y \neq h(\boldsymbol{X}))$. In the binary case, it can be proved that the classifier minimizing the classification risk depends

on the conditional expectation

$$m(\boldsymbol{x}) = \mathbb{E}[Y \mid \boldsymbol{X} = \boldsymbol{x}] = \mathbb{P}(Y = 1 \mid \boldsymbol{X} = \boldsymbol{x}),$$

where a unit is assigned to the class 1 whenever $m(\boldsymbol{x}) > \frac{1}{2}$. As a consequence, a good classifier is the one providing an accurate approximation of $m(\boldsymbol{x})$, say $\widehat{m(\boldsymbol{x})}$, the estimate of the conditional probability $\pi_{Y|X}$ and $h(\boldsymbol{X})$ assigns $\widehat{Y} = 1$ whenever $\widehat{m(\boldsymbol{x})} > \frac{1}{2}$. The algorithm CART also adopts this kind of classifier as it utilizes a *majority vote* prediction rule. A classifier is typically trained on a subset of data called *training data*, while the rest of the data, called *test data*, are used to assess prediction accuracy.

Let S represent the group attribute to be protected, such as, for instance, gender or race. It can or cannot be included within the set of explanatory variables $\boldsymbol{X}$, as a subject-specific choice. Notice that if one is interested in more than one sensitive attribute, S can be defined on the cross-product of the sensitive attributes. For simplicity, we assume S to be binary.

Several fairness measures have been proposed in the literature due to the increased interest in fair machine learning. For brevity, we focus here on one specific metric, statistical parity, but the consideration provided can be easily extended to other measures, such as those proposed by (12).

Definition 1. ***Statistical parity*** *is a group fairness metric that requires the distribution of positive predictions to be equal across the different levels of the sensitive variable S, taking values in $\mathcal{S}$. It can be defined as*

$$\mathbb{P}\Big(Y = 1 \mid S = s\Big) \;=\; \mathbb{P}\Big(Y = 1\Big) \qquad \forall s \in \mathcal{S}. \tag{1}$$

to measure unfairness in the sample or the population, and

$$\mathbb{P}\Big(\widehat{Y} = 1 \mid S = s\Big) \;=\; \mathbb{P}\Big(\widehat{Y} = 1\Big) \qquad \forall s \in \mathcal{S}. \tag{2}$$

to measure unfairness in the prediction.

The metric (1) may serve as an initial method for detecting unfairness in data, whereas the metric (2) can be used to assess fairness in the predicted values. When Y is binary, statistical parity, also known as demographic parity, implies that $Y \perp\!\!\!\perp S$ for (1) or $\widehat{Y} \perp\!\!\!\perp S$ with equation (2). When Y is multinomial, statistical parity is achieved if $\mathbb{P}(Y = y \mid S = s) \;=\; \mathbb{P}(Y = y)$ or $\mathbb{P}(\widehat{Y} = y \mid S = s\Big) \;=\; \mathbb{P}(\widehat{Y} = y)$, for each $y \in \mathcal{Y}$ and $s \in \mathcal{S}$. Hereafter, we assume that both Y and S are binary variables, with $\mathcal{Y} = \{0, 1\}$ and $\mathcal{S} = \{s, \overline{s}\}$.

Statistical parity considers the conditional distribution of Y given S once marginalized over $\boldsymbol{X}$. As a consequence, it is subject to the Simpson paradox (14). It can happen that, even if (1) and (2) are satisfied, there might exist some discrimination for specific sub-populations, conditional on $\boldsymbol{X}$. On the other hand, if also $Y \perp\!\!\!\perp S \mid \boldsymbol{x}$ for each $\boldsymbol{x} \in \mathcal{X}$, then there is no context-specific unfairness that cancels out when marginalizing over $\boldsymbol{X}$. Other fairness metrics are conditional on X and, therefore, do not have this issue. However, they require further assumptions on the dependence of Y on $\boldsymbol{X}$.

A metric for violation of statistical parity is therefore

$$\Delta = \mathbb{P}\Big(Y = 1 \mid S = s\Big) \;-\; \mathbb{P}\Big(Y = 1 \mid S = \overline{s}\Big).$$

for the population, and

$$\Delta_P = \mathbb{P}\Big(\widehat{Y} = 1 \mid S = s\Big) \;-\; \mathbb{P}\Big(\widehat{Y} = 1 \mid S = \overline{s}\Big)$$

for the prediction. These quantities are actually unknown and the values computed from observed data are only estimates of these metrics. Training data can be used to compute a consistent estimate $\widehat{\Delta}$ of the population's lack of statistical parity, as it is a simply the difference of conditional probabilities. An *honest* estimator $\widehat{\Delta}_p$ can be obtained by the sample proportions computed from the test data set, used neither for learning nor tuning the parameter of the classifier,

$$\widehat{\Delta}_P = \frac{1}{n_{\text{test}|s}} \sum_{i=1}^{n_{\text{test}}} \mathbb{I}\{\widehat{Y}_i = 1\} \cdot \mathbb{I}\{S_i = s\} \;-\; \frac{1}{n_{\text{test}} - n_{\text{test}|s}} \sum_{i=1}^{n_{\text{test}}} \mathbb{I}\{\widehat{Y}_i = 1\} \cdot \mathbb{I}\{S_i = \overline{s}\}.$$

where n_{test} is the dimension of the test set, with $n_{\text{train}} = n - n_{\text{test}}$, and with

$$n_{\text{test}|s} = \sum_{i=1}^{n_{\text{test}}} \mathbb{I}\{S_i = s\}.$$

Large values of $\widehat{\Delta}$ can be attributed to both sample and population unfairness. Unfortunately, no metrics or test statistics on the observed data can disentangle a lack of fairness due to population bias from sampling bias. Large values of $\widehat{\Delta}_P$ when $\widehat{\Delta}$ is close to zero may suggest algorithm bias. As $\widehat{\Delta}$ and $\widehat{\Delta}_P$ are simply an estimate of the *true* statistical parity measures, it is essential to consider the uncertainty in the estimate of such metrics.

3. Uncertainty evaluation

To check the source of unfairness and to evaluate their uncertainty, one can think of several statistical tests and confidence intervals for $\widehat{\Delta}$ and $\widehat{\Delta}_P$. Let us denote with $n_{\text{test1}|s} = \sum_{i=1}^{n_{\text{test}}} \mathbb{I}\{\widehat{Y}_i = 1\} \cdot \mathbb{I}\{S_i = s\}$ and with $n_{\text{train1}|s} = \sum_{i=1}^{n_{\text{train}}} \mathbb{I}\{Y_i = 1\} \cdot \mathbb{I}\{S_i = s\}$. In addition, we denote $n_{\text{test0}|s}$ and $n_{\text{train0}|s}$ the observed frequency of $\widehat{Y} = 0$ in the test set and $Y = 0$ in the training set. A similar notation is adopted for the subsets with $S = \overline{s}$. In the case of large sample sizes, one can define the confidence intervals for the metrics of interest as follows.

$$\text{CI for } \Delta: \quad \left(\frac{n_{\text{train1}|s}}{n_{\text{train}|s}} - \frac{n_{\text{train1}|\overline{s}}}{n_{\text{train}|\overline{s}}}\right) \pm z_{\alpha/2} \sqrt{\frac{n_{\text{train1}|s} \cdot n_{\text{train0}|s}}{n^3_{\text{train}|s}} + \frac{n_{\text{train1}|\overline{s}} \cdot n_{\text{train0}|\overline{s}}}{n^3_{\text{train}|\overline{s}}}} \tag{3}$$

$$\text{CI for } \Delta_P: \quad \left(\frac{n_{\text{test1}|s}}{n_{\text{test}|s}} - \frac{n_{\text{test1}|\overline{s}}}{n_{\text{train}|\overline{s}}}\right) \pm z_{\alpha/2} \sqrt{\frac{n_{\text{test1}|s} \cdot n_{\text{test0}|s}}{n^3_{\text{test}|s}} + \frac{n_{\text{test1}|\overline{s}} \cdot n_{\text{test0}|\overline{s}}}{n^3_{\text{test}|\overline{s}}}} \tag{4}$$

These are Wald-type confidence intervals. The Agresti and Caffo (1) confidence intervals can be obtained by adding one success and one failure to each one of the groups defined by S. Confidence intervals (3) and (4) that include zero suggest that we cannot exclude statistical parity in the sampled population and the prediction, respectively. An interval consisting in only negative values suggest discrimination toward the subgroup with $S = s$, whereas positive values suggest discrimination toward the subgroup with $S = \overline{s}$. A further possible evaluation of uncertainty in fairness concerns the comparison of the two observed metrics, for instance, to evaluate a fairness-aware algorithm. Assuming a null hypothesis $H_0\, \Delta = \Delta_P$, we could be interested to an alternative $H_1 : \Delta > \Delta_P$ to verify if the fairness-aware algorithm is effective. Conversely, we can chose an alternative such as $H_1 : \Delta < \Delta_P$ to check if an algorithm is inducing lack of fairness.

A test statistic that can be used at the aim concerns the difference of differences of proportions (8). The test statistic has the form

$$T = \left(\frac{n_{\text{train1}|s}}{n_{\text{train}|s}} - \frac{n_{\text{train1}|\overline{s}}}{n_{\text{train}|\overline{s}}}\right) - \left(\frac{n_{\text{test1}|s}}{n_{\text{test}|s}} - \frac{n_{\text{test1}|\overline{s}}}{n_{\text{train}|\overline{s}}}\right).$$

Under the null, it is normally distributed with mean zero and variance equal to

$$\sigma^2_T = \frac{n_{\text{train1}|s} \cdot n_{\text{train0}|s}}{n^3_{\text{train}|s}} + \frac{n_{\text{train1}|\overline{s}} \cdot n_{\text{train0}|\overline{s}}}{n^3_{\text{train}|\overline{s}}} + \frac{n_{\text{test1}|s} \cdot n_{\text{test0}|s}}{n^3_{\text{test}|s}} + \frac{n_{\text{test1}|\overline{s}} \cdot n_{\text{test0}|\overline{s}}}{n^3_{\text{train}|\overline{s}}}$$

Such variance is appropriate as, under the assumption of *iid* data, train data and test data are independent. When the overall sample dimension n is small, the random splitting of the data set can make the results unstable and alternative solutions should be preferred.

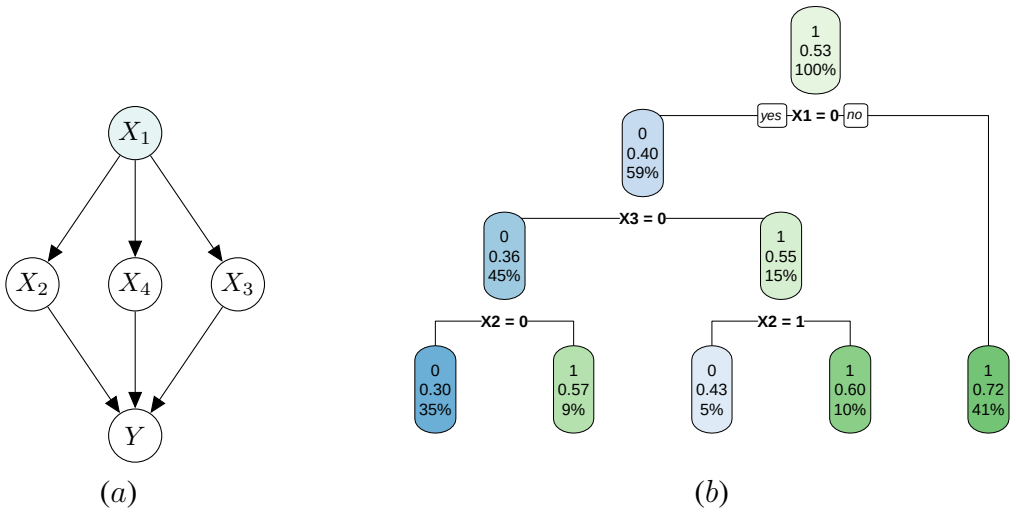

Figure 1: Data generating process (a) and tree learn by CART (b) for the synthetic data example

3.1 Example on synthetic data

Consider the data generating process shown in Figure 1(a), where X_1 is a binary sensitive attribute, with distribution $X_1 \sim \text{Ber}(\pi_1 = 0.5)$. The three predictors X_j, $j = 2, 3, 4$ are also binary and have conditional distributions $X_j \mid X_1 = s \sim \text{Ber}(\pi_s)$ with $\pi_1 \approxeq 0.69$ and $\pi_0 \approxeq 0.27$. We assume that the three predictors X_j, $j = 2, 3, 4$ with a logistic regression parametrization with intercept -1 and the same coefficient, 0.8. According to Figure 1(a), $Y \perp\!\!\!\perp X_1 \mid X_2, X_3, X_4$ but $Y \not\perp\!\!\!\perp X_1$. By marginalizing over X_2, X_3, X_4, the conditional distribution of $Y \mid X_1 = s$ is $\text{Ber}(\pi_{Y|s})$, with $\pi_{Y|1} \approxeq 0.65$ and $\pi_{Y|0} \approxeq 0.42$. The true value of the statistical parity is therefore 0.23, indicating mild unfairness.

We generated a data set of size 300 from this data generating process and split the data into equal-sized training and test sets. We fitted a classification tree on the training data using the `rpart` package in R with default settings and computed the predicted values for the test data.

Regarding fairness in the population, we estimated $\widehat{\pi}_{Y|1} = 0.721$ and $\widehat{\pi}_{Y|0} = 0.404$, resulting in $\widehat{\Delta}_P = 0.317$, which is slightly overestimating the true value. The 95% confidence interval for Δ_P is $(0.165; 0.469)$, not including zero, correctly suggesting lack of fairness.

Regarding the fairness of the algorithm, we know from (9) that this data generating process tends to make CART over-utilize the background variables. Figure 1(b) shows that the first variable selected by the greedy algorithm for slitting is exactly the sensitive variable X_1. The estimate of $\widehat{\Delta}$ is indeed 0.563 with a 95% confidence interval $(0.448; 0.679)$, and the test statistic T yields a p-value 0.0056, indicating that the algorithm is significantly increasing bias.

A common approach is to make the algorithm blind to the sensitive variable and exclude X_1 as a predictor. In this case, the estimate of $\widehat{\Delta}$ is reduced to 0.393 and the confidence interval to $(0.257; 0.529)$. This time the test T cannot reject the null hypothesis, as the resulting p-value is around 0.2.

4. Concluding remarks

As machine learning becomes increasingly integrated into human life, it is important to recognize that these algorithms have the potential to be both groundbreaking and problematic. They can inadvertently perpetuate or alleviate bias toward certain protected attributes, such as race, religion, and gender. As a result, it is crucial for researchers and practitioners to carefully evaluate the fairness of their data and models. In this paper, we emphasize that the fairness measure computed from the data is actually an estimate of the unknown *true* fairness metric. Therefore, it is essential to assess uncertainty the uncertainty of this estimate. These measures are easy to compute and could therefore be included in fairness-aware algorithms to relax the trade-off between different metrics of fairness simultaneously and

accuracy. Discussion of this trade-off can be found, for instance, in (2) and (5).

Furthermore, we propose a method for differentiating between discrimination resulting from data or Nature and discrimination induced by the algorithm, also taking into account sample variability.

Acknowledgments I wish to express my sincere gratitude to Tamàs Rudas for providing invaluable insights during our discussions on the topic. Additionally, I would like to extend a special thank you to Sabrina Giordano for her unwavering support and encouragement.

Analysis of University Grades: An IRT Model for Responses and Response Times with Censoring

Michela Battauz[a]

[a]Department of Economics and Statistics, University of Udine; michela.battauz@uniud.it

Abstract

In this paper, we proposed an Item Response Theory (IRT) model to analyze the grades obtained by the university students and the time needed to pass the exams. The model includes two latent variables which an be interpreted as ability and speed. In fact, in Italian universities, the students have a great flexibility in the choice of the order in which to give the exams and they have several occasions to give them during the academic career. However, in our dataset, the grade is available only for the students who pass the exam. Furthermore, several students drop out of university before completing their studies. It is then fundamental to account for these two sources of censoring when modelling these data. An application to a real dataset illustrates the model.

Keywords: academic careers, academic performance, censoring, IRT, response time.

1. Introduction

In the Italian university system, the students have a great flexibility in the choice of the order in which to give the exams and they have several occasions to give them during the academic career. Furthermore, they can drop out of university before completing their studies, hence introducing missing values in the data composed of the grades. For these reasons, the analysis of the grades should take into account the censoring process and the time plays an important role in it. The availability of the only positive grades in our dataset is another cause of censoring that should be taken into proper account. In this paper, we use a graded response model (Samejima, 1969) for the ordinal grades, though other choices are possible. Following van der Linden (2006), the response times are modelled using a lognormal distribution, jointly with the grades. Our proposal shares many similarities with Guo, Xu, Ying and Zhang (2022), who dealt with computer-based assessment with time limits. The main differences of

our work are the ordinal responses, an additional source of censoring due to the lack of availability of the grades for non-passed exams, and the censoring time being a random variable rather than a known constant. A different approach to the analysis of the university grades is given by Bacci, Bartolucci, Grilli and Rampichini (2017), who do not consider the time needed to pass the exams, but rather indicator variables of the choice of the students to attempt the exams.

In the following sections, after introducing the model and the relative likelihood-based methods, an application will be presented and some concluding remarks will be given.

2. Models and methods

Let X_{ij} be an ordinal grade obtained by student i in exam j. According to the graded response model, the probability of observing a response equal to x is given by

$$P(X_{ij} = x|\theta_i) = P(X_{ij} \geq x|\theta_i) - P(X_{ij} \geq x+1|\theta_i) \ , \tag{1}$$

with

$$P(X_{ij} \geq x|\theta_i) = \frac{e^{\alpha_j\theta_i+\beta_{jx}}}{1+e^{\alpha_j\theta_i+\beta_{jx}}} \ , \tag{2}$$

where α_j is a slope parameter, β_{jx}, $x = 1, \ldots, m_j$, are category-specific intercept parameters, m_j is the number of response categories, and θ_i is a latent variable which represents the ability of the student.

The time at which exam j is passed by student i is denoted by T_{ij}. We assume a log-normal distribution for the response times

$$\log T_{ij}|\tau_i \sim N\left(\gamma_j - \tau_i, \frac{1}{\lambda_j^2}\right) \ , \tag{3}$$

where γ_j and λ_j^2 are the parameters that determine the average time required to pass exam j and its variability, while τ_i is a latent variable which represents the speed of the student.

The latent variables are assumed to follow a bivariate normal distribution

$$\begin{pmatrix}\theta_i \\ \tau_i\end{pmatrix} \sim N\left(\begin{pmatrix}0\\0\end{pmatrix}, \begin{pmatrix}1 & \rho\sigma_\tau \\ \rho\sigma_\tau & \sigma_\tau^2\end{pmatrix}\right). \tag{4}$$

Both the grade and the time are observed only if the grade is positive, so that the exam is passed, and the student does not drop out of university before succeeding in the exam. Let C_i be the time at which the student graduates or drops out and R_{ij} an indicator variable equal to 1 if grade and time are observed. Hence, $R_{ij} = 1$ if $T_{ij} \leq C_i$ and $X_{ij} \geq x_{min}$, where x_{min} is the threshold for passing the exam. It can be shown that the joint probability of R_{ij}, X_{ij}, T_{ij}, given the latent variables, is then given by:

$$f(r_{ij}, x_{ij}, t_{ij}|\theta_i, \tau_i) = P(x_{ij}|\theta_i)^{r_{ij}} f(t_{ij}|\tau_i)^{r_{ij}} \left\{1 - P(T_{ij} \leq c_i|\tau_i)P(X_{ij} \geq x_{min}|\theta_i)\right\}^{1-r_{ij}} , \tag{5}$$

The censoring time C_i is a random variable in this context. However, it is sensitive to assume that its distribution does not depend on the parameters that determine the distribution of the grades and the times to pass the exams. This assumption, which is usually referred to as noninformative censoring in the literature (Kalbfleisch and Prentice, 2002), allows to drop the distribution of C_i from the likelihood function, which can be expressed as follows:

$$L(\boldsymbol{\alpha}, \boldsymbol{\beta}, \boldsymbol{\gamma}, \boldsymbol{\lambda}, \rho, \sigma_\tau^2) = \prod_{i=1}^{n} \int \int \prod_{j \in P_i} f(r_{ij}, x_{ij}, t_{ij}|\theta_i, \tau_i) f(\theta_i, \tau_i) d\theta_i d\tau_i, \tag{6}$$

where n is the number of students, P_i is the set of courses in the programme of student i, $\boldsymbol{\alpha} = (\alpha_1, \ldots, \alpha_J)^\top$, $\boldsymbol{\beta} = (\boldsymbol{\beta}_1^\top, \ldots, \boldsymbol{\beta}_J^\top)^\top$, with $\boldsymbol{\beta}_j = (\beta_{j1}, \ldots, \beta_{jm_j})^\top$, $\boldsymbol{\gamma} = (\gamma_1, \ldots, \gamma_J)^\top$, and $\boldsymbol{\lambda} = (\lambda_1, \ldots, \lambda_J)^\top$. As frequently happens in IRT modelling, the integrals do not have a closed form solution and they are approximated by numerical methods, such as Gaussian quadrature. The maximization of the log-likelihood function provides estimates of the parameters.

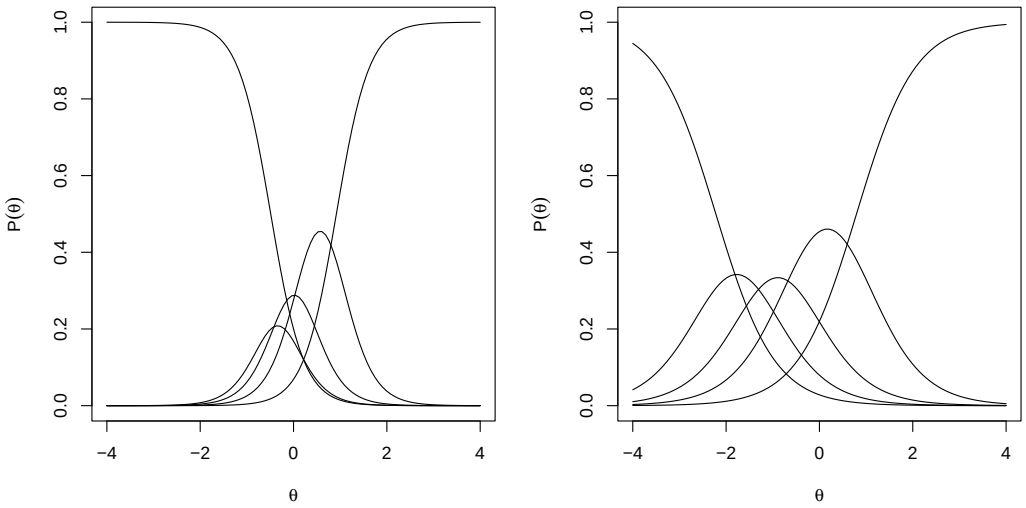

Figure 1: Probability curves for one exam. On the left panel the curves are obtained without correction for censoring, on the right panel the curves are corrected for censoring. The first category refers to non-passed exams, the others refer to the grades grouped in 4 classes.

3. Application

The model proposed in this paper was used to analyze the grades obtained by university students in Economics and Business from the University of Udine. These two bachelor degrees share many courses, especially at the first and second year, thus permitting to analyze them together. The sample is composed of a cohort of 324 students who enrolled in 2017. 128 of them dropped out of university or decided to change bachelor course, 180 attained the degree, while 16 are still enrolled in 2022, last year of data available. For this analysis we considered only courses with at least 50 students that have passed the exam, resulting in a total of 22 courses. For each student, we observed only the grades in passed exams which are in the programme of the student and are among the 22 selected ones. Hence, the number of observed exams per student is variable and ranges from 4 to 20, the median is 17.5, while the mean is 15.1. The grades, which range from 18 to 30, have been grouped in 4 classes to reduce the number of parameters of the model. The time is considered equal to the days between the date when the exam is passed and the 1st of October 2017, conventionally assumed as the beginning of the career.

All analyses were performed in R. In order to understand the effect of ignoring the censoring process, we estimated two separate models for the grades and for the times that do not account for censoring. We applied a graded response model to the grades, substituting the missing values with a unique value below the threshold for passing the exam. For this purpose we used the mirt package. Doing so, we incorrectly assume that the students that have an exam in their programme with a missing value for the grade, failed the exam, while it might also be that they dropped out or changed course before even attempting. The analysis of the times that ignores the censoring process was performed by fitting a random effects model to the logarithms of the times with random intercepts for the students, and where the independent variables are dummy variables that identify the exam. The variability of the level-1 errors is allowed to vary across subjects. In this model, the missing values are simply omitted. This model was fitted using the package nlme.

Figure 1 shows the probability curves for one exam taken as example ignoring the censoring process (on the left) and applying our proposal (on the right). The curve that presents the most important change is the one that refers to grades below the threshold for passing. Assuming that the students that don't have the grade registered failed the exam, erroneously results in higher probability of failing the exam for students located at lower levels. This effect was observed for the other exams as well, though the figures are not shown in the paper for space reasons.

Figure 2 shows a comparison of the predicted values of the latent variables ignoring the censoring process and accounting for it by applying the proposal of this paper. In the first case, the predicted values

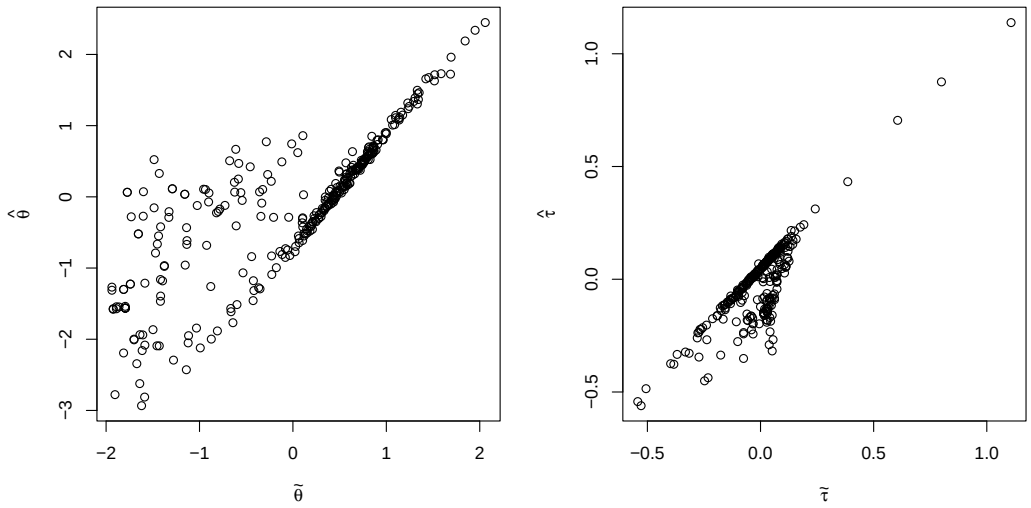

Figure 2: Predicted values of the latent variables obtained without correcting for censoring (horizontal axis) and correcting for censoring (vertical axis).

are denoted by $\tilde{\theta}$ and $\tilde{\tau}$, while in the second case they are denoted by $\hat{\theta}$ and $\hat{\tau}$. It is possible to observe that the predicted values for some students are unchanged since they lay on a line. Such line is not the bisector because of the unidentifiability of the scale of the latent variables, with θ assumed to have zero mean and variance equal to one. The students with predicted ability levels that do not lay on the line, when accounting for the censoring process, present higher values. This is easily explainable since these are students whose missing values were considered as negative grades. These are anyway students on the lower range of ability, since the high achievers tend to not have missing values as they have passes all the exams in their programme. Observing, instead, the predicted speeds, some students present lower values when accounting for the censoring process. These are students that passed a few exams before dropping out or changed course. Hence, just omitting the non-passed exams leads to assign them higher values than their actual speed.

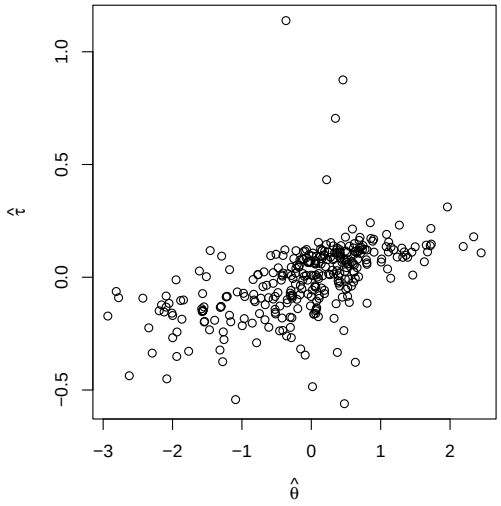

Figure 3: Scatter plot of the predicted values of the latent variables.

Figure 3 shows a scatter plot of the predicted abilities against the predicted speeds. It is apparent a positive correlation between the two. In fact, the correlation index ρ is estimated at about 0.25. A few students present outlier values, with average values of ability and very large values of speed. These students graduated at the second year, hence anticipating the attainment of the degree which normally

requires three years. This suggests a trade-off between attaining high grades and speed at the individual level, though in this population the students who perform well in terms of grades tend to be the fastest too. The standard deviation of τ, which is estimated at about 0.2, is considerably smaller than that of θ, fixed at 1.

4. Conclusions

The analysis of the students' performance can provide important information about the careers of the students, including dropping out of university. In this paper we have proposed a model to analyze the students' grades and the time needed to pass the exams taking into account two sources of censoring that are present in our data. Specifically, these are the availability of the only positive grades and dropping out before attempting the exams. Our analyses showed that it is fundamental to take in proper account the censoring process in the estimation of the parameters and the prediction of the latent variables.

In future research, we aim at expanding our model by considering multidimensional ability and speed latent variables. In fact, we suspect the presence of at least two dimensions in these data, which could capture different abilities required by the courses. Another extension of the model that we will pursue is the use of regularization methods for the IRT parameters in order to allow for the estimation of a large number of parameters and thus avoid grouping of the grades. Finally, we will conduct an extensive simulation study to better understand the properties of the estimators and the effect of ignoring the censoring process.

Abstract

This work aims to predict student performance for a high school in Italy using Machine Learning algorithms, particularly the innovative Ordinal Random Forests. The study intended to find the optimal moment to obtain accurate predictions of students' final marks as early as possible during the academic year to support timely interventions from schools. The models used data from electronic registers, which were updated weekly, and showed that predictive models after four months of schooling could correctly predict the final marks of a high percentage of students. The study's findings have implications for research and practice as school managers can use these models to promote improvements.

Keywords: Early Warning Systems; Learning Analytics; Students' performance prediction; Machine Learning

1. Introduction

The use of Early Warning Systems (EWS) is becoming increasingly prevalent in education, as they enable the development of personalized interventions aimed at improving student outcomes. To create these systems, it is necessary to predict student performance as soon as possible (1)(2). This prediction is a crucial area of research in Learning Analytics. Early and accurately predicting academic performance can aid in the planning and implementation of personalized and timely remedial interventions for students, which can improve their academic achievement and prevent failure (3). The prediction of students' performance is challenging due to various factors that influence it, such as psychological traits, socio-demographic characteristics and educational experiences. These factors are often complex and nonlinearly correlated, making it difficult to accurately model their interrelationships (4).

This study addresses the primary research question of how accurately and early machine learning models can predict students' final marks.

2. Data and methodology

This study aims at predicting students' performance (Y) using both time-invariant (Z) and time-varying (X_t) predictors. Data from the electronic register merged with administrative data of students in an Italian high school are used to predict students' average of all final marks and

the final marks in three specific subjects: Mathematics, Italian, and English. More specifically, administrative database provide information regarding the personal characteristics of students such as demographic information (gender, citizenship, age) and indicators about minor or major certified disabilities; information about classes - such as the total number of teachers and the type of their contract or the school track; and information of students' academic performance obtained in the previous year such as whether the student was promoted in June or he/she had some specific restorative exams in September or he/she was rejected or transferred, the average of marks in the previous academic year (on a scale between 1 and 10) and the final mark obtained in Mathematics, Italian and English. The second source of information is the electronic registry database updated weekly. These data allow for the construction and updating of summary variables regarding marks in Mathematics, Italian and English, the number of delays, absences, and merit, diligence and disciplinary notes. This typology of data makes the work innovative and relevant in the field of Early Warning System. It allows to predict students' performance in different time points in students' academic careers, deepening the mechanisms behind it. Object of this work is to find the optimal moment for final marks' prediction, balancing between earliness and accuracy. Data of 438 students enrolled in a private high school in Milan during the year 2018/2019 are analysed.

Machine Learning approaches have been adopted in this context to formulate accurate predictions and deal with highly complex data. In particular, the Random Forest algorithm for the classification of ordinal output is performed (5) (6). Iteratively, using updated data every week, the models are constructed and validated computing, with 10-fold cross validation, two performance indices: Youden's J statistic and Mean Square Error.

Due to the limited amount of available observations, a Monte Carlo simulation is developed to test the results over a larger sample.

3. Results

The evolution over the year of performance indices are shown in Figure 1 and Figure 2.

At the beginning of the year the Youden's J statistic is equal to 0.27 for the prediction of Mathematics grade, it increase during the year to reach the value of 0.43 in the last week of school; for the same models MSE is equal respectively to 1.18 and 0.54. For what concern final Italian mark, at the beginning of the year Youden's J statistic is equal to 0.33 while MSE to 0.73, at the end of the year the first one increases of 0.29 and the second one decreases of 0.42. The Youden's J statistic in the model that predict English final mark pass from 0.39 to 0.60 while the MSE from 0.71 to 0.29. Finally, for what concern the average of all marks, the indices at the beginning of the year are respectively equal to 0.48 and 0.39 while at the end of the year 0.59 and 0.26.

4. Conclusions

The innovative aspects of this paper rely on the model adopted (Ordinal Random Forest) and on the data used. Indeed, the model combines weekly data from the school register, including intermediate evaluations, disciplinary notes, and delays, with administrative data to predict final outcomes. Findings show that, as expected, going forward with the weeks, the predictions' performance improve. Interestingly, mathematics' marks are the hardest to predict, probably because of the fluctuations over the academic year.

The models, and related results, can be used as input to decide the optimal moment to intervene, balancing between early and accurate predictions. Also, the EWS can be used to create

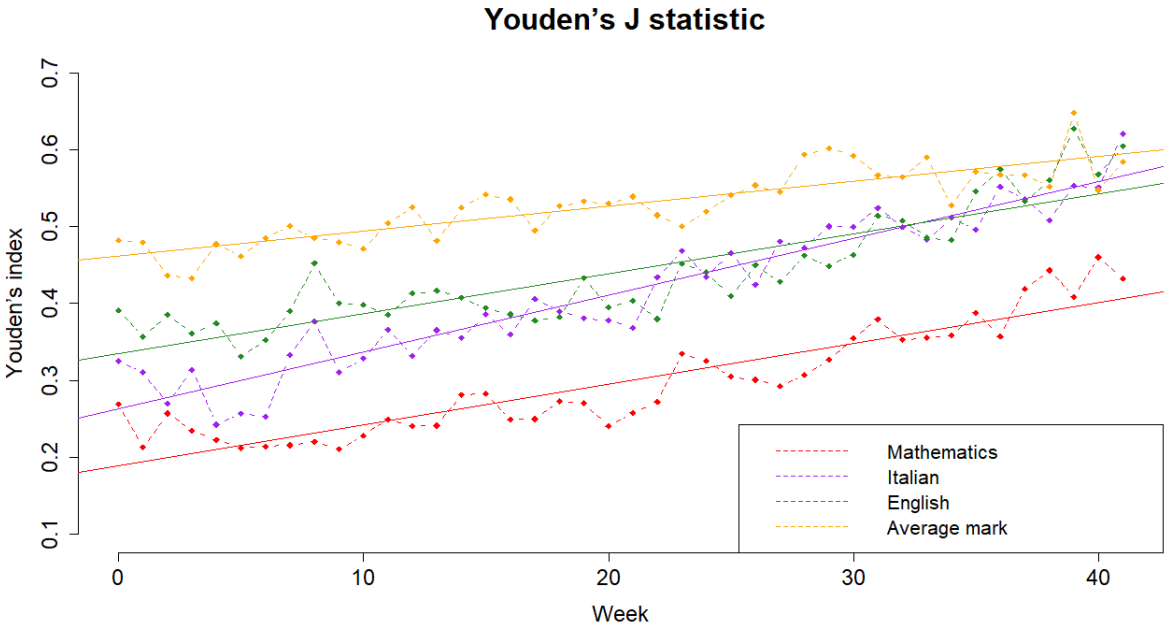

Figure 1: Evolution over time of Youden's J statistic applying Random Forest on the original dataset

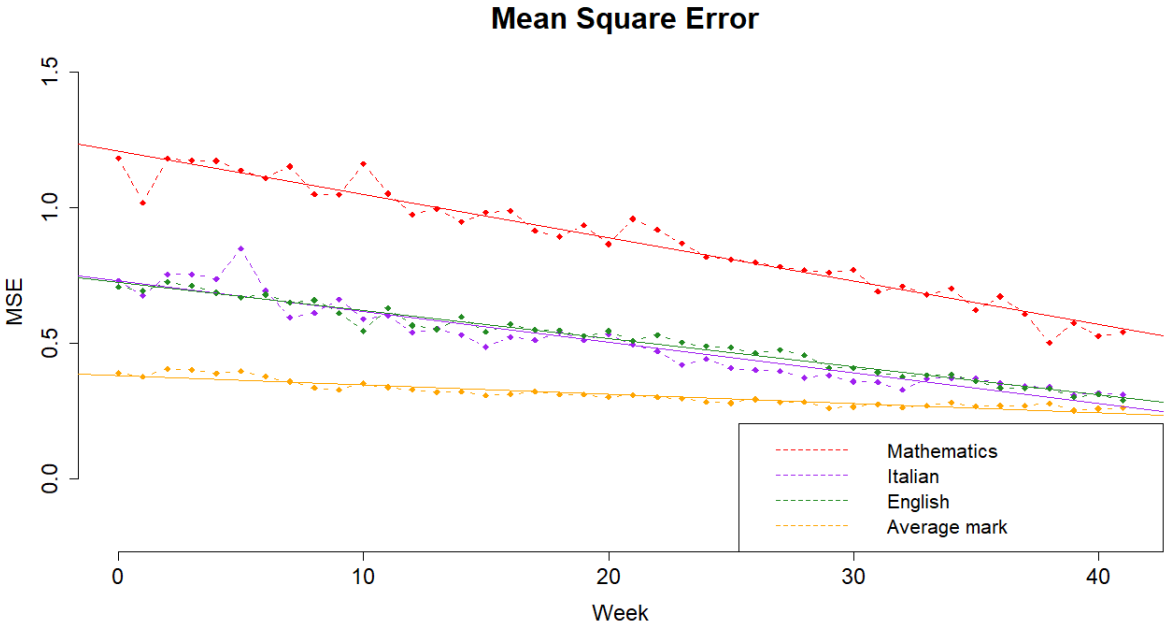

Figure 2: Evolution over time of Mean Square Error applying Random Forest on the original dataset

informative dashboards for teachers and principals, but caution must be taken to ensure that it complements, rather than replaces, teachers' professional judgment, to follow data security and privacy protocols, and to ensure accurate and regular data collection.

Further research is needed to validate the EWS's ability to predict results in standardized tests.

Abstract

In this paper, we introduce a method that can identify those who are cheating during a test, to modify the test itself, the ability and the speed estimation methods, while the test is still ongoing. The model is based on the idea of using response times to estimate e a new person fit statistic that can be updated as the test is carried out, to mark as outliers those who overcome a certain threshold. At that point, the items' selection algorithm will choose only those items that have been previously indicated as more secure, decreasing the probability that the cheater already knows the correct answer. In this way, as shown by a simulation study, we have considerably improved the estimates of cheaters' ability, while not affecting those of non-cheaters.

Keywords: computerized adaptive testing, response times, aberrant behaviours, simulation.

1. Introduction

Due to advances in information technology, many standardized tests rely on computer-based testing (CBT) because of its operational advantages. In fact, CBT offers the opportunity to administer large-scale test at frequent time intervals (also for online classes), which is referred to as continuous testing. In addition, CBT enables testing organizations to record scores more easily and to provide feedback and test results immediately after the test administration.

Another advantage of CBT is that it offers the possibility of collecting response time (RT) information on items. RTs provide information not only about candidates' ability (θ_i) and response behaviour, but also about item and test characteristics. This information can be used for testing operation, such as item calibration and test design, but also for more. For instance, in computerized adaptive testing (CAT), a type of CBT, the difficulty level of items is adapted to the response pattern of the candidate. In fact, items are sequentially selected in real time from a large item pool with hundreds of items, according to the candidate's current performance. In this context, RTs can also be used to improve the estimation of interim ability (θ_{i_m}) and the adaptive item selection. Lastly, RTs could be used for the detection of cheating.

In fact, although continuous testing provides test takers with considerable flexibility and convenience, it also raises serious security concerns. Frequently administered items are at great risk for becoming compromised, thereby undermining the integrity of the test. Individuals who take the test earlier (the sources) could share the items orally or online, which would benefit subsequent test takers (beneficiaries), compromising the validity and fairness of the test.

To counter such a security issue in CAT, much psychometric research has been focused on preventive measures involving some kind of item exposure control while still maintaining the efficiency or accuracy of ability estimation as much as possible. The Sympson-Hetter (SH) method (Sympson and Hetter,

1985) is one of the widely used applications of this strategy. However, even the most successful exposure controls cannot entirely prevent cheating since most items will necessarily be administered multiple times. Therefore, there is a great need for diagnostic measures to also spot anomalous behaviours of test takers. The general strategy is to detect an aberrant pattern of responses or RTs across all items that have been administered to the test-taker. There is extensive literature on the use of person misfit statistics, for example the person fit statistic l_i^t (Marianti et al., 2014, Fox and Marianti, 2017).

However, most of the literature focuses on methods that are viable only after the test has ended, making the resulting intervention less effective (for example, replacing items which are identified as compromised) and sometimes impractical or time consuming (for example, to check for cheating, alternative forms of testing, such as oral testing, may be used).

In this article, we would like to propose and evaluate, through a simulation study, a method based on RT to identify cheating behaviours and intervene while the test is taking place.

2. Method

In this section, we present a method for the identification of test takers who, during a CAT, are presumed to have come into possession of the correct answers to some questions even before having started the test (pre-knowledge). They may have got this information in many ways: they found the questions and the related solutions online, or by word of mouth of those who had already done the test, or even managed to hack the database with the questions. The aim of the method is to detect aberrant behaviours of the test takers, so it tends to focus more on test takers' response patterns, rather than on identifying compromised items.

Like other methods already proposed in the literature (Marianti et al. 2014; Fox and Marianti, 2017), the identification of cheaters takes place through the analysis of RTs: those who tend to have RTs that differ greatly from the expected time for each item, may be possible cheaters.

The peculiarity of this approach, compared to the existing literature, is that such identification takes place while the test is carried out and not after. The idea is to define a person misfit statistic that can be calculated in real time during the test, and that is updated as the test taker answers to the items that are administered. In this way, the misfit statistic can be integrated within the item selection algorithm to try to compensate for the supposed cheating.

First, we define a misfit statistic starting from the current literature. We start from the person misfit statistic based on RT defined by Marianti et al. (2014) and then modified by Fox and Marianti (2017):

$$l_i^t = \sum_{k=1}^{K} \left(\frac{lnRT_{ik} - \mu_{ik}}{\sigma_k} \right)^2, \tag{1}$$

where RT_{ik} is the response time of subject i to item k, μ_{ik} indicates the expected time that a test taker i, with an estimated speed ζ_i, takes to respond to item k and σ_k is the standard deviation of the logarithm of the RT for item k, for $i = 1, \dots, n$ and $k = 1, \dots, K$ (where K is the total test length). In fact, in the literature, a widely used choice is to assume a log normal distribution for the RT (van der Linden, 2006):

$$RT_{ik} = \lambda_k - \varphi_k \zeta_i + \varepsilon_{ik} = \mu_{ik} + \varepsilon_{ik}, \varepsilon_{ik} \sim N(0, \sigma_{\varepsilon_k}^2), \tag{2}$$

where ζ_i is the speed parameter, representing the constant working speed of that test-taker i, λ_k is the time-intensity parameter of item k, representing the population-average time (on a logarithmic scale) needed to complete item k, φ_k is the time-discrimination parameter of item k, representing the sensitivity of the item for different speed levels of the test takers. Lastly, ε_{ik} is an additional error term that can model variations in RTs that cannot be explained only by the structural mean term, such as when test-takers operate with different speed values, take small pauses during the test, or change their time management.

From Equation (1), the statistic l_i^t is defined as a sum of differences that includes all the test items, and these differences are calculated with respect to the estimate of the response speed ζ_i, that is derived at the end of the test using the Gibbs sampling algorithm (Fox et al., 2021), which is very difficult to implement during the test, because it is very time-consuming, thus undermine one of the main advantages of CAT, where the next item has to be selected almost instantly. For this reason, l_i^t can only be defined after the test has been completed.

Our proposal of real-time computable statistics provides for the replacement of μ_{ik} and σ_k with parameters that can be calculated in each step *m* of the test (where each step *m* consists of both the phase of interim ability estimation and that of item selection). Under the hypothesis of log normal distribution of RTs, such parameters are the *expected response time* (Fan et al., 2012, Veldkamp, 2016) and the *reciprocal time-discrimination* (van der Linden, 2006):

$$E\left[RT_{ik}\middle|\hat{\zeta}_{MLE_m i}\right] = e^{(\lambda_k - \hat{\zeta}_{MLE_m i} + \frac{1}{2\,{\varphi_k}^2})}\ ;\ \hat{\zeta}_{MLE_m i} = \frac{\sum_{k\in R_m}[\,{\varphi_k}^2(\lambda_k - lnRT_{ik})]}{\sum_{k\in R_m}[\,{\varphi_k}^2]}$$

$$\sigma_k = \frac{1}{\varphi_k}. \tag{3}$$

The new statistic, called *interim* person fit statistic, is defined as follows:

$$l_{i_m}^t = \sum_{k=1}^{m}\left(\frac{lnRT_{ik} - ln\ \left[RT_{ik}\middle|\hat{\zeta}_{MLE_m i}\right]}{\frac{1}{\varphi_k}}\right)^2. \tag{4}$$

The statistic in Equation (4), as well as in Equation (1), follows a χ^2 distribution with *m* degrees of freedom, as it represents the standardized error of normally distributed logarithms of RT. This means that if a significance level of α is chosen, the threshold value *C* can be easily found from the χ^2 (*m*) distribution. If the threshold *C* is exceeded, the test taker is identified as a cheater.

As proposed by Veldkamp (2016), after a test taker has been flagged as a cheater, the item selection algorithm, through an approach called the shadow test approach (STA; van der Linden, 2010), will start to administer the next items from a *more secure* bank of items (a bank of items that has a very low exposure rate), in order to reduce the probability that the cheater has pre-knowledge of the answers to those items.

3. Simulation study

Our proposal was tested by a simulation study. This section presents the characteristics of the simulations and the main results.

3.1. Simulation design

In the simulation, we compare the method we propose, i.e., a constrained method to identify cheaters during the test, with a method without constraints. We compare the goodness of the ability estimates for both the methods by considering bias and RMSE. In addition, as for the constrained method, we keep track of the times a student has been correctly identified as a cheater or as not a cheater to check for the classification accuracy of the approach.

Both methods were tested in different simulated scenarios, in which some characteristics are kept fixed and other characteristics are manipulated.

- $n = 100$.
- Fixed length CAT with $K = 35$.
- For each student we simulated θ_i and ζ_i from a bivariate normal distribution (van der Linden et al. 2007, van der Linden et al. 2016, Fox et al. 2021) with mean equal to zero and an assumed negative correlation (-0.5), so, on average, more proficient students tend to respond more slowly, not to risk mistakes, while less proficient students tend to underestimate the test and respond quickly. Of course, this does not exclude the possibility that more proficient students respond faster because they understand the item.
- 20% of the students are *cheaters*. θ_i and ζ_i of *cheaters* follow the same distribution as the other students. A *cheater* is assumed to always respond correctly to items on which she/he has pre-knowledge, regardless of her/his ability and the item difficulty. A *cheater* responds faster than average to items on which she/he has pre- knowledge.

- RTs that *cheaters* take to respond to items on which they have pre-knowledge depends on the scenario and can be equal to ¼ or ½ of the time that it would take in case they were not cheaters.
- The number of items in the main database on which the *cheaters* have pre-knowledge depends on the scenario and can be 50%, 75% or 100% of the total. It is also assumed that *cheaters* have no item pre-knowledge for the *more secure* database.
- The main database consists of 170 items taken from the *Credential Form* database (available in the *R* package `LNIRT`; Fox et al., 2021), whose psychometric characteristics (α, β, φ and λ) have been estimated using the *R* package `LNIRT`. The *more secure* database is mirrored to the main one, therefore it contains items with the same psychometric characteristics.

The simulations were performed on *R studio* using the packages: `LNIRT` (Fox et al., 2021), `ShadowCAT` (Karel-Kroeze, 2017) and `catIrt` (Steven Nydick, 2022). Each scenario (2 speed multiplier and 3 item pre-knowledge proportion, for a total of 6 scenarios) has been simulated 100 times (keeping fixed person and item parameters) and the results reported in the next paragraph are the average of the simulation results.

3.2. Results

Table 1 shows the bias and RMSE of the ability estimates for the two methods (unconstrained and constrained) for different levels of pre-knowledge (p-k) of cheaters, by keeping the speed multiplier equal to 4.

Table 1: Ability estimates for different levels of pre-knowledge (speed multiplier equal to 4).

Methods	RMSE	BIAS	BIAS CHEATERS	BIAS NON-CHEATERS	ACCURACY CHEATERS[a]
No constraints (p-k 50%)	0.288	0.196	0.861	0.030	0
No constraints (p-k 75%)	0.968	0.398	1.869	0.030	0
No constraints (p-k 100%)	7.238	1.212	5.940	0.030	0
Constraints (p-k 50%)	0.095	0.050	0.128	0.030	0.940
Constraints (p-k 75%)	0.094	0.055	0.153	0.030	0.974
Constraints (p-k 100%)	1.847	0.338	1.571	0.030	0.790

[a] Indicates the ratio of times the model correctly identified a cheater to the total number of cheaters.

As can be seen from Table 1, the use of the constrained method results in an improvement of the estimates compared to the non-constrained model (lower bias and RMSE), for all the three pre-knowledge levels. Also, from the separate bias analysis for cheaters and non-cheaters (columns 4 and 5 of Table 1), it is possible to notice that the bias of non-cheaters is the same for both methods.

However, as the level of pre-knowledge of cheaters increases, the bias grows, reaching high levels for 100% of pre-knowledge. This is also explained by the analysis of classification accuracy, in fact for cheaters, the constrained method goes from an accuracy of 0.94 for a 50% pre-knowledge, to an accuracy of 0.79 when the degree of pre-knowledge is 100.

Finally, the sensitivity level of the proposed method was also tested, decreasing the speed multiplier from 4 to 2. Lower speed multiplier results in a slight decrease in classification accuracy and a corresponding increase in bias and RMSE for low pre-knowledge levels, while it increases considerably for high pre-knowledge levels (clearly, the method without constraints is not affected by the different speed multiplier of cheaters).

Table 2: Ability estimates for different levels of pre-knowledge (speed multiplier equal to 2).

Methods	RMSE	BIAS	BIAS CHEATERS	ACCURACY CHEATERS[a]
Constraints (p-k 50%)	0.099	0.06	0.177	0.869
Constraints (p-k 75%)	0.159	0.087	0.312	0.922
Constraints (p-k 100%)	7.238	1.212	5.940	0

[a] Indicates the ratio of times the model correctly identified a cheater to the total number of cheaters.

4. Concluding remarks

In conclusion, the method proposed for the identification of cheaters during the test, with the introduction of a new *interim* person fit statistic $l_{i_m}^t$, fully meets expectations: it manages to considerably improve the estimates of cheaters' ability, while not going to affect those of non-cheaters. In fact, as confirmed also by an analysis carried out on the degree of classification accuracy, the constrained method has been able to identify non-cheaters as such 100% of the time.

Although, this improvement tends to decrease, even considerably, both when the percentage of cheaters' pre-knowledge increases and when their speed multiplier decreases. This decrease in classification accuracy is due to an important limitation of this method, which this preliminary analysis has shown, namely the fact that statistic (4) reacts well to a change in speed, however, if a student keeps her/his speed more or less constant throughout the test (and a cheater who knows all the answers will have a very high speed and always constant), then the statistic has more difficulty to identify a cheater. Surely this is an important aspect to take into account for the improvement of the method.

A possible idea to improve this limitation could be to administer, during the initial stages of the test, items from the more secure database to those who have a high interim speed estimate (3). In this way, cheaters who will face a question of which they do not know in advance the answer will tend to slow down and the statistic will be able to better identify them. This would also help to better distinguish those who have item pre-knowledge from those who make *fast guessing* (not knowing the answer, they choose it very quickly at random).

Future developments will test this as well as analysing the issue of item exposure and fast guessing in more complex scenarios than those shown in this preliminary study.

Abstract

We explore the relationship between ammonia (NH_3) emissions and manure processed in the Lombardy region (Italy) at the sub-regional level (i.e., the agrarian subregions). We propose a two-step spatio-temporal statistical analysis. In the first step, we use several spatio-temporal specifications of area-level Small Area (SAE) Models to obtain credible estimates of the quantity of animal manure processed for each agrarian subregion from 2016 to 2020 using data provided by the Italian Farm Accountancy Data Network annual survey. In the second step, we perform an exploratory data analysis studying the empirical relationship between NH_3 emissions and manure processed. Preliminary results reveal a strong positive but non-linear relationship between processed manure and ammonia emissions generated by livestock farms.

Keywords: Small Area Models; Spatio-temporal statistics; Manure and livestock; Lombardy; Ammonia emissions

1. Introduction

Ammonia (NH_3) is a crucial contributor to air pollution levels, as it can become particulate matter after combining with other pollutant materials from various sources. Reducing ammonia emission limits both the potential for air pollution and the wider environmental impact associated with nitrogen pollution. Around 75% of European ammonia emissions come from livestock production. Emissions occur at all stages of manure management: from buildings housing livestock; during manure storage; following manure application to land; and from urine deposited by livestock on pastures during grazing (3).

Specifically, the Lombardy Region of Italy is characterized by high intensity of production and concentration of crops and livestock, mainly in the plains area in the South (1). In this framework, the difficulty of the relationship between agricultural activities and the environment is evident. This situation is also exacerbated by the fact that, in the last decades, the imbalance between animal breeding activities and land used for animal feed production increased. In principle, it is possible to avoid large

part of ammonia emissions from agricultural activities. This is possible if sufficient investments are made in suitable technologies or infrastructures. However, such investments can be very expensive. The burden can be particularly onerous for the many farms that do not have access to external financial support and for which long-term investments are very challenging. However, some interventions require only minor management changes, and although they may make only modest gains, any reduction in emission rates contributes to an overall net benefit. Therefore, even for farms where investment is not possible, minor improvements in existing management can still help achieve emission reduction targets.

Motivated by important production and policy implications, this article investigates the relationship between ammonia emissions and manure processing in the Lombardy region, Italy, using different data sources, including the Italian Farm accountancy data network (FADN). From a methodological point of view, we propose a two-step spatio-temporal statistical analysis. Each step is associated with a specific goal. In the first step, we aim at obtaining a reliable estimate of the manure processed at the sub-regional level by implementing spatio-temporal Small Area Estimation (SAE) techniques (2). In the second step we explore the empirical relationship between manure and NH_3 emissions for sub-regions using a data-driven statistical analysis.

The research is part of the Agrimonia (1) project (https://agrimonia.net/), an international research group that aims at quantifying the influence of agriculture on local air quality for Lombardy region using statistical learning and data science methodologies.

2. Data and pre-processing

Data used in this paper are collected from several institutional sources and comprise survey sampling data, census (administrative) information, and satellite measurements.

The farm-level annual data from 2016 to 2020 are provided by Italian Farm Accountancy Data Network (FADN). The FADN is an annual sample survey established by the European Economic Commission in 1965, with EEC Regulation 79/56 and updated with EC Reg. 1217/2009 and subsequent amendments. It has been carried out in Italy since 1968 with a similar approach in all Member States of the European Union and represents the only harmonized source of micro-level data on the evolution of incomes and production systems, and on the economic-structural dynamics of farms. Italian FADN provides yearly information on the economic (balance sheet and the income statement), productive, and structural characteristics of Italian farms. At the national level, the annual sample counts about 11000 farms, while the Lombardy sample includes around 600 farms corresponding to a grand total of about 34 thousand farm companies.

According to the Italian FADN, Lombardy is partitioned into the so-called *agrarian sub-regions*, that is, internally homogeneous areas with similar agricultural characteristics (e.g., Oltre Po Pavese for wine production or Lomellina for rice production). Officially, Lombardy is partitioned into 77 areas. However, some of them have very few or even none farms in the regional sample.Therefore, we performed a spatial aggregation of the poorly represented territories, eventually obtaining 66 areas. In Figure 1, we represent the spatial distribution of the farms across the sub-regions. The figure shows that farms are heterogeneously distributed throughout Lombardy. Indeed, farms are mainly concentrated in the southeastern plain, where the region's large intensive livestock farms are located, while the alpine areas in the North are poorly covered. This fact is consistent with the morphological conformation of the region, with the sparsely inhabited mountain range of the Alps and little agricultural space at North, and the intensively agriculture-oriented Po Valley at South.

For each farm, among the other information, FADN provides annual measurements of the total amount (quintals) of manure produced by swine and bovines and the total amount of manure processed (i.e., spread across the agricultural land). Farm-level data are then aggregated at the area-level by employing the sampling weights representative of the overall regional population[1]. Specifically, farm-level quantities of manure produced and processed are aggregated to area-level measurements through the

[1]The regional samples are built using a stratification approach based on two criteria: economic size (production volume) and techno-economic orientation (https://rica.crea.gov.it/APP/documentazione/?tag=ote). Also, only farms with at least 8000â¬$of standard output production are considered.$

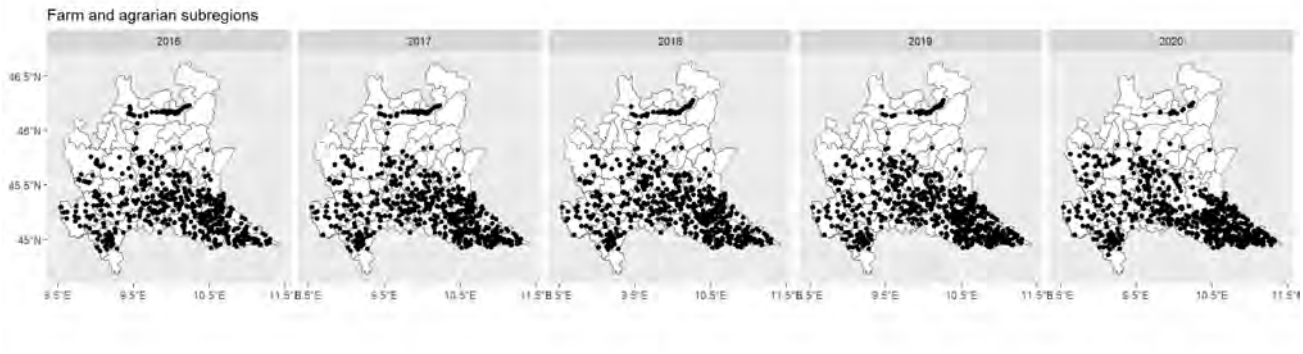

Figure 1: Agrarian sub-regions of Lombardy and spatial distribution of sampled farms from 2016 to 2020.

Hájek direct estimator of the mean (see Section 2.8.2 of (2)), denoted as $\hat{\bar{y}}$.

Further, we consider census information on livestock from the Banca Dati Nazionale Veterinaria (BDN). Data are collected at the municipal level for the whole period and then aggregated at the sub-regional level as the total number of heads per area. Data on NH_3 emissions (kg/hm^2) from the livestock sector management are collected from the CAMS-anthropogenic emissions dataset. Starting from the total annual emissions on $0.1° \times 0.1°$ grid, the total emissions of each agricultural subregion are given by the sum of the cells in the area. The amount of manure spread in the soil depends on the agricultural land available and the quality of the terrain. Therefore, we consider soil use information gathered from the Lombardy Region Agriculture Information System (SIARL). In particular, we extracted the total agricultural land surface (hm^2) and the total surface of soil classified as high-quality agricultural land (hm^2). Finally, we consider the average elevation of the sub-regions provided by ISTAT. Full data descriptions on BDN livestock, CAMS emissions data and SIARL data are available in (1).

The final dataset is structured in a longitudinal format with yearly data from 2016 to 2020 ($T = 5$) and $N = 66$ cross-sectional units, i.e., the agrarian sub-regions.

3. Empirical strategy

The proposed two-step analysis approach combines several statistical methodologies for modeling spatiotemporal data. In the first step, the goal is to obtain reliable estimates of the quantity of animal manure processed for each agrarian subregion from 2016 to 2020. To do so, we employ several spatio-temporal specifications of area-level SAE models (2). The rationale behind SAE models is to refine a direct estimate of the population mean or the population total through linear mixed models capable of leveraging exogenous information (covariates) of phenomena correlated with the response variable. Specifically, we take advantage of auxiliary information on animals and soil to improve direct estimates of thousand tonnes of manure processed for each agrarian region, while also taking into account the spatio-temporal structure of the data.

Let d be a generic agrarian sub-region and t a generic year from 2016 to 2020. Also, let $\hat{\bar{y}}_{dt}$ be the direct estimate of the average processed manure (Hájek direct estimator) at time t at the agrarian subregion d obtained aggregating the survey data from the FADN. The SAE models can be expressed as a linear mixed model including a linear fixed effects (regression) component and a random effect component as follows:

$$\hat{\bar{y}}_{dt} = X_{dt}\beta + u_{dt} + e_{dt} \tag{1}$$

where X_{dt} is the design matrix of area-level covariates for year t, which includes the total number of cattle and pigs, the total agricultural land, the amount of land with highly-rated agricultural value, and the average elevation of the agrarian subregion d at time t. The term u_{dt} is a model-specific random effect that accounts for purely random, spatial, or spatio-temporal effects.

- Simple Fay-Herriot model with area-level covariates (hereafter FH), i.e., yearly-specific LMM where sub-regions are linked from independent random effects;
- Spatial FH model with Queen contiguity structure for the neighbors and area-level covariates (hereafter SFH), i.e., a yearly-specific LMM where sub-regions are linked from spatially-correlated random effects;
- Spatio-temporal FH model with independent domain-time random effects and area-level covariates (hereafter STFH), i.e., LMM where sub-regions are linked from spatially-correlated random effects in addition to an independent time random effect;
- Spatio-temporal FH model with autoregressive AR(1) domain-time random effects and area-level covariates (hereafter STFH-AR1), i.e., LMM where sub-regions are linked from spatially-correlated random effects plus an AR(1)-like temporal random effect.

In model FH, u_{dt} is a collection of independent Gaussian distributed random variables; in model SFH they are a collection of spatially correlated following a simultaneously autoregressive (SAR) process with Queen proximity matrix; in STFH, in addition to the spatial effect, we include a temporal random effect using a sequence of mutually uncorrelated Gaussian random variables and uncorrelated in space; in model STFH-AR1, the previously stated temporal random effects follow an AR(1) temporal structure. Eventually, e_{dt} is the sampling error term.

The second step consists of an exploratory data analysis (EDA) of the empirical relationship between NH_3 emissions and manure processed. We propose to employ several spatio-temporal linear models, that is Linear Models (LMs), LMMs, and Generalized Additive Models (GAMs) (4). In particular, LMMs and GAMs are implemented to accommodate non-linear relationships and to exploit the spatiotemporal dynamics of the observations. Let $\hat{M}_{dt}$ be EBLUP estimate (2) of the total annual amount of manure processed for region d at time t computed from the SAE models in the first step. Further, let E_{dt} be the NH_3 emissions for region d and year t. Then, the ammonia-manure relationship can be specified as follows:

$$E_{dt} = f(\hat{M}_{dt}) + \varepsilon_{dt} \tag{2}$$

where $f(\hat{M}_{dt})$ is a smooth function of the estimated region-and-year-specific manure processed, and ε_{dt} is an error term. Depending on the specification of the model, the smooth function $f(.)$ can be set with a linear form (for LMs) or with a non-linear form, e.g., with an expansion of splines bases in GAMs. Eventually, the error term ε_{dt} is defined as a i.i.d. term.

4. Results

For the sake of brevity, here we report only the essential results relevant to the understanding of the phenomenon of interest. Extensive analyses and full results are available at the following GitHub webpage https://github.com/PaoloMaranzano/PM_KMC_PO_FC_ManureSAE.

The main findings can be summarized as follows. First, the use of SAE specifications that account for spatio-temporal effects strongly improves the fit to the data. In fact, both AIC and BIC identify STFH, which includes independent spatial and temporal effects, as the best model. Second, we consider the estimated quantities of manure and the degree of territorial heterogeneity. As previously stated, farms are mainly concentrated in the southern area of Lombardy, that is the Po Valley. Comparing the annual estimates reported in Figure 2, it can be observed that the direct estimator (upper panel), which does not use auxiliary information, shows poor territorial heterogeneity, except for some areas with higher density. On the contrary, the STFH estimates (lower panel), which make use of covariates, such as the number of animals, and that explicitly shape the spatiotemporal dynamics of the data, highlight how the agricultural subregions in the southeast process much more manure than the rest of the region. Further analyses show

that the heterogeneity of the SAE models is strongly guided by the total number of animal heads, that is, by the actual source of manure. Eventually, the variability of the estimates (i.e., the coefficient of variability) computed on the direct estimates tends to be much higher than that of the SAE models when the number of sampled companies in the areas is small, while for large samples, the variability is very similar.

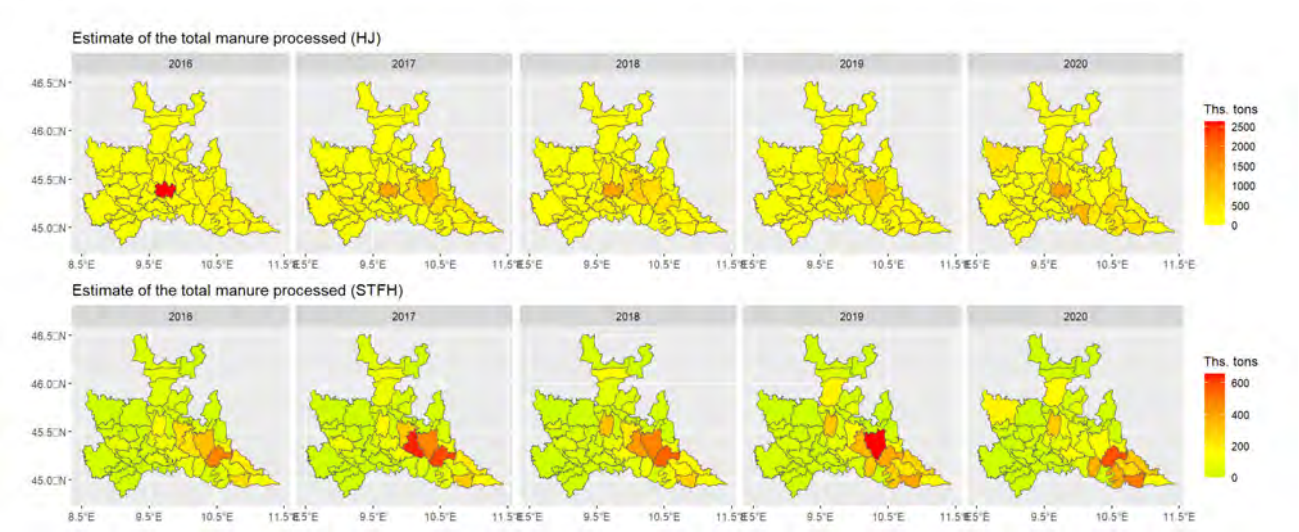

Figure 2: Upper panel: direct estimate (Hájek estimator) of the total manure processed by agrarian subregion. Lower panel: estimated total manure processed using the spatio-temporal Fay-Herriott model with independent temporal effects and spatial random effect (STFH model).

In Figure 3 we report the empirical relationship among the estimated quantity of manure processed from model STFH and the NH_3 emissions by livestock farms. The plot reveals a strongly positive but non-linear relationship between the two quantities, meaning that a high concentration of livestock farms and the following spread of manure is associated with a higher, but not proportional, emissions of NH_3 in the atmosphere. The non-linearity is well identified by the regression models reported in Table 1, in which the flexible regression models are able to detect the positive relationship while providing better fitting performances.

5. Conclusions and policy implications

Ammonia is released in large quantities by livestock production. Poor manure management practices, which are common issues worldwide, can lead to significant emissions of greenhouse gas methane, as well environmental degradation, negative health impacts, and the loss of valuable nutrients that could be added to soil. Suitable policies could facilitate changes in manure management practices at local levels. This study proposes a statistical approach that allows to provide a knowledge on the spatio-temporal relationships between livestock farms present in the sub-regional areas and the levels of ammonia, facilitating knowledge sharing and support for selective interventions of policy.

Bayesian multi-species N-mixture models for large scale spatial data in community ecology

Michele Peruzzi[a]

[a]Department of Statistical Science, Duke University; michele.peruzzi@duke.edu

Abstract

Community ecologists seek to model the local abundance of multiple animal species while taking into account that observed counts only represent a portion of the underlying population size. Analogously, modeling spatial correlations in species' latent abundances is important when attempting to explain how species compete for scarce resources. We develop a Bayesian multi-species N-mixture model with spatial latent effects to address both issues. On one hand, our model accounts for imperfect detection by modeling local abundance via a Poisson log-linear model. Conditional on the local abundance, the observed counts have a binomial distribution. On the other hand, we let a directed acyclic graph restrict spatial dependence in order to speed up computations, and use recently developed gradient-based Markov-chain Monte Carlo methods to sample a posteriori in the multivariate non-Gaussian data scenarios in which we are interested.

Keywords: multi-species N-mixture, spatial, gradient-based MCMC, large scale data, Bayesian, multivariate

1. Introduction

The total number of individuals of a certain animal species in a region is known as the local abundance. A species' local abundance is influenced by environmental factors as well as the abundance of other species, in a context of resource scarcity. For example, two bird species might eat from the same food source; if food is scarce, one might expect the abundance of the two species to exhibit negative spatial correlations. Thus, the local abundance of one species should be negatively correlated with abundance of the other species, and this negative correlation should reduce in magnitude at longer spatial distances. Even when resources are not scarce, presence of some species in a territory might inform about the likelihood of other species also occupying the same territory.

Community ecologists seek to estimate abundance using spatially replicated count data of multiple species. There are two issues in this context. First, the data dimension is massive because it is increasingly typical to collect abundance data at a large number of spatial locations (large n) and for a large number of species (large q). Second, at each spatial location, the observed counts correspond to only a portion of the latent abundance of each of the q species. This phenomenon is referred to as *imperfect detection*. See (9), (5) and reference therein. In this article, we introduce a Bayesian model for multivariate spatially oriented count data in the presence of imperfect detection and outline the related posterior sampling algorithm. We illustrate the model on simulated data as well as data from the North American Breeding Bird Survey.

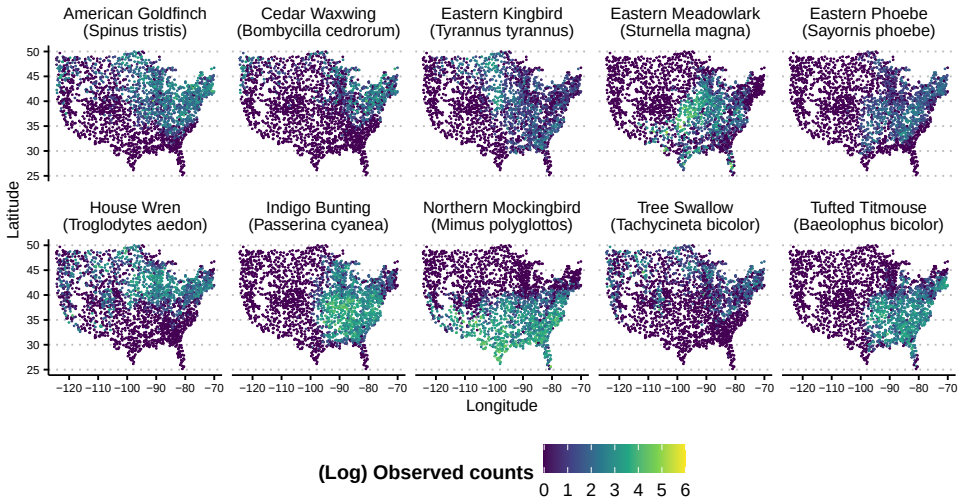

Figure 1: Observed counts of 10 bird species from the North American Breeding Bird Survey data, 2019.

2. Multi-species N-mixture modeling with spatial random effects

In joint species distribution models of count data, local abundance can be modeled via a Poisson log-linear model as depending on covariates and latent variables accounting for cross-species dependence. Conditional on the local abundance, the observed counts have a binomial distribution. We consider an extension of the model of (5) and include coregionalized Gaussian process random effects to model cross-species spatial dependence:

$$\begin{aligned} v_h(\cdot) &\sim GP(\mathbf{0}, \rho_h(\cdot,\cdot;\boldsymbol{\theta}_h)), & h &= 1,\dots,k \\ w_j(\boldsymbol{\ell}) &= \boldsymbol{\lambda}_{[j,:]}\boldsymbol{v}(\boldsymbol{\ell}) & j &= 1,\dots,q \\ N_j(\boldsymbol{\ell}) \mid \boldsymbol{\beta}_j, \boldsymbol{\lambda}_{[j,:]}, \boldsymbol{v}(\boldsymbol{\ell}) &\sim \text{Poisson}(\mu_j(\boldsymbol{\ell})) & \mu_j(\boldsymbol{\ell}) &= \exp\{\boldsymbol{x}_j(\boldsymbol{\ell})^\top \boldsymbol{\beta}_j + w_j(\boldsymbol{\ell})\} \\ y_j(\boldsymbol{\ell}) \mid N_j(\boldsymbol{\ell}), \boldsymbol{\xi}_j &\sim \text{Binomial}\left(N_j(\boldsymbol{\ell}), p_j(\boldsymbol{\ell})\right) & p_j(\boldsymbol{\ell}) &= \left[1+\exp\{-\boldsymbol{z}_j(\boldsymbol{\ell})^\top \boldsymbol{\xi}_j\}\right]^{-1}. \end{aligned} \tag{1}$$

The species-specific covariates $\boldsymbol{x}_j(\boldsymbol{\ell})$ and $\boldsymbol{z}_j(\boldsymbol{\ell})$ explain the latent species abundance and the detection probability, respectively, leading to the observed counts $y_j(\boldsymbol{\ell})$. The latent factors $v_h(\cdot)$ characterizing latent spatial and cross-species dependence. Their number $k \leq q$ can be chosen to reduce the computational complexity of the resulting posterior sampling algorithm, see (8) for additional details. A larger number of factors may aid in more accurately making predictions, at the cost of interpretability and model complexity. It is in general difficult to strike a good balance between model expressiveness and computational efficiency. One option is to use cumulative shrinkage priors acting on columns of $\boldsymbol{\Lambda}$ to adaptively learn the number of factors, see e.g. (1).

2.1 Estimation and prediction

In the context of (1), we are interested in estimating $\boldsymbol{\beta}_j$ and $\boldsymbol{\xi}_j$ for $j = 1,\dots,q$, the cross-covariance function $\boldsymbol{C}_{\boldsymbol{\theta}} = \boldsymbol{\Lambda}\boldsymbol{\rho}(\boldsymbol{\ell},\boldsymbol{\ell}',\boldsymbol{\Phi})\boldsymbol{\Lambda}^\top$ and specifically $\boldsymbol{\theta} = (\text{vec}(\boldsymbol{\Lambda})^\top, \boldsymbol{\Phi}^\top)^\top$, where $\boldsymbol{\Phi} = (\boldsymbol{\theta}_1^\top,\dots,\boldsymbol{\theta}_k^\top)^\top$, and the local abundance of species j at $\boldsymbol{\ell}$, $N_j(\boldsymbol{\ell})$. Posterior computations for (1) simplify by marginalizing $N_j(\boldsymbol{\ell})$ from the model likelihood: $p(y_j(\boldsymbol{\ell}) \mid —) = \text{Poisson}\left(p_j(\boldsymbol{\ell})\mu_j(\boldsymbol{\ell})\right)$. After collecting posterior samples of $\boldsymbol{\beta}_j, \boldsymbol{\xi}_j, \boldsymbol{\Lambda}, \boldsymbol{v}$, we move to estimating $N_j(\boldsymbol{\ell})$, the latent abundance of species j. If we have observed $y_j(\boldsymbol{\ell})$ individuals at $\boldsymbol{\ell}$, then we can use the fact that $N_j(\boldsymbol{\ell}) \mid N_j(\boldsymbol{\ell}) > y_j(\boldsymbol{\ell}) = y_j(\boldsymbol{\ell}) + \widetilde{N}_j(\boldsymbol{\ell})$, where we define $\widetilde{N}_j(\boldsymbol{\ell}) \sim \text{Poisson}([1-p_j(\boldsymbol{\ell})]\mu_j(\boldsymbol{\ell}))$. On the other hand, if the count variable $y_j(\boldsymbol{\ell})$

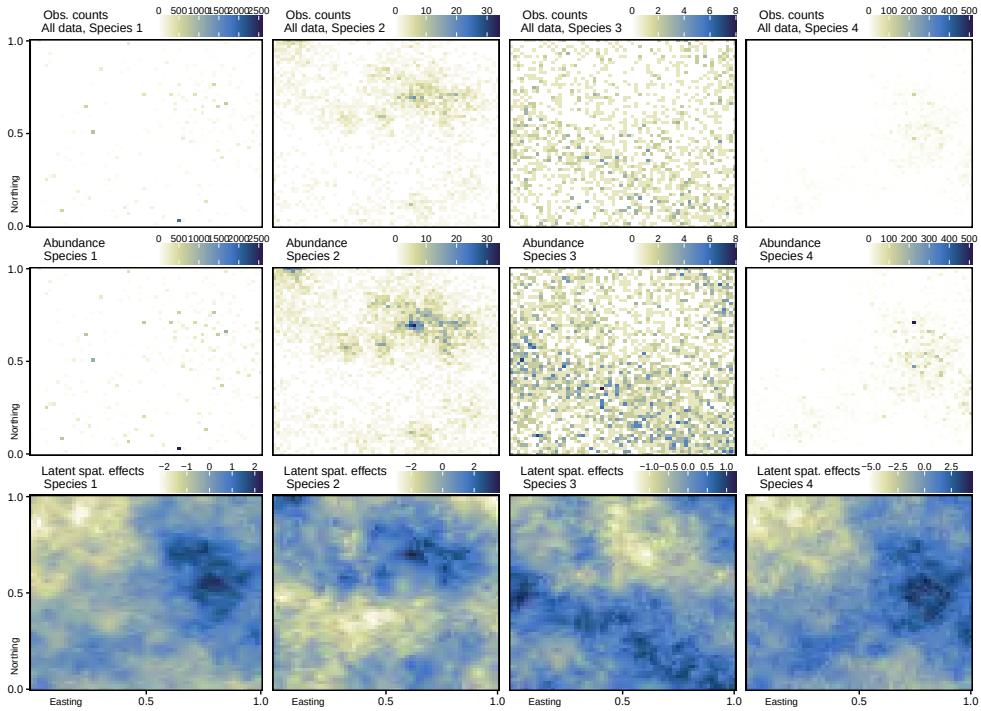

Figure 2: Simulated observed data and latent variables for four of the total twelve species in the simulated data illustration.

is missing at $\boldsymbol{\ell}$, we proceed by first sampling from $\pi(\boldsymbol{v}(\boldsymbol{\ell}) \mid \boldsymbol{v}_{\mathcal{T}}, \boldsymbol{\Phi})$, where $\mathcal{T}$ is the set of locations at which the counts of at least one species are observed. Then, $N_j(\boldsymbol{\ell}) \sim \text{Poisson}(\mu_j(\boldsymbol{\ell}))$.

2.2 Gradient-based posterior sampling

Posterior computations of model 1 are complex due to the high dimensionality of the data; specifically, using a GP prior on the latent spatial effects leads to well-known bottlenecks. We thus simplify computations by replacing the GP prior with a cubic meshed GP (QMGP) prior (7). A QMGP restricts spatial dependence by making conditional independence assumptions as prescribed by a fixed directed acyclic graph (DAG). Rather than doing so via neighbor search (see, e.g., (10; 2; 4) and reference therein), a QMGP is built by first tessellating the spatial domain using axis-parallel domain partitioning, then associating each partition to a node in a DAG whose properties are data-independent, leading to improved computations via blocking and parallelization. Similar models are popular for replacing a parent GP and may lead to provable accuracy in approximating it (11). In practice, computing the posterior amounts to a large Gibbs sampler which visits each node of the Bayesian model DAG–i.e., $\boldsymbol{\beta}_j$, $\boldsymbol{\lambda}_{[j,:]}$, $\boldsymbol{\xi}_j$ for $j = 1, \ldots, q$ –as well every node of the prior DAG. Because the data are counts, however, the Markov-chain Monte Carlo (MCMC) updates will need to involve a proposal distribution and accept/reject steps. We consider proposals of the following general form

$$\begin{aligned} q(\boldsymbol{x}_i^* \mid \boldsymbol{x}_i) &= N\left(\boldsymbol{x}_i + \varepsilon_i^2 \boldsymbol{M} \nabla_{\boldsymbol{x}_i} \log p(\boldsymbol{x}_i \mid —)/2, \varepsilon_i^2 \boldsymbol{M}\right), \\ \text{i.e.} \quad \boldsymbol{x}_i^* &= \boldsymbol{x}_i + \frac{\varepsilon_i^2}{2} \boldsymbol{M} \nabla_{\boldsymbol{x}_i} \log p(\boldsymbol{x}_i \mid —) + \varepsilon_i \boldsymbol{M}^{\frac{1}{2}} \boldsymbol{u}, \end{aligned} \tag{2}$$

where $\boldsymbol{x}_i$ is a node in the Bayesian DAG and $p(\cdot)$ is the full conditional distribution of node $\boldsymbol{x}_i$, conditional on its Markov blanket. The Markov blanket of $\boldsymbol{x}_i$ includes nodes with edges directed to $\boldsymbol{x}_i$ (the parents), the set of nodes with edges from $\boldsymbol{x}_i$ (the children), as well as the set of nodes that are parents of nodes of which $\boldsymbol{x}_i$ is also a parent (the co-parents).

Updating via 2 amounts to a preconditioned Metropolis-adjusted Langevin algorithm (MALA), where $\boldsymbol{M}$ is the preconditioning matrix. Choosing a good preconditioner is not straightforward in the

Method	Time (s)	ESS/s $\boldsymbol{w}(\cdot)$	RMSE $N_j(\boldsymbol{\ell})$	RMSE $(\beta, \boldsymbol{\xi}, \boldsymbol{\lambda}_{[j,:]})$	ESS/s $(\beta, \boldsymbol{\xi}, \boldsymbol{\lambda}_{[j,:]})$

Table 1: A comparison of posterior sampling methods for fitting the same model for abundance data with imperfect detection based on latent QMGPs. We compare the root mean squared error (RMSE) in estimating the latent abundance $N_j(\boldsymbol{\ell})$, averaged across the 12 species. For $\boldsymbol{w}_j(\boldsymbol{\ell})$, we report the median effective sample size (ESS) per unit time across spatial locations. We also report the RMSE and median ESS/s in estimating the vector $(\beta, \boldsymbol{\xi}, \boldsymbol{\lambda}_{[j,:]})$, averaged across species.

contexts in which we operate. For improved sampler efficiency, we use the simplified manifold preconditioner adaptation (SiMPA) method of (8). SiMPA is a gradient-based method that adapts the preconditioner of a Metropolis-adjusted Langevin algorithm using second-order information about the target, using similar intuitions but simpler computations relative to the simplified Riemannian-manifold method of (3). In the context of model 1, one just needs to compute the negative Hessian matrix for updating all parameters in a SiMPA-within-Gibbs scheme.

3. Illustration: simulated data

We simulate abundance data of $q = 12$ species at n =3600 spatial locations on a regular grid using model (1). We sample $k = 3$ latent factors from independent unrestricted GPs with exponential correlation and spatial decays $\phi_1 = \phi_2 = \phi_3 = 1.5$. We sample $\lambda_{jh} \sim N(0, 1)$ independently for $j = 1, \ldots, q$, $h = 1, \ldots, k$, $h \leq j$, and set $\lambda_{jh} = 0$ if $h > j$. In order to generate the latent abundance and the observed counts at each location, we sample the covariate vector $(x(\boldsymbol{\ell}), \boldsymbol{z}(\boldsymbol{\ell})^\top)^\top$ independently from a Gaussian distribution with correlation matrix Σ_x whose off-diagonal elements are $\sigma_{x,z_1} = 0.8$, $\sigma_{x,z_2} = -0.3$ $\sigma_{z_1,z_2} = -0.7$. We sample each element of $\boldsymbol{\beta}_j$ and $\boldsymbol{\xi}_j$ independently from a standard normal distribution. Finally, for each of the 12 species, we introduce missingness by independently dropping 20% of the observed count data from the training set uniformly at random. As a consequence, not all species are observed at all spatial locations, thus mirroring a setting in which a subset of the total number of individuals of species j are counted at a subset of all locations. Figure 2 shows a subset of the data.

We fit model (1) with a QMGP prior on the latent effects. To build the QMGP prior, we use axis-parallel partitioning to tessellate the spatial domain into 36 blocks each including 100 spatial locations. We choose this partitioning setup to ensure all sampling methods proceed swiftly and without making the overly restrictive spatial conditional independence assumptions that would result from a finer partitioning scheme.

We compare our proposed SiMPA with MALA, simplified Riemannian manifold MALA (3) which we label SM-MALA, and the elliptical slice sampler of (6). All methods perform 20,000 MCMC iterations, of which we drop the first half as burn-in. As shown in Table 1, SiMPA is on par or better than other state-of-the-art methods when estimating unknown model parameters, but outperforms them in terms of sampling efficiency measured as ESS per unit time.

4. North American Breeding Bird Survey data

The North American Breeding Bird Survey dataset contains avian point count data for more than 700 North American bird taxa (species, races, and unidentified species groupings). These data are collected

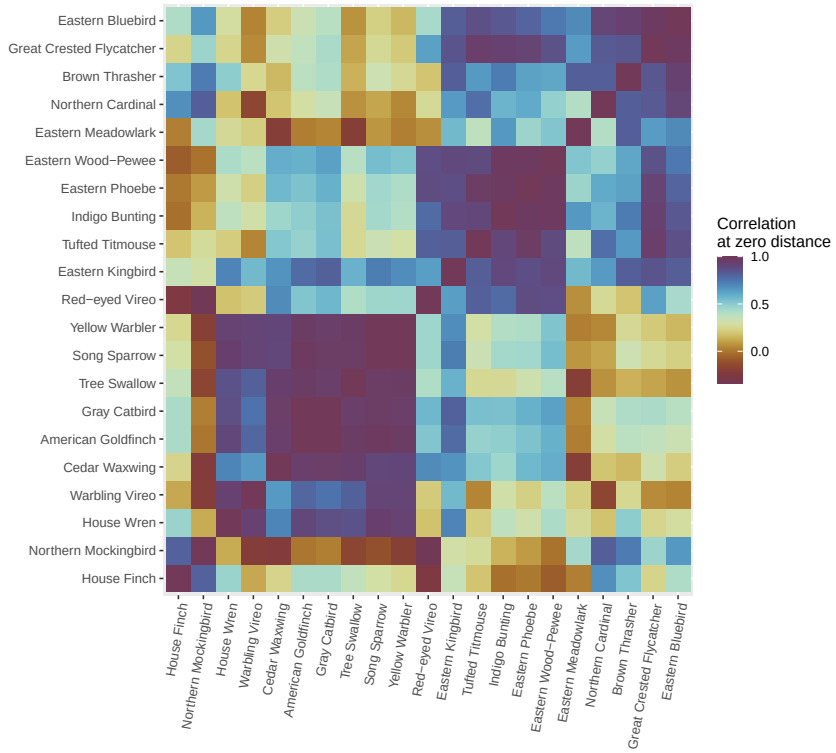

Figure 3: Latent correlation at zero spatial distance between the local abundance of the bird species under consideration.

annually during the breeding season, primarily June, along thousands of randomly established roadside survey routes in the United States and Canada.

We consider a dataset of $n = 2292$ locations spanning the continental U.S., and $q = 21$ bird species – Figure 1 shows a subset of the data. The effective data size is $nq = 48132$. We implement model 1 using $k = 4$ spatial factors and partitioning the spatial domain using a 6×6 axis-parallel tesselation to construct a QMGP prior for the latent effects. We seek to estimate the latent abundances using observed count data. We model the unobserved local abundance as depending on elevation, which we use as a spatially-referenced covariate. Because the data includes weather conditions during observation, we use cloud and wind data as covariates modeling imperfect detection. We perform 20000 MCMC iterations of SiMPA, of which we leave the first half as burn in. The total compute time is under 8 minutes running on 16 threads.

The results of our model fitting are summarized in Figure 3, which displays the latent correlations between bird species at zero spatial distance, and Figure 4, which maps the estimated local abundances for a subset of all species under consideration. In particular, following Section 2.1 we estimate that only about 63% of the total abundance of cedar waxwings have been observed in 2019, as well as 70% of the red-eyed vireo and 71 % of the Eastern meadowlark. Our model also estimates that elevation has a significant nonzero impact on the local abundance of 19 out of 21 species. For 17 of these species the effect is negative, i.e. the population size is reduced at higher altitudes.

Acknowledgments The author has received funding from the European Research Council (ERC) under the European Union Horizon 2020 research and innovation programme (grant agreement No 856506), and grant R01ES028804 of the United States National Institutes of Health (NIH).

Minimum contrast for point processes' first-order intensity estimation

Nicoletta D'Angelo[a] and Giada Adelfio[a]

Abstract

In this paper, we exploit some theoretical results, from which we know the expected value of the K-function weighted by the true first-order intensity function of a point pattern. This theoretical result can serve as an estimation method for obtaining the parameter estimates of a specific model, assumed for the data. The only requirement is the knowledge of the first-order intensity function expression, completely avoiding writing the likelihood, which is often complex to deal with in point process models. We illustrate the method through simulation studies for spatio-temporal point processes.

Keywords: Second-order characteristics, Spatial statistics, Spatio-temporal point processes, Local models, Minimum contrast

1. Introduction

In this work, we introduce some preliminary results of a novel point processes' first-order intensity estimation procedure. We start from the theoretical result related to the expectation of the weighted K-function, using the true first-order intensity function. This theoretical result can serve as an estimation method for obtaining the parameters' estimates of a specific model assumed for the data. Indeed, parameters in spatial-temporal point process models are typically estimated by maximum likelihood method or some of its variants. Such a novel procedure may become crucial to avoid dealing with the complex likelihoods of some point process models, like the ETAS process, and their maximization. By further considering the local second-order characteristics, we can obtain the whole set of parameters assumed for the fitted model, one for each point of the analysed point pattern.

The structure of the paper is as follows. Section 2. recalls spatio-temporal K-function and its estimator. Section 3. introduces the proposed method. Section 4. shows some provisional simulation results. Section 5. outlines future works.

2. The spatio-temporal K-function and its estimator

We consider a spatio-temporal point process with no multiple points as a random countable subset X of $\mathbb{R}^2 \times \mathbb{R}$, where a point $(\mathbf{u}, t) \in X$ corresponds to an event at $\mathbf{u} \in \mathbb{R}^2$ occurring at time $t \in \mathbb{R}$. A typical realisation of a spatio-temporal point process X on $\mathbb{R}^2 \times \mathbb{R}$ is a finite set $\{(\mathbf{u}_i, t_i)\}_{i=1}^n$ of distinct points within a bounded spatio-temporal region $W \times T \subset \mathbb{R}^2 \times \mathbb{R}$, with area $|W| > 0$ and length $|T| > 0$, where $n \geq 0$ is not fixed in advance. In the sequel, $N(A)$ denotes the number of events of the process falling in a bounded region $A \subset W \times T$.

For a given event $(\mathbf{u}, t)$, the events that are close to $(\mathbf{u}, t)$ in both space and time, for each spatial distance r and time lag h, are given by the corresponding spatio-temporal cylindrical neighbourhood of the event $(\mathbf{u}, t)$, which can be expressed by the Cartesian product as $b((\mathbf{u}, t), r, h) = \{(\mathbf{v}, s) : ||\mathbf{u} - \mathbf{v}|| \leq r, |t - s| \leq h\}, (\mathbf{u}, t), (\mathbf{v}, s) \in W \times T$, where $||\cdot||$ denotes the Euclidean distance in $\mathbb{R}^2$. Note that $b((\mathbf{u}, t), r, h)$ is a cylinder with centre (**u**, t), radius r, and height $2h$.

Product densities $\lambda^{(k)}$, $k \in \mathbb{N}$ and $k \geq 1$, arguably the main tools in the statistical analysis of point processes, may be defined through the so-called Campbell Theorem (2), which states that, given a spatio-temporal point process X, for any non-negative function f on $(\mathbb{R}^2 \times \mathbb{R})^k$

$$\mathbb{E}\left[\sum_{\zeta_1,\ldots,\zeta_k \in X}^{\neq} f(\zeta_1, \ldots, \zeta_k)\right] = \int_{\mathbb{R}^2\times\mathbb{R}} \cdots \int_{\mathbb{R}^2\times\mathbb{R}} f(\zeta_1, \ldots, \zeta_k)\lambda^{(k)}(\zeta_1, \ldots, \zeta_k) \prod_{i=1}^{k} \mathrm{d}\zeta_i,$$

that constitutes an essential result in spatio-temporal point process theory. In particular, for $k = 1$ and $k = 2$, these functions are respectively called the *intensity function* λ and the *(second-order) product density* $\lambda^{(2)}$.

(3) define the spatio-temporal inhomogeneous K-function and propose a non-parametric estimator for it.

Definition 1. *(3) A spatio-temporal point process is second-order intensity reweighted stationary and isotropic if its intensity function is bounded away from zero and its pair correlation function depends only on the spatio-temporal difference vector (r, h), where $r = ||\boldsymbol{u} - \boldsymbol{v}||$ and $h = |t - s|$.*

Definition 2. *(3) For a second-order intensity reweighted stationary, isotropic spatio-temporal point process, the space-time inhomogeneous K-function is*

$$K(r, h) = 2\pi \int_0^r \int_0^h g(r', h')r'dr'dh'$$

where $g(r, h) = \lambda^{(2)}(r, h)/(\lambda(\boldsymbol{u}, t)\lambda(\boldsymbol{v}, s)), r = ||\boldsymbol{u} - \boldsymbol{v}||, h = |t - s|$.

The simplest expression of an estimator of the spatio-temporal K-function is given as

$$\hat{K}(r, h) = \frac{1}{|W||T|} \sum_{i=1}^{n} \sum_{j>i}^{n} \mathbf{1}(||\mathbf{u}_i - \mathbf{u}_j|| \leq r, |t_i - t_j| \leq h). \tag{1}$$

For a homogeneous Poisson process it holds $\mathbb{E}[\hat{K}(r, h)] = \pi r^2 h$, regardless of the intensity λ. The spatio-temporal K-function can be used as a measure of spatio-temporal clustering and interaction (3). Usually, the estimate $\hat{K}(r, h)$ is compared with the theoretical $\mathbb{E}[\hat{K}(r, h)] = \pi r^2 h$. Values $\hat{K}(r, h) > \pi r^2 h$ suggest clustering, while $\hat{K}(r, h) < \pi r^2 h$ suggests a regular pattern.

The spatio-temporal inhomogeneous version of the K-function in (1) is given by (3) as

$$\hat{K}_I(r, h) = \frac{|W||T|}{n(n-1)} \sum_{i=1}^{n} \sum_{j>i} \frac{\mathbf{1}(||\mathbf{u}_i - \mathbf{u}_j|| \leq r, |t_i - t_j| \leq h)}{\hat{\lambda}(\mathbf{u}_i, t_i)\hat{\lambda}(\mathbf{u}_j, t_j)}, \tag{2}$$

where $\lambda(\cdot)$ is the first-order intensity at an arbitrary point. We know that $\mathbb{E}[\hat{K}_I(r, h)] = \pi r^2 h$, that is the same as the expectation of $\hat{K}(r, h)$ in (1), when the intensity used for the weighting is the true generator model. This is a crucial result that allows to use the weighted estimator $\hat{K}_I(r, h)$ as a diagnostic tool, for assessing the goodness-of-fit of spatio-temporal point processes with generic first-order intensity functions. Indeed, if the weighting intensity function is close to the true one $\lambda(\mathbf{u}, t)$, the expectation of $\hat{K}_I(r, h)$ should be close to $\mathbb{E}[\hat{K}(r, h)] = \pi r^2 h$ for the Poisson process. For instance, values $\hat{K}_I(r, h)$ greater than $\pi r^2 h$ indicate that the fitted model is not appropriate, since the distances computed among points exceed the Poisson theoretical ones.

Successively, (1) introduced local versions of both the homogeneous and inhomogeneous spatio-temporal K-functions, and used them as diagnostic tools, while also retaining for local information. Defining an estimator of the overall intensity by $\hat{\lambda} = n/(|W||T|)$, they propose the local version of (1) for the i-th event $(\mathbf{u}_i, t_i)$ as

$$\hat{K}^i(r,h) = \frac{1}{\hat{\lambda}^2|W||T|} \sum_{(\mathbf{u}_i,t_i)\neq(\mathbf{v},s)} \mathbf{1}(||\mathbf{u}_i - \mathbf{v}|| \leq r, |t_i - s| \leq h) \tag{3}$$

and the local version of (2) as

$$\hat{K}^i_I(r,h) = \frac{1}{|W||T|} \sum_{(\mathbf{u}_i,t_i)\neq(\mathbf{v},s)} \frac{\mathbf{1}(||\mathbf{u}_i - \mathbf{v}|| \leq r, |t_i - s| \leq h)}{\hat{\lambda}(\mathbf{u}_i, t_i)\hat{\lambda}(\mathbf{v}, s)}, \tag{4}$$

with $(\mathbf{v}, s)$ being the spatial and temporal coordinates of any other point. The authors proved that the inhomogeneous second-order statistics behave as the corresponding homogeneous ones, basically proving that the expectation of both (3) and (4) is equal to $\pi r^2 h$.

3. Proposal

Suppose that the intensity $\lambda(\mathbf{u}, t; \boldsymbol{\theta})$ (in brief: $\lambda(\boldsymbol{\theta})$) of the given point process model incorporates a vector of parameters $\boldsymbol{\theta} \in \Theta$. By minimizing

$$\mathcal{M}(\boldsymbol{\theta}) = \int_{h_0}^{h_{max}} \int_{r_0}^{r_{max}} \phi(r,h)\{(\hat{K}_I(r,h;\lambda(\boldsymbol{\theta})) - \pi r^2 h)\}^2 \mathrm{d}r\mathrm{d}h \tag{5}$$

with respect to $\boldsymbol{\theta}$, we obtain a vector of estimates $\hat{\boldsymbol{\theta}}$:

$$\hat{\boldsymbol{\theta}} = \arg\min_{\boldsymbol{\theta}\in\Theta} \mathcal{M}(\boldsymbol{\theta}).$$

Here r_0, h_0, r_{max} and h_{max} are the lower and upper space and time lag limits of the contrast criterion, and $\phi(r,h)$ is a weight that depends on the space-time distance.

For this purpose, we further suggest using a penalized objective function

$$\mathcal{M}^R_{tot}(\boldsymbol{\theta}) = \mathcal{M}(\boldsymbol{\theta}) + \mathcal{M}^R_{pen}(\boldsymbol{\theta})$$

by means of the radial penalization presented in (5)

$$\mathcal{M}^R_{pen}(\boldsymbol{\theta}) = \tau(||\boldsymbol{\theta} - \hat{\boldsymbol{\theta}}||_2 - R)^2,$$

where $||\boldsymbol{\theta} - \hat{\boldsymbol{\theta}}||_2 = \sqrt{\sum_{\boldsymbol{\theta}_j\in\Theta}(\theta_j - \hat{\theta}_j)^2}$, τ is the tuning parameter representing the penalization strength, and it is commonly selected as $1/R^2$ (5).

The penalty term $\mathcal{M}^R_{pen}(\boldsymbol{\theta})$ has its minimum at a sphere with radius R centered around $\hat{\boldsymbol{\theta}}$. The final estimates are found as

$$\boldsymbol{\theta}^* = \arg\min_{\boldsymbol{\theta}\in\Theta} \mathcal{M}^R_{tot}(\boldsymbol{\theta}).$$

Our proposal poses the basis for a local extension. Suppose that the model incorporates a vector of parameters $\boldsymbol{\theta}$. Let $\hat{K}^i_I(r,h;\lambda(\boldsymbol{\theta}))$ denote the local estimators calculated from the data. For each point indexed by i we consider

$$\mathcal{M}_{local}(\boldsymbol{\theta}_i) = \int_{h_0}^{h_{max}} \int_{r_0}^{r_{max}} \phi(r,h)\{(\hat{K}^i_I(r,h;\lambda(\boldsymbol{\theta})) - \pi r^2 h)\}^2 \mathrm{d}r\mathrm{d}h.$$

Then, we can obtain a vector of estimates $\hat{\boldsymbol{\theta}}_i$, one for each point i, as

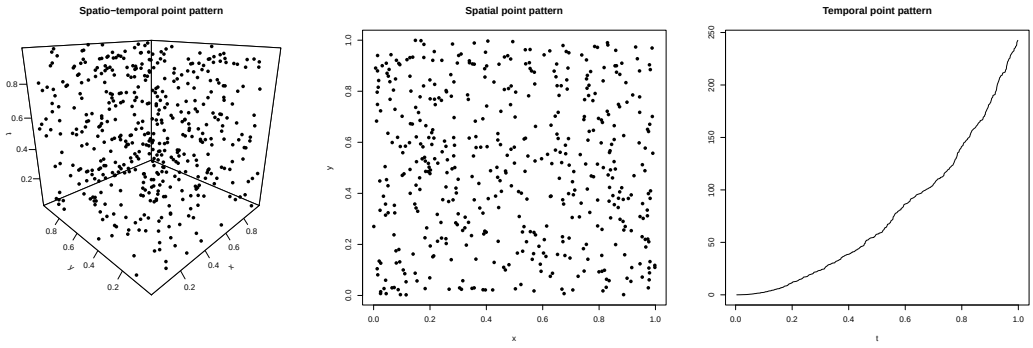
$$\hat{\boldsymbol{\theta}}_i = \arg\min_{\boldsymbol{\theta}\in\Theta} \mathcal{M}_{local}(\boldsymbol{\theta}_i).$$

4. Simulations

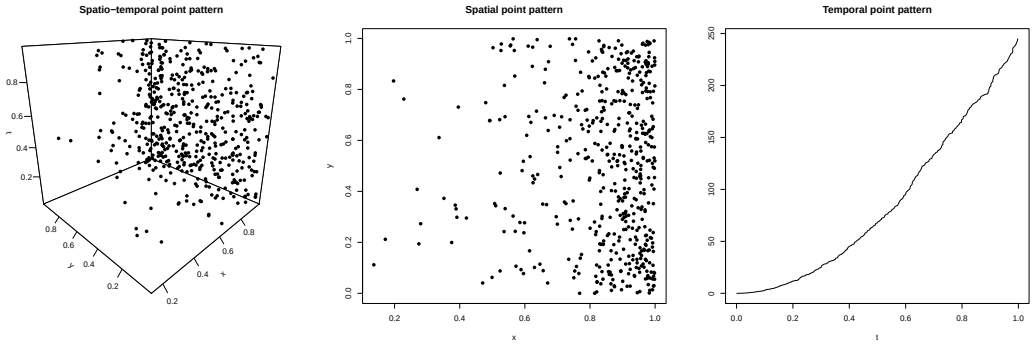
In this section, we report some provisional simulation results, for assessing the proposed estimation procedure. We simulate 1000 space-time point patterns in the unit cube with $n = 500$ number of points on average from the following point processes:

- homogeneous Poisson process with constant intensity λ;
- inhomogeneous Poisson process with intensity $\lambda(x, y, t) = \exp(\alpha + \beta x)$.

Examples of such simulated patterns are in Figure 1.



(a) Realization of a homogeneous point process with intensity $\lambda(x, y, t) = 500$



(b) Realization of an inhomogeneous point process with intensity $\lambda(x, y, t) = \exp(2 + 6x)$

Figure 1: Space and time locations of two examples of simulated homogeneous and inhomogeneous patterns.

Table 1 reports the $mean$, $RMSE$, and the mean of the standard errors ($mean(s.e.)$) of the estimated of the two considered processes, averaged over 1000 simulations. In particular, the spatial and temporal distances in the observed weighted K-functions are 15 values ranging from 0 to r_{max} and h_{max} in Equation (3), equal to 1/4 of the maximum (space or time) distances.

We notice that the mean of the intensity function for the homogeneous scenario appears systematically overestimated. This might be due to different approximations in the computation of the space-time K-function.

For the inhomogeneous point processes, we employ the penalized procedure, where the penalty enters like an additional data point which is used to "pull" in the parameter direction where the data provide the least information. The mean of the (unpenalized) estimates for the α and β parameters are 4.3780 and 2.9476 (with 2.1560 and 2.3885 as standard errors, respectively). Adding the penalization, with radius $R = 2.5$ as in the purely spatial case, the estimated parameters are pulled towards the true values (see Table 1).

Further results, not shown for brevity, indicate that the proposed procedure works quite well also in the purely spatial case, especially when the parameter to estimate is unique. This scenario includes both

Table 1: Results over 1000 simulations.

			MLE		Min. Con.		
Process	$\mathbb{E}[n]$	True par	mean	RMSE	mean	RMSE	mean(s.e.)
Hom. Pois.	500	$\lambda = 500$	523.0372	517.3331	529.3286	39.1756	414.0448
Inhom. Pois.	500	$\alpha = 2$	2.5129	2.4991	2.8496	2.3815	1.1852
$R = 2.5$		$\beta = 6$	5.3527	2.4289	4.8887	2.3385	1.5173

a homogeneous specification and inhomogeneous one with only a slope (i.e. $\alpha = 0$). Moreover, we still encounter the same identifiability problem of the spatio-temporal context when dealing with multiple parameters. However, also in the purely spatial case, this problem can be overcome including a penalty in the objective function to minimize.

We note that the computational times of our proposal are longer than the MLE ones, increasing more than linearly with the number of points and the space and time lags considered in the employed K-function. Note instead, that the computational times are not influenced nor by r_{max} or h_{max}.

5. Future work

The idea presented in this paper represents a work in progress. Therefore, much can be done in future. First, we want to run extended simulation studies to assess the performance of the proposed procedure in more complex settings, for instance, with Self-Exciting models such as the ETAS ones. A similar idea is being developed by (4), who showed that parameters in spatial-temporal point process models, alternatively to MLE, can be estimated consistently, under general conditions, by instead minimizing the Stoyan-Grabarnik (SG) statistic. Therefore, we wish to compare our proposal based on the K-function to both the Maximum Likelihood Estimation and (4)'s proposal. Moreover, we want to explore the local extension to fit local models to the data.

Abstract

Tourism in Sicily from January 2016 to December 2019 is here investigated by a data science approach based on the Benford's Law. The empirical distribution of first digits for monthly arrivals and overnight stays in hotels, B&Bs, and complementary accommodations in the seven provinces of the island is compared with the theoretical Benford's distribution, for identifying possible irregular patterns in the numerical data reported by tourism providers.

The compliance with the law is assessed by a visual inspection of the difference between the empirical and the theoretical distributions and several statistical tests.

Results confirm the conformity to the Benford's distribution for the total number of overnight stays and the arrivals and nights spent in Sicily in 2018. Data broken down by nationality of tourists and accommodation type shows an evident deviation from the Benford's Law, instead. A possible explanation of the deviations found is provided.

Keywords: Tourism, Sicily, data science; Benford's Law

1. Introduction

According to the Benford's law, in a set of numerical data, each leading digits (d) should appear a number of times given by the rule:

$$P(d) = log_{10}\left(1 + \frac{1}{d}\right), \quad (1)$$

where, P indicates the probability of occurrence of d in the dataset, being $d = \{1, 2, 3, \cdots, 9\}$ the first digit in a number. Hence, number 1 should appear as leading digit about 30% of the times, number 2 about 17% of the times and so on, until number 9, which should appear as the significant leading digit less than 5 % of the times. In other words, the distribution of leading digits of numbers is more concentrated on smaller values. Such a statement is against the uniform distribution where each number from 1 to 9 occurs about 11.1 % of the times. The distribution of leading digits according to the Benford's Law is reported in Table 1.

Table 1: Distribution of leading digits according to the Benford's Law

First digit	1	2	3	4	5	6	7	8	9
Frequency	30.1%	17.6%	12.5%	9.7%	7.9%	6.7%	5.8%	5.2%	4.6%

Benford also made predictions about the distribution of second, third, and subsequent leading digits and digit combinations. However, results for these cases are not as verified as for the first digits.

Not all the dataset are suitable for this kind of analysis, as a few conditions must be fulfilled for the Benford's Law to hold (Dumas and Devine, 2000; Durtschi et al., 2004; Brown, 2005). First, numbers must not be assigned following a rule as it happens, for instance, for zip codes, telephone numbers, account numbers, social security numbers, etc. This allows for numbers 1 to 9 to have an equal chance of being the leading digit in the dataset. Second, data must not be restricted by a minimum and/or a maximum value (e.g., hourly wage rate) and values should spread at least across one order of magnitude. Third, sets of data made of 500 or more numbers are more appropriate for this type of analysis, although the law has been shown to hold for data sets containing as few as 50 to 100 numbers. Fourth, the distribution of first digits should exhibit right (positive) skewness, which means that smaller values predominate in the data set.

Because of the regularity shown by the leading digits, the Benford's Law is nowadays used to detect data manipulation. In other words, when the distribution of first digits is far from Benford's, it is quite likely that the integrity of data has been accidentally or intentionally manipulated (Nigrini and Mittermaier, 1997).

In this study, the Benford's Law was used to evaluate the reliability of tourism data in Sicily, a southern region in Italy. In particular, we examined whether monthly arrivals and nights spent in the nine provinces of the island from January 2016 to December 2019 conform to the Benford's Law. Data were kindly provided by the 'Assessorato Regionale del Turismo dello Sport e dello Spettacolo - Dipartimento Regionale del Turismo dello Sport e dello Spettacolo' (ARTSS), which contributes to the official statistics on tourism in Italy.

Reliable data is a precondition for policy makers and practitioners to take effective decisions, implement suitable policies and operational plans, allocate resources, and allow for sustainable tourism development. On the contrary, data self-reported by tourism structures, mainly the accommodation sector, could be flawed by incorrect or inaccurate measurement (De Cantis et al., 2015; Demunter, 2017). For instance, "pure" tourists are often mixed with seasonal workers, students, travellers for business purposes, people visiting friends and relatives, and similar. The same tourist staying in different establishments during her journey could be recorded separately each time, which could lead to an unrealistic increase in the number of arrivals (the so-called "double counting effect", De Cantis et al., 2015). Finally, for the case of "underground tourism" (De Cantis et al., 2015) and "hidden tourism" (Parroco and Vaccina, 2004), tourist arrivals and overnight stays are only partially recorded by the tourism structures. In all these hypotheses, official data are not reliable anymore and can lead to wrong decisions and inaccurate policy interventions.

With reference to the dataset here used, results show conformity to the Benford's Law for the total number of nights spent in all accommodation types in Sicily. Irregular patterns are shown by domestic and international tourism as well as by figures for hotels, B&Bs, and other accommodations, instead. We do not investigate the reasons for such deviations. However, no clear evidence of fraud or intentional data manipulation was found and, therefore, we believe that the divergences from the theoretical distribution found could be caused by errors or inaccuracies in the transmission of detailed information about the nationality of tourists and the lodging type.

The proposed study contributes to the existing literature by extending the applications of the Benford's Law to a sector, the tourism market, not inspected enough. We also provide evidence to policymakers in the tourism sector that data could be flawed and more accurate tourism traffic recordings are needed for the decision process.

The rest of the paper is organized as follows. In the next section, the most recent literature is presented. Section 3 introduces the data sets and the methodology used for the study. Results are presented and discussed in Section 4. Conclusive remarks and the limitations of the study conclude.

2. Literature review

The Benford's Law is named after the physicist Frank Benford (Benford, 1938) who first tested the logarithmic pattern shown in eq. 1 for the frequency of leading digits in 20 sets of data, including rivers, areas, populations, physical constants, mathematical sequences, sports, streets addresses, and an issue of Reader's Digest. Yet, the first to discover this sort of regularity for the leading digits in a dataset was the astronomer–mathematician Simon Newcomb (Newcomb, 1881) more than fifty years before Benford, starting from the observation of pages in a used book of logarithmic tables: pages with a number starting with 1 and 2 were more used than pages with a number starting with 8 and 9.

Nowadays, the stated regularity is known more as the Benford's Law than as the Newcomb–Benford's Law. The law of anomalous numbers or the first-digit law are two other names.

Literature is full of example of the use of the Benford's Law to identify potential fraud, manipulations, and irregularities in environmental data (Brown, 2005; De Marchi and Hamilton, 2006; Dumas and Devine, 2000; Fu et al., 2014; Nigrini and Miller, 2007; Nigriniand Miller, 2009; Zahran et al., 2014), natural science observations (Joannes-Boyau et al., 2015; Sambridge et al., 2010), accounting datasets (Carslaw, 1988; Durtschi et al., 2004; Nigrini, 1992, 1994, 1996, 1999, 2003, 2005, 2011, 2012), financial data (Carslaw, 1988; Nigrini, 2012, Riccioni and Cerqueti, 2018; Ausloos et al., 2021), taxable income (Christian and Gupta, 1993; Mir et al., 2014; Ausloos et al., 2017), election results (Roukema, 2014; Tunmibi and Olatokun, 2020), the maternal mortality rate (Pollack, 2015), and many other fields like physics, chemistry, astronomy, geology, biology, and so on.

The theoretical properties of the Benford's Law and the statistical methodology to test its validity have been recently analysed in Cerqueti and Lupi (2021), Cerqueti and Maggi (2021), Kossovsky (2021) and Nigrini (2017).

Applications of the Benford's Law to tourism data are less frequent, instead. We here provide our contribution to the literature by presenting the case of tourism in Sicily, a southern Italian region whose economy is strongly grounded on tourism.

3. Data and methodology

Monthly international and domestic arrivals and overnight stays in hotels, B&Bs, and other accommodations, in the nine provinces of Sicily, from January 2016 to December 2019 (the last year before COVID), compose the set of data to be investigated.

The whole dataset for arrivals and overnight stays is made of 2,592 observations (obs.). The analysis is carried out with reference to the whole dataset (2,592 obs.), for each year in the set of data (648 obs.), for the international and domestic tourism (1296 obs.), and the three types of lodging (hotels, B&Bs, and other accommodations; 864 obs.). All sets of data have a cardinality bigger than 500, and values span at least three orders of magnitude, as recommended. For all the datasets investigated the distribution of figures is highly and positively skewed and leptokurtic. Some descriptive statistics for the whole dataset and each subset are reported in tables 2 and 3.

Suspicious patterns in the data were first detected by graphical representations of the empirical and expected frequencies of the first digits. Then, several goodness-of-fit tests were run to assess the compliance with Benford's Law as no real data will ever follow the distribution strictly. The Pearson's Chi-squared ($\chi 2$), the Kolmogorov-Smirnov statistic (*KS*), the Anderson-Darling statistic (*AD*), the Euclidean distance (*d*), the Mean Absolute Deviation (*MAD*), and the Sum of Squared Difference (*SSD*) were the preferred methods. We assume hereafter that $\tilde{p} = (\tilde{p}_1, \dots, \tilde{p}_9)$ and $p = (p_1, \dots, p_9)$ are the observed and theoretical frequencies, respectively.

The $\chi 2$ is known to be sensitive to the sample size. When the sample size is too big, 5,000 observations or more, or too small, the null hypothesis will likely be rejected even though there is no significant difference between the actual data and the theoretical distribution (Bushee, 2018; Farhadi, 2021). The test is computed as follows:

$$\chi^2 = \sum_{i=1}^{9} \frac{(\tilde{p}_i - p_i)^2}{p_i}.$$

The test is here evaluated by using 8 degrees of freedom. At the significance level of 0.05, the critical value is 15.51.

Table 2: Descriptive statistics for arrivals

Numerical data	Observations	Min	Max	Mean	Skewness	Kurtosis
Tot. arrivals	2,592	7	86,237	7,467.93	2.85	11.67
2016	648	7	74,651	6,711.09	2.82	8.24

KS is one of the most precise techniques to assess Benford's Law (Idrovoet al., 2020; Farhadi, 2021) The statistic is distribution-free and quantifies the empirical distance between the observed and expected frequencies through a non-parametric test. The test is based on the comparison between the cumulative density function of the empirical distribution of digits 1 to 9 and the theoretical cumulative density functions. When the *KS* statistic is greater than the square root of the total number *N* of the leading digits observed in a probability sample (cutoff), manipulation is evident. Once the *KS* statistic is identified, the null hypothesis can be accepted if:

$$\sqrt{N}D_n > K_n,$$

where N is the size of the dataset, $D_n = Max_x|F_n(x) - F(x)|$, F_n is the cumulative distribution observed, and F is the Benford's cumulative distribution. The critical value K is set to 1.36 at a 5% significance and 1.63 at 1% significance (Simard and L'Ecuyer, 2011; Farhadi, 2021).

The *AD* test statistic is defined as:

$$AD = \frac{N}{2}\sum_{i=1}^{8}\frac{(p_i + p_{i+1})(\tilde{P}_i - P_i)^2}{P_i(1 - P_i)},$$

where N is the sample size, $P_i = \sum_{j=1}^{i} p_j$ is the cumulative probabilities of the expected frequencies (p_i) and $\tilde{P}_i = \sum_{j=1}^{i} \tilde{p}_j$ is the cumulative probabilities of the measured frequencies $(\tilde{p}_i)$.

The Euclidean distance (d) between the empirical and the theoretical frequencies is calculated as follows:

$$d = \sqrt{N}\sqrt{\sum_{i=1}^{9}(\tilde{p}_i - p_i)^2}.$$

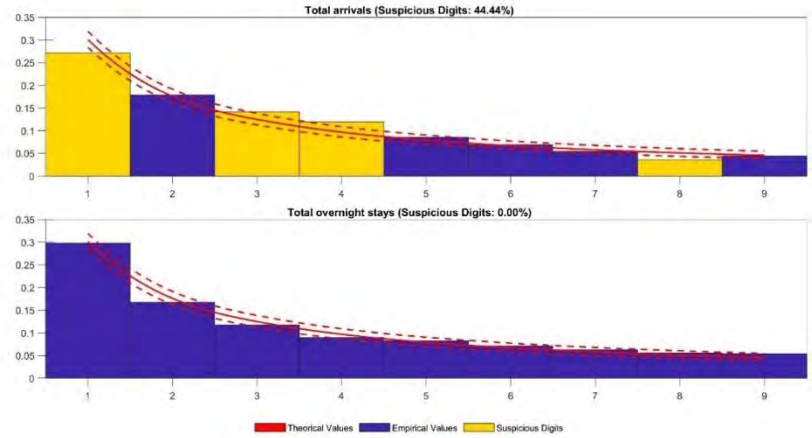

Figure 1: First digits analysis (a = 0.05) of total arrivals and overnight stays for the whole time horizon

MAD is calculated as the average absolute deviation between $\tilde{p}$ and p:

$$MAD = \frac{1}{9}\sum_{i=1}^{9}|\tilde{p}_i - p_i|$$

The *MAD* test provides reliable results with as low as 200 observations (Druica, Oancea, and Vâlsan, 2018). In Nigrini (2012) critical ranks for the *MAD* statistics are provided: close conformity (0.000-0.006]; acceptable conformity (0.006-0.012]; marginally acceptable conformity (0.012-0.015]; and nonconformity (above 0.015).

SSD takes the sum of the squares of the deviation between $\tilde{p} = (\tilde{p}_1, \dots, \tilde{p}_9)$ and $p = (p_1, \dots, p_9)$ as follows:

$$SSD = \sum_{i=1}^{9}(\tilde{p}_i - p_i)^2 \times 10^4$$

Both the *MAD* and the *SSD* are less dependent on the sample size (Nigrini, 2012; Slepkov et al., 2019; Kossovsky, 2014). *MAD*> 0.015 and *SSD*> 100 indicate non-conformity with the law (Slepkov et al., 2019; Kossovsky, 2014).

4. Results

Conformity of the distribution of first digits in the sets of data investigated with the Benford's Law was first inspected by several plots (Figs. 1-4), where the histogram represents the empirical distribution of leading digits, the red line represents the Benford's distribution, and the red dotted lines represent the 5% confidence range.

The total number of arrivals does not look to conform to the Benford's Law (Fig. 1). Figures starting with 1 and 8 are less frequent than expected according to Benford's, whereas leading digits 3 and 4 are more frequent than expected. This entails four digits out of nine (44.44%) violate the theoretical distribution. On the contrary, the distribution of leading digits in the dataset of total overnight stays complies with the Benford's Law very strictly.

Looking at Fig. 2b, it seems quite evident that data collected in 2017 for tourism arrivals could be responsible for the missing conformity to the Benford's Law for the total number of arrivals. In fact, observations for arrivals in 2017 show the same deviation from the law as for total arrivals: lower empirical frequencies for digits 1 and 8, and higher frequencies for digits 3 and 4. Yet, very slight deviations from the theoretical distribution for the yearly sets of arrivals are shown by numbers starting with 8 in the years 2016 and 2019.

Regarding the overnight stays, data for the year 2016 show lower frequencies for the leading digit 2 and higher frequencies than expected for the numbers starting with 8. Conformity with the Benford's Law for the other years looks pretty good, instead.

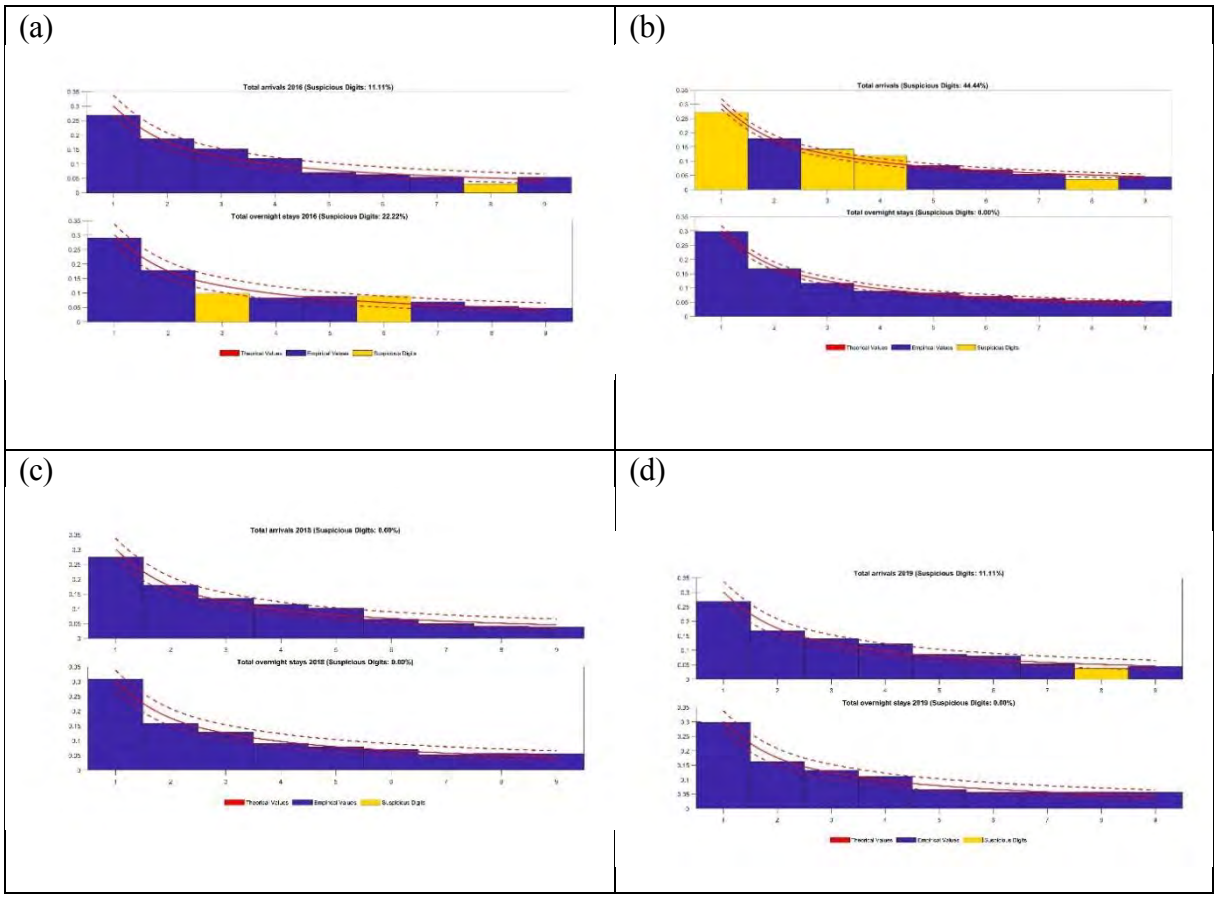

Figure 2: First digits analysis (a = 0.05) for total arrivals and overnight stays in the years 2016(a), 2017(b), 2018(c), and 2019(d)

In Fig. 3, a and b, the analysis is carried out on the two subsets obtained by rearranging the whole set of data by nationality of tourists: international and domestic. Visual inspection reveals substantial deviations from the Benford's Law for both international and domestic arrivals: 44.44% and 88.89%, respectively.
Data for international arrivals shows first digits 1 and 6 more frequent than expected whereas the same digits are less frequent than expected in the subset of domestic tourists. First digits 2, 3, 4, and 5 appear more frequently than expected in domestic arrivals, whereas figures for international arrivals starting with digits 2 and 3 are less frequently than expected. 2 and 6 are the suspicious digits for both the international and domestic overnight stays. Figures starting with 9 are more frequent for domestic overnight stays than expected according to the Benford's Law. Yet, the 22.22% of suspicious digits for the international nights and the 33.33% of irregular patterns for the domestic ones cancel out when the two subsets are summed up into the whole number of overnight stays. This circumstance let us think of possible errors in the classification of tourists by nationality.

Fig. 4 shows the results for the analyses carried out on the subsets obtained by type of accommodation: hotels, B&Bs, other accommodations.
Among the three type of accommodations, hotels show a number of suspicious digits (11.11%) lower than the irregular patterns shown by the number of arrivals in B&Bs (44.44%), and in other accommodations (33.33%). The situation shown by numbers get worst when the analysis is carried out using nights spent in Sicily in the three different types of accommodations. Nights in hotels show suspicious digits in 33.33% of the cases, in B&Bs in 44.44% of the cases, and in other accommodations in 66.67% of the cases.

Tables 4 and 5 sum up the results of the analyses carried out for arrivals and overnights stays, respectively, and show Benford's frequencies in the last column for easy comparison.

Several statistical tests were also run to underpin results from the visual inspection. Results are shown in tables 6 and 7. Results from the goodness-of-fit tests mostly confirm the outcomes from the graphical inspection.

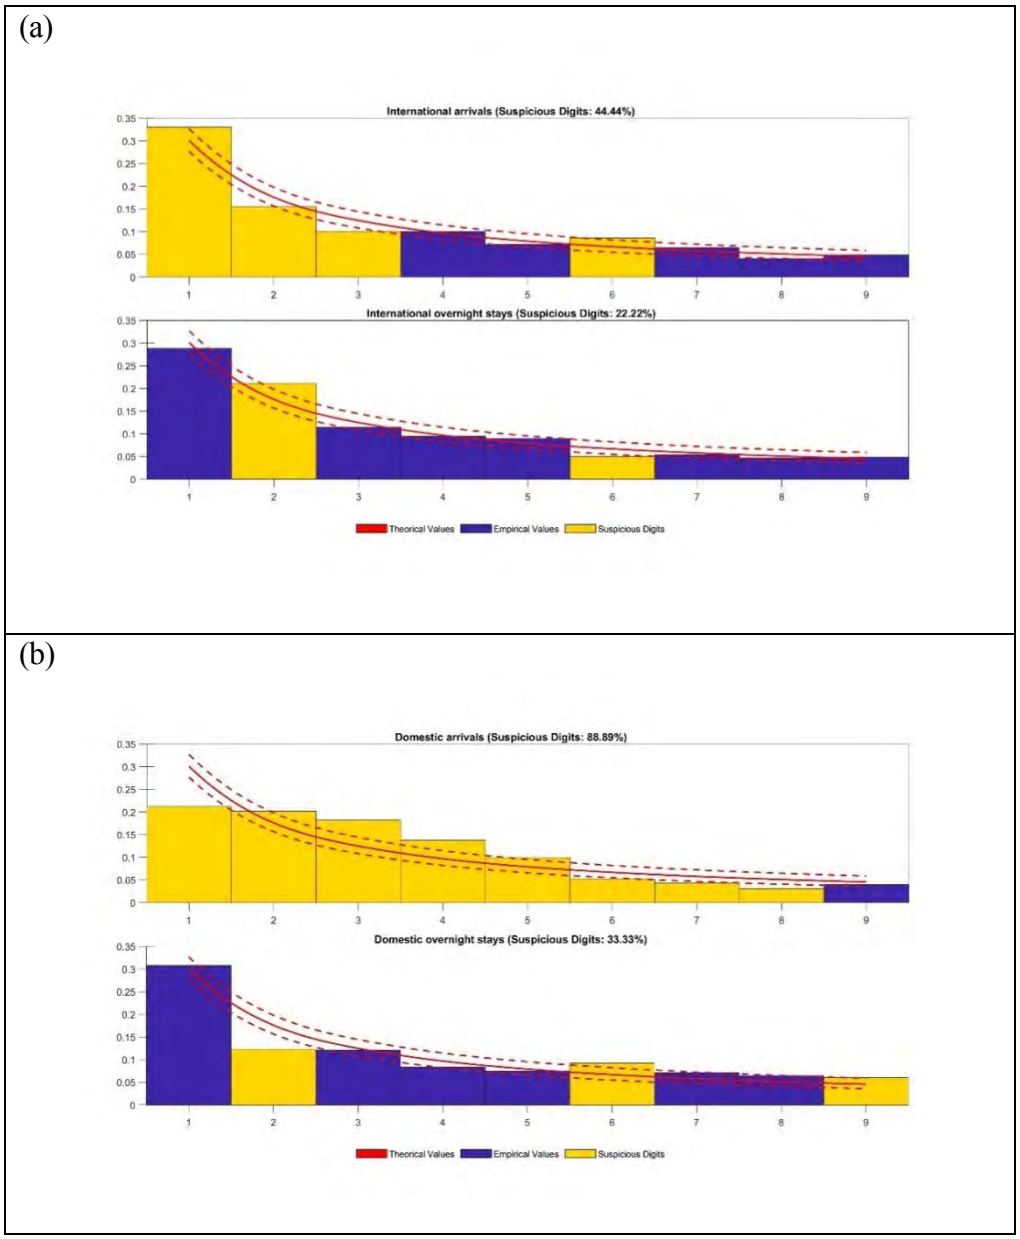

Fig. 3.: First digits analysis (a = 0.05) for international(a) and domestic(b)arrivals and overnight stays.

Thus, leading digit distribution for total arrivals, domestic arrivals, and arrivals from hotels, B&Bs, and others accommodations do not comply with the Benford's Law according to most of the tests. Conformity for domestic arrivals is rejected by *d*, *MAD*, and *SSD* as well. Statistically significant deviations from the Benford's Law are also found for arrivals in 2016 and international arrivals by the $\chi 2$ and *d* tests. Conformity to Benford's is proven by all the tests run for arrival in 2017, 2018, and 2019, instead.

About the whole dataset of overnight stays in Sicily, *AD* is the only test that reject conformity. Data broken down by nationality of tourists provide different results: international nights conform to the Benford's Law for four tests (*KS*, *AD*, *MAD*, and *SSD*) out of six, whereas domestic nights show conformity to the theoretical distribution by the *SSD* test only.

Statistical tests run on data by type of accommodation confirm the statistically significant deviations of the distribution of nights in hotels, B&B, and other accommodations from the Benford's Law already found by visual inspection. *SSD* is the only test not rejecting conformity for all the sets of data related to the number of nights spent in Sicily.

Results from the analyses lead us to some conjectures about the irregular patterns shown by the sets of data investigated. Yet, our hypothesis will be explored in detail and with scientific rigour in future studies. The main consideration here is that compliance with the Benford's distribution is confirmed for aggregated data and rejected for data broken down by nationality and lodging type.

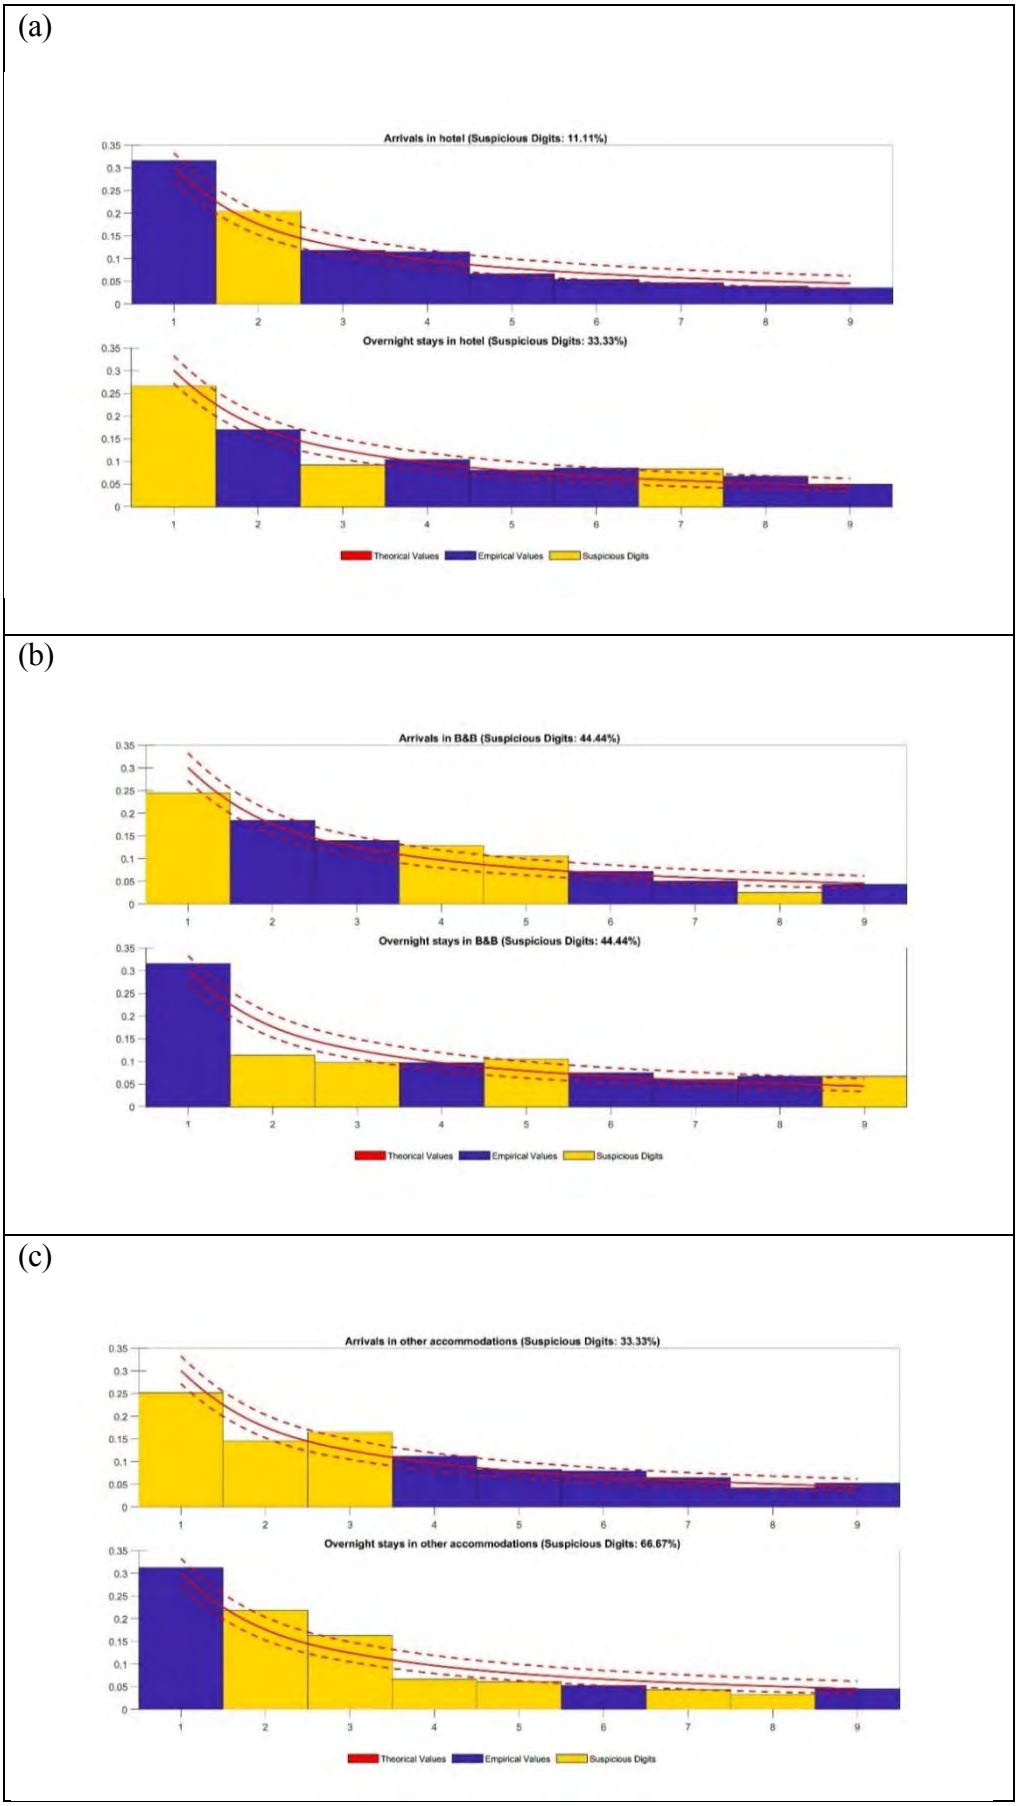

Fig. 4.: First digits analysis (a = 0.05) for total arrivals and overnight stays in hotels(a), B&Bs(b), and other accommodations(c).

Table 4: Test results for arrivals

G-o-f test Data set	χ^2	*KS*	*AD*	*d*	*MAD*	*SSD*

Other Accommodations	41.38	2.73	7.77	2.14	0.021****	53.14

Note: Critical values to reject conformity to the law (confidence level = 0.05): $\chi^2 = 15.507$ for a number of "degrees of freedom" $\delta = 8$ (χ^2 at a significance level 0.10 = 13.362); *KS* = 1.36 (*KS* at a 1% significance = 1.63); *AD* = 2.304 (*AD* at a 1% significance = 3.688); *d* > 1.25; *MAD*: * = close conformity, ** = acceptable conformity, *** = marginally acceptable conformity, **** = nonconformity (> 0.015); *SSD* > 100. We underline the cases of non-compliance with Benford's Law.

Tourism data collected by the ARTSS comes from the obligation applicable to each accommodation provider in Sicily to record and submit the number of arrivals and overnight stays through the Turist@t system introduced for the acquisition, management, and processing of the number of tourists and nights spent in the region. Thus, unintended typos, misplacements, and mere negligence in reporting tourism flows may occur when data are filled into the collection and delivery system. Tax evasion, in the particular form of sojourn tax, may also be at the origin of data manipulation.

Results do not support any conclusion about possible fraud or intentional data manipulation. On the contrary, both the visual inspection and the statistical tests provide evidence that data for the total number of overnight stays in Sicily comply with the Benford's Law. Compliance with the theoretical distribution is also verified for the data disaggregated on a yearly basis.

Suspicious patterns stand out when the number of tourists and nights are broken down by nationality of tourists and accommodation type. Yet, when overnight stays in hotels, B&Bs, and other accommodations are summed up into the total number of overnight stay in Sicily, compliance is restored. The same happens when considering the data broken down by the nationality of tourists.

This result leads us to believe that inaccuracy or errors made by the accommodation providers when entering

the system may be at the origin of the suspicious patterns found. This hypothesis will be investigated in depth in a future research.

5. Conclusions

The reliability of the data recorded by accommodation providers in Sicily in the period 2016-2019 is here investigated by relying on a data science approach.
In particular, the compliance of a high-quality dataset regarding tourism flows in Sicily was assessed with the Benford's distribution.
According to the Benford's Law, first digits in figures do not appear randomly but follow a logarithm pattern so that lower digits are more frequent than higher ones. Hence, a deviation from the such regularity may indicate that the set of data is compromised, namely, it was accidentally or intentionally manipulated.

We assessed the compliance of the dataset in use with the Benford's Law by a visual inspection of the empirical and theoretical distribution of the leading digits, and by a wide set of test statistic.
Deviations from the Benford's Law were found and possible reasons for outcomes were discussed as well.
A conclusive response about the possible origin of the irregular patterns found is left for future research.
Results confirm the reliability of the method for identifying potential discrepancies in the tourism data and provide policymakers and practitioners a warning about the accuracy of the data used for taking decisions and implementing intervention plans.
This paper contributes to the scope of the Benford's Law in the empirical applications.
Furthermore, the methodological instruments employed here are so versatile that they can be effectively used
The time frame of the data is the main limitation of this study. A longer time series could allow for a deeper analysis and may better reveal the possible causes of the irregular patterns verified in the data broken down by tourists' nationality and accommodation type.
Provincial data would also be desirable for a deeper analysis.

Exploring the level of digitalization of the Italian museums through a multilevel ordered logit model

Claudia Cappello[a], Sabrina Maggio[a], and Sandra De Iaco[a]

[a]Department of Economic Sciences, University of Salento, Complesso Ecotekne, Lecce (Italy), claudia.cappello@unisalento.it, sabrina.maggio@unisalento.it, sandra.deiaco@unisalento.it,

Abstract

The Italian cultural heritage includes a wide range of museums, with different institutional features, types of collection, exhibition space and number of visitors. Museums contribute to enrich the Italian social and cultural background, since they are places in which education, research, exhibition and aesthetics harmoniously combine, in order to improve the visitor-experience. The use of digital technologies can be considered as a keystone of the attractiveness of the cultural sites. In this context, this paper aims to model the probability for the museums to adopt ever-increasing degrees of digitalization, by using a multilevel approach which takes into account the geographical locations of the investigated units. In particular, a multilevel multinomial ordered model will be implemented in order to evaluate how the level of digitalization of Italian museums is influenced by prominent factors which might stimulate to invest in new digital technologies.

Keywords: multilevel ordered model; medium/low digitalization, high digitalization

1. Introduction

During the last decades, the digital transformation has involved museums, with the construction of more and more sophisticated websites, as well as the adoption of increasingly advanced digital technologies to improve the visitors experience ([6; 13]). Indeed, the proliferation of information technology is transforming all aspects of museum operations while enhancing the traditional functions.

In Italy, many initiatives have been promoted by the national Ministry of Culture over the past twenty years. The latest one dates back to July 2019 with the approval of the Three-Year Plan for the Digitalization and Innovation of Museums, aimed at supporting the digitalization process. Although the pandemic crisis has given a boost to digitalization, this topic has not been widely investigated in the literature. The contribution of [11] applied a mixed methodological approach consisting of a descriptive comparison of three museums acting in the Apulia region. Moreover, the study of [8] analyzed the use of information technologies and innovation processes in the Uffizi Gallery in Florence (Tuscany region), based on the Virtual Value Chain Model.

As far as is known, no work in this context has ever dealt with in-depth research at national level on the determinants of digital technologies. In such perspective, this paper aims to estimate the probability for museums to achieve a growing level of technological innovation (no, medium/low, high digitalization), by applying a multinomial multilevel ordered model. The net

effect deriving from the contribution of some key factors which might affect the level of digitalization will be also evaluated.

After a brief theoretical description of the multilevel logit ordered model (Sect. 2), some details will be provided on the dataset and on the methodology applied (Sect. 3) and the corresponding results will be given in Sect. 4.

2. Some theoretical hints on the multinomial ordered logit model

The multinomial ordered logistic model is a cumulative regression model which connects an ordinal variable of multiple categories to a set of indipendent variables (or covariates) ([4]). The first papers appeared in the literature concern multilevel regression models for ordinal data ([9; 10]). Additional examples of ordered logistic regression models can be found in [1; 2; 3; 5].

Let Y_{ijk} be a multinomial ordered response variable with values $s = 1, 2, ..., t$ (response categories), where t is selected as the reference category and with the index i ($i = 1, \ldots, n_{jk}$) denoting the level 1 unit, the index j ($j = 1, \ldots, N_k$) corresponding to the level 2 unit and the index k ($k = 1, \ldots, K$) representing the level 3 unit.

Given the probability $\pi_{ijk}^{(s)}$ that the i-th first level unit presents a response variable value of s, let $\{X_{1\cdot}, X_{2\cdot}, \ldots, X_{H\cdot}\}$ be a set of covariates which influences the dependent response variable.

In order to consider the ordering, the identified model is based on the cumulative response probabilities defined as follows:

$$E(Y_{ijk}^{(s)}) = \gamma_{ijk}^{(s)} = \sum_{h=1}^{s} \pi_{ijk}^{(h)}, \qquad s = 1, 2, \ldots, t-1$$

where $Y_{ijk}^{(s)}$ describes the observed cumulative proportions for the i-th unit.

The category probabilities can be expressed in terms of the cumulative probabilities, thus obtaining:

$$\pi_{ijk}^{(h)} = \gamma_{ijk}^{(h)} - \gamma_{ijk}^{(h-1)}, \qquad 1 < h < t$$

$$\pi_{ijk}^{(1)} = \gamma_{ijk}^{(1)}; \qquad \gamma_{ijk}^{(t)} = 1$$

A multinomial ordered model with a logit link can be formalized as:

$$\gamma_{ijk}^{(s)} = \left\{ 1 + \exp\left[- \left(\beta_{0jk}^{(s)} + \sum_{h=1}^{H} \beta_{hjk}^{(s)} \, x_{hijk} \right) \right] \right\}^{-1}$$

or analogously:

$$\eta_{ijk} = \log it(\gamma_{ijk}^{(s)}) = \beta_{0jk}^{(s)} + \sum_{h=1}^{H} \beta_{hjk}^{(s)} \, x_{hijk}$$

with

- $\beta_{hjk}^{(s)} = \beta_{h}^{(s)} + \nu_{hk}^{(s)} + u_{hjk}^{(s)}, \qquad h = 0, 1, \ldots, H$
- $\begin{bmatrix} \nu_{0k}^{(s)} \\ \nu_{1k}^{(s)} \\ \vdots \\ \nu_{hk}^{(s)} \\ \vdots \\ \nu_{Hk}^{(s)} \end{bmatrix} \sim N(\mathbf{0}, \mathbf{\Omega}_{\nu}),$ • $\begin{bmatrix} u_{0jk}^{(s)} \\ u_{1jk}^{(s)} \\ \vdots \\ u_{hjk}^{(s)} \\ \vdots \\ u_{Hjk}^{(s)} \end{bmatrix} \sim N(\mathbf{0}, \mathbf{\Omega}_{u}).$

This implies that increasing values of the linear components are associated with increasing probabilities as s grows ([12]). All the terms $\beta_{hjk}^{(s)}$ vary across categories ($s = 1, 2, \ldots, t-1$); analogously for the random-effect variance term ([5]).

3. Data and methods

The microdata used in this paper concern a census survey on the Italian public and private museums carried out by the Italian National Institute of Statistics (ISTAT) in 2018. In this context, a multilevel multinomial ordered model has been implemented in order to measure the probability for the museum of being without significant digital innovations, or adopting medium/low or high level of digitalization. In particular, three hierarchical levels have been analyzed: *the first level*, that is the museums (3,217 museums); *the second level*, corresponding to the Italian provinces where the museums are placed (108 provinces); *the third level*, concerning the Italian regions where the museums are located (20 regions).

The choice of three levels of aggregation is justified by the underlying hierarchical structure of data, where the regions represent the highest level in which the cultural heritage can offer different opportunities; on the other hand, the museums are considered as the lowest level of nesting. A detailed descriptive analysis on the ISTAT microdata has been conducted on the features of museums, distinguished by management, access, visits, staff, financial resources, structures, support of fruition, relationship with the territory, activities and services.

The multinomial scheme of the model allows to catch the effects that regional and provincial characteristics might have on the level of digitalization, which represents the dependent variable sorted into three categories (none, medium/low, high digitalization). More specifically, the level of digitalization has been recoded considering up to 15 digital technologies, including digital inventory, digital catalogue, video and audio guides, applications for smartphones and tablets, among others. From the descriptive analysis, the following covariates have been derived:

- network of museums, access absolutely free or with admission fee, research activities, partnership, guided tours, exhibition space, type of institution, percentage of Italians vs Foreigners (Individual covariates);
- number of tourist accommodation establishments (Provincial-level covariate);
- expenditure for recreation, culture and religion, Gross domestic product per capita, current prices (Regional-level covariates).

The selected covariates have been considered for evaluating their effects on the probability of catching ever-growing levels of digitalization for museums.

4. Results and discussion

According to the modeling results, it has to be pointed out that apart from the covariate "Access", which has a negative impact on the probability to have a medium/low or high level of digitalization, all the other covariates listed in Sect. 3 produce a positive effect on the probability to introduce both a medium/low and a high level of digitalization. In addition, from the estimates of the multinomial ordered logit model, it has to be highlighted that it is much more probable that museums in Italy are likely to introduce a medium/low level of digitalization (with estimated values ranging from 0.495 to 0.714) than a high level of digitalization (values from 0.141 to 0.495).

For what concerns the regional-level, Lazio, Tuscany, Emilia-Romagna, Trentino-Alto Adige, Lombardy and the islands of Sardinia and Sicily are the Italian regions with the highest estimated probability of adopting at least a medium/low level of digitalization, with a number of structures ranging from 201 to 553 museums. Besides these regions, also Umbria, Apulia and

Basilicata have to be mentioned, with up to 170 museum structures in their territories. As regards the provincial level, the greatest estimated probability of adopting mainly high digitalization can be found for the provinces of Milan, Mantova, Cremona and Como (Lombardy), as well as for Ferrara (Emilia-Romagna), Venice (Veneto), Naples (Campania), Prato (Tuscany) and Rome (Lazio).

Abstract

Functional regression is a statistical method that is used to model the relationship between a response variable and a set of predictor variables that are functions. Functional Partial Least-Squares (PLS) regression is a form of functional regression analysis that is particularly useful when the number of predictors is large compared to the number of observations, or when the predictors are highly correlated. The basic idea of functional PLS via regression splines is to transform both response and predictors by using a set of spline-basis functions, such as B-spline basis, and then use the standard PLS technique to estimate the optimal transformed predictors. We show its performance on a real data set concerning the sustainable development goals of Agenda 2030.

Keywords: B-splines, Nodal coefficients, Partial Least-Squares, Sustainability

1. Introduction

Functional data analysis (9) has gained significant attention in recent years due to technological progress allowing for the collection of high-dimensional functional data in various fields (biology, econometrics, environmetrics, sustainability, etc.). Hence, the result of one observation can be viewed as a discretized version of one curve (Near InfraRed spectrum, radar waveform, physiological signals), or of one surface (3D image). This kind of high-dimensional data needs new functional statistical tools. The basic idea of functional regression is to represent the predictor variables as a linear combination of basis functions, such as Fourier basis or B-spline basis, and then use standard regression techniques to estimate the coefficients of the basis functions. Unfortunately, these methods often transform the functional model into a multiple regression model with high multicollinearity. To address this issue, several approaches have been proposed, among which functional principal component regression and functional partial least squares (PLS) regression (2; 6; 10; 18; 1; 11) which estimate a scalar response from predictor curves.
Due to the great interest raised by PLS, we focus on functional PLS regression. To our knowledge, there is no work for dealing with both predictor and response functional variables in the PLS regression. In Section 2, we aim to develop an approach for estimating a functional response from functional predictors. The last section concludes with an application on Italian sustainability development goals data.

2. Functional Partial Least Squares Regression

Partial least-squares (PLS) is a statistical technique used for regression analysis, where the goal is to find a linear relationship between the response and predictor variables. PLS is particularly useful when the number of predictor variables is large, and there may be some degree of multicollinearity or correlation between them (14; 15; 16).

Similarly, functional partial-least squares via regression splines allows to model the relationship between a response variable and a set of predictor variables highly correlated where the variables of interest are not simple scalars, but instead are spline functions. Different types of PLS functional regression can be discussed, depending on the type of transformation functions for the predictor variables and the nature of the response variable; see (2; 6; 10; 18; 1; 11). For example, when only the predictor variables are functions, Durand (6) proposed an extension of the linear PLS method towards nonlinearity via regression splines and called this method partial least-squares splines with the acronym PLSS.

Here we consider that the response is a spline function or a multifunction valued in a set of some B-spline functions, and that the new predictors are B-spline functions associated to each original predictor. The PLSS regression model is used to estimate the coefficients of these basis functions. We call this model Functional Partial Least-Squares via regression Splines (FPLSS). The crucial property of the B-spline family associated to x, the generic variable among the p predictors, is that it constitutes a basis for the linear space of the spline functions $s(x)$ that are piecewise polynomials of degree d that join end to end with some regularity on K points called the knots. So, $s(x)$ is a linear combination of a set of $r = d + 1 + K$ basis functions called the B-splines, see (12). The idea behind PLSS and then behind FPLSS is that the estimated functional response becomes a linear combination of A pseudo-predictors $t_1, ..., t_A$, called the components, the latent variables or the base learners, see (3), where A is generally estimated by cross-validation. Therefore, the generic component can be written as

$$t_i = s_1^i(x_1) + ... + s_p^i(x_p), \quad i = 1, ..., A. \tag{1}$$

Given the nonlinear additive relationship between the components t_i ($i = 1, ..., A$) and the predictors x_j ($j = 1, ..., p$), in order to interprete the influence of the predictors on the component t_i we look at the shape of the coordinate functions $\{s_j^i(.)\}_{j=1,...,p}$. These functions are classified in decreasing order of influence according to the range of their values (recall that the predictors are normalized). FPLSS has some challenges, such as the need to choose the sets of appropriate basis functions. We adopt an heuristic strategy consisting in increasing/decreasing progressively the spline parameters, see (6), default values for the knot locations being the quantiles or equally spaced positions. As a summary, the tuning parameters of FPLSS are the degree, the knots (number and location) for the predictors, and the number A of components.

Inherited from linear PLS, functional PLSS can handle

- a large number of predictors possibbly highly correlated and a small number of observations;
- continuous and categorical response and predictor variables;
- nonlinear relationships and bivariate interactions through tensor products of B-splines, see (8).

The FPLSS algorithm using basis-spline functions involves the following steps:

- Create different sets of B-spline functions to transform both response and predictors.
- Use these B-splines and PLS to create a new set of pseudo predictors in small number (the PLSS components) that nonlinearly capture in (1) the variation in the predictors.
- Use the PLSS regression model (2) to predict the functional response.

The FPLSS model can be written as

$$S(\hat{y}(A)) = \sum_{j=1}^{p} \sum_{l=1}^{r_j} \hat{\beta}_l^j(A) B_l^j(x_j), \tag{2}$$

where $S(y)$ is a functional transformation of the response y by splines that aims at producing a good model (goodness of fit and prediction) as well as easy interpretable results.

For example, it can be $S(y) = s_{id}(y)$, the "spline function identity", where $s_{id}(y) = y$ for any y. See Shumaker (12) for its construction when $d > 0$ by using the so called "nodal" β coefficients defined by the mean of some knot locations. The spline identity has been also used by Durand (4; 2) in nonlinear multiple regression as the initial step of a sequence of transformations of the predictors through regression splines. In FPLSS the choice $S(y) = s_{id}(y)$ leads to FPLSS = PLSS.

Inspired by the rather formal preceding option for $S(y)$, we propose a sensitive strategy for the response transformation consisting in a local departure from the spline identity by slightly perturbing the β nodal coefficients of $s_{id}(y)$. Therefore, decision makers have the ability to controll on-line what is changing in the model (1) and (2) by locally modifying the values of the observed response.

At last, a multi-function $S(y)$ valued in a set of binary disjunctive functions (B-splines of degree 0) leads to functional discriminant PLS regression, see (3; 5), where the components play the role of discriminant variables of the constructed response groups. Added to cross-validation, a way of assessing the goodness of the model is to check in the $\{t_i\}_{i=1}^{A}$ space, the observations that are well affected to the "true groups" by using their Mahalanobis distances to the centroids.

3. Example: Sustainable Development Goals Data

Equation (1) of FPLSS finds a straightforward application in the context of functional discriminant analysis. The response Migration Policy, *MigraPol*, is split up according to 2 break-points (the knots) to decompose the observations (20 Italian regions) into 3 groups characterized by 3 B-splines of degree 0 that constitute the new responses $\{MigraPoli\}_{i=1}^{3}$. Each response indicates (by 0 or 1) respectively low, mean and large values of MigraPol. Then, the multiresponse PLSS algorithm has been run using the free open-source package "Boosted PLS Regression" available at *http://www.jf-durand.pls.com*. Here, the aim is to study $p = 49$ socio-economic variables with regard to the 3 response variables *MigraPol1*, *MigraPol2* and *MigraPol3*.

The 2030 Agenda has been designed to be an universal and global action plan to address the challenges of the 21st century. The Sustainable Development Goals (SDGs) are a set of 17 goals. Here, we consider the Italian Strategy for Sustainable Development (see SDGs 2021 Report: Statistical information for the 2030 Agenda in Italy, published by ISTAT) which concerns the measurement of the sustainable development across the 20 Italian regions. In particular, we focus our attention on Migration Policy which belongs to SDG 10 (reducing inequalities) and is described by a composite indicator constructed by using five simple indicators: 1) Permits issued for non-EU citizens; 2) Share of long-term permits; 3) New permits issued; 4) Percentage of permits issued for political asylum and humanitarian reasons; 5) Citizenship acquisitions. Indeed, Migration Policy and SDGs are interconnected, as Migration Policy can both contribute to and hinder the achievement of the SDGs. The determinants or predictors of Mi-

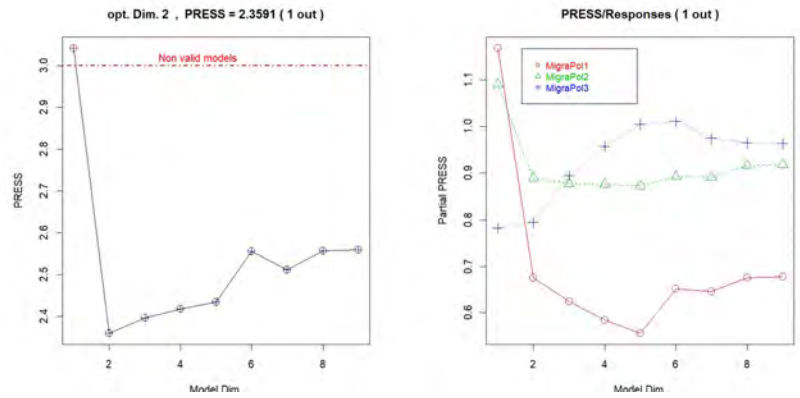

Figure 1: The PRESS criterion for the choice of the number of FPLSS components

gration Policy belonging to SDGs 3, 4 and 8 consist of $p = 49$ indicators. Here for brevity, instead of

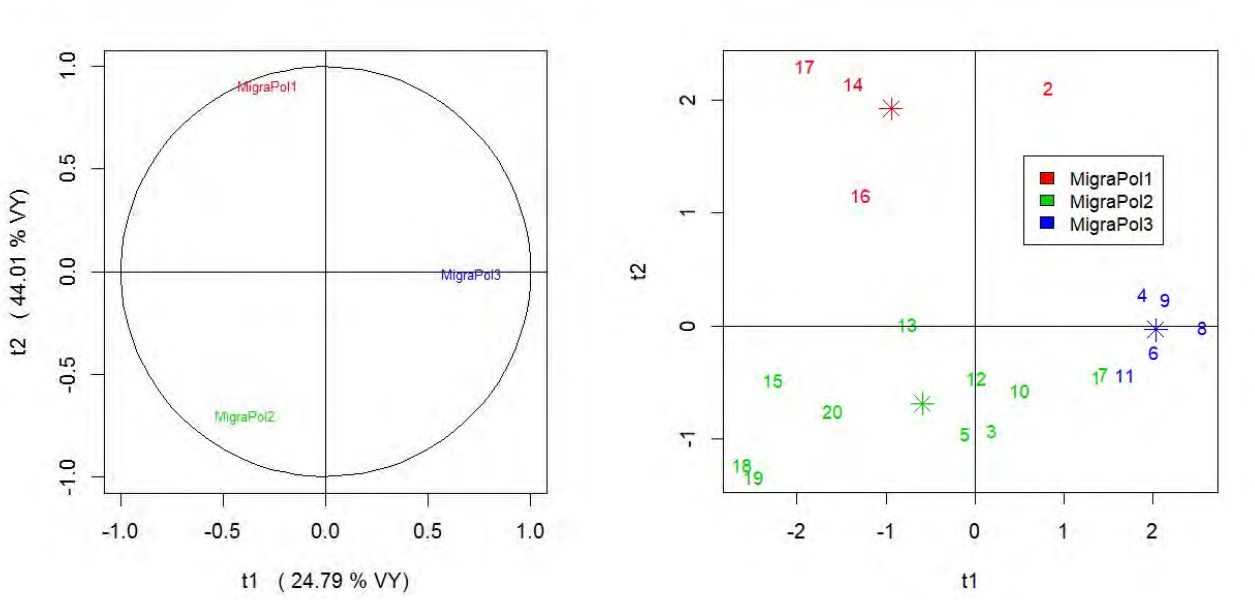

Figure 2: Correlation circle and observation plot. Note that 1=Piemonte, 2=ValleAosta, 3=Liguria, 4=Lombardia, 5=TrentinoAA, 6=Veneto, 7=FriuliVeneziaGiulia, 8=EmiliaRomagna, 9=Toscana, 10=Umbria, 11=Marche, 12=Lazio, 13=Abruzzo, 14=Molise, 15=Campania, 16=Puglia, 17=Basilicata, 18=Calabria, 19=Sicilia, 20=Sardegna.

Table 1: FPLSS model performance in fit

	R^2 of the responses on the t subspaces			var Y = 3	reconstituted var Y=2.5658	
dimension	*MigraPol1*	*MigraPol2*	*MigraPol3*	Y var	%	cumul. %
1	0.081	0.154	0.509	0.7436	24.79	24.79
2	0.896	0.659	0.509	1.3204	44.01	68.80
3	0.897	0.861	0.808	0.5018	16.73	85.53

providing the list of these predictors we briefly present the SDGs 3, 4 and 8.
SDG 3: "Ensure healthy lives and promote well-being for all at all ages" (**HealthWell**), described by 12 indicators. SDG 4: "Ensure inclusive and equitable quality Education and promote lifelong learning opportunities for all" (**QualEdu**), explained by 27 indicators. SDG 8: "Promote sustained, inclusive and sustainable economic growth, full and productive employment and decent work for all, and an enhanced productive capacity for least developed regions" (**WorkGrowth**), related to 10 indicators.
After transforming the predictors (by using B-splines of degree 2 with 2 knots at quantiles), it results that the predictive ability of the model is good, and the optimal leave-one-out PRESS suggests to consider 2 components ($PRESS_{total,2} = 2.359$). However, we prefer to take 3 components with similar PRESS ($PRESS_{total,3} = 2.396$) that better discriminate the three groups of observations since three components leads to 0 error of misclassication. So, three components explain 85.53% of the response variability. Table 1 shows the percentage of $S(\hat{y}(A = 3))$ variability with respect to each model dimension. Furthermore, it results that the FPLSS model fits each response very well, i.e. $R^2_{MigraPol1} = 0.897$, $R^2_{MigraPol2} = 0.861$ and $R^2_{MigraPol3} = 0.808$.

When performing FPLSS regression, it is usual to visualize the relationship between the responses and the latent variables by using the correlation circle coupled with the scatterplot of the components (see Figure 2). On the left side of Figure 2, the correlation circle on the plane t_1, t_2, shows a high negative correlation between the two responses *MigraPol1* and *MigraPol2* which are strongly correlated with the

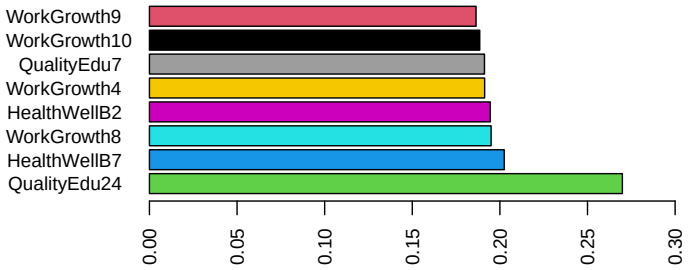

Figure 3: The most important predictors for t_1 and *MigraPol3*

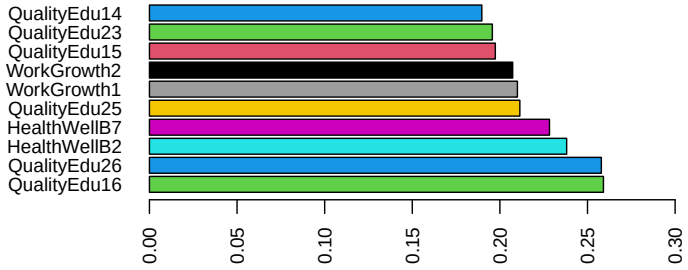

Figure 4: The most important predictors for t_2, *MigraPol1* and *MigraPol2*

second component t_2. While *MigraPol3* is correlated with the first component t_1. Moreover, the right side of Figure 2 shows the FPLSS (t_1, t_2) score plot. We can see three colored groups of regions related to the responses *MigraPol1*, *MigraPol2* and *MigraPol3*, the group centroid is marked with a star. Component t_1 separates the blue group (4=Lombardia, 9=Toscana, 8=EmilaRomagna, 6=Veneto, 11=Marche) of high migration policy *MigraPol3* from the two other groups. Also, component t_2 separates the red group (4=ValleDAosta, 14=Molise, 16=Puglia and 17=Basilicata) of low migration policy from the large green group (13=Abruzzo, 15=Campania, 20=Sardegna, 18=Calabria, 19=Sicilia, 12=Lazio, 10=Umbria, 5=TrentinoAltoAdige, 3=Liguria, 1=Piemonte, 7=FriuliVeneziaGiulia) of mean migration policy.

In linear PLS, to interpret the role of the predictors on t_i one can look at their correlations displayed on the correlation circles. Here, equation (1) shows a nonlinear additive relationship, so it is informative to look at the coordinate function plots $s_j^i(x_j), j = 1, ..., p$ for t_i. However, for the sake of brevity we just display the barplots of the most influent predictors classified in descending order, see Figures 3 and 4. These figures show the most relevant predictors for the components in descending order according to the range of the values of the coordinate spline functions. We can observe a high influence on t_1 of:

- the response *MigraPol3* and the predictors **QualityEdu24** (schools with pupils with disabilities), **HealthWellB7** (beds in ordinary hospitalization in public and private healthcare institutions) **WorkGrowth8** (employment rate (20-64 years)), **HealthWellB2** (excess weight), **WorkGrowth4** (employed in fixed-term jobs for at least 5 years), **QualityEdu7** (inadequate listening comprehension of the English language), **WorkGrowth10** (young people who are not working or studying (15-24 years)) and **WorkGrowth9** (young people who are not working or studying).

Furthermore, looking at Figure 4, we can note a high influence on t_2 of:

- the responses *MigraPol1* (large positive values) and *MigraPol2* (large negative values), and the predictors **QualityEdu16** (pupils with disabilities), **QualityEdu26** (secondary schools with pupils

with disabilities), **HealthWellB2** (excess weight), **HealthWellB7** (beds in ordinary hospitalization in public and private healthcare institutions), **QualityEdu25** (primary schools with pupils with disabilities), **WorkGrowth1** (annual growth rate of real GDP per employee), **WorkGrowth2** (annual growth rate of value added in volume per employee), **QualityEdu15** (disabled pupils in primary school), **QualityEdu23** (physically accessible schools), and **QualityEdu14** (pupils with disabilities in kindergarten).

In summary, knowing how different (or not) the migration policy is across Italian regions can help policymakers in deciding what reform would be helpful to reduce inequalities.

Abstract

The aim of this paper is to analyse the effect of Covid-19 on multidimensional poverty in Italy and its provinces by measuring changes in individual poverty before and during the pandemic outbreak. To capture the multidimensional nature of poverty, we consider different dimensions: economic well-being, health condition, education, neighborhood quality, subjective well-being.

The empirical application is based on micro-data from the 'Aspects of daily life' (AVQ) survey by Istat for the years 2019 (pre-Covid period) and 2020 (Covid period).

Since survey direct estimates are reliable only at regional (NUTS 2) level, the introduction of small area estimation (SAE) techniques becomes of crucial importance to monitor and contrast the phenomenon at a finer geographical level.

Keywords: Multidimensional poverty index, composite indicators, small area estimation, EBLUP estimator.

1. Introduction

In the recent years there has been a considerable agreement that poverty is a multidimensional phenomenon, which cannot be adequately explained by considering only monetary variables. (1) confirms the existence of significant mismatches between monetary poverty and multiple deprivations and, therefore, the need to include many aspects of poverty, such as health, education, housing, satisfaction with life, security.

Few empirical studies have analyzed multidimensional poverty in Italy at sub-national level; see, among others, (5), (4) and (3). In this paper, we propose a deeper attempt in this direction by looking at the provincial level changes in the multidimensional poverty due to Covid-19 pandemic.

The empirical application is based on micro-data from the 'Aspects of daily life' (AVQ) Italian survey over the years 2019 (pre-Covid period) and 2020 (Covid period).

Since the AVQ survey is planned to obtain precise estimates at regional level, some alternative solutions should be evaluated to estimate poverty at provincial level. More specifically, two main possible strategies can be employed: i) increasing the sample size of AVQ for the specific province of interest (oversampling) so that direct estimates become reliable and ii) apply small area estimation (SAE) techniques; see, among others, (12) and (9).

We apply the Fay-Herriot (FH) small area estimation model proposed by (6) to estimate dashboard indicators at provincial level. Then, we propose an aggregation technique based on the Adjusted Mazziotta-Pareto Index (see (7) and (8)) for the FH estimates in order to obtain reliable estimates of the multidimensional poverty for the local areas of interest as in (11).

Therefore, the aim is to enhance the knowledge of the spatial distribution of the multidimensional poverty index at local level in Italy, focusing on Italian provinces, in order to help the policy maker to address resources towards the areas where the phenomenon is strongly present.

The empirical analysis reveals that the traditional Italian divide North vs. South becomes less clear when analyzing poverty at provincial level and for the different domains of poverty.

The remainder of the paper is as follows. Sections 2. and 3. describe data and methodologies considered in the analysis. Section 4. is devoted to results of the empirical application. Finally, Section 5. draws some conclusions.

2. Data

Our analysis is based on data from the 'Aspects of daily life' (AVQ) survey conducted by Istat, focusing on the years 2019 and 2020. The units of analysis are the Italian households and the original samples include 19536 and 18529 households, for the two years considered respectively.

To assess the multidimensional poverty over 105 Italian provinces[1], we consider five domains (health, education, economic well-being, neighborhood quality and subjective well-being), each composed of different dashboard indicators as described in Table 1.

In order to classify a household as deprived in each of the 13 dashboard indicators, we first identify the deprivation cut-offs following the approach proposed in (5), which we have slightly modified due to the data availability at provincial level. The deprivation cut-offs refers to the head of the household.

Table 1: Multidimensional poverty framework: domains, dashboard indicators, deprivation cut-offs.

Domains	**Deprivation Indicators**	**Deprivation cut-offs**
Health	Nutrition	A person is deprived if s/he consumes less than 3 portions of fruits or vegetables a day.
Education	Educational deprivation	A person is deprived if s/he has not completed higher-secondary school.
	Cultural deprivation	A person is deprived if in the 12 months before the interview s/he has joined less than 2 among the following activities: 1) at least once to cinema, theatre, exhibitions and museums, archaeological sites, monuments, concerts of classical music, opera, concerts of other kind of music; 2) read the newspaper at least once a week; 3) read at least a book.
Economic well-being	Material deprivation	A person is deprived if s/he possesses less than 4 out of 6 following items: washing machine, color tv, scooter/moto or car, phone, personal computer.
	Housing deprivation	A person is deprived if s/he experiences 3 or more among the following deprivations related to the house: overcrowding; distance from basic services (pharmacy, shops, school); overall poor condition of the floors and/or walls; expenses too high; house not owned).
	Gas	A person is deprived if the house is not served by methane gas.
	Water	A person is deprived if s/he declares to have irregularities in their water supply.
	Unemployment	A person is deprived if s/he is unemployed.
	Financial distress	A person is deprived if her/his economic sources are not sufficient to make ends meet.
Neighbourhood quality	Noise Crime Pollution	A person is deprived if the area in which s/he lives is declared to be very noisy; at risk of crime; polluted.
Subjective well-being	Life satisfaction and future expectations	A person is deprived if experiences 3 or more deprivations related to personal satisfaction (life, economic situation, health, familiar and friends relationship, leisure and future expectations).

[1]The provinces of Vibo-Valentia and Benevento have been excluded from the analysis due the very high percentage of missing data.

3. Methodology

Small area estimation (SAE) combines survey data with auxiliary variables of the population of interest to break down regional estimates into sub-regional ones. These variables are commonly obtained from population censuses or from administrative registers. If auxiliary information are available at unit-level (e.g., individual or household-level) one can consider unit-level SAE models[2]. When, on the contrary, the auxiliary data are available only at area-level (e.g., district, municipality or provincial level), one can use area-level SAE models.

We follow the latter approach and apply the Fay-Herriot area-level small area estimation model introduced by (6), which proposes the empirical best linear unbiased predictor (EBLUP) estimator to obtain estimates of the poverty dashboard indicators at provincial level[3].

Consider a finite population U, partitioned into $d = 1, \ldots, D$ mutually exclusive and exhaustive areas (in our case, provinces); the Fay-Herriot (FH) model is defined in two stages.

Let $\hat{\delta}_d^{DIR}$ be a direct estimator of δ_d, the parameter of inferential interest for area (province) d. In the first stage, we assume that $\hat{\delta}_d^{DIR}$ is an unbiased estimator of δ_d:

$$\hat{\delta}_d^{DIR} = \delta_d + e_d, \qquad e_d \overset{ind}{\sim} N(0, \psi_d), \tag{1}$$

where ψ_d is the sampling variance of the direct estimator $\hat{\delta}_d^{DIR}$ given δ_d, assumed to be known for all $d = 1, \ldots, D$.

In the second stage, we assume that the area parameters δ_d are linearly related with a p-vector x_d of area-level auxiliary variables as follows:

$$\delta_d = x_d^T \beta + u_d, \qquad u_d \overset{ind}{\sim} N(0, A). \tag{2}$$

Model (1) is known as *sampling model* because it represents the uncertainty due to the fact that δ_d is unobservable and the direct estimator is based on the sample data, $\hat{\delta}_d^{DIR}$. While, model (2) is called *linking model* because it relates all areas through the common regression coefficients β, allowing us to borrow strength from all areas.

Combining the two model components (1) and (2), we obtain the linear mixed model:

$$\hat{\delta}_d^{DIR} = x_d^T \beta + u_d + e_d, \tag{3}$$

where u_d is independent of e_d.

The EBLUP estimator is the combination of the direct and the regression-synthetic estimators:

$$\hat{\delta}_d^{EBLUP} = \hat{\gamma}_d \hat{\delta}_d^{DIR} + (1 - \hat{\gamma}_d) x_d^T \hat{\beta} \tag{4}$$

where $\hat{\gamma} = \frac{\hat{A}}{\hat{A} + \hat{\psi}_d}$ represents the shrinkage factor.

For each of the 13 dashboard indicators of deprivation j and for each province d we obtain an EBLUP estimate, denoted with $\hat{\delta}_{dj}^{EBLUP}$. For sake of simplicity we will denote estimator $\hat{\delta}_{dj}^{EBLUP}$ with $\hat{\delta}_{dj}$.

Then, in order to obtain a composite indicator of multidimensional poverty, we aggregate the EBLUP provincial estimates $\hat{\delta}_{dj}$, where d indicates the province and j the dashboard indicator, using the Adjusted Mazziotta-Pareto Index (AMPI); see (8).

The AMPI approach considers the normalized provincial estimates r_{dj} defined as:

$$r_{dj} = \frac{\hat{\delta}_{dj} - Min(\hat{\delta}_{dj})}{Max(\hat{\delta}_{dj}) - Min(\hat{\delta}_{dj})} 60 + 70. \tag{5}$$

Denoting with Ref_{δ_j} the reference value for the indicator j, the 'goalposts' $Max(\hat{\delta}_{dj})$ and $Min(\hat{\delta}_{dj})$ are defined as:

$$\begin{cases} Min(\hat{\delta}_{dj}) = Ref_{\delta_j} - \Delta \\ Max(\hat{\delta}_{dj}) = Ref_{\delta_j} + \Delta \end{cases} \tag{6}$$

[2]The Battese-Harter-Fuller (BHF) model is one of the most used unit-level small area estimation model (2).

[3]See (10) for notation details.

where $\Delta = \frac{Sup_{\delta_j} - Inf_{\delta_j}}{2}$. Inf_{δ_j} and Sup_{δ_j} are the overall minimum and maximum of the indicator $\hat{\delta}_{dj}$ across all provinces and the two years considered. To facilitate the interpretation of results, we choose as Ref_{δ_j} the mean of the year 2019. The normalized values r_{dj} will fall approximately in the range $(70; 130)$, where 100 represents the reference value.

Denoting with M_d and S_d , respectively, the mean and standard deviation of the normalized indicators r_{dj} of province d, the multidimensional poverty index of province d is computed as:

$$AMPI_d = M_d + S_d \times cv_d \tag{7}$$

where $cv_d = \frac{S_d}{M_d}$ is the coefficient of variation for the local unit d; see (8).

4. Empirical findings

Figures 1 and 2 illustrate a geographical representations of how the multidimensional poverty indicator as well as the domain-specific deprivation indices are distributed across the Italian provinces in the years 2019 and 2020, respectively. In each panel, value 100 corresponds to the Italian average in 2019, and darker colors indicate higher levels of deprivation.

Comparing Figures 1(d) and 2(d) it emerges how health deprivation strongly worsened during the Covid-19 pandemic especially in Sicily, Sardinia, Lombardy and Piedmont and for the provinces located along the Tyrrhenian coast. On the contrary, Figures 1(e) and 2(e) reveal that life satisfaction and future expectations have not been affected by Covid-19.

Overall, the multidimensional poverty index (Figures 1(a) vs. 2(a)) does not seem to have deteriorated after the first year of the pandemic, although its levels remain higher in the South of Italy. We note that some domains of poverty (economic, education, health) have worsened in many provinces, but their effects have been compensated by the opposite trend registered for subjective well-being and quality of neighborhood. Anyway, the result refers only to the first year of the pandemic. In order to have a complete overview of the effect of Covid-19, one should analyze more recent data.

5. Conclusion

In this paper we have estimated the multidimensional poverty of the Italian households during the period of Covid-19 at provincial level. Since the AVQ survey is planned to obtain precise estimates at regional level, we have applied the FH small area estimation model in order to obtain reliable estimates of the dashboard indicators of deprivation at this finer geographical level. The overall composite indicator of multidimensional poverty has been then obtained using the AMPI approach.

Empirical findings suggest that, among the different domains of poverty considered, health deprivation has strongly worsened during the first year of the pandemic especially for provinces of the Islands (Sicily and Sardinia), Lombardy, Piedmont and the whole region located along the Tyrrhenian coast. Subjective deprivation, on the contrary, has reduced in the period of analysis. Overall, data reveals that the multidimensional poverty has not worsened relevantly, although the provinces of southern Italy are multidimensionally poorer than those of the north.

Further research could be devoted to the use of different techniques of aggregation of the dashboard indicators.

Abstract

Monitoring living conditions at local level is becoming an important goal for policy maker - especially after the pandemic – in order to identify and measure the incidence of new vulnerable people and worsening of existing vulnerabilities. However, its measurement is complex and multi-faceted, and, as current and future living conditions depend upon a great number of variables. Moreover, there is no doubt that pandemic impacted differentially in different areas and sub-groups of population. Against this background, the aim of this article is to provide a better understanding of the changes in living conditions in Tuscany at the local level. In order to achieve it, the paper used a multidimensional and fuzzy approach to measure living conditions in Tuscany in a dynamic perspective. The study is based on two *ad hoc* surveys conducted in 2021 and 2022.

Keywords: living conditions, fuzzy approach, pandemic, local level, Tuscany

1. Introduction

The intent of this study is to measure how and how much the consequences of the COVID-19 pandemic affected socio-economic living conditions of the Tuscan household population going below the regional level and using a multidimensional perspective. This exercise will inform us whether households, at the end of 2022, experiment a phase of improvement of their living conditions with respect their situation during the pandemic in 2021, or the new economic shocks due to the war, the rising of energy prices and inflation worsening existing socio-economic vulnerabilities. The final aim is to obtain new information for designing preventive and protective measures at local level. From a methodological point of view, we start from the consideration that the traditional poverty measures lack to properly estimate the vulnerability of households towards poverty. The reason behind this inability is mainly the failure of the existing measures to recognize the graduality inside the concept of poverty (Chiappero-Martinetti,1994; Cheli and Lemmi,1995). The Integrated Fuzzy and Relative (IFR) approach was developed in this perspective because the graduality within a vague concept can well be represented by the idea of fuzzy logic (Zadeh, 1965). In other words, IFR approach is based on the assumption that poverty is a multidimensional phenomenon and a vague predicate that manifests itself in different shades and degrees (fuzzy concept) rather than an attribute that is simply present or absent for individuals in the population (Betti et al., 2006). The IFR approach in a "modern statistical language" can be also defined an unsupervised learning method since it addresses a data reduction issue. IFR method does not presume any structure of the data. In fact, several elementary indicators represent the potential set of indicators that are single observable manifestations of the multidimensional concept of poverty and explorative factor analysis is performed for discovering if the multidimensional concept should be broken down into more than one

dimension. The empirical analysis is based on two *ad hoc* and cross-sectional sample surveys conducted in 2021 and 2022 by the Regional Institute for Economic Planning of Tuscany in collaboration with the University of Siena.

2. Data

Data on living conditions of resident households in Tuscany between pandemic and post-pandemic period have been drawn from two cross-sectional surveys. The first survey was conducted in September 2021 approximatively after eighteen months from the pandemic beginning, while the second in October 2022, when the pandemic issues was reduced, but households were in difficulty with the rising energy prices and inflation. Both surveys focus on the economic and social features of households, with particular attention to the current economic situation and prospects. The survey design of the two surveys is very similar: households have been drawn to achieve representativity at NUTS-3 level (the sample size is reported in Table 1); most of the interviews was conducted by C.A.T.I. and C.A.M.I. methods, interviewing one adult household member; the two questionnaires share most of the questions. As regards to some specific features of the 2022 survey it is worth to highlight that some interviews (29%) were conducted by C.A.W.I., and that the survey 2022 includes a set of questions as regards to the family's strategies to face the high energy price. A weighting adjustment procedure has been performed so that the sample totals conform to the population totals of specific domains obtained as an aggregation of functional geographies, clustering according to economic characterization of the so-called Local Labour Market Areas. Such grouping, in six different areas, refers also to the levels of employment and of the remuneration of productive factors (labour and capital) and consequently to different level of wellbeing. As regards item nonresponses, missing data have been imputed by deductive imputations based on logical or mathematical relationships between the variables, where it was possible. Item nonresponses relative to some quantitative and qualitative variables were imputed with stochastic imputation methods, assuming fully conditional specification[1]. The largest number of missing values (respectively 14.5% for 2021 and 10.7% for 2022) were registered for the only question adopted to collect the approximative monthly total net household income. The approximative values collected lead to a bracket distribution, and continuous values within each bracket have been imputed considering the kernel density estimate of the empirical distribution. Based on the total household disposable income, we retrieved the equivalized income using the OECD-modified equivalence scale. The poverty line was taken as the 60% of the median of the equivalised income distribution respectively for 2021 and 2022.

Table I: Sample sizes by Province (surveys 2021 and 2022).

	Prato	Massa	Livorno	Grosseto	Pistoia	Arezzo	Lucca	Siena	Pisa	Firenze	Tuscany
2021	83	94	164	166	175	207	263	320	336	691	2499
2022	142	248	265	306	200	182	437	268	328	641	3017

Several non-monetary indicators (binary variables) were collected in both surveys. These indicators are based on the standard questions as regard to affordability, such as affordability to eat nutritional meals, to keep household adequately warm and the capacity to cover costs for health, for one week holiday, for cinema or theatre, for eating out once a month, to cover costs for transport, for children clothes, toys, or specific children food; to cover costs for education such as taxes, books and materials and finally and then ability to cope with unexpected expenses of different amount. When necessary, these indicators have been transformed according to a positive polarity: the indicator is one in a situation of vulnerability to poverty or zero otherwise.

[1] FCS method of the MI procedure of the SAS software.

3. Methodology

The Integrated Fuzzy and Relative (IFR) assumes that poverty is a multidimensional phenomenon and a fuzzy concept rather than an attribute that is simply present or absent for individuals in the population, as the traditional poverty approach assume. In particular, it belongs to the fuzzy methods whose membership function is based on a distribution function (Betti et al., 2023). For a detailed discussion of IFR methodology reader is referred to Betti et al. (2006). Very briefly, IFR approach includes a non-fixed value of poverty risk and deprivation, through the introduction of a membership function, i.e. a quantitative specification of individual/household degrees of poverty and deprivation depending on the other individuals or households included in the analysis. A membership function's value of 0 is always associated with the lowest risk of poverty and deprivation, whereas a value of 1 is associated with the highest risk. Furthermore, the multidimensional framework of the IFR approach works up on several non-monetary indicators, assumed to be the manifest representation of a restricted number of underlying dimensions of deprivation, besides a monetary indicator based on the equivalent disposable income. In this paper, let FM be the membership function defined for the monetary variable (i.e. household income) and FS_j be the membership function referring to dimension j ($j = 1..D$).

4. Results

4.1 Traditional approach

The so-called traditional approach has been performed by calculating the Eurostat "At-risk-of-poverty" rate (ARPR), based on the 60% of the median household equivalised income. Although the both median and mean income have been substantially stable from 2021 and 2022 (see Table II), the ARPR increased from 11.58% in 2021 to 15.79% in 2022. The deeper analysis conducted taking into account other EU Laeken indicators, such as 40%, 50% and 70% of the equivalised income, have confirmed this change in the reported income values (only) in the left-side if the income distribution itself: in fact, all such additional traditional indicators have increased from 2021 to 2022.

Table II: Traditional approach: the Laeken indicators (2021 and 2022)

	Mean	Median	40% median	50% median	**60% median**	70% median
2021	1295	1196	2.41 %	5.72 %	**11.58 %**	20.20 %
2022	1377	1207	4.93 %	9.29 %	**15.79 %**	24.13 %

Such traditional approaches to the measurement of poverty have received some critics in the literature of the last three decades; i) first of all, they depend on a poverty line, and thus dichotomise the population into the poor and the non-poor (Cheli and Lemmi, 1995); ii) they are mainly unidimensional – i.e. they refer to only one proxy of poverty, namely, low income or consumption expenditure (Bourguignon and Chakravarty,1999; Anand and Sen, 1997); iii) in the research on poverty dynamics, spells usually replaced households or individuals as units of analysis, which led to a concentration on the duration of poverty and loss of sight of its severity (Ashworth et al., 1993); iv) moreover, small changes in the monetary variable may let individuals cross the poverty line, thus overestimating transitory poverty (Cheli and Betti, 1999), which may have been the case of the situation in Tuscany from 2021 and 2022. As introduced in the previous sections, the fuzzy and multidimensional approach to poverty and well-being measurement could be a statistical learning method able to overcome some of such critics.

4.2 Multidimensional and fuzzy approach

We used data collected in 2021 for identifying significant dimensions of our data. Accordingly, we used Exploratory Factor Analysis (EFA) for determining whether the 12 items listed in Table III can be arranged in a restricted number of dimensions. Table III reports the final structure provided by data. We identified three dimensions reflecting i) Basic needs & social life, ii) More specific Utilities and iii) Financial issues whose membership functions are FS1, FS2 and FS3, respectively. The last dimension represents the membership function based on the monetary variable (FM). These dimensions have been assumed also for the 2022 survey, in order to perform a longitudinal analysis.

At regional level we observed an unnoticeable difference between 2021 and 2022 in the FM indicator. FM indicator increases indeed from 0.116 to 0.117, although the so-called traditional approach has shown a worsen situation based on the poverty lines and the solely left-side part of the equivalised income distribution. Whereas results suggest an improvement of living conditions in two dimensions (Basic needs & Social life and Specific Utilities) because FS1 and FS2 indicators decrease from 0. 241 to 0.176 and from 0.1394 to 0.0650, respectively. Financial issue (FS3) dimension deserves particular attention because its value is the only one increased from 0.115 to 0.142 in the two years period. These general findings stress that the new current socio-economic shocks seem to contribute to increase final insecurity more than other aspects, or at least its perception. The perception of financial insecurity could also have caused a sort of underreporting in the left-side of the income distribution (without affecting its median or mean); this perception is clearly an important aspect that can contribute to other detrimental outcomes such us undermined basic psychological needs and lowered well-being (measured in terms of self-esteem, depression, and anxiety).

Table III: Dimension and items

Membership function label	Dimension descripti	Items
FS1	Basic needs & Social life	Meals with meat or fish // Household adequately warm // cover costs for health// cover costs for 1 week holiday// cover costs for cinema, theatre, eating out once a month;
FS2	Specific utilities	Costs for: children (clothes, toys, child's food)// education (taxes, books and materials) // transports
FS3	Financial issues	Inability to cope with unexpected expenses: 5,000, 2,000, 800 Euros;
FS4	Monetary dimension	Equivalised monthly income

It was also fairly clear that not all Provinces showed the same intensity of the multi-dimensional indicators and the same variation from 2021 to 2022 (see Figure 1)[2]. For instance, in 2021, the FM indicator present values larger than the regional level (0.116) in Lucca and Grosseto while Siena, Firenze and Arezzo present figures below the regional estimate. The same pattern is confirmed in 2022. Looking at difference over the period, results show light improvements for Arezzo, Pisa and Siena, while the monetary situation seems to get worse for Firenze, Livorno, Pistoia and Prato. Other interesting findings can be stressed by observing the other dimensions and comparing different provinces characterized by different level of urbanisation. For instance, Florence and Grosseto share a similar value of FS3 in 2021, whereas in 2022 household living in Florence, province characterized by high urban functions and widespread tertiarization, suffer less of financial insecurity that people living in Grosseto that is instead a rural district.

5. Conclusion

The consequent picture therefore is that even if the families have below of the poverty threshold, their economic behaviour could be curbed, by the financial fragility, and also by fear for the near future.
Finally, although the presented findings highlight some interesting information for policy maker by comparing living conditions and subnational level in Tuscany between 2021 and 2022, further analyses at finer territorial levels or peculiar groups of the population are necessary for designing preventive and protective measures at local level. These analyses will be the natural development of the preliminary results discussed in this paper.

[2] The estimates for Massa Carrara and Prato should be used with caution, according to Statistics Canada recommendation (Neri & Crescenzi, 2022).

A Bayesian framework for early cancer screening

Sally Paganin[a] and Jeff Miller[a]

spaganin@hsph.harvard.edu

Abstract

There is growing interest in developing tools for cancer screening and monitoring based on the analysis of DNA sequencing data derived from non-invasive procedures such as blood samples. At early cancer stages, such samples contain DNA from a majority of normal cells and a low fraction of tumor cells. Cancer presence can be assessed by measuring allelic imbalance: since a person inherits one allele from each parent, the allele proportion at heterozygous loci is close to 0.5 in normal cells, whereas significant deviations from 0.5 are indicative of the presence of cancer. To efficiently and sensitively detect such deviations, we model the allele proportions over the genome via a Bayesian hierarchical Hidden Markov Model.

Keywords: Allelic imbalance, Bayesian modeling, biological priors, NIMBLE.

1. Introduction

Cancer screening and monitoring are crucial for early detection and better treatment outcomes. With the advancement of next-generation sequencing (NGS) technologies, there has been a growing interest in developing minimally invasive procedures. One of the most promising technologies is the use of *cell-free DNA* (cfDNA), which refers to DNA fragments that can be found in the bloodstream. These fragments are released by cells during their normal life cycle. The cfDNA can be extracted from a bodily fluid sample, such as blood, making it a minimally invasive and accessible method for cancer screening.

Cancer is a genetic disease defined by alterations of the DNA that occurs in some cells. It has been shown that fragments of this altered DNA can also be found in the bloodstream and thus potentially used to detect cancer. Such tumor-derived DNA is commonly referred to as *circulating tumor DNA* (ctDNA). The main challenge in using ctDNA as a cancer biomarker is whether ctDNA can be distinguished from cfDNA. Moreover, in most cancer patients, ctDNA constitutes a very small proportion of the cfDNA, especially when cancer is at its early stages. Hence, advanced statistical methods are needed to extract the signal from the noise at such a small resolution.

We propose a hierarchical Bayesian framework for genomic signals of cancer to efficiently enable cancer detection at early stages. We focus on measuring allelic imbalance: since a person inherits one allele from each parent, the allele proportion at heterozygous loci is typically distributed around 0.5 when DNA fragments come from healthy cells. Small significant deviations from 0.5 can be indicative of DNA alterations, and hence the presence of DNA from cancerous cells.

2. Allelic imbalance in genomic data

Evidence for cancer presence in genomic data is typically inferred by modeling different data summaries derived from sequencing data. This kind of data is derived from a multi-stage process where

DNA strands are unraveled, cut into pieces and amplified, so that, at the end of the process, we have multiple observations at each genomic position (locus). These pieces of DNA are referred to as *reads*, and to be analyzed, researchers need to know where they are located on the genome. Reads are typically aligned using a reference genome, which provides a standardized map of the entire genetic makeup of an organism. At the end of the process, genomic data consists of multiple observations at each locus of the nucleotide bases (A, T, C, G) that makes up the DNA code.

The term *allele* indicates one of two or more versions of a DNA base. Since a person inherits half of their genome from each parent, at each locus we can either observe the same allele (homozygous) or two different ones (heterozygous). For healthy human cells, allele frequencies at heterozygous loci are expected to be distributed around 0.5. If one allele has a higher frequency than the other—i.e., the two alleles are expressed differently—one can individuate a major and a minor allele. *Allelic imbalance* describes the situation where the allele frequency deviates from the expected 0.5 value. This can result from deletion or duplication of part of a chromosome and is often related to cancer development.

Information about which is the minor or major allele is not directly available in genomic data, as alleles are distinguished using the reference genome used in the alignment phase. The term *reference allele* indicates the base that is found in the reference genome at a certain position, while the *alternative allele* refers to any base, other than the reference observed at the locus. This is also known as *B-allele* and we will use this term in the manuscript. Since B-alleles are defined with respect to the reference genome, they can either represent the major or minor allele.

Information related to parental origin can be used to aid the correct identification of minor alleles. It is known from biology, that stretches of the genome containing variants tend to be inherited together from one of the parents. These stretches are called *haplotypes*, and we can obtain an estimate of the haplotype for each locus by using a *phaser algorithm* (e.g., SHAPEIT2 (4)). This is based on a Hidden Markov model that uses use information about genotype and genomic locations, which can be considered as "external data" for the allele counts.

3. A Hidden Markov Model for allele proportions

We model observations within each chromosome independently and illustrate the model for one generic chromosome. Let y_i and n_i denote the number of B-alleles and the total number of reads at each locus i, for $i = 1, \dots, m$. We want to estimate the minor allele proportion, which can be described as a piecewise function over the chromosome. Sections of the chromosome where it is locally constant are referred to as *segments*. Segments are typically unknown and estimated via a statistical model; here we assume that they are given and ignore the associated uncertainty. We introduce a variable $s_i \in \{1, \dots, J\}$ indicating which segment locus i belongs to. Interest is in estimating $\theta_j \in (0, 0.5], j = 1, \dots, J$, which is the average minor allele proportion for each segment.

To do so, we model the number of B-alleles assuming a Binomial distribution at each genomic position

$$y_i \sim \text{Bin}(n_i, \theta_{s_i}), i = 1, \dots, m, s_i \in \{1, \dots, J\}. \tag{1}$$

As explained in Section 2, the observed number of B-alleles does not necessarily reflect the minor allele proportions. This means that the observed number of B-alleles y_i at some loci corresponds the number of major alleles, and should be considered to estimate $1 - \theta_{s_i}$, rather than θ_{s_i}. To reflect this, we introduce an indicator variable $h_i \in \{0, 1\}$ encoding whether or not the B-allele is the minor allele, so that

$$(\theta_{s_i} \mid h_i) = \theta_{s_i}^{h_i}(1 - \theta_{s_i})^{(1-h_i)} \quad i = 1, \dots, m. \tag{2}$$

Finally, we include in the model the haplotype information obtained from the phasing algorithm via a Hidden Markov Model. We do this by interpreting the haplotype as a prior estimate $\hat{h}_i$ for the latent variable h_i, for $i = 1, \dots, m$. Although $\hat{\boldsymbol{h}}$ cannot be expected to perfectly recover $\boldsymbol{h}$, it can be expected to either match or not match $\boldsymbol{h}$ for long stretches of the genome. To account for occasions of mismatch, we introduce a variable $w_i = I(h_i \neq \hat{h}_i)$ indicating whether or not the haplotype of the minor allele

coincides with the estimate, with $w_i \in \{0,1\}$. In other words, w_i tells us when we should switch the label given by $\hat{h}_i$. We model dependence between loci within the chromosome assuming a Markovian model

$$
\begin{aligned}
(\theta_{s_i} \mid h_i) &= \theta_{s_i}^{h_i}(1-\theta_{s_i})^{(1-h_i)} \\
(h_i \mid \hat{h}_i, w_i) &= \begin{cases} \hat{h}_i & \text{if } w_i = 0, \\ 1-\hat{h}_i & \text{if } w_i = 1, \end{cases} \\
\Pr(w_i = t \mid w_{i-1} = v) &= \pi_{tv} \quad t, v \in \{0,1\}, \quad i = 1, \ldots, m.
\end{aligned}
$$

The model above can be interpreted as a Hidden Markov Model, where $\boldsymbol{w}$ is the vector of latent states with 2 possible states, $\mathbf{T}_w = \{\pi_{tv}\}_{t,v\in\{0,1\}}$ the transition matrix, and $\boldsymbol{y}$ the vector of emissions.

Prior choice. We use a spike-and-slab prior to distingush between regions of standard (healthy) behavior and regions of allelic imbalance. Conceptually, as spike distribution $\mathrm{p}_{0.5}(\cdot)$ we look for a distribution concentrated around 0.5, representing the behavior of allele proportions as in a healthy sample, while we denote as $\mathrm{p}_{AI}(\cdot)$ the slab distribution over $(0, 0.5]$ for situations of allelic imbalance.

$$
\begin{aligned}
(\theta_{s_i} | s_i = j) = \theta_j, \quad & i = 1, \ldots, m, \\
\theta_j \sim \nu_j \mathrm{p}_{0.5}(\theta_j) + (1-\nu_j)&\mathrm{p}_{AI}(\theta_j) \\
\nu_j \sim \text{Bern}(0.5), \quad & j = 1, \ldots, J.
\end{aligned} \tag{3}
$$

We use $\mathrm{p}_{0.5}(\cdot) = Unif(0.47, 0.5)$ as spike distribution, while for the slab distribution, we use $\mathrm{p}_{AI}(\cdot) = \text{Beta}_{(0,0.5)}(2,2)$, where $\text{Beta}_{(a,b)}$ indicate a truncated Beta distribution in the (a,b) interval. To elicit the spike distribution, one can also calibrate the model on control samples containing DNA from healthy cells.

We assume a symmetric transition matrix $\mathbf{T}_w$, with $\pi_{00} = \pi_{11} = 1-p$ and $\pi_{01} = \pi_{10} = p$. Since we expect $\hat{\boldsymbol{h}}$ and $\boldsymbol{h}$ to match for long stretches of the genome, probabilities $\pi_{01} = \pi_{10}$ can be interpreted as the probability of an error in the haplotype estimate. Hence we set $p = 1/1000$ which corresponds to an estimated error rate for the haplotype phaser (1).

Posterior computation. We estimate the model via MCMC, making use of the nimble software (2; 3), which provides a flexible `R` framework for hierarchical models. Nimble comes with a suite of built-in customizable samplers (e.g., conjugate, Metropolis-Hastings, automated slice samplers, etc.) requiring only the coding of new sampling algorithms. To estimate the model in (1)-(3) we use a combination of conjugate Metropolis-Hastings, altogether with a custom algorithm to sample the latent states for the Hidden Markov Model component. A naive implementation that samples each latent state via Gibbs sampling tends to be inefficient and has been often replaced by alternative sampling algorithms in the literature. We consider here the approach in (5) which uses the forward-backward (FB) algorithm to sample the latent states sequentially from their joint posterior distribution at each MCMC iteration.

4. Application to laboratory experiment data

In this application, we use data derived from samples generated in a laboratory experiment using cell lines, which are cultures of cells that can be propagated multiple times while maintaining the same characteristics. The DNA extracted from two cancer cell lines (HCC38, HCC1143) was mixed with DNA from matched B-lymphocyte cell lines (HCC38BL, HCC1143BL) in various proportions measured in volume, to mimic mixed blood samples from subjects developing cancer. Here we show some preliminary results from our model for chromosome 1 across 3 different samples, containing respectively about $3\%, 10\%, 20\%$ DNA from cancerous cells. In this type of application, a sample containing 20% tumor DNA tends to provide strong evidence for allelic imbalance for the majority of chromosomes.

Chromosome 1 comprises 3827 heterozygous loci, divided into 48 segments of different sizes. Observed raw B-allele frequencies (BAF) are reported in the top row of Figure 1, while in the bottom row,

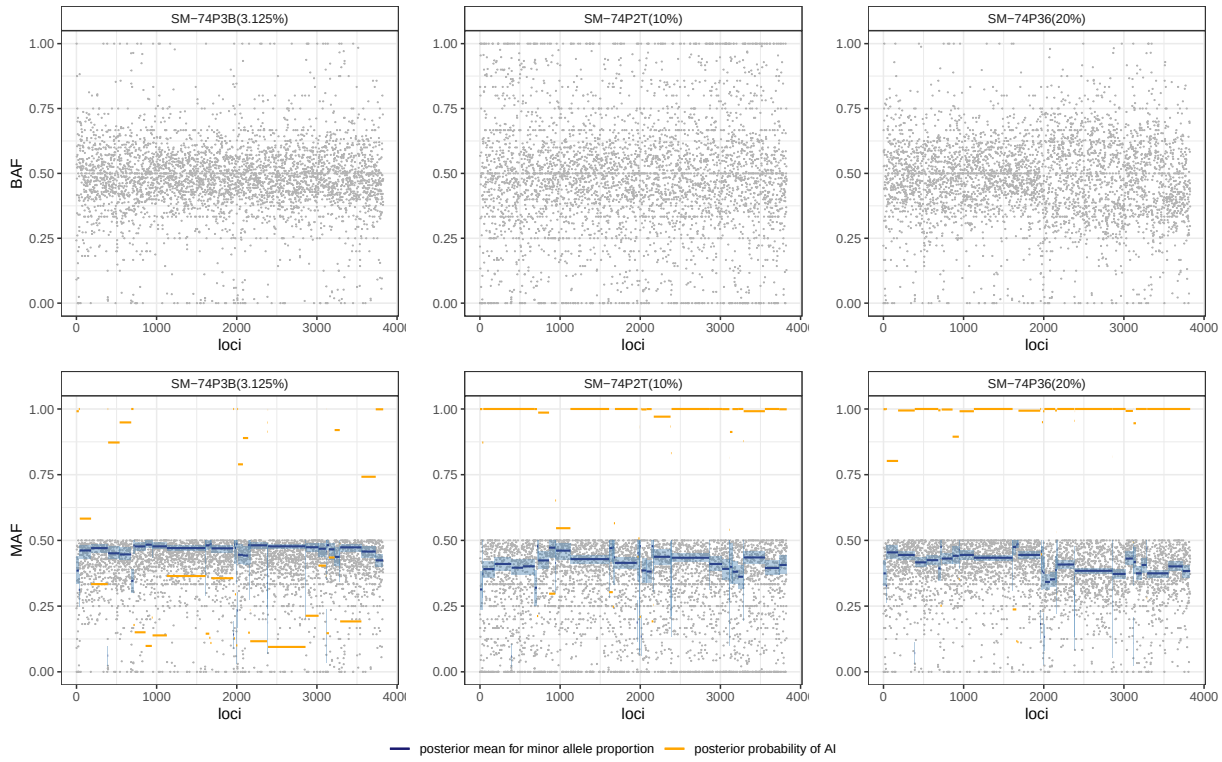

Figure 1: Top row. Observed B-allele frequency for 3 laboratory samples containing respectively $3\%, 10\%, 20\%$ DNA from cancerous cells. Bottom row. Results from our model. Gray dots are the MAF based on $\hat{\boldsymbol{w}}$. Blue lines represent posterior means for the minor allele proportions for each segment, while shaded blue areas represent high-density credible intervals at 95%. Yellow lines quantify the posterior probability of allelic imbalance for each segment.

we show the results from our model. For each sample, adjust the raw BAF to show the minor allele frequencies (MAF) based one the posterior estimate for the sequence of switches $\boldsymbol{w} = \{w_i\}$. We use the maximum a posterior, in this case corresponding to the sequence of w_i's that occurs in the posterior samples for the higher number of the iterations. We also plot the posterior means for the minor allele proportions for each segment, along with the highest posterior density intervals at 95%. Finally, we show the posterior probability of allelic imbalance for each segment, i.e. the posterior probability that the segment mean is a draw from the slab distribution $p_{AI}(\cdot)$.

It can be seen that there is an increase in the number of segments with a high probability of allelic imbalance probability as the percentage of tumor DNA increases. For the sample containing 20% tumor DNA, almost all segments are in allelic imbalance.

5. Discussion

In this work, we present a Bayesian model for allele proportions to detect allelic imbalance in samples containing signals from both healthy and cancerous cells, presenting preliminary results on laboratory experiments. Immediate extensions of the model will focus on including multiple samples from the same subject; although the segment's allele proportions can vary across samples, the haplotype information is shared and multiple samples can aid a better identification of the minor allele and, consequently, higher power in detecting allelic imbalance.

Finally, although the model is carefully constructed accounting for biological information related to the data, there are still factors that have not been considered in this application. For example, in genomic data there is a tendency to systematically observe more reads containing a reference allele

than an alternative one, due to different factors intrinsic to the sequencing process. The introduction of genomic covariates when modeling allele proportion can aid mitigation of such bias.

Linear models with assumptions-free residuals: a Bayesian Nonparametric approach.

Filippo Ascolani[a] and Valentina Ghidini[a]

[a]Bocconi University, Milan; filippo.ascolani@phd.unibocconi.it, valentina.ghidini@phd.unibocconi.it

Abstract

Assumptions on residuals limit the application of simple-to-interpret models to real world phenomena, especially when they are not mere measures of error but rather encode assumptions about the framework. For this reason, this work proposes a Bayesian nonparametric approach to relax some common assumptions on errors (such as homoskedasticity and symmetry), exploiting a nonparametric prior on the space of distributions of residuals. In particular, we design a methodology aimed at creating a more flexible model, yet retaining desirable parametric properties (such as interpretability). The final application involves a linear model, where the residual distribution is heavy tailed.

Keywords: Bayesian nonparametrics, linear model, flexible residuals

1. Introduction and Motivation

Linear models are ubiquitous in statistics and machine learning. They start from the collection of n observations (y_i, X_i'), where $y_i \in \mathbb{R}$ and $X_i \in \mathbb{R}^{p\times 1}$ and the assumption

$$y_i = X_i'\beta + \varepsilon_i, \quad \varepsilon_i \sim f, \quad i = 1,\dots,n \tag{1}$$

with $\beta = (\beta_1,\dots,\beta_p)$ unknown parameters, with $p < n$, and $f \in \mathscr{F}$, where

$$\mathscr{F} = \left\{ g \mid \int x g(x)\,\mathrm{d}x = 0, \int x^2 g(x)\,\mathrm{d}x < \infty \right\}.$$

From a classical perspective, the advantage of the formulation in (1), with the general assumption of zero mean and finite variance of the residuals (called second order conditions) is that the estimate of β that minimizes the square distance can be computed with the well known formula

$$\hat{\beta} = \left(X'X\right)^{-1} X'Y \tag{2}$$

with $X = [X_1',\dots,X_n'] \in \mathbb{R}^{n\times p}$ and $Y = (y_1,\dots,y_n)'$. In other words, under model (1) and quadratic loss, (2) is the optimal estimate of β. However, in order to perform statistical inference (e.g. computing confidence intervals), a distributional assumption on ε_i is required and the most common choice is given by $\varepsilon_i \sim N(0,\sigma^2)$. This setting is extensively studied and is endowed with many nice statistical and computational properties. Nevertheless, placing such a restriction poses many issues: not only the coverage of the confidence intervals and the power of the statistical tests will depend crucially on the distance between the data generating distribution and the Gaussian case, but also the symmetry of the residuals

is required, together with the assumption of light tails. This can be particularly relevant in the economic and econometric literature, where the ε_i are not just mere errors, but are often a crucial component of the model. For instance, in the well known Capital Asset Pricing Model (3), assuming symmetric residuals implies symmetric returns, that can be an unrealistic assumption (10). Therefore, it makes sense to look for methodologies more capable of exploring the space of the residual distributions.

The goal of this work is to propose a novel methodology, based on a suitable countable mixture of normal distributions, that combines the theoretical generality of the Bayesian nonparametric (BNP) approach (see (5) for a review) with the appealing simplicity of linear models. On the one hand it will have better performances than the OLS estimate, both in terms of point estimate of β and coverage, even with extreme residual distributions, on the other it will provide the researcher with simple ways of performing inference, similarly to the classical case. Finally, all the parameters involved will have an intuitive role, making prior elicitation less mysterious; in particular, it will allow us to easily study the possible asymmetry of the residuals.

The problem of modelling the residual through a BNP approach has been already discussed in the literature (e.g. (6; 9)): however the proposed methodologies either assume symmetry of the residuals, or can be difficult to interpret for a practitioner.

The rest of the paper is organised as follows. In Section 2 the methodology is introduced and thoroughly discussed. In Section 3 an algorithm to estimate the proposed model is presented and a simulation study is conducted. The paper ends with a discussion.

2. Methodology: theory

2.1 Formulation

In the Bayesian context, after setting the model (1), the statistician places a probability distribution, called *prior*, on the parameters (the coefficients β's, for instance); then, instead of considering the Maximum Likelihood Estimates, inference is made through the *posterior distribution*, that is the distribution of the parameters given the observed data. In other words, we update the prior beliefs through the collected observations. The main advantage of this framework is that the researcher is endowed with an entire distribution for the parameter instead of a single numerical estimate: in this way, for instance, evaluation of the uncertainty of the analysis becomes immediate. See (5) for more details on Bayesian inference.

Considering more formally our problem, we start by the standard setting of Bayesian linear models:

$$\begin{aligned} y_i \,|\beta &= X_i'\beta + \varepsilon_i, \quad i = 1,\dots,n \\ \beta &\sim N_p(\cdot \mid b_0, B_0) \end{aligned} \tag{3}$$

where $N_p(\cdot \mid b_0, B_0)$ is the p-variate normal distribution, with mean vector $b_0 \in \mathbb{R}^p$ and covariance matrix B_0. The characteristic feature is given by the assumption on the residuals. Indeed, denoting $\mathrm{TN}(\cdot \mid \mu, \sigma_0^2)$ the normal distribution truncated on the interval $[0,\infty)$ and $\mathrm{IG}(\cdot \mid s, S)$ the inverse gamma distribution, we have

$$\begin{aligned} &\varepsilon_i \,|\mu_i, \tau_{1i}^2, \tau_{2i}^2 \overset{\text{ind}}{\sim} \frac{1}{2}N(\cdot \mid \mu_i, \tau_{1i}^2) + \frac{1}{2}N(\cdot \mid -\mu_i, \tau_{2i}^2) \\ &(\mu_i, \tau_{1i}^2, \tau_{2i}^2) \mid P \overset{\text{iid}}{\sim} P \\ &P \sim \mathrm{DP}(P_0, \theta), \quad P_0(\cdot) = \mathrm{TN}(\cdot \mid \mu_0, \sigma_0^2) \times \mathrm{IG}(\cdot \mid s_1, S_1) \times \mathrm{IG}(\cdot \mid s_2, S_2), \end{aligned} \tag{4}$$

where $\mathrm{DP}(P_0, \theta)$ is a *Dirichlet process* (DP) (introduced by (4)), with probability distribution P_0, called *baseline distribution*, and $\theta > 0$.

In the setting of (4), conditional to P, for the i-th residual a triplet $(\mu_i, \tau_{1i}^2, \tau_{2i}^2)$ is sampled from P and the distribution of ε_i is given by a mixture of two Gaussian distributions with opposite means and (possibly) different variances; thus the mean of ε_i is zero, but the symmetry around the origin is not required. Since the Dirichlet process is almost surely discrete (see (4)), considering (4) and integrating

out P, the unconditional density of ε_i is given by

$$\varepsilon_i \sim \sum_{j\geq 1} W_j \left[\frac{1}{2}N(\cdot \mid \mu_i, \tau_{1i}^2) + \frac{1}{2}N(\cdot \mid -\mu_i, \tau_{2i}^2)\right], \quad (\mu_i, \tau_{1i}^2, \tau_{2i}^2) \overset{\text{iid}}{\sim} P_0, \tag{5}$$

where $\{W_j\}_{j\geq 1}$ are random probability weights. Therefore, the distribution of the residual is assumed to be a countable mixture of a mixture of two Gaussians.

3. Methodology: computations

3.1 Algorithm

Considering model specification (3) with residuals (4), it is in general not possible to compute analytically the density $p(\beta \mid Y, X)$ with an explicit formula.

This issue holds for the vast majority of Bayesian models, especially in nonparametric contexts. However, many algorithms have been developed and studied to collect a sample $\{\beta_t\}_{t\geq 0}$ such that $\beta_t \sim p(\beta \mid Y, X)$, at least approximately. The idea is to create a Markov chain (hence the name Markov Chain Monte Carlo), whose invariant distribution is given by the posterior distribution of interest. In this paper we construct a chain $\{\beta_t, P_t\}_{t\geq 0}$ through the Gibbs sampler methodology (see (2) and (8) for more details). The procedure works as follows

1. Initialize β_0 with random starting values.
2. For $t = 1, \ldots, B$ do:
   (a) Sample $P = P_t$ from its conditional distribution given (β_{t-1}, Y, X).
   (b) Sample β_t from the conditional distribution given (P_t, Y, X).

In order to sample P_t, that is a infinite dimensional object, we use a suitable truncation and employ the blocked Gibbs sampler proposed in (7). Thus, all the quantities of interest can be approximated through a simple Monte Carlo approach, i.e.

$$\mathbb{E}[h(\beta) \mid Y, X] \approx \frac{1}{B}\sum_{t=1}^{B} h(\beta_t).$$

In this way, for instance, the posterior mean and higher moments can be computed with $h(x) = x^k$. Similarly, credible intervals for the quantities of interest can be estimated by suitable empirical quantiles of $\{\beta_t\}_{t\geq 0}$.

3.2 Application - Heavy tailed residuals

To assess the performance of the proposed method, we consider a number of simulation examples varying the distribution of the residuals ε, and here we report the results regarding heavy tailed residuals $\varepsilon \sim T_q$, where T_q denotes a Student's t distribution with q degrees of freedom. The true coefficients are

$$\beta = (-1, -1, -1, 0, 1, 1, 1, 1, 1, 1)$$

The goodness of the model is measured with the mean width of empirical credible intervals, and the mean euclidean distance between the true coefficients and the estimated ones; then, we compute the median of those quantities over 100 randomly generated samples and compared with the ones obtained using the standard linear OLS regression.

In Figure 1 and 2, we can see the results for simulated residuals $\varepsilon \sim T_{1.1}$. Figure 1 displays the comparison between the point and interval estimates of the coefficients provided by the proposed method and by OLS: in particular, we can see that our method returns estimates (blue line) much closer to the true β (black line), while OLS (red line) can not retrieve most of the estimates in a precise way.

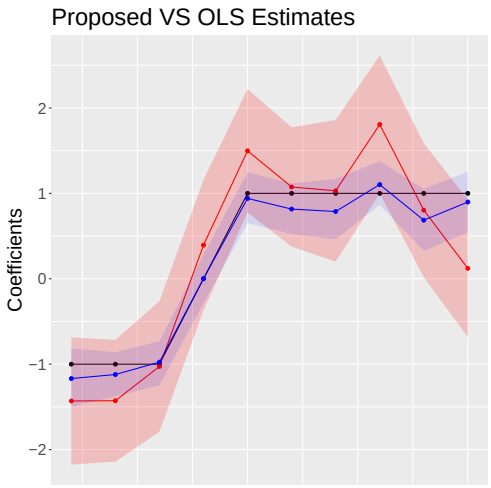

Figure 1: True coefficients (black), estimated with the proposed algorithm (blue), OLS Regression (red). True residual Density: $\varepsilon \sim T_{1.1}$.

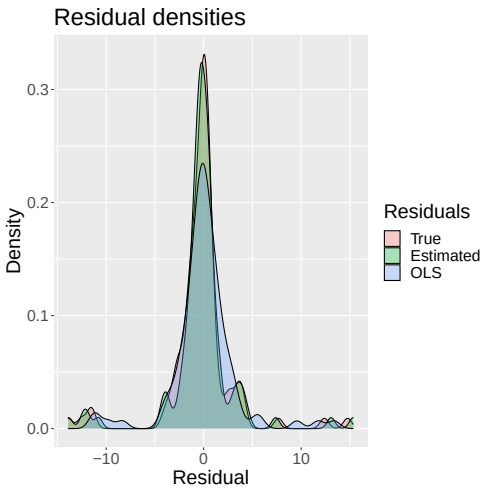

Figure 2: Residual Density: true (orange), posterior estimation with the proposed algorithm (green), estimation with OLS (blue). True residual Density: $\varepsilon \sim T_{1.1}$.

Moreover, the OLS confidence intervals are much wider than the posterior credible intervals computed with the proposed algorithm (confidence and credible level: 0.95). In Figure 2 we can see the difference in the estimated law of the residuals: the posterior density provided by the Gibbs sampler in Section 3.1 (green curve) is much closer to the true law from which the residuals are simulated from (orange curve). On the contrary, residuals from OLS can not retrieve the heavy tailed behaviour of the distribution in a proper manner.

Finally, in Table 1 we can see the mean interval width and the mean distance from the true coefficients obtained by 100 generated samples according to the same model. In particular, we can see that for residuals distributed according to a Student T with 1.1 and 2.1 degrees of freedom, the proposed method returns more precise estimates, closer to the true coefficients and with narrower intervals. Observe that these are the most problematic cases, with the heaviest tails.

However, for 50 degrees of freedom, the performance of the Bayesian method and of the OLS is perfectly comparable: this is because a Student's t distribution with 50 degrees of freedom is close to a Gaussian, which is the case where the OLS model is perfectly specified. Thus, we can conclude that our method performs better for heavy-tailed residuals, and it is also a good alternative to OLS even in the case of Gaussian residuals.

Table 1: Comparison of our method with classical OLS

Df	Mean interval width	Mean interval width (OLS)	Mean distance from true coefficients	Mean OLS distance from true coefficients
1.10	0.69	8.86	0.25	2.05
2.10	0.55	1.13	0.19	0.34
3	0.51	0.69	0.16	0.20
50	0.39	0.42	0.14	0.13

4. Discusssion

We have proposed a new methodology to avoid restrictive assumptions on the residuals of a linear model: it works by combining the interpretability of parametric models with the great flexibility guaranteed by Bayesian nonparametric methods. The methodology is shown to empirically outperform the MLE estimate, when the residuals are heavy tailed.

Future work will focus on how to exploit the discreteness of the realisation from a Dirichlet process; indeed, it can be used to identify outliers or to identify relevant subgroups of the observations. The methodology could be also applied to hierarchical models, to combine information from different populations. The results will be detailed and developed in (1).

Abstract

Data visualization is a powerful tool for conveying data and information in a way that is both accessible and engaging for any kind of organization or business. In a world where data is being generated and accumulated at an unprecedented rate, data visualization has become increasingly essential to make sense of it and support decision-making processes at all levels. Through a number of case studies, this paper presents the perspective of a Data Science team that works in the financial services industry and has acquired a solid experience in data visualization applications at all stages of analytical projects.

Keywords: data visualization, data science, crisp-dm, visual analytics

1. Introduction

Data visualization is the rigorous and scientific representation of quantitative information in the form of visual elements. As argued by Tufte in his principles of graphical excellence, "it is a matter of *substance*, *statistics*, and *design*" that allows communicating complex ideas with clarity, consistency and efficiency [8]. In the process of making data easily accessible to a broader audience and for a variety of purposes, data visualization plays a key role in the democratisation of information. It does not merely translate into an attempt at simplifying reality, but rather at capturing and explaining phenomena in all their nuances and implications, bridging people of different cultures and knowledge backgrounds.

The act of visualizing data entails the constant search for new structures to produce valuable revelations of the data in a visual manner. They might be functional to showcase hidden connections, discover trends and patterns, or convey stories that spark discussions and even determine courses of action. Widely accepted definitions of data visualization delineate two distinct approaches: explorative [3] and explanatory [9].

- Explorative data visualizations support all stages of a data analysis that focus on deepening the understanding of the data, in terms of their underlying structure, quality and multidimensional relationships.
- Explanatory data visualizations are used to provide guidance, reveal insights and communicate results on a certain topic when the research about it is more mature, stable and ready to be shared with some generic audience.

Besides this broad distinction, the two approaches are often combined to serve a spectrum of different needs and uses that are intertwined with its inherent multidisciplinarity, as many disciplines actually contribute to defining data visualization (e.g. statistics, graphical design, computer science, communication, psychology, semiotics). In the private sector, data visualization has become a common language among executives, business leads and data analysts to cooperate, interpret data and disseminate information that might have far-reaching business impact. This paper illustrates applications of data visualization from the point of view of an analytical team that leverages data science techniques to support clients in the financial services industry.

2. Data visualization in data science projects

Data science projects are aimed at solving typically complex and real-world problems by means of data-driven techniques and domain knowledge considerations. Data visualization is tailored to underpin a deeper interpretation of data and models as the project evolves during its life cycle and has to adapt to the variability of the context to which it is applied. Over the years, several methodologies have been proposed to standardize data science workflows through comprehensive, application- and technology-agnostic frameworks [2]. Among these, the CRISP-DM (CRoss-Industry Standard Process for Data Mining) paradigm [6] is a popular standard. It prescribes the steps to be taken, along with practical advice, in a structured yet flexible manner that is well suited to the needs of different use cases. Despite more recent advancements, we still refer to the original methodology, as newer approaches are mostly aimed at integrating team-based project management practices [5], which are outside the scope of this paper. The CRISP-DM is a circular and iterative process model consisting of six interconnected phases, as described in Fig. 1.

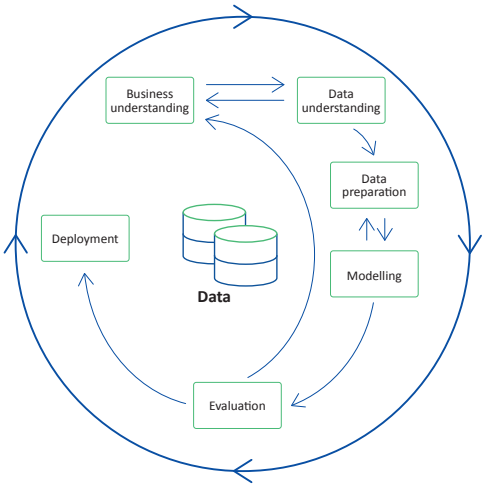

Figure 1: Phases of the CRISP-DM process model.

- *Business understanding*: comprehension of the context and customer's needs, definition of business requirements and conception of a preliminary project plan.
- *Data understanding*: initial data exploration towards a general understanding of the available data and its sources.
- *Data preparation*: data analysis and processing to produce a clean version of the original raw data, to be used for the subsequent phases.
- *Modelling*: training and evaluation of multiple models with chosen performance metrics.
- *Evaluation*: interpretation of the results and selection of the model that best suits the initial business requirements.
- *Deployment*: deployment of the completed pipeline and sharing of the results with external people.

3. Case studies description

This section draws on the Prometeia s.p.a. Data Science Team (in the following DST) experience to illustrate applications of data visualization that have proven particularly beneficial and effective in bringing innovation to the analytical projects undertaken. The first two examples (Fig. 2, Fig. 3) are exploratory charts that provide non-standard perspectives on model evaluation by enlightening on complementary aspects: model sensitivity and interpretability. The last three (Fig. 4, Fig. 5, Fig. 6) are well-rounded explanatory data visualizations, developed to be precious allies for decision-making processes either for internal or external stakeholders. Most of the presented charts have been developed with Python and its graphical libraries (e.g. *Seaborn*[1], *Matplotlib*[2]) – apart from a few exceptions that will be specified accordingly.

Model sensitivity analysis The case study presented in Fig. 2 refers to the outcome of a binary classification model for predicting the probability of default (probability of not repairing a loan) for some customers within the year following the period of model estimation. The idea is to compare the past trend for the predicted probabilities of the two classes to understand the sensitivity of the model in detecting long-term signals, i.e. how far in advance the model is able to detect significant deviations in the behaviour of the two populations, which might indeed turn useful in other applications of risk estimation. Hereafter, we refer to the defaulting class as the positive class and to the other one as the negative class – respectively in red and green in the chart. The two bands describe the model scores distribution over time for two samples of clients drawn in December 2018 from the test set. They are both delimited by the 25th and 75th percentiles – lower and upper bounds – with a straight line in the middle representing the median. In this case, the trend analysis outlines that the model is able to discriminate between the two classes even years before the default date. In fact, the scores for defaulting clients are systematically higher than those of the other class and the gap between them not only increases with the approaching of the default event but also appears at an unexpectedly early stage, leading to conclude that the model is able to detect never-seen-before signals.

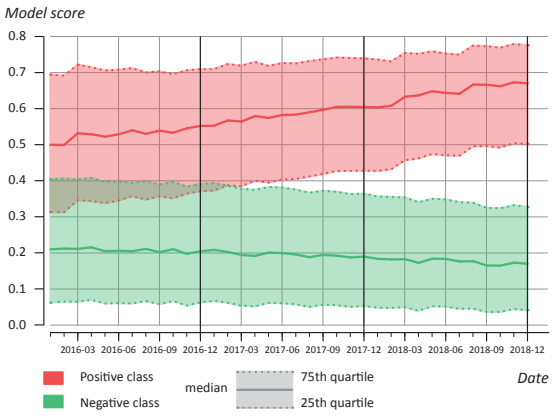

Figure 2: Model scores distribution for out-of-sample data over time, for both the positive and negative class.

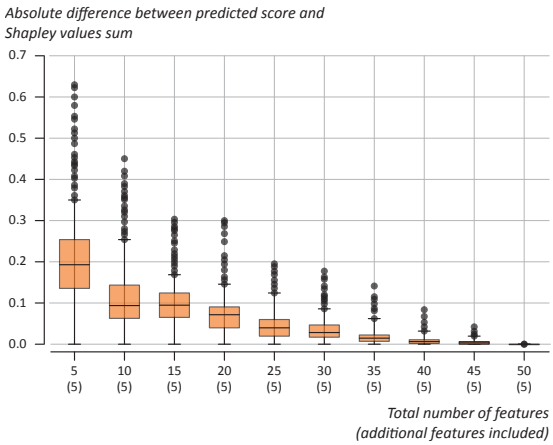

Figure 3: Fraction of the model output explained by the Shapley values sum as the number of included features increases.

Feature selection for model explainability The chart reported in Fig. 3 leverages SHAP (SHapley Additive exPlanations) [4] to provide guidance on the number of features actually needed to explain an adequate fraction of the model output. SHAP is a method of model interpretability widely used to

[1] https://seaborn.pydata.org/
[2] https://matplotlib.org/

facilitate the usage of *black-box* models in all those domains where explaining the model outcome is a strong requirement. For each feature, every single data instance receives a Shapley value that expresses the weight of that feature on its *local* model prediction, with the constraint that all the Shapley values must sum to the score. In other words, every observation has its own personal feature importance ranking. The idea is thus to support the human comprehension of the model considering – ideally – only a few *ad-hoc* features for interpreting any single prediction while retaining most of its accuracy. The box plots summarise this concept by showing the distribution of the absolute deviation of the Shapley values sum from the predicted scores, as the number of included features increases. The first box plot, for instance, considers only the five most relevant features in terms of Shapley values for every unit. With five features rather than fifty (the complete feature set), it is possible to explain 75% of the predictions with an approximation error of about 25%, which is the absolute deviation on the y-axis. As features are added to the model, the Shapley values' sum comes closer to the model score, until they are all included.

Visualizing process mining results for credit requests Process mining is the integration of data science and process management techniques to support the analysis of operational processes, with the final goal of characterising the processes and identifying eventual bottlenecks or opportunities for increasing efficiency. In the scenario presented, we are considering an application to the credit risk management area, where credit requests are taken over by specialised officers from the collection of the initial documentation to the final outcome of approval or rejection. In this case, data visualization exploits the results of a process mining pipeline carried out through the Python library *pm4py*[3] by providing a graphical representation of the process analysed, which is the whole life cycle of credit requests (Fig. 4). While these requests are expected to follow straightforward paths – with just a few variations – the map clearly outlines the presence of three main workflows: the most standard and linear one lies in the centre, while the other two, less common and therefore hard-to-detect, lie on the edges. This example emphasises how the visual display of tabular data brings nontrivial information to light, enabling the prompt detection of anomalies that can trigger further investigations. For instance, additional charts and metrics may reveal interesting insights about the average execution time of each phase and the presence of loops, thus explaining unusual behaviours and providing data-driven best practices to handle them. Data visualization fills a strategical gap in the bank's risk infrastructure by empowering credit officers with insights that actively support their daily work and speed up business decisions, such as actions to reduce delays when processing a practice, leading to increased efficiency with a timely and standardised organization of the credit approval process.

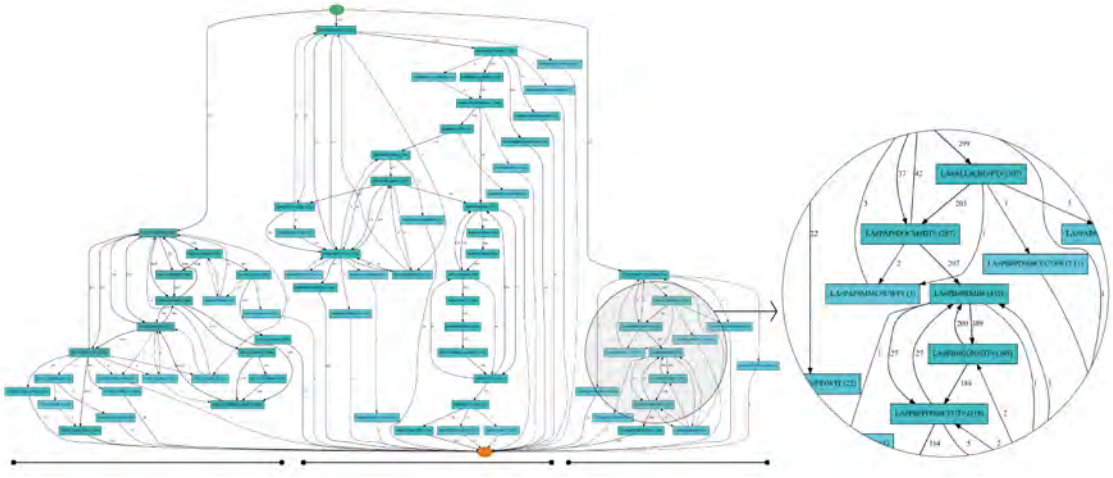

Figure 4: The life cycle of credit requests, grouped in three main buckets.

[3]https://pm4py.fit.fraunhofer.de/

A dashboard to centralise scattered data and highlight event connections Behind data visualization artifacts, there is usually a tangled journey of data gathering, cleaning, aggregation, and analysis to move from non-structured data sources to a structured collection of data, ready to be translated into some visual representation. However, all this underlying work is rarely evident in the data visualizations that come at the end of a project's life cycle and tend to be more result-oriented. In contrast, the complex process of data aggregation is at the heart of the presented case study, where we developed a *Power BI*[4] dashboard (Fig. 5) for the risk and compliance function of a bank. The objective was to connect several business processes and explain them through a number of summary statistics and key indicators. The project started with an extensive work of data understanding in order to link all the data sources used by analysts in their daily activities, followed by a stage of data cleaning and homogenisation. The purpose was to provide them with a centralised tool in which all their single reports would converge, with the immediate effect of abating their workload and preventing undesired errors either due to manual operations of data linkage or inconsistency between data sources. Besides connecting all the data, the dashboard presents several indicators to interpret phenomena more efficiently, identify emerging trends and retrace the underlying chain of events, supporting the comparison of interconnected statistics that may guide more reliable analyses about potential cause-effect relationships rather than isolated metrics.

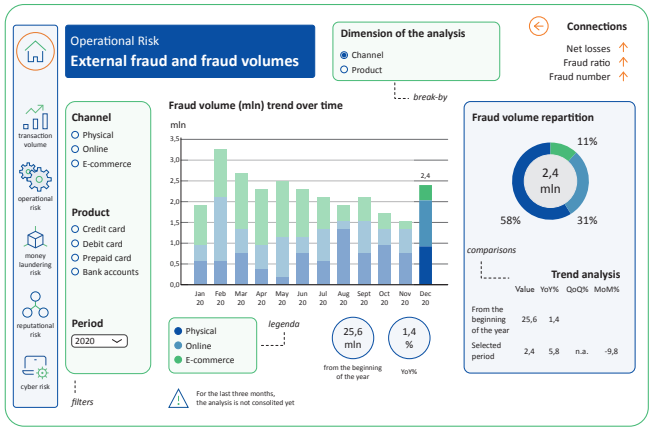

Figure 5: An example of a dashboard page.

Skills mapping to foster cohesion within a team The skill map is a powerful tool the DST has developed to depict the landscape of people skills over time and support several other internal processes, ranging from upskilling to resource allocation. It has been conceived as a guided self-assessment exercise with about 80 technical skills arranged in 10 macro groups (e.g. *programming* is a *macro-skill* that includes skills such as *Python*, *R*, *Bash* and others), to be updated on a 6-month basis. For each skill, people are asked to assess their proficiency level on a scale from 1 to 5 (from *no experience* to *expert*). Data visualisation allows to effectively summarise the results of every assessment both individually and in aggregated form. While the former enables personalised and professional growth initiatives, retention strategies and more optimised resource allocation for project teams, the latter reveals any potential skill gap to be handled in the hiring or upskilling process. The representation in Fig. 6 is a comprehensive view of the team composition in terms of proficiency level in all the assessed skills. The graph, produced in *Gephi* [1], depicts data-driven skills clusters from the questionnaire results at a given snapshot date. It originated as a tool to investigate the team composition and then turned into an experiment to explore whether the team intrinsically embeds current professional roles as per the market. Each graph node is a skill connected by edges that are weighted by the cosine similarity of the vectors of proficiency levels. Overlapping circles represent our attempt to find professional roles by skills, which we do not expect to reflect widespread established roles but ones tailored to our reality. The cluster at the centre, associated with the data scientist label, consists of skills that characterise this professional role and are shared by

[4]https://powerbi.microsoft.com/en-au/

most analysts in the team, thus typical among more functions. The other clusters of professional figures encompass more field-oriented competencies, e.g. text analysts relate to a pertinent cluster. In general, the more peripheral the skill clusters are, the more peculiar and less widespread these skills also are.

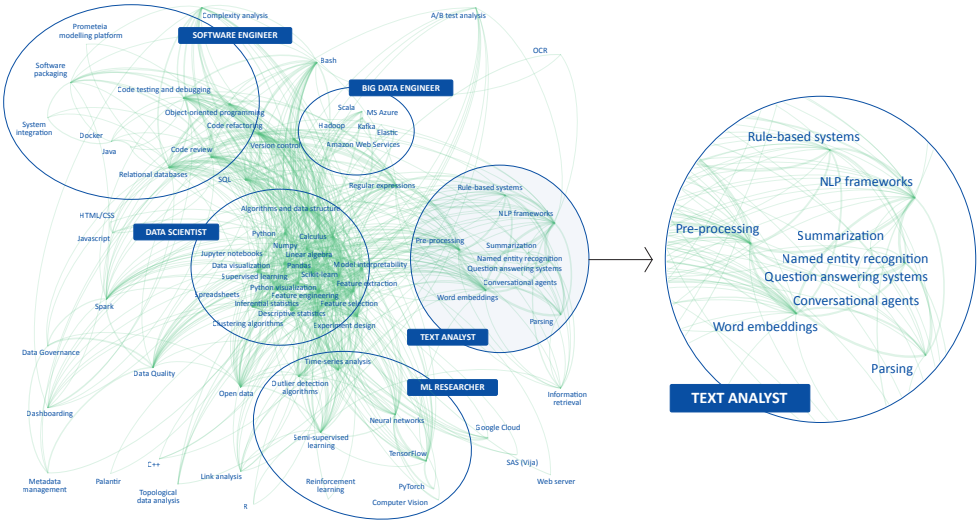

Figure 6: Skill map results: data-driven skill clusters and professional roles overlapped.

4. Conclusion

This paper advocates for a conscious use of data visualization as a communication vehicle to fill the gap between different professional roles. The DST constantly relies on visual insights to support any phase of project development and guide business decisions, striving to structure visualization tools that accomplish a variety of goals in the most reproducible and domain-agnostic manner. Further progress is expected toward more interactive visualizations capable of increasing engagement in the end users.

Acknowledgments Thanks to Prometeia s.p.a. and the Data Science Team for supporting this work, especially to Federico Crecchi and Maurizio Monaco.

TERRA: a smart visualization tool for international trade in goods statistics

Francesco Amato[a], Mauro Bruno[a] and Maria Serena Causo[a]

[a] Istat; framato@istat.it, mbruno@istat.it, causo@istat.it

Abstract

International trade in goods statistics is a rich data source, freely available on Eurostat open-data portal and updated at high timeliness. Data users can explore several aspects of the statistical domain, but, as it happens when many paths depart in front of us without no clear road signs, some users could find themselves "lost in data". In such a complex context, a smart data visualization tool, i.e., TERRA, can bring a relevant added value to data dissemination providing relevant timely indicators and a first approach to exploratory trade data analysis. In this work we describe the core functionalities of TERRA and provide a brief overview of the architectural components of the dashboard. The latest version of TERRA will be soon published as an experimental statistic by Istat.

Keywords: Smart data visualization, External Trade, COMEXT, Graph analysis, Time series

1. Introduction

International trade in goods statistics published by Eurostat measure the value and quantity of goods traded between the EU Member States (intra-EU trade) and goods traded by the EU Member States with non-EU countries (extra-EU trade). Data are compiled by Member States in harmonised way based on concepts and definitions set out in EU legislation and are characterised by many dimensions of analysis and high granularity level not only in terms of geographical destination of trade flows, but also in terms of traded products. Indeed, trade data are disseminated at monthly time frequency at the most detailed level of the following product nomenclatures: the Combined Nomenclature (CN), the Standard International Trade Classification (SITC), the Broad Economic Categories classification (BEC), the Classification of Products by Activity (CPA) and the Standard Goods Classification for Transport Statistics/Revised (NST/R). Moreover, trade flows are classified by mode of transport, providing relevant information for defining transportation policy, monitoring international transport routes, and assessing the impact of trade on the environment.

As international trade forms a major part of the world economy, statistics on trade in goods are an instrument of primary importance for numerous users [1, 2], including public and private sector decision makers. For example, international trade in goods statistics are valuable in order to:

- inform on recent and long-term developments in trade and economy;
- help EU businesses conduct market research and define their commercial strategy;
- enable EU authorities to prepare multilateral and bilateral negotiations under the common commercial policy;
- enable EU authorities to evaluate the progress of the Single Market and the integration of EU economies;
- enable EU authorities to define and implement anti-dumping policies;

- provide an essential source of information for other statistical domains, as Balance of Payment (BoP) statistics or national accounts.

With such a rich data source, freely available and updated at high timeliness, data users can explore several aspects of international trade, but, as it can happen when many paths depart in front of us without no clear road signs, some users could find themselves "lost in data". A smart visualisation tool, presenting trade data in suitable graphical form that illustrates the evolution of trade flows not only in terms of trading volumes, but also in terms of composition of the basket of traded goods, and that provide, moreover, tools for analysis embedded in the system, can bring relevant added value to data dissemination, and facilitate a first approach to exploratory trade data analysis. TERRA (imporT ExpoRt netwoRk Analysis) is a data visualization tool specifically designed at Istat for this purpose.

2. The dashboard TERRA

TERRA monthly processes about one billion records relating to the commercial exchange of goods with foreign countries, produced by the 27 Member States according to harmonized methodologies and publicly available on Eurostat's COMEXT[1] database. Therefore, official estimates on trade flows in monetary value and in physical quantities at the maximum granularity in temporal resolution (monthly frequency), characteristics of the traded product, trading partner countries, mode of transport, provide TERRA with the source of information for further elaboration.

The main functions implemented in TERRA[2] allow to analyse the impact of shocks in means of transport and the effects of interruptions in trade relations between countries for specific products with social network analysis techniques, offering a set of global indicators, typical of graph analysis. The dashboard is publicly available at the following link: https://terra.statlab.it/.

2.1 Economic and international trade indicators

This section provides a map showing, for each Member State, macroeconomic indicators, main imported and exported products, main trading partner countries (as shown in Figure 1). A time-lapse functionality displays the time evolution of year-on-year changes in traded values for the last three years, giving a simple and clear picture of country trade effectiveness.

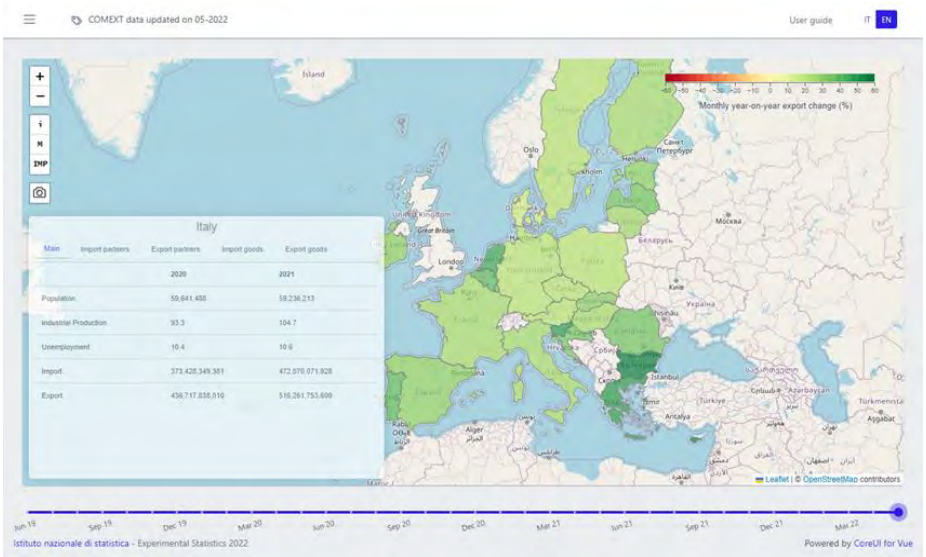

Figure 1: TERRA interactive map

[1] COMEXT database can be accessed using the Eurostat bulk download tool, available from: https://ec.europa.eu/eurostat/data/bulkdownload

[2] TERRA is an open-source project, the source code is publicly available from: https://github.com/istat-methodology/terra

2.2 International trade EU - Extra EU relations

This section displays graphs representing the network of international trade between EU and extra-EU countries by product and mode of transport, together with relevant global and local graph indicators [3,4,5]. In the right panel (as shown in Figure 2), through the drop-down menus, the user can select the parameters of the analysis. Based on the values chosen, the graph is created, and the respective centrality measures are calculated. The main indicators displayed by TERRA are the following:

- *Product spread*: global measure corresponding to the graph density and representing how much the product is spread through the graph.
- *Vulnerability*: local measure corresponding to (1 - the indegree centrality[3])
- *Export strength*: local measure corresponding to the outdegree centrality[4].
- *Hubness*: local measure corresponding to the closeness centrality for each country.

The tool contains a panel showing, in tabular form, the metrics of the graph for each country: *Export strength*, *Hubness*, *Vulnerability*. The user can sort the results by clicking on the arrows in the numerical columns. It is also possible to filter the results by code and country name.

The tool allows to explore possible new scenarios by deleting edges, i.e., interrupting trade paths between specific countries and for specific modes of transport. An animation tool is provided to follow evolution of the graph structure over time. An example of the analysis that can be performed using TERRA is displayed in Figure 2.

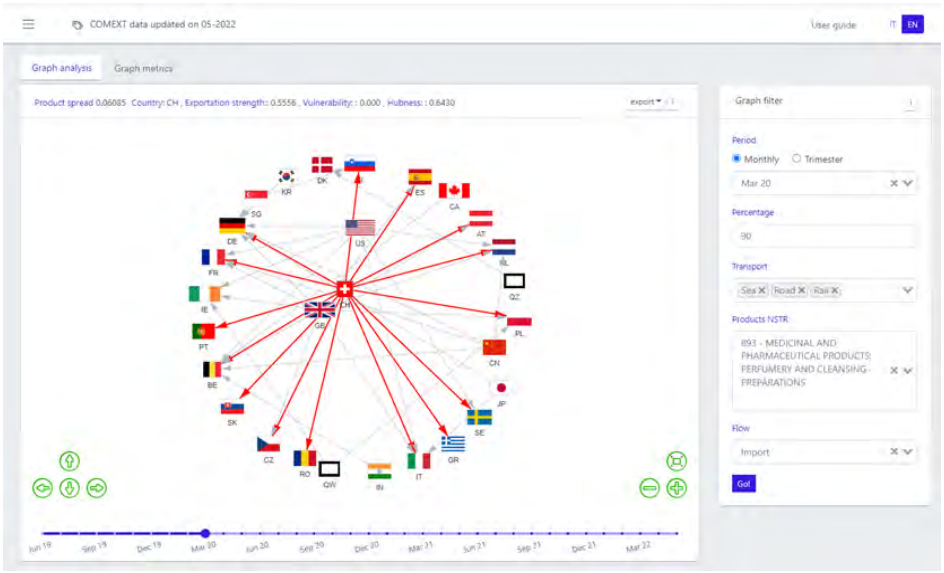

Figure 2: TERRA graph analysis

2.3 Time series visualization

Tool for visualizing times series monthly traded values and quantities between partner countries and for products (see Figure 3). Series autocorrelation functions and Q-Q plots are provided, allowing a first approach to exploratory time series analysis. The section provides users with a large number series representing bilateral trade for specific products. Series and indicators can be downloaded in several formats suitable for further analysis.

[3] The indegree centrality is the number of connections that point inward at a vertex.
[4] The outdegree centrality is the number of connections that originate at a vertex and point outward to other vertices.

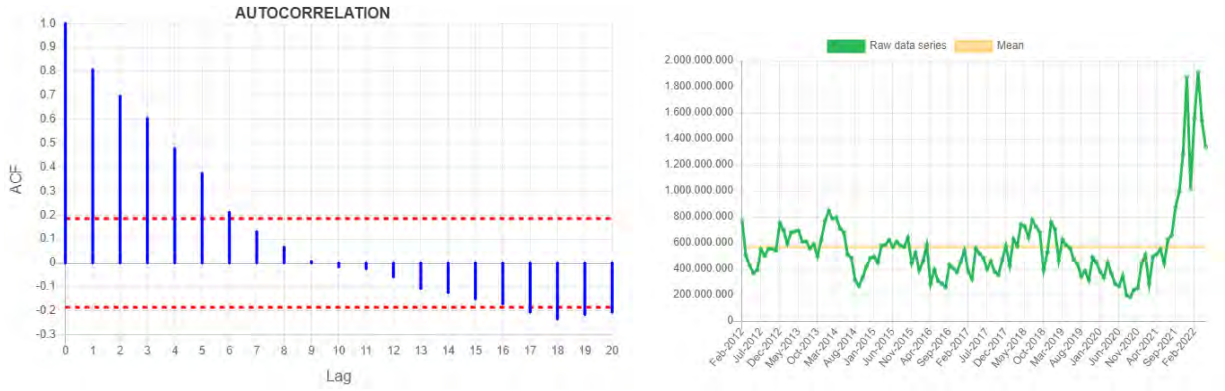

Figure 3: TERRA time series visualization

2.4 Basket of products

In the section relating to the basket of traded products, the trends of the monthly shares, in value or quantity, of imported and exported products as defined according to the two-digit breakdown of the CPA 2.1 classification are represented for each Member State, together with the related trend variations. The interest of the section lies in the possibility of monitoring which types of products are more traded in periods of markets non-equilibrium, associated with crisis and subsequent economic recovery phases. An example, concerning the increase in the trade of essential products during the first phase of the COVID pandemic, is displayed in Figure 4. The section allows an easy country level comparison of different trade strategies put in place as a reaction to external shocks, or as a long-term trend. As an example, in Figure 4 year-on-year percentage changes in the share of Italian exported product are displayed. One can notice that in spring 2020, first phase of Covid-19 pandemic, the share of exported basic necessities (basic pharmaceutical products, food products, products of agriculture) increased with respect to the previous year, and, at the same time, export of less necessary products (motor vehicles, leather, wearing apparel, textiles, furniture) faced a contraction. The opposite phenomenon is evident in the 2021 economic recovery phase, where the gain in share for motor vehicles, furniture, leather and wearing apparel, is very evident.

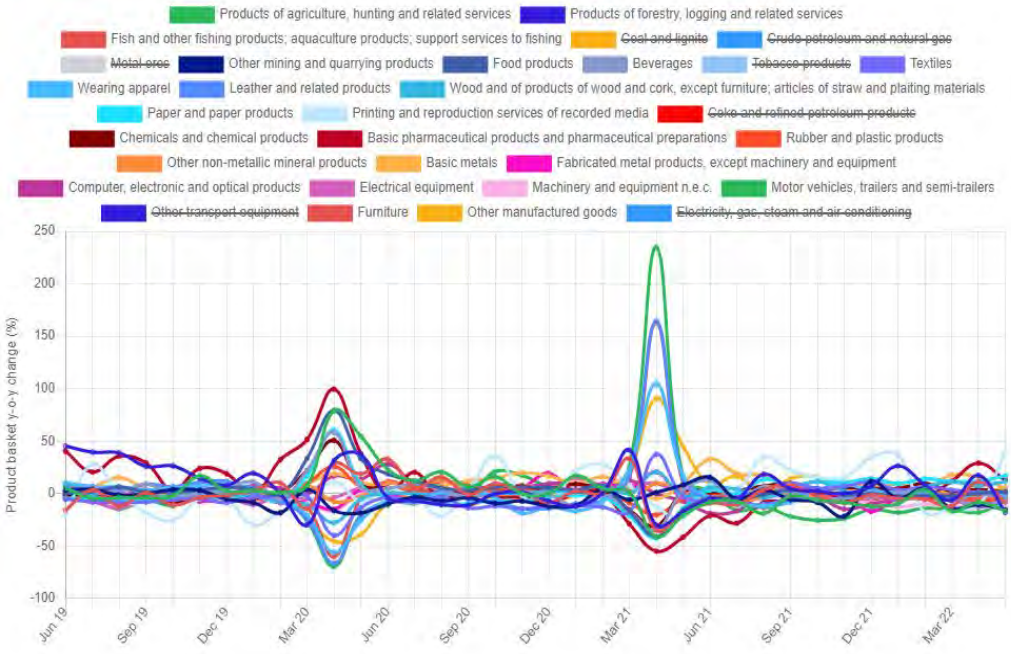

Figure 4: TERRA, share variation in the basket of Italian exported products

3. Architecture

The architectural solution adopted for the implementation of TERRA arise from the need to make the data analysis timely and available to the stakeholders a few hours after Eurostat COMEXT monthly data is published. The application retrieves and processes each month data covering a time series of 10 years. Further, TERRA allows to select two different type of monthly time series - raw data and yearly variation, until the latest released update. This corresponds to processing about 1 billion records each month.

To get and process such a large amount of data, we realized a specific batch program (Batch processing in the left panel of Figure 5), implemented in Python language. The batch script is scheduled to start every 24th day of the month, and, automatically, downloads file, performs processing, produces outputs and, finally, updates the data stored on the server.

To speed up the elaboration time, the script runs in cloud platform, and data are processed using high-performance algorithms, using the library PySpark on Apache Spark Framework. The script is configured to access to COMEXT bulk download section of EUROSTAT portal and starts a parallel process of downloading 136 files of monthly products data, 2 files for annual products data, 36 files for monthly transport data and the files containing their classifications. Because of the heterogeneity and complexity of the data analysis algorithms, we chose a microservices architectural paradigm [6]. This approach of dividing the functions performed by the application into n-services allows the principle of individual responsibility: each service is implemented and distributed separately from the others.

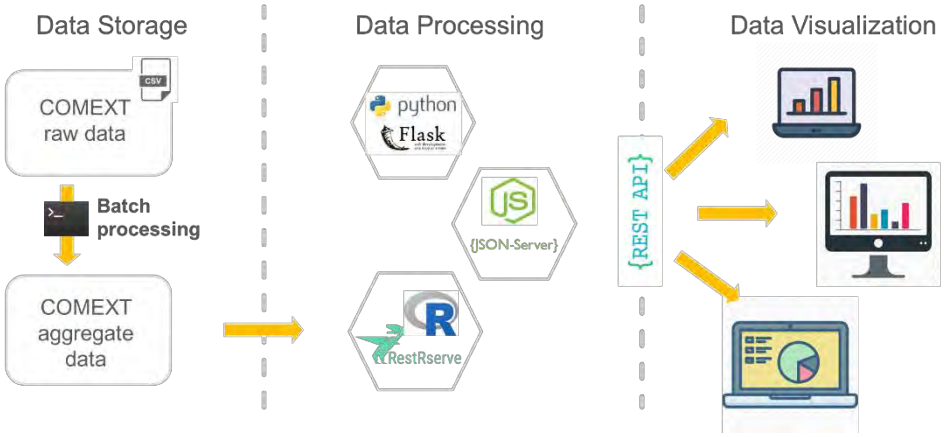

Figure 5: TERRA main architectural layers and components

Figure 5 sketches the main architectural components of TERRA. Three different layers can be identified in the architecture: data storage, data processing, and data visualization.

- **Data storage layer**, contains the raw data downloaded from COMEXT portal, as described above. Further the Batch processing stores in this layer the aggregated data that are further processed by the microservices in the data processing layer.
- **Data processing layer**, or backend, includes the three microservices: the first is devoted to the processing of Python scripts; in the same way, the second is dedicated to the processing of scripts in R. Finally, the third microservice exposes static data, such as classifications and metadata. The frontend communicates with the microservices through requests according to the HTTP protocol, exchanging messages in JSON format.
- **Data visualization layer**, or frontend, includes the web component as the user interface. This application was implemented as a Single Page Application (SPA) using open-source web frameworks. The use of these modern technologies makes the application responsive, i.e., the layout adapts to the size of the display, therefore it is possible to access the dashboard both from PCs and mobile devices.

4. Conclusions

TERRA is the first example of smart visualization tool for international trade statistics specifically developed with the aim of bridging the gap between simple graphical web-based tools for data visualization and more complex data processing systems. The result is a system, which is user friendly as a simple graphical tool, but in the other hand has a hidden complex core for massive data processing and statistical indicators calculation. Although further improvements can be introduced by enlarging the set of synthetic indicators provided, the product has been so far welcomed by the statistical community and can be used as a prototype for applications in different statistical domains.

Abstract

In this paper, we present a new clustering algorithm for data represented in the form of distributions. The contribution of this work, compared to clustering methods for distributional data ((7)), is to consider a suitable data transformation. We referred to a logarithmic transformation of the derived quantile functions (LDQ) associated with the distributional data. This transformation makes it possible to provide a mapping of the density functions in a Hilbert space. The proposed method is based on the classical dynamic clustering algorithm (4) on the LDQ data transformation. The results are then compared with those of an extension of the k-means clustering algorithm on distributional data. Finally, given the different partitions provided by the data distribution, such as quantile and LDQ functions, we propose to combine the partitions obtained on the different transformed data to obtain a single partition. Preliminary results on real environmental data have confirmed the effectiveness of the proposed method.

Keywords: Distributional data, Dynamic clustering, LDQ transformation

1. Introduction

In this work, we present a new clustering algorithm for data represented in the form of distributions. The input consists of a set of N observed with respect to $X_1, \ldots, X_p$ distributional variables. Each individual is represented by p $x_{i1}, \ldots, x_{ip}$, probability functions or estimated ones, like histograms. Distributional Data are defined according to (2) and in the recent years many Data analysis techniques have been developed on such kind of data, some references are available in (3) and Several clustering algorithms were proposed for a partitioning a set of distributional data into subgroups using a K-means like algorithm. The centroids of the clusters are represented by barycentric functions according to the appropriate dissimilarity measure. Elements are assigned to clusters with respect to the minimum distance from the centroid consistent with the algorithm's optimised criterion of minimum internal variability of clusters.

Previous works, such as (1) and (8), proposed clustering models for distributional data based on the Euclidean and the Wasserstein metric in a linear space. Recent developments in distributional data analysis (DDA), have introduced a transformation of the quantile functions into the Logarithm of the derivative of the quantile functions (9). This transformation allows for mapping density functions into a Hilbert space addressing some issues in DDA. As is well known, a vector representation of complex data (such as distributions) in a Hilbert space allows the definition of numerical operators (e.g. the inner

product) and distance measures to compare distributions. The LDQ transformation can return the results of the analysis in the same form as the original data through an inverse transformation.

Based on this new transformation of the distributional data, we propose a clustering method by performing a partitioning of the set of objects in k clusters according to the minimum internal variability of the clusters formed by LDQ functions. The centroids of the clusters are defined as the average of the LDQ functions of the elements of each cluster and the dissimilarity measure for assigning elements to clusters is taken as the Euclidean distance between the LDQ functions.

The clustering process is performed in two alternating phases. Once a predefined number of K clusters has been set, the first stage involves the representation of the clusters with the averages of the LDQ functions of the cluster elements; in the second stage, the elements are assigned to the clusters according to the minimum of the sum of the squared distances between the LDQ functions of the cluster elements and the respective centroid. This process is repeated until convergence to stable clusters.

The outcome of the partition obtained by this new clustering method has been compared with the results of the clustering method on DD based on the Wasserstein squared distance. It was worth noting that the results of the achieved partitions are different, due to the kind of LDQ transformation which enounces the characteristics of the distributions for effect of the derivative of the quintile functions and of the logarithmical transformation of the derivatives of the quantiles. Some interesting considerations on the different similarity of the distributional data captured by this LDQ transformation made one consider the idea of combining the two distributional data descriptions through a partitioning strategy. Therefore, the proposal has considered a combination of the two partitions by associating the descriptors with a weight related to the importance given to the original distributions by the quantiles and the LQD transformed functions, in the partitioning process.

Preliminary results on the environmental data observed over time, aggregated in the form of distributions, made it possible to assess the effectiveness of the proposed strategy and to indicate different weight settings in the combined partition strategy.

2. Distributional-valued data

Let Ω be a set of objects. A modal (2) variable X with domain $\mathscr{D}$ on the set Ω is a mapping $\Omega \to \mathscr{M}$ of all possible measures π on $\mathscr{D}$: $\omega \to X(\omega) \in \mathscr{M}$, for $\omega \in \Omega$.

Histograms are a suitable way of representing aggregated data, like distributions. In the context of SDA, a variable X is considered a histogram-valued variable if each object ω is represented by an estimate distribution in the form of a histogram (2; 3).

Formally, let's x be a realization of X with support $D = [a_1, b_H]$, that is partitioned into a set of contiguous no-overlapped intervals (or bins) $I_h = [a_h, b_h]$, $\forall h : I_h \subseteq D$.

A non negative weight π_h (a probability or a relative frequency) is associated to each I_h. A histogram data is defined by a sequence of intervals (bins) with associated respective weights:

$$x_i = X(\omega_i) = [(I_1, \pi_1), \ldots, (I_h, \pi_h), \ldots, (I_H, \pi_H)] \tag{1}$$

A cumulative distribution function $F(x)$ is associated to each x. $F(x)$ is a continuous function and, for cumulative distribution function is a piece-wise function, strictly increasing in the interval $[a_1, b_H]$; $0 \leq F(x) \leq 1$; $F(x)$ is differentiable on $[a_1, b_H]$.
The inverse of a distribution function $F^{-1}(x) = Q(t)$ is denoted as a quantile function. It is a monotone increasing function with support in $[0,1]$ (for a histogram, it is a piece-wise function). $Q(t)$ is also differentiable on $[0,1]$.

More recently a suitable transformation has been introduced for mapping probability densities to a Hilbert space of functions through a continuous and invertible map (9). A probability density function is firstly transformed by the derivative of its quantile function:

$$q(t) = \frac{dQ(t)}{dt} = \frac{dF^{-1}(t)}{dt} = \frac{1}{f(Q(t))}$$

which is strictly positive and continuous in its domain $[0,1]$, and then, by the logarithmic transformation of $q(t)$, as follows:

$$l(t) = \ln q(t) = \ln \frac{1}{f(Q(t))} = -\ln f(Q(t))$$

Let $l(t)$ denote the Logarithm Derivative of the Quantile function (LDQ). On these functions it is possible to define the addition and scalar multiplication operations, the inner product and the Euclidean norm. The squared Euclidean distance between two LDQ functions $l_1(t)$ and $l_2(t)$ is given by:

$$d^2_{LDQ}(l_1(t), l_2(t)) = \|l_1(t) - l_2(t)\|_2 = \int_0^1 (l_1(t) - l_2(t))^2 \, dt$$

The main problem with LDQ transformation is that it loses information on the location parameters of the density distribution. In fact, the derivatives of two quantile functions that differ by a constant term are equal.

2.1 Clustering algorithm of distributional data

In the framework of distributional-valued data analysis, many statistical analysis methods have been proposed, as clustering methods, regression models, factorial approaches, and many others. A reference book on these themes is (3).

Clustering methods for DD have been proposed mainly based on the classical Dynamic Clustering Algorithm (DCA).

DCA looks for the partition $P \in P_k$ of Ω in k classes, among all the possible partitions P_k, and the vector $L \in L_k$ of k prototypes representing the classes in P, such that, the following Δ fitting criterion between L and P is minimized:

$$\Delta(P^*, L^*) = Min\{\Delta(P,L) \mid P \in P_k, L \in L_k\}. \tag{2}$$

Such a criterion is defined as the sum of dissimilarity or distance measures $d(x_i, G_h)$ of fitting between the elements x_i belonging to a class $C_h \in P$ and the representative of the class $G_h \in L$:

$$\Delta(P,L) = \sum_{h=1}^{k} \sum_{x_i \in C_h} d(x_i, G_h). \tag{3}$$

Generally the criterion $\Delta(P,L)$ is based on an additive distance on the p descriptors. As the criterion is additive, the optimization problem can be solved for each variable X_j (for $j = 1, \ldots, p$).

The representative or prototype G_h associated to a class C_h is an element or a function of the elements $\omega_i \in \Omega$ belonging to C_h. The prototype of a cluster C_h of the partition P is defined as the element G_h which minimize the following function:

$$f(G_h) = min_{j=1,\ldots,k} \sum_{x_i \in C_h} d^2(x_i, G_j) \tag{4}$$

- The algorithm is initialized by generating k random clusters or, alternatively, k random prototypes.

The criterion function $\Delta(P,L)$ is optimised in two alternating steps:

1 - a representation step (P, L^*): the protopypes of the clusters are computed as the elements which minimizing the $f(G_h)$;
2 - an assignment step (P^*, L): the elements are assigned to the clusters according to the minimum distance $d(x_i, G_h)$ to the prototype G_h:

$$x_i \to C_h \quad \text{if} \quad d(x_i, G_h) < d(x_i, G_{h'}) \quad \text{with} \quad h \neq h'$$

According to the above Clustering algorithm, we assume to partition the set of elements of Ω, on the distributional data transformed in LDQ functions $l_i(t) \in \Lambda$

The DCA performs the best partition of the set Λ alternating the 1 - representation step and the 2 - assignment step. The Euclidean distance d_{LDQ} between LDQ functions is assumed as the dissimilarity measure in the algorithm.

1 - The prototype L_h of the cluster C_h is defined as the average $L_h(t)$ of the $l_i(t)$ for $i \in C_h$ as the minimizing elements of the function **??**.

2 - the $l_i(t)$ are assigned to the class C_h if $d_{LDQ}(l_i, L_h) < d_{LDQ}(l_i, L'_h)$ with $h \neq h'$

The main clustering approach on DD (7) is based on a suitable metric for comparing distributions, the quadratic $2-norm$ Wasserstein distance (known as the Mallow distance). In one-dimensional space, this metric corresponds to the Euclidean distance between the two quantile functions, $Q_i(t)$ and $Q_{i'}(t)$, associated with the representation of the two objects $\omega_i, \omega_{i'}$:

$$d_W(x_i, x_{i'}) = \int_0^1 (Q_i(t) - Q_{i'}(t))^2 dt. \tag{5}$$

We have observed on synthetic and real data that the partitions P_k's obtained with the two approaches are different. That is due to the different information about the characteristics of the distributional data expressed by the quantile and the LDQ transformation functions. In order to preserve both types of information, we introduce a combination of clustering approaches by collaborating the two types of functions. The criterion function is thus expressed as follows:

$$\Delta(P, L) = \sum_{h=1}^{k} \sum_{x_i \in C_h} [\alpha_{1h} \cdot d_{LDQ}(l_i, L_h) + \alpha_{2h} \cdot d_W(Q_i, G_h)] \tag{6}$$

where: $\alpha_{1h} \in A_1$ and $\alpha_{2h} \in A_2$ are two sets of k weights related to the different importance assumed by the two representation functions of the distributional data, that is the LDQ and quantile functions.

A double set of prototypes $G_1, \ldots, G_k$ and $L_1, \ldots, L_k$, respectively associated to the quantile function $Q_i \in \Omega$ and to the LDQ $l_i(t) \in \Lambda$, are obtained as solutions of the optimizing process at the step 1.

The assignment of the elements ω_i to a cluster C_h is performed according to the minimum weighted distances of the associated functions from the respective prototypes:

$$(\alpha_{1h} \cdot d_{LDQ}(l_i, L_h) + \alpha_{2h} \cdot d_W(Q_i, G_h)) < (\alpha_{1h'} \cdot d_{LDQ}(l_i, L_{h'}) + \alpha_{2h'} \cdot d_W(Q_i, G'_h))$$

at the step 2. The algorithm is iterated until a stable partitions in k clusters of the DD in Ω is reached. The convergence of the criterion $\Delta(P, L)$ is guaranteed by the decreasing of the criterion in the alternating steps (the demonstration is referred to the classical DCA one (5)).

3. Preliminary results on real data

The performance of the proposed method was tested on real data. The dataset consists of 59 observations from various monitoring stations collecting environmental data on an hourly basis, located in different regions of Italy. Four variables were considered: X1 (Benzene), X2 (NO2), X3 (PM2.5) and X4 (PM10), each represented by a density function. In order to compare the clustering results calculated with respect to the two sets of functions, a concordance measure is required.

The Rand index is a measure of similarity between two clusters of data, ranging from 0 to 1. When the two partitions are in perfect agreement, the Rand index is equal to 1.

A problem with the Rand index is that the expected value of the Rand index of two random partitions does not assume a constant value (e.g. zero). The corrected Rand index proposed by (6) assumes the generalised hypergeometric distribution as a model of randomness, i.e. the two partitions are chosen at random and the number of objects in the classes and clusters is fixed ((10)).

From the comparison of the quantile and LDQ partitions, the Rand index value is 0.52, with an adjusted

Rand index of 0.04 for k=2. When k=3, the Rand index value increases to 0.64, with an adjusted Rand index of 0.20. Similarly, for k=4, the Rand index value is 0.66, with an adjusted Rand index of 0.08. The partitions are significantly different from each other and capture distinct information. Therefore, we propose combining the partitions obtained from the different data transformations to obtain a single partition.
The better results are reached for $k = 3$ clusters according to the Elbow method. The quality of the partition computed as ratio between the internal and total variability is 0.12 confirming the performance of the method in partitioning the distributional dataset.

Abstract

This article deals with the challenges of processing and analyzing data streams due to their high speed and large volume, which makes traditional data mining and statistical techniques impractical. The study proposes a multi-step data stream dimensionality reduction procedure using functional data analysis and probability density functions' simplicial functional principal components decomposition in separate time windows to build the so-called simplicial functional classification trees. The simplicial functional classification trees are trained using the scores of the decomposition, and the weighted ensemble's majority vote gives the class labels' final prediction over the whole time domain. The goal is to create a classifier capable of extracting information from data streams and systematically updating the classification rule as new data becomes available without the need to store past data.

Keywords: probability density functions; simplicial functional classification trees; functional principal components; functional data analysis.

1. Introduction

Recent advances in computing technology have enabled the collection of a vast amount of data, which arrives continuously as streams. Data streams are realisations of huge amounts of information that are fast, continuous, mutable, ordered, and unbounded. For this reason, data streams need to be processed and analysed once they arrive. Examples of data streams can be found in several fields, such as sensor networks, mobile data collection platforms, traffic management, and bank transactions.
The main problems in mining data streams are the high speed and large volume of the arriving information, and thus it is either unnecessary or impractical to store them in some forms. As a consequence, data streams lead to the curse of dimensionality issues, which makes traditional data mining and statistical multivariate techniques inappropriate. Furthermore, every learned model should be updated continuously and rely more on the most recent data in the stream (17). Thus, research on this topic is lively in the statistical literature (19; 14).
Usually, data streams are processed by computing suitable summaries of the data and splitting the time domain into intervals. Recent studies have proposed using distributional data analysis techniques to deal with clustering data streams (19). Density estimation has also been considered for analysing this type of data (10) as probability density functions (pdfs) make it possible to reduce the dimensionality in the time domain by discovering additional information in specific time intervals. Many authors also have

proposed the use of the functional data analysis approach (FDA) (18) as a dimensional reduction technique able to provide additional insights on phenomena (6; 2; 5). The basic idea of the FDA approach is to treat the entire streams as single functional objects. In this context, FDA has been applied to deal with different practical problems, e.g. unsupervised and supervised classification, outlier detection and forecasting.
Several functional classifiers have been proposed concerning supervised classification, which is the area of interest of this article. The latter offers promising tools to reduce the dimensionality of phenomena and improve accuracy by combining FDA and tree-based methods (9; 13; 15). The limit of these classifiers is that they immediately become obsolete because data is constantly evolving. This research proposes a methodological tool to solve this problem by the joint use of functional classifiers and pdfs. Specifically, a multi-step data stream dimensionality reduction procedure is suggested using the functional data representation. In the first step, data streams are divided into non-overlapping time-based windows and for each a pdf is estimated to capture the main streams' characteristics. Since pdfs are treated as functional data, the Simplicial Functional Principal Component (SFPC) decomposition is used in the second step. In the third step, simplicial functional classification trees (SFCTs) are built for each time window. Functional classification trees (13) are trained using the scores of the SFPC decomposition leading to an ensemble of classifiers. The final prediction of the class label for each stream is given by a weighted majority vote of the ensemble.
The ultimate goal is to create a classifier capable of extracting information from data streams and systematically updating itself as new data becomes available. In particular, a novel algorithm is proposed to update the classification rule by training new SFCTs as new information are available.
The remainder of the paper is the following: the proposed algorithm is presented in Sect. 2. A simulation study is shown in Sect. 3. Conclusions are provided in Sect. 4.

2. Materials and Methods

Let $S_i = \{x_{i1}, x_{i2}, ..., x_{it}, ..., x_{iT}\}$ be the i-th observed data stream, $i = 1, ..., n$, whose generic element x_{it}, $t = 1, ..., T$, is a real-valued scalar observed at time t. S_i can be partitioned into a sequence of J equally spaced time-based windows of length q as follows:

$$W_j = \{x_{q\times(j-1)+1}, .., x_t, ..., x_{q\times j}\}, \quad j = 1, ..., J. \tag{1}$$

For each j-th window, a probability density function, $\widehat{f}_{ij}(x)$, can be estimated to summarize the behaviour of the i-th stream in the time interval j. Most existing approaches for estimating the density of data streams are based on the Kernel Density Estimation (KDE) method (17).

A natural way to address density functions is FDA. Most methods in FDA implicitly assume that the data objects can be embedded in the L_2 space, which can be used as embedding for unconstrained data. However, the L_2 space becomes meaningless in the presence of density data (3). Indeed, pdfs represent a special case of functional data because they are constrained functions (18):

$$f(x) \geq 0, \quad \int_{\mathcal{I}} f(x)\, dx = 1 \Rightarrow f(x) \notin L^2. \tag{2}$$

where $\mathcal{I} \subset R$ is a closed interval with log in L_2.

Thus, features of pdfs are accounted for in the Bayes spaces, B^2, which generalizes the Aitchison geometry for compositional data (1) to the functional setting. Hence, pdfs can be interpreted as functional compositional data, i.e. parts of some whole, which carry only relative information (3; 4; 11; 16). $\mathcal{B}^2$ is the space of (equivalent classes) of positive functions integrating to a constant, with square-integrable logarithm:

$$B^2 = \left\{ f : f > 0, \int_{\mathcal{I}} f(x)\, dx = c, \, log(f) \in L^2 \right\}. \tag{3}$$

An isometric isomorphism between B^2 and L^2 is defined by the Centered log-ratio (clr) transformation:

$$clr(f)(x) = f_c(x) = log\, f(x) - \frac{1}{\eta}\int_I log\, f(s)\, ds; \tag{4}$$

where η stands for the length of the interval pdf support I; and, by construction, clr-transformed data have zero integral.
To reduce the dimensionality of a set of pdfs, we consider the Simplicial Functional Principal Component (SFPC) decomposition (11), which reformulates FPC decomposition in terms of Bayes spaces. Starting from a sample of n centred pdfs:

$$\tilde{f}_{ij}(x) = \hat{f}_{ij}(x) \ominus \bar{f}_j(x); \quad \bar{f}_j(x) = \frac{1}{n} \odot \bigoplus_{i=1}^{n} \hat{f}_{ij}(x),$$

For a specific j-window, SFPCs capture the main modes of variability of the densities, finding the SFPCs, $\zeta_k \in B^2(I)$, maximizing the following objective function over $\zeta \in B^2(I)$:

$$\frac{1}{n}\sum_{i=1}^{n}\langle \tilde{f}_i; \zeta\rangle^2_{B^2}, \quad subject\, to \quad \|\zeta\| = 1;\ \langle \zeta_k, \zeta_{k'}\rangle_{B^2} = 0,\ k < k'. \tag{5}$$

Hron et al. (2016) proved that the maximization problem in (5) can be performed by solving an equivalent FPC decomposition in L^2, by considering the clr-transformed pdfs.

$$\frac{1}{n}\sum_{i=1}^{n}\langle clr(\tilde{f}_i); \xi\rangle^2_{L^2},\ subject\, to\, \|\xi\|_{L^2} = 1;\ \langle \xi_k, \xi_{k'}\rangle_{L^2} = 0,\ k < k'; \quad \int_I \xi_k = 0. \tag{6}$$

Eq. (6) is solved by the eigenfunctions, ξ_k of the sample covariance operator of the clr-transformed data, V_{clr}, obtaining the FPCs ξ_k, that are linked to the SFPCs by the relation:

$$\zeta_k = clr^{-1}(\xi_k); \tag{7}$$

and the scores, v_{ik}, that are equivalent to the scores obtained in the SFPC decomposition:

$$v_{ik} = \int_{\mathcal{I}} f_c(x)\xi_k(x)\, dx.$$

In the functional supervised classification context, the starting point is a training set of functions whose labels are known a-priori. Hence, we consider a functional data-set of the following form: $\{y_i, f_{ij}(x)\}$, where $f_{ij}(x)$ is a predictor pdf, and y_i is the scalar response value observed at sample $i = 1, ..., n$, which could be either numeric or categorical, and that, in this context, is assumed to be constant over time (so, it does not depend on j). For simplicity, we will consider the case where y is a binary variable. The known labels of the functions are used to train a functional classifier, which is a classification rule that can be exploited to predict the class labels of new functional observations In the literature, several classifiers have been proposed for functional supervised classification, e.g. Logistic Classifier, k-Nearest Neighbor Classifier, Maximum Depth Classifier, and Kernel Classifier (8; 12; 14; 15).

The basic idea of this paper is to create a functional classification rule that can be updated when new data are available. In particular, our proposal is to introduce the so-called Simplicial Functional Classification Trees (SFCTs), which extends the Functional Classification Trees (FCTs) proposed by (13; 14) to the context of pdfs by using the scores of SFPCs computed on the clr-transformed pdfs. Therefore, the coefficients of SFPC decomposition are used as new features to predict the response.

The proposed algorithm is composed by the following steps:

1. Given $S_i = \{x_{i1}, x_{i2}, ..., x_{it}, ..., x_{iT}\}$, create J equally spaced time-based windows of length q;
2. For each W_j window ($j = 1, ..., J$), convert raw data into pdfs;
3. Compute the clr transformation and implement the SFPCs using the clr transformation for the j-th time window;

4. Use the scores of the j-th SFPCs to build the j-th SFCT for the j-th time window;
5. Delete the original data and pdf and store only the j-th SFCT;
6. Predict the curves' labels using a weighted majority vote from the ensemble, where the weights give more importance to the most recent SFCTs. Thus, the posterior probability for each class is computed as follows:

$$P(\hat{y}_i = G_c \mid W_1, W_2, ..., W_J) = \frac{\sum_{j=1}^{J} I_j(y_i = G_c) w_j}{J},$$

where G_c represents the possible labels of Y, i.e. the groups to predict, and the weigths are computed as follows:

$$w_j = (1/J)^{(1/j)}$$

7. Evaluate, the performance of the functional classifiers.
8. After observing q new time observations, repeat steps 2-7 for each new time window $W_{j'}$, with j' $\in$[J+1,+∞[, and update the functional classification rule updating the ensembles.

3. Simulation study

Data streams are simulated by considering $n = 200$ observations, for $T = 600$ instants of time (days), with $n_1 = 100$ observations with label 1 (red) and $n_2 = 100$ observations with label 2 (black). We assume that the class membership does not change over time. As a consequence, future observations that are added are used to refine the predictive power of the classifier based on the new temporal information. The simulation scheme for functional data belonging to two classes is the same as used in (14), following scenario 3. The charts of the first row of Fig. 1 show how data flowing over time are split over time into windows of the same widths. Once the width of the window has been fixed, each new set of data is aggregated with those of the previous intervals. The second row of Fig. 1 shows the second step of the algorithm, where the time data of each series are converted into pdfs, individually. The third row of Fig. 1 highlights the correspondence between the original data in each window and the clr transformations of each interval. The charts in the last row of Fig. 1 illustrate the forth step of the algorithm, i.e. SFCTs are computed separately for each window and pruned using the cost-complexity pruning.

Table 1 illustrates the results of the SFCTs of each single window and the proposed algorithm. As we can see, SFCTs performance improves as new data is added, and the final classification rule W_{all}, which is based on the time-weighted majority vote in the ensemble of SFTCs, proves to significantly refine the results. Indeed, the proposed algorithm has the power of the ensemble methods in terms of variability reduction and considers the peculiarities of the functions in single windows by capturing the distinctive features of the original classes in detail and specific time intervals.

W_j	Accuracy
W_1	0.81
W_2	0.83
W_3	0.86
W_4	0.86
W_5	0.87
W_{all}	0.94

Table 1: Results of the SFCTs for each window and using the proposed weighted ensemble W_{all}.

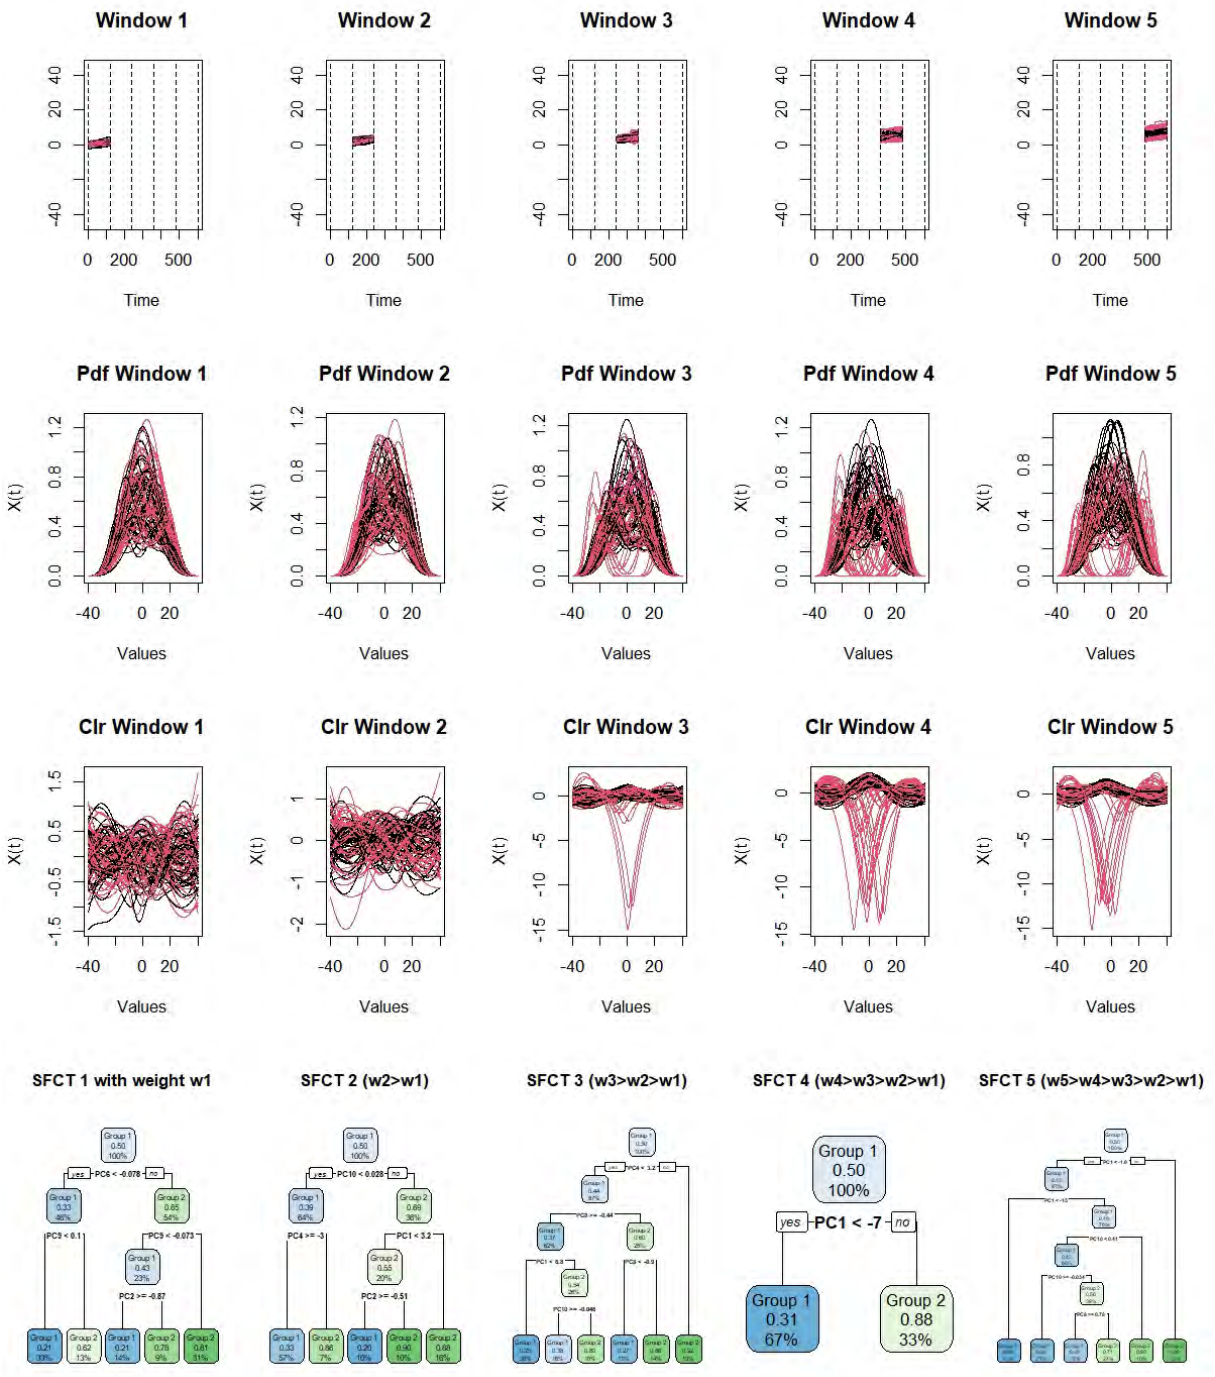

Figure 1: The visual explanation of the proposed algorithm.

4. Conclusions

In this paper, we have proposed a new algorithm to classify data streams via a dynamic classifier based on the joint use of FDA and density functions. Our approach is based on the so-called Simplicial Functional Classification Trees (SFCTs) which extends Classification Trees (CTs) to the context of pdfs viewed as functional data. The accuracy of the functional classifier is evaluated via bootstrap but different methods can be used, such as via cross-validation or a functional test set as in (14). The main objective of this study is to propose a classification method for high-dimensional data that achieves excellent levels of precision and is able to eliminate past datastreams by keeping only the necessary information of the

classification rule. In this way, the functional classification rule can be updated as new data arrives without the need to keep the huge amounts of data that are difficult to store due to their size.

Social networks and loneliness among older migrants in Italy

Viviana Amati[a], Eralba Cela[b], and Elisa Barbiano di Belgiojoso[a]

[a] University of Milano-Bicocca; viviana.amati@unimib.it,elisa.barbiano@unimib.it
[b] University of Milan; eralba.cela@unimi.it

Abstract

Ageing and migration are two of the major demographic trends in Western societies. Their intersection generates a considerable diversity of older migrants' groups that range from the more privileged international retirement migrants to the more disadvantaged refugees and 'zero generation' migrants. Different groups present wide variations in their needs and vulnerabilities. Nonetheless, older migrants are still an under researched group mainly because scholars' and policy-makers' attention has focused primarily on issues of border control, integration and the second generation, and the myth of return that projects migrants re-settled in their home countries. Empirical evidence shows however that retirement may trigger return migration. Still, most ageing labour migrants in Western countries stay put or adopt pendular strategies, travelling back and forth. In this paper we focus on the overlooked topic of loneliness among older migrants residing in Italy. We rely on a unique survey carried out by ISTAT during 2011–2012, specifically addressing migrant population.

Keywords: Loneliness, older migrants, social networks, Italy

1. Introduction

Loneliness has been defined as an unpleasant experience of a perceived mismatch between the available and desired number and quality of social relations. Unlike social isolation, which refers to the objective lack or the limited number of social relationships, loneliness represents a subjective feeling thatmight be present even when an individual is surrounded by an extensive network of family and friends or might be absent even if one is socially isolated.

Loneliness is not an individual problem only. It has multiple societal implications because of substantial negative consequences on physical and mental health and is associated with a lower quality of life.

Thus far, most of the research on loneliness among older adults is concentrated on the native population. In contrast, individuals with a migratory background have not been looked at extensively, although there has been a consistent increase in recent years (Fokkema & Ciobanu 2021). In the Italian context, the issue of loneliness among migrants (and even older ones) is rarely analysed. With the few exceptions of the studies of Cela and Fokkema (2017) and Cela and Barbiano di Belgiojoso (2021), no other studies have been carried out so far on this topic.

In the present study, we aim to fill this critical gap by focusing on loneliness among older migrants in Italy and analysing the impact of different types of support networks, namely the instrumental/support and emotional networks, while controlling for standard socio-economic variables.

2. Determinants of loneliness

The few existing quantitative studies investigating loneliness among older migrants have shown that, on average, older migrants are more likely to feel lonely than native peers (e.g., de Jong Gierveld et al., 2015). The main factors that explain the higher loneliness prevalence are related to general and specific risk factors associated with the status of being a migrant.

Among the general risk factors, empirical studies have shown that several demographic characteristics, such as gender, ethnicity, and marital status, are important predictors of loneliness. Health is also a significant determinant as it enables or hampers participation in different social activities; being healthy enables individuals to engage in differentiated social activities with friends and in community life, associations, and religious activities, whereas poor health is associated with a high risk of loneliness. Related to this, empirical evidence shows that older migrants are more likely to experience (earlier) poor objective and subjective health than their native peers (Cela & Barbiano di Belgiojoso, 2021).

Examples of migrant-specific risk factors are family disruption, language and cultural barriers, length of permanence in the host country, lack of social support, discrimination, and hostility in the host country, to name a few.

Among these migrant-specific factors, language proficiency and migration duration are critical determinants of the heterogeneity and size of migrants' support networks (Djundeva & Ellwardt, 2020). Specifically, those migrants who have spent more time in the host country might be less prone to feel lonely. They are more proficient in the local language, have had more opportunities to establish their local networks and frequently have other family members living nearby (Cela & Fokkema, 2017).

Recent studies (de Jong Gierveld et al., 2018; Djundeva & Ellwardt, 2020) have investigated the role of social networks in protecting (or not) against loneliness. They found out that being engaged in narrowed and poor-quality social contacts regarding composition and functioning are essential predictors of loneliness. Although there is no ideal size for social networks, having heterogeneous networks and frequent contacts with others is usually considered a safety net, as different types of relations play different roles and may result in various meeting opportunities and support exchanges (Litwin & Stoeckel, 2013). Among the web of social networks, family ties have a key role; the presence of a partner is the most crucial protective factor, as the partner represents the primary source of emotional and practical support. In contrast, the condition of being a widow or divorced or living alone often lead to loneliness. Parents, siblings and kin are also sources of emotional and instrumental support, especially in later life and are, therefore, a protective factor against loneliness. Other sources of support and protection against loneliness are friends and co-workers. Empirical evidence has also shown that participating in volunteerism, community activities, and religious services protects from loneliness as these activities are usually associated with a higher level of (given and received) social support and integration (Luhmann & Hawkley, 2016).

3. Data and methods

We rely on unique data from the "Social Condition and Integration among Foreign Citizens" survey administered by the Italian National Institute of Statistics during 2011 - 2012 on a sample of 25,000 individuals living in a household with at least one foreign member. The selected sample addressed specifically migrants, thereby capturing the multifaceted nature of the migration process. We analysed the subsample of 3,104 (12.26%) migrants older than 50.

The survey collected information on traditional socio-economic variables, such as gender, age, migration duration, area of origin, education, and employment. Additional information concerns discrimination, perceived wealth and health, health condition, and difficulties with the Italian language (reading, writing, speaking, and listening). Information on loneliness was collected through the question: "Do you feel lonely?". In the sample, 5.2% (162) do not feel lonely, 14.1% (438) feel lonely a little, 27.4% (852) somewhat lonely, and 53.2% (1652) very much lonely.

Quite a few questions collected information on the social relationships of the migrants. We used this data to construct ego network typologies following the approach presented in Amati et al. (2015) and Pelle & Pappadà (2021). Ego networks are the set of relationships in which an individual (hereafter referred to as

Ego) is embedded. It comprises Ego and its relations with alters along with Ego and alters characteristics. The survey provides information on different sets of alters that include the partner/spouse, parents, children, relatives, friends, co-workers, people who helped Ego with childcare, housekeeping, or important matters and associations with Ego as a member. The granularity of the information varies according to the alter's role and cohabitation with Ego. Thus, the alters in the ego network are represented by alter's categories rather than the individuals belonging to those categories. Based on the data, we defined seven alter categories: partner/spouse, parents, children, relatives, friends, members of the place of worship and others. We established the presence of alters based on cohabitation, and the frequency of contact between the migrant and the alters to whom it is tied. Figure 1 represents the ego network as a graph where the nodes depict Ego and alters while a tie identifies the presence of a support relationship.

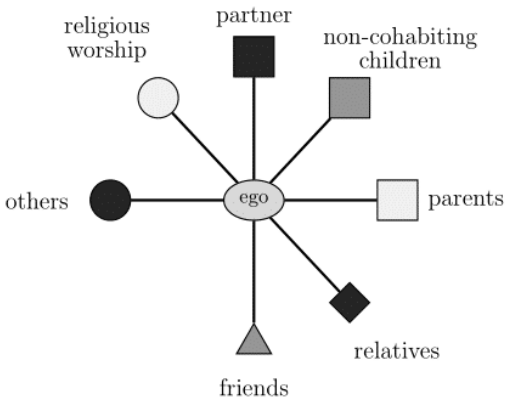

Figure 1 – Ego network of a migrant. A squared node indicates that the alters belong to the immediate family, a diamond that they are part of the extend family, a triangle that are friends, and a circle that are members of the religious worship or others. The colour of the nodes is used to distinguish the role of the alter.

We clustered the ego networks into groups to identify network typologies, ranging from the complete network where all the alters are present to sparse networks where only a few are present.

The network typologies were included as explanatory variables in a logistic regression model to make inferences on the effect of social networks on loneliness while controlling for the standard socio-economic variables described above. The dependent variable takes value 0 if migrants do not feel alone and 1 if they feel a little, somewhat, or very much lonely. While, in traditional analyses, the relationships in which Ego is embedded are treated as separate variables, the network typologies have the advantage of summarising those relationships to obtain a more parsimonious model and jointly analyse different combinations of alters.

We repeated the analysis using an adjacent category model to distinguish among the different categories of loneliness. The two models led to the same results.

4. Results

Seven different network typologies have been identified, ranging from the complete ego network, where all the alters are present, to the almost empty network comprising only children and friends. Table 1 reports the absolute and relative frequency distributions of the network typologies.

The network typologies are widespread among different groups of migrants and therefore are not specific to, e.g., females or the age of the migrants.

Table 2 reports the estimates of the model coefficients describing the association between feeling lonely and the network typologies. The coefficients are all statistically significant, but the one related to the ego network immediate family (no parents) + friend typology. Compared to the complete ego, we observe that

all the other network typologies have higher odds of feeling alone, as suggested by the positive estimates of the coefficients and the corresponding odds ratios greater than 1. Specifically, the odds of feeling alone are: 1.37 times (37%) larger for those with a Complete network (no parents), 1.52 times (52%) larger for those with an Immediate family + non-kin ego-network, 2.08 times (108%) larger for those with an Immediate family + friends; 2.01 times (101%) larger for those with an Extended family + non-kin groups; and 1.93 times (93%) larger for those with a Children + relatives ego-network.

Table 1 – Absolute and relative frequency distribution of the network typology.

Network typology	n	%
Complete network (no others)	399	12.9%
Complete network (no parents)	487	15.7%
Immediate family + non-kin groups	240	7.7%
Immediate family + friends	351	11.3%
Immediate family (no parents) + friends	503	16.2%
Extended family + non-kin groups	527	17.0%
Children + friends	597	19.2%

Table 2 – Model results for the network typologies: estimates (Est.), odds ratio (OR), p-value (p-value) and percentage change (%change)

	Est.	OR	p-value	%change
Network typologies (ref. Complete network (no other))				
Complete network (no parents)	0.31	1.37	**	36.60
Immediate family + non-kin groups	0.42	1.52	**	51.55
Immediate family + friends	0.73	2.08	***	107.91
Immediate family (no parents) + friends	0.21	1.23		22.99
Extended family + non-kin groups	0.70	2.01	***	101.19
Children + friends	0.66	1.93	***	92.70

We controlled the results for common factors such as gender, area of origin, education, economic and health conditions, knowledge of the Italian language and discrimination. Results are in line with previous research. We also considered interactions between the network structures, and gender and migration duration, respectively, but none of the interactions was significant.

The results of our study indicate that there is an association between loneliness and network typologies. However, loneliness might also affect the embeddedness in a network since it might lead to isolation from others. Applying models accounting for endogeneity is the next step of this research.

The Italian Decree on Security: An Analysis of the Impact on Asylum Applications

Giorgio Piccitto
Department of Political and Social Sciences - University of Bologna - - Strada Maggiore 45, Bologna - giorgio.piccitto3@unibo.it

Keywords: AsylumAapplications; Decree on Security; Asylum Recognitions;

1. Introduction

Despite the existence of a normative space as the European Union (EU), the rates of recognition for asylum seekers' protection statuses remarkably vary across different countries (Van Wolleghem, Sicakkan, 2022). Several studies have attempted to examine the potential explanations of these different between-countries rates of recognition, considering both economics and political reasons, without finding any clear driver (Toshkov, 2014), up to the point that it has been commented that «asylum decisions in Western Europe are highly arbitrary» (Bronkhorst, 1991, p.151). At the same time, it has been argued that changes in asylum policies within a given country may be associated with changes in recognition rates on asylum application flows (Thielemann, 2003), modifying the level of deterrence characterizing a determined socio-economic context (Holzer et al., 2000).
On December 3rd 2018, the Italian government approved the so-called "Immigration and security" decree. Among its intentions, regarding a wide range of matters (contrast to mafia and terrorism, urban security), the decree remarkably changed the regulation of asylum, immigration and citizenship (De Petris, 2019).
This contribution aims to evaluate the association between the "Immigration and security" decree and recognition rates of asylum applicants in Italy and if and how this association has been conditional on the applicant's socio-demographic characteristics. This goal will be accomplished by performing some statistical analyses on a dataset created from the annual Eurostat database on the first instances decisions on applications.

2. Data and method

The data used for this work are recorded by Eurostat at an aggregated level, considering the outcomes of first instances decisions on asylum applications in Italy by applicant's citizenship, age and sex. Age is recorded in the following classes: 1 = 0-13 years old (19.3% of the sample); 2 = 14-17 years old (11.2% of the sample); 3 = 18-34 years old

(39.0% of the sample); 4 = 35 years old or more (30.5% of the sample). Sex is recorded as follows: 1 = female (40.8% of the sample); 1 = male (59.2% of the sample). The dependent variable is a dummy, indicating a positive decision (1) or a rejection(0). We consider all the applications in the period from 2008 to 2021 (N= 667,065). For each combination of the above-mentioned categories, the aggregated database of Eurostat provides the number of applicants rounded up to the nearest 5. As an example, female citizens of Afghanistan aged 0-13 who received a positive response to their asylum application in 2009 were 5. We used this information on the number of applicants per each combination of categories to weight our sample: by doing so, we were able to create a dataset containing information at the micro-level.
In order to answer our research questions, we perform a set of logit models as follows:

$$\textbf{M1: } Y = \beta_0 + \beta_1(Year) + \beta_2(Sex_i) + \beta_3(Age_i) + \beta_4(Citizenship_i) + \varepsilon_i$$

$$\textbf{M2: } Y = \beta_0 + \beta_1(Year\ X\ Sex_i) + \beta_2(Age_i) + \beta_3(Citizenship_i) + \varepsilon_i$$

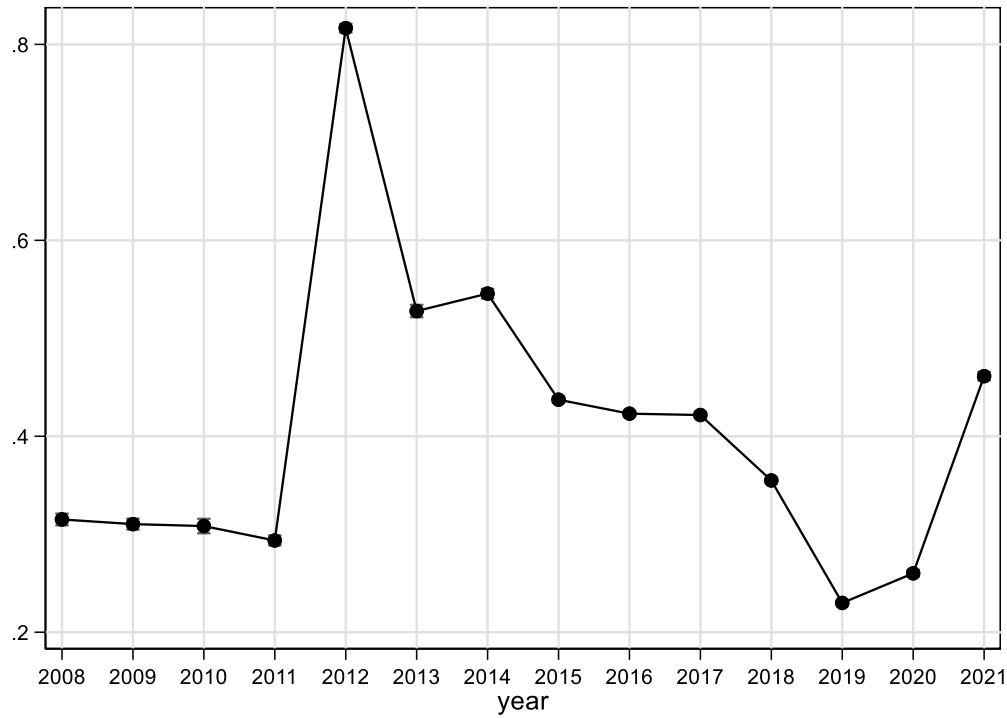
$$\textbf{M3: } Y = \beta_0 + \beta_1(Year\ X\ Age_i) + \beta_2(Sex_i) + \beta_3(Citizenship_i) + \varepsilon_i$$

Model 1 estimates the association between year and rates of recognition of asylum applicants in Italy, net of the individual socio-demographic controls. With this model we are able to shed light on whether the "Immigration and security" decree has changed the acceptance rate of asylum requests in Italy. Model 2 and model 3 allows the conditionality on sex (model 2) and age (model 3) of the association between year and rates of recognition of asylum applicants, by including an interaction term between year and sex (model 2) and year and age (model 3). All models control for individual citizenship. Results are presented and commented in terms of predicted probabilities, since the interpretation of logit coefficients is not straightforward (Mood, 2010).

3. Main results

In figure 1 are shown the predicted probabilities of the likelihood of asylum recognition by year, as estimated in Model 1.

Figure 1. *Logit model on the likelihood of asylum recognition by year. Model 1. Predicted probabilities. The model controls for sex, age, and citizenship*.



The analysis of this figure permits evaluating the trend of recognition of asylum applicants, with particular attention to the years following the implementation of the "Immigration and security" decree in 2018. The results seem to underline the decree's important role in driving the acceptance rate of asylum recognition. Indeed, after an apex of recognition in 2012[1], when more than 80% of asylum requests were accepted, the trend started to assume a downward shape, and the recognition rate began to drop. Nevertheless, the most substantial drop (after that between 2012 and 2013) has been recorded from 2018 (the year of the application of the "Immigration and security" decree) to 2019, passing from the 35.5% to the 23.0% of acceptances. In this sense, the legislation has remarkably impacted our outcome of interest.

Figure 2. *Logit model on the likelihood of asylum recognition by year and sex. Model 2. Predicted probabilities. The model controls for age and citizenship.*

[1] The strong increase recorded in 2012 is due to the response of the Italian Government to the unrest in North Africa in 2011. On April 5th, 2011, recognizing the exceptional situation of North Africa, the Government adopted temporary measures of humanitarian protection in favor of refugees from North Africa ("*Emergenza Nord Africa*", ENA). The ENA provisions temporarily relaxed immigration policies: migrants who fled from Algeria, Egypt, Libya, Morocco and Tunisia to Italy between January 1st and April 5th, 2011 were automatically granted a temporary permit of stay for humanitarian reasons. On August 3rd, 2011, the duration of this regime was extended due to the persistent situation of instability in North Africa. Some specific emergency measures were lately applied also to migrants the Horn of Africa, Kenya, Sudan and Uganda (dalla Pellegrina et al., 2014).

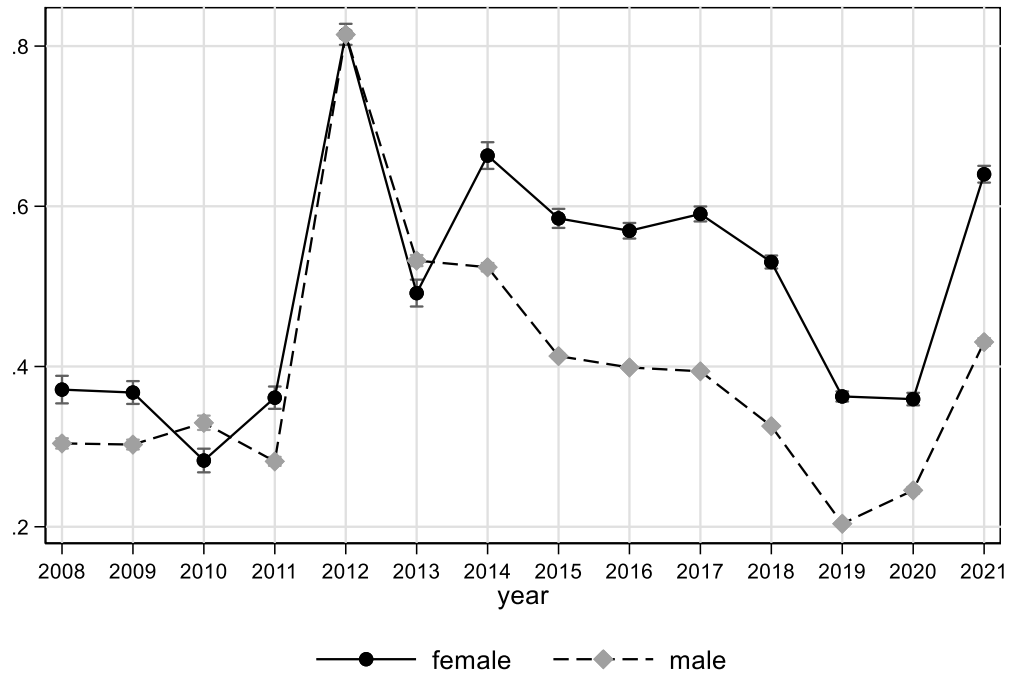


Figure 2 shows the predicted probabilities of asylum recognition by year and sex, as estimated in Model 2. This graph allows to evaluate if the association between year and asylum recognition was conditional on the applicant's sex. Results show that up to 2013, the rates of recognition of asylum applicants were very similar between men and women, with the highest difference between male and female applicants being recorded in 2011 (average marginal effect = .08). But from 2013 onwards, it emerges a gender gap in the asylum recognition, with female applicants more likely to have their request accepted, a result already observed in other European countries (Plümper, Neumayer, 2021). Such a higher likelihood is also maintained in the aftermath of the application of the decree, which lowers the acceptance at a similar pace both for men and for women.

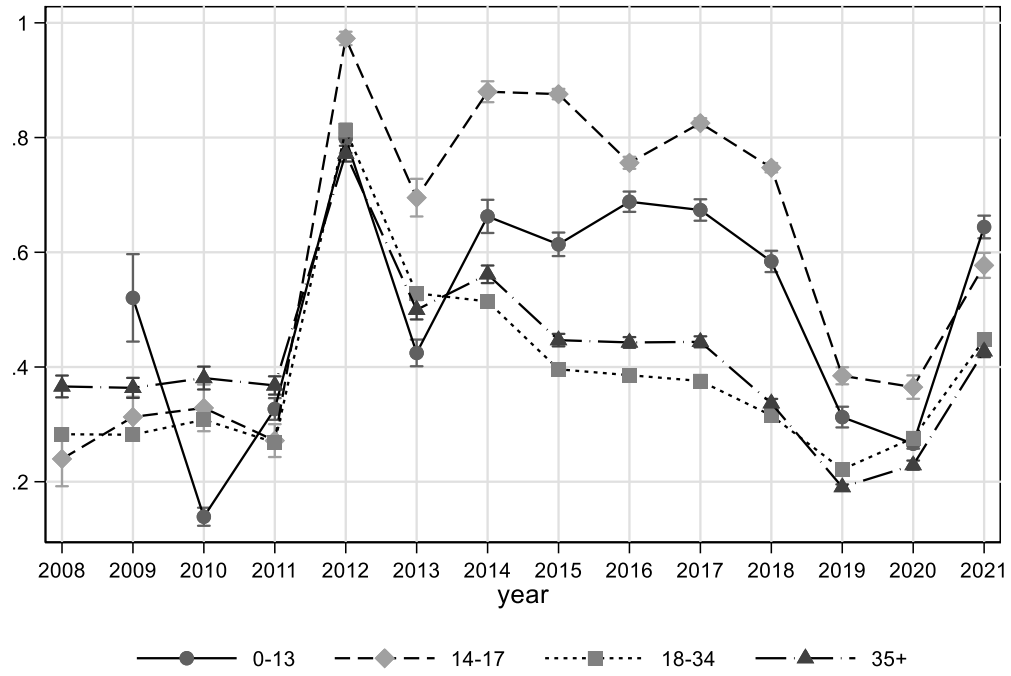
Figure 3 shows the predicted probabilities of the likelihood of asylum recognition by year and age, as estimated in Model 3. Analyzing these predicted probabilities makes it possible to shed light on the interplay between year and applicant's age on asylum recognition. Differently from what emerged concerning the applicant's sex, the pattern of asylum acceptance by age does not seem to vary during the period considered in our analysis. Indeed, the highest likelihood of acceptance is observed for younger applicants, particularly those between 14 and 17 years old. This holds true from 2012 onwards, while before, the differences across different ages were less marked. On May 6th 2017, new legislation regarding the "Protection Measures for Unaccompanied Minors" (law n. 47/17, "*legge Zampa*") entered into force in Italy. This law has filled significant gaps in the protection of unaccompanied children, introducing important provisions, among other issues, on age assessment procedures. However, our results suggest that higher acceptance rates were observed before the law's implementation, which resulted from more than three years of advocacy efforts by Save the Children and other NGOs (Rozzi, 2017). In general, the older cohorts experience a lower likelihood of asylum request acceptance with respect to the younger ones, and this pattern is confirmed also in the aftermath of the "Immigration and security" decree of 2018.

Figure 3. *Logit model on the likelihood of asylum recognition by year and age. Model 3. Predicted probabilities. The model controls for sex, and citizenship.*



4. Conclusion

The "Immigration and security" decree has lowered the probability of asylum request acceptance in Italy. Although the pattern showed a downward trend from 2012, the drop after 2018, the decree's implementation year, was particularly remarkable, and the recognitions passed from 35.5% to 23.0% in 2019. Interestingly, from 2013 onwards, it emerged a gender gap in asylum recognition, with women having a higher likelihood of request acceptance than men; this gender-based difference has also been confirmed after the decree of 2018. Finally, our analysis showed that older cohorts have always experienced a lower acceptance rate of their requests than younger ones.

Adaptive combinations of tail-risk forecasts

Alessandra Amendola[a], Vincenzo Candila[a], Antonio Naimoli[a], and Giuseppe Storti[a]

Abstract

The continuous evolution of financial markets highlights how quantitative financial risk management has become a key tool in investment decisions, capital allocation, and regulation. Although several methods have been proposed to estimate the risk of an investment in capital markets, Value-at-Risk (VaR) and Expected Shortfall (ES) can be considered the standard measures of market risk, as they are used both for internal control of financial institutions and for regulatory purposes. In this direction, the choices of modelling and estimation methods for VaR and ES play a critical role. Nowadays, a variety of possibilities is available. For instance, there are models belonging to the class of parametric, semi-parametric, and non-parametric methods. Moreover, among the class of parametric models, there are several error distributions that could be considered. Also, some models allow for the use of variables mixed at different frequencies. To mitigate the impact of these sources of uncertainty, we propose a forecast combination strategy by adaptively weighting the pool of most accurate predictors based on the Model Confidence Set (MCS) results. The empirical analysis suggests that combinations of VaR and ES forecasts lead to higher predictive accuracy over a wide range of competitors.

Keywords: Value-at-Risk, Expected Shortfall, Model Confidence Set, Volatility

1. Introduction

The past financial crisis has emphasized the importance for financial institutions to rely on reliable forecasts of Value-at-Risk (VaR) and Expected Shortfall (ES). In light of the Basel Capital Accords, VaR and ES can be considered the leading measures of tail risk forecasting.

The VaR, being a conditional quantile in the lower tail of a portfolio's return distribution, has been widely used as a measure of financial market risk for both regulatory and internal risk management purposes. It quantifies the maximum amount of loss for a portfolio of assets, under normal market conditions, over a given time period and at a certain confidence level. However, VaR has been subject to criticism because it fails to meet the requirements of a coherent risk metric (5), and at the same time has the limitation of not providing information on potential exceedances beyond the quantile.

Recently, the ES has received increasing attention as an alternative tail risk metric and is now recommended by the Basel Committee on Banking Supervision. The ES is a coherent risk metric (5) and provides the expected loss conditional on returns exceeding the VaR threshold (1).

However, despite its attractive properties, in contrast to VaR, the ES is not an "elicitable" measure, meaning that there is no loss function such that the ES is the solution that minimizes the expected loss. Consequently, this poses a challenge for ES estimation and backtesting (18). As a partial remedy to this problem, (15) define a set of joint loss functions, named FZ, for VaR and ES for which these two measures are jointly elicitable.

VaR and ES forecasts can be obtained through several approaches that are substantially attributable to parametric, non-parametric, and semi-parametric models (22). Parametric approaches are often based on GARCH models, which require the specification of the conditional distribution of returns and volatility dynamics. Semi-parametric approaches, such as quantile regression models (14; 27), include those based on methods that instead require specific assumptions about the dynamics of risk, but no assumptions about the distribution of returns. Finally, a popular example of non-parametric approach is the historical simulation (21).

The previous discussion highlights how the identification of an optimal forecasting model is subject to data, parameter and model uncertainty. In this context, a possible solution is to resort to combining forecasts. The idea of combining forecasts generated by different models dates back to (7). Since then, many articles have emphasized the advantages of combining forecasts of volatility (3; 2), VaR (8) or VaR and ES (28; 25) as a way to reduce the risk of selecting a single predictor, which may not always be optimal during the forecast period.

Combination has the greatest potential when the individual methods use different information or use information in different ways. Among the whole universe of potential VaR and ES forecasts, the chosen set of candidate models covers a wide range of frequently used parametric, semi-parametric and non-parametric techniques, as well as methods based on intraday data and mixed frequency variables.

Aiming to reduce the impact of model uncertainty in tail-risk forecasting, a novel tail-risk forecasting strategy is proposed. The proposed approach is based on a truncated mean in which only models that perform significantly better than others are considered in the combination. To select the set of best-performing models to be involved in the combination, the Model Confidence Set (MCS) by (20) is used. The proposed procedure is adaptive because the composition and dimension of the set of "best" models involved in the combined forecast varies over time and and does not require parameter estimation.

The performance of the proposed combination approach is compared to each individual model in the universe. For forecast evaluation, we use backtesting via the Unconditional Coverage (UC) backtest by (23), the Conditional Coverage (CC) backtest by (12) and the dynamic quantile (DQ) backtest of (14), together with the Regression-Based Expected Shortfall Backtesting (BD) of (9). Furthermore, we compare the forecasts with the MCS of (20) to determine the approach that produces the most accurate predictions.

The results on the S&P500 index indicate that the proposed combined predictors enter the set of superior models in the MCS evaluation, while all backtesting procedures are passed at the 1% significance level.

The rest of the paper is organized as follows. Section 2. illustrates the methodology adopted and the proposed combined predictors. Section 3. is devoted to the empirical application.

2. Methodology

In this work, three different combined predictors for VaR and ES are proposed. All the combined predictors are based on the models which, dynamically, enter the Set of Superior Models (SSM) according to the MCS procedure. We defined as *training* MCS the procedure used to find the best models in the so-called training or in-sample period. The loss used in the *training* MCS belongs to the class of FZ. More in detail, the loss is that of (24) labelled as $FZ0$. Formally:

$$FZ0(VaR_{i,t}(\tau), ES_{i,t}(\tau), r_{i,t}) = \frac{1}{\tau ES_t(\tau)} \mathbb{1}_{(r_{i,t} \leq VaR_{i,t}(\tau))}(r_{i,t} - VaR_{i,t}(\tau)) + \frac{VaR_{i,t}(\tau)}{ES_{i,t}(\tau)} + \log(-ES_{i,t}(\tau)) - 1, \quad (1)$$

where τ is the coverage level chosen, $r_{i,t}$ is the log-returns for day i of the period t and $\mathbb{1}_{(\cdot)}$ is an indicator function.

The chosen set of candidate models covers a wide range of frequently used parametric, semi-parametric and non-parametric techniques, as well as methods based on intraday data and mixed frequency variables. Table 1 reports the set of candidate models.

Table 1: Candidate models

Model	Functional form	Err. Distr.
GARCH–N, GARCH–t (10)	$r_{i,t}\|\mathcal{F}_{i-1,t} = \sqrt{h_{i,t}}\eta_{i,t}$ $h_{i,t} = \omega + \alpha r_{i-1,t}^2 + \beta h_{i-1,t}$	$\eta_{i,t} \overset{i.i.d}{\sim} \mathcal{N}(0,1)$, $\eta_{i,t} \overset{i.i.d}{\sim} t_\nu$

CAViaR-AS (14)	$VaR_{i,t}(\tau) = \beta_0 + \beta_1 VaR_{i-1,t}(\tau) + (\beta_2 \mathbb{1}_{(r_{i-1,t}>0)} + \beta_3 \mathbb{1}_{(r_{i-1,t}<0)})\|r_{i-1,t}\|$	
CAViaR-IG (14)	$VaR_{i,t}(\tau) = -\sqrt{\beta_0 + \beta_1 VaR_{i-1,t}^2(\tau) + \beta_2 r_{i-1,t}^2}$	
CAViaR-X (16)	$VaR_{i,t}(\tau) = \beta_0 + \beta_1 VaR_{i-1,t}(\tau) + \beta_2 x_{i-1,t}$	

In this work, we propose three different combined predictors: MCS-Comb, W-MCS-Comb and MW-MCS-Comb. In particular:

- MCS-Comb: equally weighting all the VaR's and ES's obtained from the models entering the SSM of the *training* MCS, using the (unweighted) $FZ0$;
- W-MCS-Comb: equally weighting all the VaR's and ES's obtained from the models entering the SSM of the *training* MCS, using the *weighted* $FZ0$;
- MW-MCS-Comb: weighting proportionally to the *cumulated* $FZLoss$ all the VaR's and ES's obtained from the models entering the SSM of the *training* MCS, using the (unweighted) $FZ0$.

The *weighted* $FZ0$ adopted in the *training* MCS weights differently remote and recent observations. According to (26), the idea is that recent observations should have more weight with respect to remote observations. We adopt the same *exponentially weighted* approach of the RiskMetrics model to weight differently the observations. The MW-MCS-Comb predictor instead weights differently the VaR's and ES's of models entering the SSM of the *training* MCS (using the (unweighted) $FZ0$). In particular, models with smaller cumulated $FZ0$ values have larger importance to define the MW-MCS-Comb predictor.

3. Empirical analysis

The empirical analysis uses daily data on S&P 500 index collected from the Oxford-Man Institute's Realized Library. The full sample covers the period from January 18, 2011 to February 11, 2021, for $T = 2525$ daily observations. High-frequency variables are the realized volatility (4) at 5 and 10 minutes and the realized kernel (6). Low-frequency variables are the Geopolitical Risk (GPR, 11) and the National Activity Index (NAI), taken as the first release from the ALFRED archive. GPR and NAI are observed monthly. Let M be the set of candidate models, T_{in} the length of the rolling period, $lstep$ the number of static one-step-ahead forecasts generated by each candidate model, T the sample size, and $nstep = (T - T_{in})/lstep$ the number of steps employed in the algorithm. The algorithm for obtaining the combined predictors is as follows:

1. Estimate all the candidate models over the window including observations from the period $t = 1 + j$ to $t = T_{in} + j$. Conditionally on the estimated parameters, generate for the following $lstep$

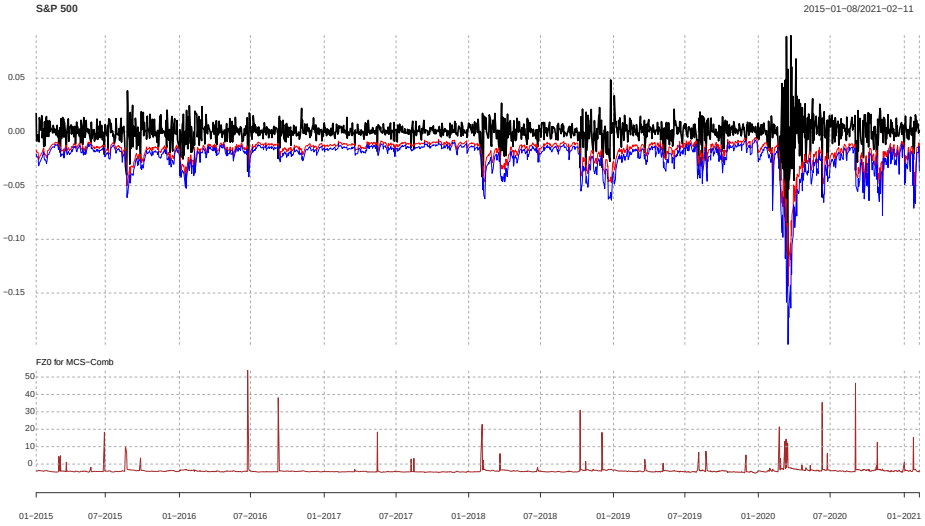

Figure 1: S&P 500 Log-returns (black line), VaR (red line), ES (blue line), and $FZ0$ values (bottom panel) of the MCS-Comb predictor

days both VaR and ES one-step ahead forecasts, with $i = 1, \cdots, M$.

2. Compute the *training* MCS over the training period going from $t = 1 + j$ to $t = T_{in} + j$.
3. Obtain the proposed combined predictors $VaR^{Comb}_{(T_{in}+j+1):(T_{in}+lstep+j)}$ and $ES^{Comb}_{(T_{in}+j+1):(T_{in}+lstep+j)}$.
4. Iterate steps 1, 2, and 3, with $j = \{0, lstep, 2lstep, \cdots, (nstep-1)lstep\}$.

We use $M = 25$ models, $T_{in} = 1000$, and $lstep = 25$. Globally, the out-of-sample period consists of 1525 observations from 8 January 2015 to 11 February 2021. The coverage level chosen is $\tau = 0.025$. Together with the three proposed combined predictors, we use two additional benchmarks: the equally weighted combination (EW-Comb) and the median combination (Median-Comb). The plot of the log-returns with the predicted VaR (red line) and ES (blue lines) obtained from the proposed MCS-Comb predictor for the out-of-sample period is in the top panel of Figure 1. The bottom panel of Figure 1 instead illustrates the $FZ0$ pattern of the MCS-Comb predictor, with the peaks observed when there are the VaR violations. Table 1 reports the violation rate (VR, in percentage) in the first column, the p-values of the UC, CC, and DQ tests for VaR in the columns from two to four, the p-values of the BD tests for VaR and ES in columns from five to eight, and the average of the $FZ0$ loss in the last column, for all the candidate models as well as the two combined benchmarks and the three proposed combined predictors. Shades of gray in the last column indicate that the model in the row enters the SSM of the MCS procedure at the significance level $\alpha = 0.25$. While many models (mainly some parametric and all the non-parametric specifications) do not perform well, all the proposed combined predictors pass the usual backtesting procedures at 1% significance level and, moreover, enter the SSM of the final MCS test.

Are Monetary Policy Announcements related to Volatility Jumps?

Giampero M. Gallo[a], Demetrio Lacava[b], and Edoardo Otranto[b]

Abstract

Central Banks interventions are frequent in response to exogenous events with direct implications on financial market volatility. In this paper, we introduce the Asymmetric Jump Multiplicative Error Model (AJM), which accounts for a specific jump component of volatility within an intradaily framework. Taking the Federal Reserve (Fed) as a reference, we propose a new model–based classification of monetary announcements based on their impact on the jump component of volatility. Focusing on a short window following each Fed's communication, we isolate the impact of monetary announcements from any contamination carried by relevant events that may occur within the same announcement day.

Keywords: Financial markets, Realized volatility, Significant jumps, Monetary policy announcements, Multiplicative Error Model.

1. Introduction

The effectiveness of monetary policy communications crucially depends on a Central bank's credibility: "the extent to which the public believes that a shift in policy has taken place when, indeed, such a shift has actually occurred" (Cukierman, 1986) needs to be built through repeatedly consistent actions.
Monetary policy announcements have an essential role in driving financial markets expectations, particularly when financial turmoil or sudden changes in price dynamics require an active stance. There is a large consensus about the increase in volatility on announcement days: on those occasions, new information becomes available, either confirming prior beliefs or as a surprise. Either way, typically, an announcement has an impact on market activity, with increases in the number of trades some of which determine price changes or even jumps. In this paper we allow for a novel time–varying impact of announcements on volatility, by exploiting the granularity of intra daily data to derive consistent measures of volatility (see McAleer and Medeiros, 2008, for an exhaustive review), and identifying *significant* jumps (Andersen et al., 2007).

We suggest a new *composite* (Brownlees et al., 2012; Otranto, 2015) Multiplicative Error Model (MEM, Engle, 2002), which splits the dynamics of expected volatility at thirty–minute bins,[1] into a component for the continuous part of volatility and one for the discontinuous jump component, while accommodating time–of–day effects. Zooming into a particular time of the day around the release of a communication by the Federal Reserve (Fed), our model allows for the identification of the impact of

[1]The data are built starting from the tick–by–tick series of prices in the Trade and Quote (TAQ) database, which were cleaned according to the Brownlees and Gallo (2006) procedure and then sampled at five–minute intervals.

monetary policy announcements on volatility in the bin following the announcement itself. Our estimated results provide the basis for a new model–based classification procedure of monetary announcements according to their impact on volatility jumps right after the time of the announcement. Our analysis on some large–cap tickers shows a consistent classification approach across tickers and reveals useful information about the impact of monetary announcements on the volatility by market sector.

2. The model

The class of MEM (Engle, 2002; Engle and Gallo, 2006) specifies conditional volatility at bin i of the day t as the product of a time-varying positive conditional mean $\mu_{i,t}$ times an error term $\epsilon_{i,t}$ with a positive support. In this paper, we propose the Asymmetric Jump Multiplicative Error Model (AJM), where the conditional mean $\mu_{i,t}$ of the realized volatility $\widetilde{RV}_{i,t}$, adjusted to remove a time–of–day pattern, is the sum of $\varsigma_{i,t}$ (related to the continuous part) and $\kappa_{i,t}$ which reacts to the significant jumps:

$$
\begin{aligned}
&\widetilde{RV}_{i,t} = C_{i,t} + SJ_{i,t} \\
&C_{i,t} = \mu_{i,t}\epsilon_{i,t} \qquad\qquad \epsilon_{i,t}|\mathcal{F}_{i-1,t} \sim \Gamma(\vartheta, \tfrac{1}{\vartheta}) \\
&\mu_{i,t} = \varsigma_{i,t} + \kappa_{i,t} \\
&\varsigma_{i,t}, = [\omega + \alpha_1 C_{i-1,t} + \alpha_2 C_{i-2,t} + \beta\varsigma_{i-1,t} + \gamma I^{-}_{i-1,t} C_{i-1,t}] + \delta_1 |r_{i,t^\star}| + \delta_2 C_{i-1,t}, D_{i-1,t} \\
&\kappa_{i,t} = \varphi\mu_{i-1,t} + \psi SJ_{i-1,t}.
\end{aligned}
\tag{1}
$$

$\mathcal{F}_{i-1,t}$ is the information set at the previous bin (for the first bin of the day it is the last bin of the previous trading day); $C_{i,t}$ is the continuous volatility series and $SJ_{i,t}$ is the significant jump series.[2] In the specification for $\varsigma_{i,t}$ we adopt a standard AMEM(2,1) dynamics (in square brackets) with the asymmetric term connected to the sign of the most recent return through the indicator function $I^{-}_{i-1,t}$, augmented by two important sources of additional dynamics, a positive impact of the overnight return $r_{i,t^\star}$, which may capture news accumulation during market closing,[3] and a diminished impact of the first bin volatility on the second bin relative to the rest of the day (through a suitable dummy variable $D_{i,t}$). We keep a simple AR(1) specification for the jump component $\kappa_{i,t}$, driven by the observed significant jumps with an expected positive coefficient ψ.

Stationarity of both $\varsigma_{i,t}$ and $\kappa_{i,t}$ is required for the model to be stationary in covariance: relying on the identifiability results of (Engle and Lee, 1999), the continuous component is considered more persistent than the short–lived jumps, that is, $0 < \varphi < \beta < 1$ in Eq. (1). As for the required positiveness, while the usual GARCH constraints ($\omega, \alpha_1, \beta, \gamma > 0$) hold even in our framework, in the AJM(2,1) α_2 can also assume negative value, with $\alpha_2 > -\alpha_1\beta$ ensuring $\varsigma > 0$ (Cipollini et al., 2020).

Among the distributions with positive support that can be specified for $\epsilon_{i,t}$, we opt for the Gamma distribution, because of its flexibility (values of ϑ ensure different shapes) and in view of its robustness (see Cipollini et al., 2013, for the equivalence between first order conditions and moment conditions in the univariate case). The Gamma generally depends only on the shape parameter ϑ, so that it has a unit mean and a constant variance ($1/\vartheta$): this makes the model very flexible with not only a time-varying conditional mean $E(\widetilde{RV}_{i,t}|\mathcal{F}_{i,t-1} = \mu_{i,t})$ but also a time varying conditional variance $Var(\widetilde{RV}_{i,t}|\mathcal{F}_{i,t-1} = \mu^2_{i,t}/\vartheta)$. The main implication of having a time varying volatility of volatility is that heteroskedasticity is implicit in the model, giving the opportunity of capturing possible structure in the innovations without resorting to any auxiliary regression.

Finally, Maximum Likelihood estimation involves Quasi Maximum Likelihood (QML) properties, ensuring consistency and asymptotic normality of the coefficient estimators (Engle, 2002), regardless the appropriateness of the selected distribution for the error term (Engle and Gallo, 2006). However, since ϑ is unknown, we resort to robust standard errors to shield against the actual shape of the distribution.

[2] $SJ_{i,t} = \mathcal{I}_{[J_{i,t} > \Phi_q]}(RV_{i,t} - BV_{i,t})$, were BV represents the realized bipower variation (Barndorff-Nielsen and Shephard, 2004, 2006) and $J_{i,t}$ is the jump statistics developed by Andersen et al. (2007).

[3] It is given by the difference between the opening log price of day t and the closing log price of the previous day $t-1$, so that $t^\star$ denotes the time between $t-1$ and t. At the end of the first bin, such information is known.

2.1 Estimation results

Estimation results are reported in Table 1. coefficients are highly significant with a persistence (measured as $\alpha_1 + \alpha_2 + \beta + \gamma/2 + \delta_2/13$) estimated around 0.96 across the considered assets. As expected, a large part of volatility comes from the ARCH terms, with $\hat{\alpha}_1$ ranging between 0.22 and 0.27 and $\hat{\alpha}_2$ between -0.11 and -0.21, given that, at an intraday level, volatility is very sensitive to news (with the first lag), but then contributes (with the second lag) to the absorption of news (see, for example Cipollini et al., 2020). This is also confirmed by the coefficients γ, which measure the impact of bad news (as represented by negative returns), are positive and significant at a 1% level, with values between 0.01 and 0.03. The positiveness of δ_1 represents evidence in favor of the *market opening effect*, i.e. a response of volatility at the beginning of each trading day between 0.008 and 0.017, due to whatever accumulation of news entails an overnight price movement. By the same token, the other bin–specific effect, marked by δ_2, enters the model with the expected (and significant) negative sign, that is, the contribution to current bin volatility from the previous one is lower for bins after the first one. In such a case, the total effect is given by $\alpha_1 + \delta_2$, ranging between 0.18 and 0.23 across the considered series.

As for the jump component, the autoregressive coefficient φ ranges between 0.017 and 0.351 across tickers, pointing out to a low persistence of the jump component - in line with the common view that volatility jumps are short-lived occurrences. The coefficient ψ is positive, with expected jumps that are an increasing function of the identified significant jumps.

To give a visual documentation of the relationship between Fed announcements[4] and significant volatility jumps, Figure 1 shows the evolution of the realized volatility, $\widetilde{RV}$ (grey line, left axis), together with the significant jump size ($SJ_{i,t}$) observed on announcement days (blue dots – both empty and solid – right axis scale) between December 14, 2016 and December 31, 2021 with a total of 44 announcements. On the basis of the empirical evidence in Figure 1, it is clear how the announcement effect is not constant over time: in particular, while some announcements have a limited impact on jumps, for some specific Fed's communications, significant jumps account for more than 20% of the overall level of volatility[5] (blue dots). This is the case, for example, of the announcement released on March 20, 2019, when the Federal Open Market Committee (FOMC) decided to maintain the federal funds rates (FFR) within the 2.25–2.50 percent bracket. Interestingly, a similar decision (with the FFR left constant at 0-0.25 percent) on September 16, 2020, is associated to a jump marking 55% of the total level of volatility. In synthesis, the same quantitative decision could translate into a different qualitative impact on jumps, pointing to the relevance of market expectations about the announcement rather than the decision per se.

[4]Data about the date, the time and the content of monetary policy announcements are available at https://www.federalreserve.gov/monetarypolicy/fomc_historical.htm

[5]The share of volatility due to significant jumps can be computed as $\frac{SJ_{i,t}}{\widetilde{RV}_{i,t}} = 1 - \frac{C_{i,t}}{\widetilde{RV}_{i,t}}$.

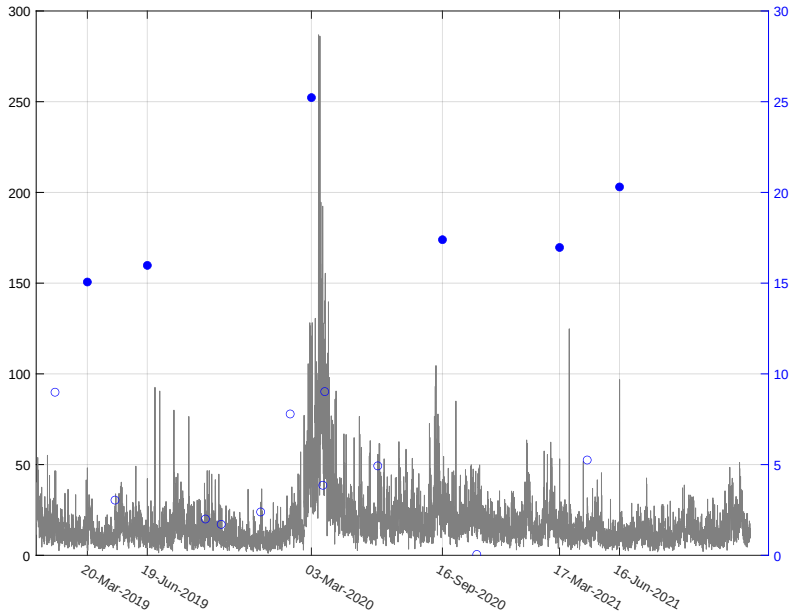

Figure 1: MSFT realized volatility (grey line, measured on the left axis) and jumps (blue dots both empty and solid, on the right axis) associated to monetary announcements (details in the text). Solid blue dots identify volatility jumps accounting for more than 20% of the overall level of volatility. Sample period: December 14, 2016 – December 31, 2021.

3. The classification method

Our model suggests a simple mechanism for a model-based classification of monetary announcements according to their impact on volatility jumps, that is, we distinguish expected jumps (as represented by $\kappa_{i,t}$ in Eq. 1) from what we call *jump surprise* or *unexpected* jumps. The latter is defined as the difference between what we expect and what we observe, $J^{surprise}_{\iota,\tau} = \kappa_{\iota,\tau} - SJ_{\iota,\tau}$ with $\tau = t$ on announcements days and ι indicating the first bin past the announcement time.

The proposed approach belongs to the class of time-point classification methods (Aghabozorgi et al., 2015): focusing on the τ announcement days, we suggest to classify Fed's announcements, according to whether at the bin ι within that day we detect

1. an Upward Spike (local maximum), if $\kappa_{\iota-1,\tau} < \kappa_{\iota,\tau} > \kappa_{\iota+1,\tau}$;
2. a Downward Spike (local minimum), if $\kappa_{\iota-1,\tau} > \kappa_{\iota,\tau} < \kappa_{\iota+1,\tau}$;
3. a Boost (an increase), if $\kappa_{\iota-1,\tau} < \kappa_{\iota,\tau}$;
4. a Drop (a reduction), if $\kappa_{\iota-1,\tau} > \kappa_{\iota,\tau}$,

for κ (and, similarly, for $J^{surprise}$). Note that the identification of the Boost or the Drop bins of the announcement day is made excluding the corresponding spikes. Our classification method has the merit of being immediately applicable when an announcement is released and has the unique characteristic of giving information about the expected jumps.

The classification results are shown in Table 2. Focusing on the expected jumps $\kappa_{\iota,\tau}$: most of the announcements (between 29% and 34%) correspond to a Upward Spike, followed by Downward Spikes (26% – 24% of the cases), and Boost (20% – 26%). Results are quite homogeneous across assets, even if only few announcements belong to the same cluster (Downward Spike) for all the considered tickers.

Interestingly, some announcements affected only specific sectors, e.g. the decisions about the FFR on June 17, 2015, July 31, 2019 and July 28, 2021, which are classified as Upward Spike only for the financial sector. Conversely, some Fed communications had a different impact in different sectors, with announcements on April 27, 2016 and August 1, 2018 causing a Upward Spike for the industrial

Table 2: Classification results based on the restricted AJM. The total 104 Fed's monetary announcements are classified basing on their effects either on $\kappa_{\iota,\tau}$ or on the jump surprise, $J_{i,t}^{Surprise}$.

	$\kappa_{\iota,\tau}$				$J_{\iota,\tau}^{surprise}$			
	Upward Spike	Downward Spike	Boost	Drop	Upward Spike	Downward Spike	Boost	Drop
MSFT	30	27	27	19	32	45	5	21
GS	30	27	30	17	34	39	11	20
JNJ	33	30	30	11	34	51	5	14
MMM	35	35	21	13	34	45	4	21

Table 3: Percentage adjusted Rand-index between: **Panel a** – pairs of assets basing either on κ (lower triangular matrix) or $J^{Surprise}$ (upper triangular matrix); **Panel b** – κ and $J^{Surprise}$, and κ and SJ.

Panel a	MSFT	GS	JNJ	MMM
MSFT	-	57.67%	55.06%	55.73%
GS	63.13%	-	56.46%	56.68%
JNJ	61.67%	61.31%	-	56.42%
MMM	61.24%	60.51%	59.65 %	-
Panel b				
κ vs $J^{Surprise}$	81.11%	75.58%	77.22%	79.37%
κ vs SJ	63.24%	56.55%	62.47%	61.82%

sectors (MMM) while they had the opposite effect (Downward Spike) on the financial and Information Technology (IT) sectors. As expected, the pharmaceutical (JNJ) sector is not integrated with the others, with around the 12% of announcements that have a different classification with respect to the other securities. This does not hold for the IT sector (MSFT), which shares the 27% of the classification with the financial sector – the percentage is 26% (31%) for announcements classified as Upward Spike (Downward, respectively). For an investor, the usefulness of this kind of information is twofold: on the one hand, knowing the degree of interconnection between sectors is important in designing diversification strategy; on the one other, predicting turning points of $\kappa_{\iota,\tau}$ is crucial for investment strategies based on momentum. When one turns to jump surprises, a higher degree of integration is encountered for the pharmaceutical sector with 37% classified as Drop only for JNJ. Similarly, the integration between the IT and financial sectors increases, with 35% of announcements having a common classification for MSFT and JPM – the percentage is 33% (62%) if the Upward Spike (Downward, respectively) is considered.

In evaluating the accuracy of our classification method, we rely on the adjusted Rand-index (Rand, 1971; Hubert and Arabie, 1985) computed between pairs of assets. Table 3 shows results deriving either from κ or $J^{Surprise}$. Consistently, elements of the lower portion (expected jumps) are pairwise larger than the corresponding elements of the upper portion (surprise jumps), with indices that are above to 60%: given their size, a similar clustering among tickers is apparent, but an idiosyncratic component of reaction to announcements is present. This is confirmed by the fact that the index is higher than 75% when κ is compared to $J^{surprise}$, while it 63% at most, when we compare κ to SJ.

4. Concluding remarks

We introduce a novel MEM to decouple the continuous part of volatility from its jump component, geared toward a model–based classification of Central Bank's announcements based on their impact on volatility jumps. Conversely to the existing approaches, we reconstruct the dynamics of intradaily volatility by thirty-minute bins distinguishing a continuous part and a jump part components and accommodating some peculiarities related to the time–of–day effect. We allow for a time-varying announcement effect, with each Central Bank's communication having its own effect on volatility, with the possibility to classify announcements according to whether we detect a local maximum (minimum) or a simple increment

(reduction) of the considered series on announcement days.

The empirical application, based on some US tickers, reveals both commonalities and differences among different sectors of the market, with a high interconnection between the IT and financial sectors, with the pharmaceutical sector being less close. The adjusted Rand-index, reveals a good accuracy of our classification, which has the merit of being immediately applicable when an announcement is released.

The model could be further refined in at least two directions: a feedback effect could be accommodated within the dynamics of the continuous part making it depend on the lagged expected jump component; furthermore, in line with the logic of the Composite MEM, the two components enter the model additively, while an interesting comparison would be with a model with multiplicative components.

Bayesian density estimation for modeling age-at-death distribution

Davide Agnoletto[a], Tommaso Rigon[b], and Bruno Scarpa[a]

[a]Department of Statistical Sciences, University of Padova, Via C. Battisti 241, Padova, Italy

Abstract

Age-at-death distribution represents a fundamental quantity for the study of mortality since it provides an important tool to evaluate the longevity and lifespan variability in a population. In this paper, we analyze the set of such curves for the male population of Campania's municipalities region in 2020. By exploiting a Bayesian nonparametric mixture model, we produce an estimate of age-at-death distributions even in presence of small populations, simultaneously modeling multiple curves.

Keywords: age-at-death distribution, Bayesian modeling, Campania.

1. Introduction

Modeling human mortality has challenged statisticians and demographers over the years, resulting in a wide range of proposed models. John Graunt and Edmund Halley developed the first life tables in the 17th century. Over time, this tool has been improved and become more mathematically rigorous, and it still represents an essential method for analyzing the behavior of the mortality phenomenon in the population. Modern life tables provide several quantities from which it is possible to derive the survival function, the hazard function, and the probability density function, which are the most diffused tools for the study of mortality. Each of these quantities is useful to analyze a specific aspect of mortality; thus, all three must be investigated to fully understand the phenomenon [3]. Historically, the literature focused on mortality rates. The first attempts to model mortality appeared in the 19th century [7; 10] and some generalizations have been proposed in the last century [14; 8]. These tools were developed within a frequentist framework and the estimation process can be problematic due to over-parametrization. For those reasons, some tools for face mortality modeling have also been developed in the Bayesian literature as well [4; 13].

More recently, other approaches focused on modeling the age-at-death distribution of a population instead of the mortality rates. The reason is that this quantity can be seen as a density function characterizing mortality. Based on this idea, [11] propose a six-parameters model for that quantity which mixes a half-normal distribution with a generalization of the skew-normal distribution while [2] offer a three-component mixture of a Dirac mass, a Gaussian distribution, and a skew-normal distribution to model and forecast dynamically the age-at-death distribution.

This paper aims to analyze the mortality phenomenon for the male population of the Campania region for the year 2020 for each municipality, focusing, on modeling the distribution of age-at-death. In particular, we are interested in detecting if the mortality phenomenon behaves similarly in some areas of the region and, eventually, in investigating the causes. To do so, we rely on the model proposed by [1], which is effective when dealing with curves related to small populations.

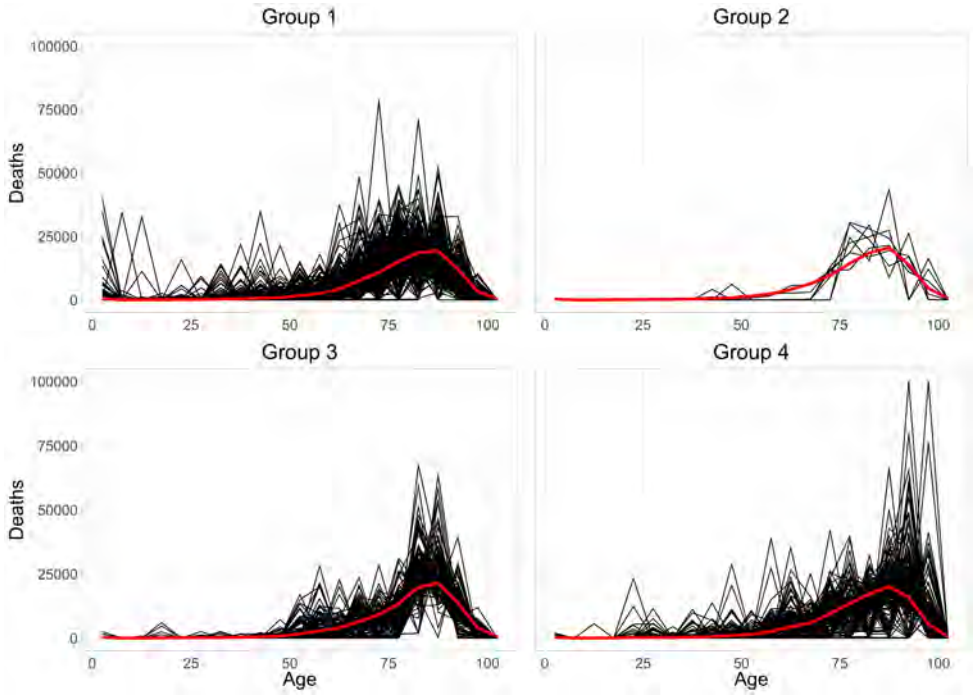

Figure 1: The age-at-death distributions $\boldsymbol{d}_j$ for each municipality computed using the classical life table technique allocated in the detected non-empty group $h = 1, \ldots, 4$ (in black), and the corresponding posterior expected quantity $\mathbb{E}(\boldsymbol{d}_j \mid G_j = h)$ (in red).

2. A Bayesian nonparametric mixture model

Let $d_{x,j}$ the number of deaths at age classes $[x, x+5)$ for population j, with $j = 1, \ldots, J$ and $x = 0, 5, \ldots, 95, 100$, where the last age class is $[100, +\infty)$, and let $\boldsymbol{d}_j = (d_{0,j}, \ldots, d_{100,j})$ represent the age-at-death distribution for population j.

Such a distribution is classically computed using life tables, that provide the key conversion from a set of observed age-specific death rates to a set of age-specific probabilities of dying. In this way, an age standardization of all the quantities is operated in order to eliminate the differences in age composition in separate populations. The computation of the tables is usually made with a decrement process starting from a standard fictitious population of size 10^5 [12]. Despite their versatility and popularity, the life-table approach has some important drawbacks when facing the simultaneous modeling of small populations. For instance, consider the case of modeling the age-at-death distribution for J municipalities. Firstly, in that situation, the life table provides an estimate for each municipality separately, although some similarities could occur. Secondly, when the resident population in a municipality is very small, so is the corresponding number of deaths. As a consequence, the shape of the age-at-death distribution can be extremely jagged and irregular. However, it is reasonable to think that such an unusual pattern is not due to some peculiarity of the mortality phenomenon but instead to the fact that each death can strongly impact the shape of the distribution in a small municipality. These two main problems also persist in the widely used model-based solutions mentioned in Sect. 1.

Based on these considerations, [1] provide a Bayesian nonparametric mixture model allowing for borrowing of information and simultaneous modeling of different populations. Assuming that each age-at-death distribution is calculated using a classical fixed initial population n [12] such that $\sum_{x \in \{0,5,\ldots,95,100\}} d_{x,j} = n$ for all $j = 1, \ldots, J$, they consider $\boldsymbol{d}_j$ as the outcome of n realizations from a multinomial random variable and model the set of J "raw" age-at-death distributions (i.e., the age-at-death distribution computed with the life-table method) as a mixture of H latent of components. We write

$$\begin{aligned} \boldsymbol{d}_j \mid H, G_j = h, \boldsymbol{\pi}_h &\sim \text{Multinomial}(n; \boldsymbol{\pi}_h), \quad \text{independently for } j = 1, \ldots, J, \\ G_j \mid H, \boldsymbol{w}_H &\sim \text{Multinomial}(1; \boldsymbol{w}_H), \quad \text{independently for } j = 1, \ldots, J, \end{aligned}$$

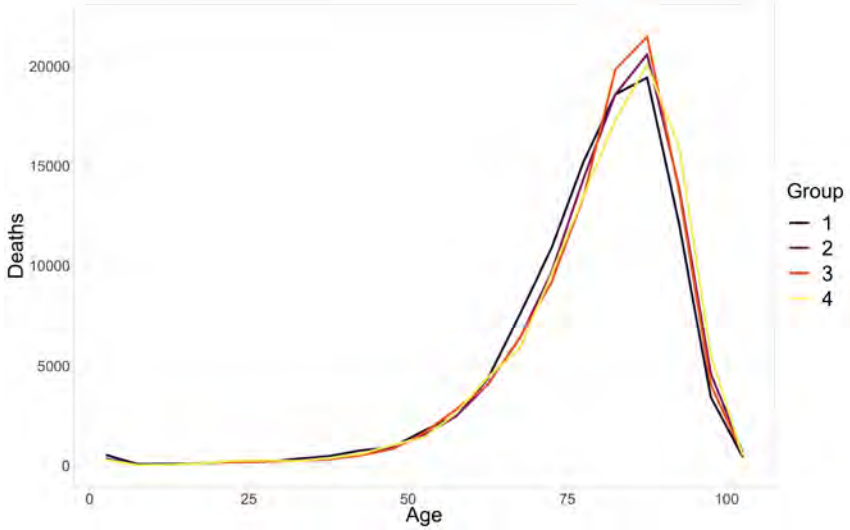

Figure 2: Expected age-at-death distribution for each group. The labeling of the groups is chosen based on the posterior median age-at-death, in increasing order. The first group contains the distributions with a higher number of deaths in adult and young-adult age classes. The raw distributions in the second cluster do not present particular irregularities. The third has its peak in the $[80, 90)$ age class and while the fourth group collects the curve with a high number of deaths which are 90 or older.

where G_j is the latent allocation variable of observation $\boldsymbol{d}^j$ and $\boldsymbol{w}_H = (w_1, \ldots, w_H)$. Each element $G_j \in \{1, \ldots, H\}$, $j = 1, \ldots, J$, take one of the H group labels as its realization. We are interested in inferring the number of non-empty components and the probabilities of dying at each age class $\boldsymbol{\pi}_h = (\pi_{0h}, \ldots, \pi_{100h})$, for all h such that $\sum_{j=1}^{J} \mathbb{1}(G_j = h) > 0$. The allocation of each raw curve to a mixture component depends only on its shape, and clustering arises in a natural way. In order to guarantee flexibility, a Dirichlet process prior is set to express the prior knowledge about the probability of dying at each age-class [9; 6], with the induced distribution

$$\boldsymbol{\pi}_h \mid \alpha, P_0 \sim \text{Dir}_{21}\left(\alpha P_0^{(0)}, \ldots, \alpha P_0^{(100)}\right),$$

for all $h = 1, \ldots, H$. The base measure P_0 represents the *a-priori* knowledge about how the mortality phenomenon behaves in relation to age, and $P_0^{(x)}$ denotes the death probability assigned to the base measure to age class $[x, x + 5)$, $x \in \{0, 5, \ldots, 100\}$. The precision parameter α regulates the shrinkage of induced distribution towards the base measure. Hence for each identified cluster, the model does borrowing of information between the base measure and the group of age-at-death distributions having similar shapes among the J curves. Coherently with the Bayesian mixture models literature, Dirichlet prior distribution for the mixture weights is specified, as

$$\boldsymbol{w}_H \mid H \sim \text{Dir}_H\left(\frac{1}{H}, \ldots, \frac{1}{H}\right).$$

Finally, we specify a beta-negative-binomial prior on the number of mixture components H. The estimation algorithm is provided in [5]. For further technical details, see [1].

3. Campania 2020 male population data

This study focuses on the mortality phenomenon for the male population of the Campania region in 2020. The daily deaths for each municipality are freely available from the Italian National Institute of Statistics (ISTAT) database and, after aggregation, the raw curve for each municipality is computed following [12]. The municipalities under examination are 550 and the associated distributions present very different shapes according to the size of their respective population.

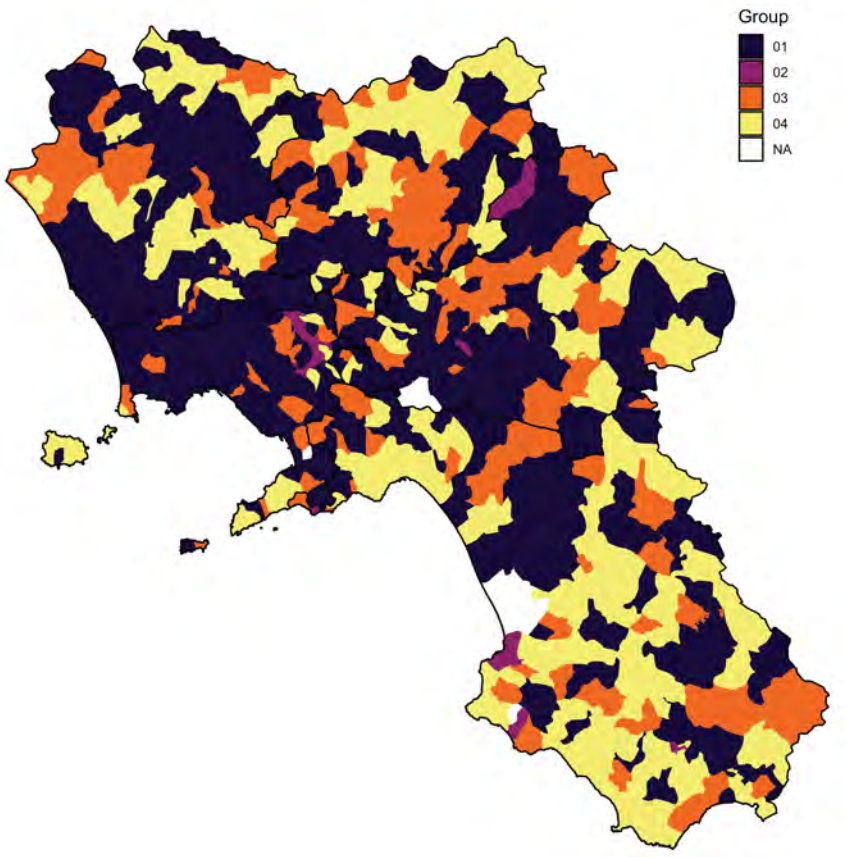

Figure 3: The geographical position of each municipality. The color represents the detected group G_j, $j = 1, \ldots, J$, in which each municipality is allocated.

Data are analyzed by applying the model proposed in [1]. In particular, we consider as baseline measure the curve of the entire Italian male population for the year 2020. Adopting a Bayesian methodology allows one to make inference on any functional of the posterior distribution. Uncertainty measures are naturally obtained from the sampling procedure.

The model detects four groups of curves, each of that is characterized by the shape of the curves allocated in, as is shown in Fig. 1. These features of the expected age-at-death distributions for each group are shown in (Fig. 2). An interesting result is obtained by observing the geographical position of the municipalities in relation to each group (Fig. 3). It is evident how the first group has a massive geographical characterization, indeed, it collects the majority of the municipalities of Naples hinterland. This area constitutes the so-called "Terra dei Fuochi," ninety municipalities between the provinces of Naples and Caserta affected by illegal dumping and wild abandonment of urban and special waste, often associated with its burning. Waste burning has caused concern because of the fumes and the pollutants poured onto farmland that can put the local population's health at risk. Several studies [15] identify a causal relationship between the presence of waste in this area and the formation of cancers in the population. This can be the reason for such anticipation of mortality in that geographical area together with the outbreak of COVID-19 pandemic that affected the region.

This analysis shows the potentiality of the Bayesian density estimation models for dealing with the age-at-death distribution of small populations. The borrowing of information that the model implements allows for estimated distributions that are a reliable representation of how mortality behaves in a set of populations of different sizes.

Bayesian Mixing Distribution Estimation in the Gaussian-smoothed 1-Wasserstein Distance

Catia Scricciolo[a]

[a]Dipartimento di Scienze Economiche, Università di Verona, Via Cantarane 24, 37129 Verona;
catia.scricciolo@univr.it

Abstract

We consider the problem of nonparametric mixing distribution estimation for discrete exponential family models. It has been recently shown that, under the Gaussian-smoothed optimal transport (GOT) distance, *i.e.*, the 1-Wasserstein distance between the Gaussian-convolved distributions, the accuracy of the nonparametric maximum likelihood estimator (NPMLE) is improved to a polynomial rate from the sub-polynomial rate with respect to the standard 1-Wasserstein distance. The focus of this work is on studying the problem taking a Bayesian nonparametric approach. We provide conditions under which the Bayes' estimator of the true mixing distribution converges at least as fast as the NPMLE in the GOT distance.

Keywords: mixture models, nonparametric MLE, Poisson distribution, rates of convergence.

1. Introduction

We consider the mixing distribution estimation problem. Let $\{p(\cdot;\theta), \theta \in \Theta \subseteq \mathbb{R}\}$ be a known parametric family of probability "densities" (including the possibility of discrete atoms) with respect to a dominating measure on $\mathscr{X} \subseteq \mathbb{R}$ and let $X^{(n)} := (X_1, \ldots, X_n)$ be n independent and identically distributed (i.i.d.) observations drawn from the mixture

$$f_{G_0}(x) := \int_\Theta p(x;\theta)\,\mathrm{d}G_0(\theta), \quad x \in \mathscr{X},$$

where the mixing distribution G_0 of θ is unknown. The goal is to estimate G_0 using the data $X^{(n)}$. We consider a one-parameter discrete exponential family, see, *e.g.*, Efron (2022) (1),

$$p(x;\theta) = g(\theta)w(x)\theta^x, \quad x \in \mathbb{N}_0 := \{0, 1, 2, \ldots\}, \tag{1}$$

with $w(x) > 0$ for all $x \in \mathbb{N}_0$ and $\theta \in [0, \theta_*]$ for $\theta_* < \theta_r$, where θ_* is a known fixed constant, $\theta_r \in (0, \infty]$ is the radius of convergence of the power series $\theta \mapsto \sum_{x=0}^\infty w(x)\theta^x$ and $g(\cdot)$ is an analytic function in a neighborhood of zero. Clearly,

$$\frac{1}{g(\theta)} = \sum_{x=0}^\infty w(x)\theta^x < \infty \ \text{ for } \theta \in [0, \theta_*]$$

and

$$\int_0^{\theta_*} g(\theta)\theta^x\,\mathrm{d}G_0(\theta) < \infty \ \text{ for every } x \in \mathbb{N}_0.$$

Examples

Model (1) includes the Poisson and negative binomial distributions:

- Poisson distribution, $\mathrm{Poi}(\theta)$, $\theta \in [0,\infty)$, with

$$g(\theta) = e^{-\theta} \quad \text{and} \quad w(x) = \frac{1}{x!};$$

- negative binomial distribution, $\mathrm{NBin}(k, 1-\theta)$, $k \in \mathbb{N}$ and $\theta \in [0,1]$, with

$$g(\theta) = (1-\theta)^k \quad \text{and} \quad w(x) = \binom{x+k-1}{x}.$$

□

For model (1) the mixture takes the form

$$f_{G_0}(x) := \int_0^{\theta_*} g(\theta) w(x) \theta^x \, \mathrm{d}G_0(\theta), \quad x \in \mathbb{N}_0. \tag{2}$$

Estimation of G_0 has been investigated using, among others, the maximum likelihood approach. The nonparametric maximum likelihood estimator (NPMLE), proposed in Kiefer and Wolfowitz (1956) (3), is defined as

$$\widehat{G}^{\mathrm{ML}} := \operatorname*{argmax}_{G \,\mathrm{on}\, [0,\theta_*]} \prod_{i=1}^{n} f_G(X_i). \tag{3}$$

It has been recently shown that the minimax lower bound on the rate relative to the 1-Wasserstein distance is sub-polynomial. To state it, we preliminarily recall the definition of the 1-Wasserstein distance. For any pair $G_1, G_2 \in \mathscr{P}_1(\mathbb{R})$, the latter being the set of all probability measures on $\mathbb{R}$ with finite first moment $m_1(G) := \int_{\mathbb{R}} u \, \mathrm{d}G(u) < \infty$, the 1-Wasserstein distance is defined as

$$W_1(G_1, G_2) := \inf_{\gamma \in \Gamma(G_1, G_2)} \int_{\mathbb{R}\times\mathbb{R}} |x-y| \gamma(\mathrm{d}x, \mathrm{d}y),$$

where $\Gamma(G_1, G_2)$ is the set of all couplings with marginal distributions G_1 and G_2. Theorem 2.1 of Han *et al.* (2021) (2) states that the lower bound for nonparametric estimation of the mixing distribution in model (2) with respect to the 1-Wasserstein distance is sub-polynomial,

$$\inf_{\widehat{G}} \sup_{G \,\mathrm{on}\, [0,\theta_*]} \mathsf{E} W_1(\widehat{G}, G) \geq \frac{c}{\log n}, \tag{4}$$

where the infimum is taken over all estimators of distributions G supported on $[0, \theta_*]$ and the constant $c \equiv c(\theta_*)$ only depends on θ_*. Such slow rate is achieved by the NPMLE $\widehat{G}^{\mathrm{ML}}$. If, in fact, there exists $C \geq 1$ such that

$$\frac{1}{w(x)} \leq C^x, \quad x \in \mathbb{N},$$

then, for some $C' \equiv C'(\theta_*, C) > 0$,

$$\sup_{G \,\mathrm{on}\, [0,\theta_*]} \mathsf{E} W_1(\widehat{G}^{\mathrm{ML}}, G) \leq \frac{C'}{\log n},$$

see Theorem 2.2, part (a), of Han *et al.* (2021) (2). By adopting, instead, the *Gaussian-smoothed optimal transport* (GOT) distance W_1^σ defined, for any pair $G_1, G_2 \in \mathscr{P}_1(\mathbb{R})$, as the 1-Wasserstein distance between their convolutions with the centered Gaussian distribution of variance $\sigma^2 > 0$, denoted by $\mathscr{N}_\sigma$ with density φ_σ,

$$W_1^\sigma(G_1, G_2) := W_1(G_1 * \mathscr{N}_\sigma, G_2 * \mathscr{N}_\sigma),$$

under some conditions on $w(\cdot)$, the rate of convergence of the NPMLE $\widehat{G}^{\mathrm{ML}}$ is improved to a *polynomial* rate,

$$\sup_{G \text{ on } [0,\theta_*]} \mathsf{E} W_1^{\sigma}(\widehat{G}^{\mathrm{ML}}, G) \leq C'' n^{-\eta}, \tag{5}$$

for constants $C \equiv C(\sigma, \theta_*, w)$ and $\eta \equiv \eta(\theta_*, w)$ only depending on $\{\sigma, \theta_*, w\}$ and $\{\theta_*, w\}$, respectively, see Theorem 3.1 of Han *et al.* (2021) (2). A motivation for using the Gaussian smoothing when studying the mixing distribution estimation problem is provided in Remark 3.2 of Han *et al.* (2021) (2). The aim of this note is to show that, by adopting a Bayesian nonparametric approach to the problem of estimating the true mixing distribution G_0 with respect to the GOT distance, also the Bayes' estimator can attain a polynomial rate. In Section 2, we state a sufficient condition on the frequentist asymptotic behaviour of the posterior distribution corresponding to a prior law on the mixing distribution so that the entailed Bayes' estimator of G_0, the posterior expected distribution, attains a polynomial rate. This condition is illustrated for Poisson mixtures. Final remarks are exposed in Section 3.

2. Main Result

Let $X^{(n)}$ be a sample of n i.i.d. observations drawn from the true data generating probability measure P_0, with probability mass function f_{G_0} as in (2). We want to estimate G_0 taking a Bayesian nonparametric approach. Let Π_n be a prior law on the set of probability measures on $[0, \theta_*]$ and let $\Pi_n(\cdot \mid X^{(n)})$ be the posterior distribution

$$\Pi_n(B \mid X^{(n)}) = \frac{\int_B \prod_{i=1}^n f_G(X_i)\, \mathrm{d}\Pi_n(G)}{\int \prod_{j=1}^n f_{G'}(X_j) \mathrm{d}\Pi_n(G')},$$

where

$$f_G(\cdot) = \int_0^{\theta_*} p(\cdot; \theta)\, \mathrm{d}G(\theta)$$

is the model probability mass function. Let

$$\widehat{G}^{\mathrm{B}} := \mathsf{E}[G \mid X^{(n)}]$$

be the Bayes' estimator of G_0, the posterior expectation of G. Our goal is to show that, under the GOT distance, also the speed of convergence of the Bayes' estimator $\widehat{G}^{\mathrm{B}}$, as that of the NPMLE $\widehat{G}^{\mathrm{ML}}$, is accelerated to a polynomial rate, from the sub-polynomial rate relative to the standard 1-Wasserstein distance. To the aim, we state the following assumption, considered also in Han *et al.* (2021) (2), on the tail behaviour of $\{1/w(x)\}_{x \in \mathbb{N}}$, which describes either a polynomial or an exponential decay rate for $\{w(x)\}_{x \in \mathbb{N}}$.

Assumption A

There exist constants $c_i, C_i > 0$, $i = 1, 2, 3$, such that either

$$c_1 c_2^x \leq \frac{1}{w(x)} \leq C_1 C_2^x \quad \text{for every } x \in \mathbb{N} \tag{6}$$

or

$$c_1 c_2^x x^{c_3 x} \leq \frac{1}{w(x)} \leq C_1 C_2^x x^{C_3 x} \quad \text{for every } x \in \mathbb{N}. \tag{7}$$

Theorem 1. *Suppose that Assumption A holds. If for $\tau > 0$ and sufficiently large $M > 0$,*

$$\mathsf{E}\Pi_n(d(f_G, f_{G_0}) > M n^{-1/2} (\log n)^{\tau} \mid X^{(n)}) \to 0 \tag{8}$$

exponentially fast, where d can be either the Hellinger or the L^1-distance, then, for positive constants $C_0 = C_0(\sigma, \theta_*, w, G_0)$ and $\eta_0 = \eta_0(\theta_*, w, G_0) < 1/2$,

$$\mathsf{E} W_1^{\sigma}(\widehat{G}^{\mathrm{B}}, G_0) \leq C_0 n^{-\eta_0}. \tag{9}$$

Proof. Set $\varepsilon_n := C_0 n^{-\eta_0}$, since W_1 is convex with respect to each argument, we have

$$\begin{aligned} W_1^\sigma(\widehat{G}^{\mathrm{B}}, G_0) &\leq \int W_1^\sigma(G, G_0)\, \mathrm{d}\Pi_n(G \mid X^{(n)}) \\ &\leq \varepsilon_n + 2\theta_* \times \Pi_n(W_1^\sigma(G, G_0) > \varepsilon_n \mid X^{(n)}), \end{aligned}$$

where the last line follows from

$$W_1^\sigma(G, G_0) \leq W_1(G, G_0) = \|F_G - F_{G_0}\|_1 \leq 2\theta_*,$$

with F_G and F_{G_0} being the distribution functions of G and G_0, respectively. It follows that

$$\mathsf{E} W_1^\sigma(\widehat{G}^{\mathrm{B}}, G_0) \leq \varepsilon_n + 2\theta_* \times \mathsf{E}\Pi_n(W_1^\sigma(G, G_0) > \varepsilon_n \mid X^{(n)}).$$

We now study $\mathsf{E}\Pi_n(W_1^\sigma(G, G_0) > \varepsilon_n \mid X^{(n)})$. Set the position $\ell_\sigma := \ell * \varphi_\sigma$, from Step 3 in Theorem 3.1 of Han *et al.* (2021) (2) with $\widehat{Q}$ and Q replaced by G and G_0, respectively, by the dual representation of W_1 for probability measures with bounded support,

$$W_1(G_1, G_2) = \sup_{\ell \in 1\text{-Lip}} \int_0^{\theta_*} \ell(\mathrm{d}G_1 - \mathrm{d}G_2),$$

where the supremum is taken over all Lipschitz functions $\ell : [0, \theta_*] \to \mathbb{R}$ with constant equal to 1, we have

$$\begin{aligned} W_1^\sigma(G, G_0) \leq & \sup_{\ell \in 1\text{-Lip}: \ell(0)=0} \int_0^{\theta_*} \Big\{ \ell_\sigma(\theta) - \ell_\sigma(0) - \sum_{x=0}^{2k} b_x p(x; \theta) \Big\} (\mathrm{d}G - \mathrm{d}G_0)(\theta) \\ & + \int_0^{\theta_*} \sum_{x=0}^{2k} b_x p(x; \theta) (\mathrm{d}G - \mathrm{d}G_0)(\theta) \\ =: & \, I + II, \end{aligned}$$

where, by Step 1 of the same theorem, for any $\sigma > 0$, integer $k \geq 2$ and $\ell \in 1$-Lip on $[-\theta_*, \theta_*]$ with $\ell(0) = 0$, there exist $C_4 \equiv C_4(\theta_*, \sigma) > 0$ and $\{b_x \in \mathbb{R}, x = 0, \ldots, 2k\}$ so that

$$I \leq C_4 \Big\{ (\theta_*^{-1} \sigma \sqrt{ek})^{-k} + \sum_{x \geq k+1} w(x) \theta_*^x \Big\},$$

while, for $\|b\|_\infty := \max_{0 \leq x \leq 2k} |b_x|$,

$$II \leq \left| \sum_{x=0}^{2k} b_x [(f_G - f_{G_0})(x)] \right| \leq \|b\|_\infty \times \|f_G - f_{G_0}\|_1 \leq \|b\|_\infty \times d_{\mathrm{H}}(f_G, f_{G_0}),$$

where $d_{\mathrm{H}}(f_G, f_{G_0}) := \|\sqrt{f_G} - \sqrt{f_{G_0}}\|_2$ is the Hellinger distance. Hence,

$$W_1^\sigma(G, G_0) \leq C_4 (\theta_*^{-1} \sigma \sqrt{ek})^{-k} + \sum_{x \geq k+1} w(x) \theta_*^x + \|b\|_\infty \times d(f_G, f_{G_0}). \tag{10}$$

By the upper bound on $\|b\|_\infty$ given in Step 2 of Theorem 3.1 of Han *et al.* (2021) (2), for any $R \in (\theta_*, \theta_r)$ and a suitable constant $C_9 > 0$, for any $k \in \mathbb{N}$,

$$W_1^\sigma(G, G_0) \leq C \times \begin{cases} (\theta_*/R)^k + C_9^{2k} d(f_G, f_{G_0}), & \text{under condition (6)}, \\ k^{-c_3 k} + k^{2C_3 k} d(f_G, f_{G_0}), & \text{under condition (7)}, \end{cases} \tag{11}$$

where the constant $C > 0$ may be different depending on the condition in force. Since, by assumption,

$$d(f_G, f_{G_0}) \leq M n^{-1/2} (\log n)^\tau$$

on a set of posterior probability tending to one, if, for some $0 < \delta < 1/2$, we choose $C_9^{2k} = O(n^\delta)$ under condition (6) or $k^{2C_3 k} = O(n^\delta)$ under condition (7), then $W_1^\sigma(G, G_0)$ is bounded above by ε_n and the assertion follows.

□

Theorem 1 shows that, under the GOT distance, the Bayes' estimator $\widehat{G}^{\mathrm{B}}$ for G_0, like the NPMLE $\widehat{G}^{\mathrm{ML}}$, can attain a polynomial speed of convergence, thus improving the slower sub-polynomial rate relative to the standard 1-Wasserstein distance. The key step in the proof is inequality (10), which, besides allowing to reduce the problem of deriving an upper bound on the speed of $\widehat{G}^{\mathrm{B}}$ to that of assessing the L^1-norm posterior contraction rate at f_{G_0}, can be directly used to derive the rate of convergence for the NPMLE, as hereafter illustrated in the case of Poisson mixtures.

Example: Poisson mixtures

For the Poisson mixture model

$$f_G(x) = \int_0^{\theta_*} \frac{e^{-\theta}\theta^x}{x!}\,\mathrm{d}G(\theta), \quad x \in \mathbb{N}_0,$$

the NPMLE in (3) has a unique solution with at most n atoms, see Simar (1976) (5). It has been recently established that

$$\sup_{G\in\mathscr{G}} \mathsf{E} d_{\mathrm{H}}^2(f_{\widehat{G}^{\mathrm{ML}}}, f_G) \leq Cn^{-1} \times \begin{cases} \dfrac{\log n}{\log\log n}, & \mathscr{G} = \{G:\ \mathrm{supp}(G) \text{ is compact}\}, \\ \log n, & \mathscr{G} = \{G:\ \int e^{cu}\,\mathrm{d}G(u) \leq 1\}, \end{cases}$$

where both upper bounds are minimax-optimal with exact logarithmic factors, see Polyanskiy and Wu (2020) (4). Then, by the inequalities in (11), we immediately get the upper bound in (5). Besides, under suitable conditions on the prior, the posterior L^1-norm contraction rate is, up to a logarithmic factor, almost parametric so that Theorem 1 goes through to the corresponding Bayes' estimator $\widehat{G}^{\mathrm{B}}$, which has polynomial rate with respect to the GOT distance.

3. Final Remarks

Theorem 1 shows that, under the GOT distance, also the Bayes' estimator, as the NPMLE, for the mixing distribution of discrete exponential family mixtures can attain a polynomial rate, improving the slower sub-polynomial rate under the standard 1-Wasserstein distance. We believe the actual rate is, up to a logarithmic factor, parametric, but a proof is still elusive to us at the moment. The problem with the above proof comes from the term C_9^{2k} or k^{2C_3k}, depending on tail behaviour of $\{w(x)\}_{x\in\mathbb{N}}$, which arises when bounding $\|b\|_\infty$ and slows down the overall rate of the product $\|b\|_\infty \times d(f_G, f_{G_0})$.

Abstract

The intrinsic dimension (id) of a dataset conveys essential information regarding the complexity of the underlying data-generating process. In particular, it describes the dimensionality of the latent manifold on which the data-generating probability distribution has support. Complex datasets may be characterized by multiple manifolds having different ids. To properly estimate these heterogeneous ids, a recent modeling approach uses finite scale mixtures of Pareto distributions aided by a homogeneity-inducing term in the likelihood. In this contribution, we explore a different modeling perspective, estimating Pareto's scale mixtures via spatial product partition models. We present the general idea and introduce Spider, our Bayesian nonparametric approach. Finally, we showcase some encouraging preliminary results.

Keywords: Intrinsic dimension, Hidalgo, spatial dependence, product partition models.

1. Introduction

The estimation of the intrinsic dimension (id) of a dataset is an essential step for many data analyses involving any dimensionality reduction steps. By reliably knowing the dimension of the latent manifold embedding the data, dimensionality reduction can be efficiently carried out, avoiding any loss of information. The literature on dimensionality reduction is vast, and a numerous methods address the id estimation problem from many different perspectives: see, for example, [4] for a review. Here, we focus on likelihood-based id estimation methods, which were pioneered by [10].

Recently, [7] introduced the `TWO-NN` model, an id estimator based on the distributional properties of the ratios of distances between each data point and its first and second nearest neighbors (NNs). In particular, under the hypothesis that the data are generated from a locally homogeneous Poisson point process, the ratios are Pareto distributed with unitary shape parameter and scale parameters equal to the id, respectively. Modeling extensions have been proposed, for example, by [6], who considered ratios of NNs of generic order, and [11], who explore the id estimation employing discrete metrics. As the majority of the proposals in the literature, these methods are devoted to estimating a single, homogeneous id for the entire dataset (sometimes obtained as the ensemble of point-wise id estimates).

The Bayesian heterogeneous id algorithm (Hidalgo) [1] extends this framework, allowing for multiple manifolds in the same dataset, each characterized by its own id. Hidalgo segments the data via a

model-based clustering approach, modeling the ratios of NN distances as a mixture of Pareto distributions. Hidalgo postulates an additional term in the likelihood to overcome the difficulties of clustering solely based on the scale parameters of highly overlapping Pareto distributions. This extra term, obtained by modeling the adjacency matrix of the data, is employed to introduce spatial information in the model estimation. The rationale for its usage is that points close to each other should be more likely to be sampled from the same manifold and, consequently, should contribute to estimating the id value of that same manifold.

Nonetheless, the local homogeneity term is mainly motivated by computational convenience rather than by realistic modeling assumptions. In this contribution, we propose to modify Hidalgo to obtain a more coherent inferential framework using product partition models (PPM) [9; 14]. In particular, we adopt the spatial extension of PPM introduced in [13] to estimate a clustering solution that is spatially informed. Our article proceeds as follows. In the next section, we briefly describe Hidalgo, discuss its structure, and then delineate our modeling proposal. Next, we show some preliminary results on simulated data in Section 3. Finally, we discuss potential future directions in Section 4.

2. Model specification

Consider a dataset $\boldsymbol{X} = (\boldsymbol{x}_1, \dots, \boldsymbol{x}_n)^\top$ where each observation $\boldsymbol{x}_i$ is embedded in an ambient space of dimension D but lies on a manifold of id d. In other words, $\boldsymbol{X}$ has D columns but each row $\boldsymbol{x}_i$ is generated from a d-dimensional probability density function. Let $r_{i,1}$ and $r_{i,2}$ be the distances between the i-th point and its first and second NNs, respectively. In [7], it is proved that $\mu_i = r_{i,2}/r_{i,1} \sim Pareto(1, d)$, for $i = 1, \dots, n$. This result is the foundation of the TWO-NN id estimator. One can generalize this framework, supposing that the data are actually generated from a mixture of densities supported on manifolds with different ids. Then, assuming independence between μ_i's the joint distribution of the random vector of ratios $\boldsymbol{\mu}$ is given by a mixture of Pareto distributions:

$$f(\boldsymbol{\mu}|\boldsymbol{p}, \boldsymbol{d}) = \prod_{i=1}^{n} \sum_{k=1}^{K} p_k d_k \mu_i^{-d_k - 1}, \tag{1}$$

where $\boldsymbol{d}$ is a vector of different ids associated with the K manifolds and $\boldsymbol{p}$ is a vector of mixture weights.

To make the estimation of the model in Equation (1) feasible, we can introduce the latent membership labels $\boldsymbol{z} = (z_1, \dots, z_n)$, where $z_i \in \{1, \dots, K\}$ for $i = 1 \dots, n$ and $z_i = k$ implies that the i-th observation is generated by the k-th mixture density. It is clear that multiple observations can be assigned to the same mixture component. In doing so, we can identify a partition of the n data points $\rho_n = \{S_k\}_{k=1}^K$, where $S_j = \{i : z_i = k\}$, $\cup_{k=1}^K S_k = \{1, \dots, n\}$, and $S_i \cap S_j = \emptyset$ for $i \neq j$. Ideally, each S_k would contain points belonging to the same latent manifold. We can rewrite model (1) as

$$f(\boldsymbol{\mu}|\boldsymbol{z}, \boldsymbol{d}) = \prod_{i=1}^{n} d_{z_i} \mu_i^{-d_{z_i} - 1}, \qquad f(\boldsymbol{z}|\boldsymbol{p}) = \prod_{i,k} p_k^{\mathbb{1}\{z_i = k\}}. \tag{2}$$

Identifying the different mixture components is complicated since the kernel Pareto densities, despite having different scale parameters, overlap to a great extent.

2.1 Hidalgo

To overcome the identification problem, [1] considered an additional source of information by jointly modeling the vector of ratios $\boldsymbol{\mu}$ and the $n \times n$ binary proximity matrix $\mathcal{N}^{(q)}$ computed from $\boldsymbol{X}$, where $\mathcal{N}_{ij}^{(q)} = \mathbb{1}\{j \in \Omega_i^q\}$ and Ω_i^q is the set of first q NNs of unit i. Then, we assume $f(\mathcal{N}_{ij}^{(q)} = 1 | z_i = z_j) \propto \zeta$ and $f(\mathcal{N}_{ij}^{(q)} = 1 | z_i \neq z_j) \propto 1 - \zeta$, where $\zeta > 0.5$, i.e., points assigned to the same manifold have more chances to be neighbors. This modeling choice introduces local homogeneity. The resulting likelihood becomes

$$\mathcal{L}(\boldsymbol{\mu}|\boldsymbol{d}, \boldsymbol{z}, \zeta) = \prod_{i=1}^{n} d_{z_i} \mu_i^{-d_{z_i} - 1} \cdot f\left(\mathcal{N}_i^{(q)} | \boldsymbol{z}, \zeta\right). \tag{3}$$

The Hidalgo model is completed by conjugate prior specifications for the parameters $\boldsymbol{d}$ and $\boldsymbol{p}$. Inference is carried out via Gibbs sampler (see the R package `intRinsic` [5] for an example of implementation).

Adding the homogeneity-inducing term in the likelihood is appealing since it introduces a spatial dependence in the model a posteriori. This addition greatly improves the identification of manifolds without compromising too much the feasibility of the posterior computations. The modeling assumption in (3) is over the neighborhood structure, *given the membership labels*. However, a more natural and coherent option that motivates our proposal is represented by the converse: modeling the distribution of membership labels informed by the spatial structure, e.g., by specifying $f(\boldsymbol{z}|\mathcal{N}^{(q)})$.

2.2 Spatial PMM for ID estimation using NNs ratios

We propose a novel method to fit a mixture model for heterogeneous id estimation that incorporates spatial information using product partition models, which we now briefly introduce. First, recall that there is a bijective map $g : \mathcal{P}^n \to \{1, \dots, K_n\}^n$ where $\mathcal{P}^n$ is the space of partitions of n data points and K_n is the number of distinct clusters which is inferred from the data. In other words, g maps the partition of the observations ρ_n to the set of membership labels so that $\boldsymbol{z} = g(\rho_n)$. Following [9; 14], we specify a product partition prior distribution on $\rho_n = \{S_1, \dots, S_{K_n}\}$. Notice that we can avoid the ex-ante specification of a fixed number of clusters K since we are working directly on the space of partitions. Formally, we define the PPM prior as

$$f(\rho_n) \propto \prod_{k=1}^{K_n} C(S_k), \tag{4}$$

where $C(\cdot)$ is a generic, non-negative *cohesion* function measuring how likely it is that elements of the cluster S_k are, a priori, grouped together. In other words, a well-defined cohesion is expected to assign higher probability to partitions that display homogeneous and well-separated clusters. A well-known example of cohesion is $C(S_k) = (|S_k| - 1)!M$, which implies the same clustering behavior induced by a Dirichlet Process [8] with concentration parameter M. This modeling framework is characterized by extreme flexibility since the cohesion can be tailored according to the specific application setting. For example, it can be a function of exogenous covariates: see, for example, the PPMx models [12]. Here, we follow [13] and specify a location-aware cohesion function. Let $\boldsymbol{s}_1, \dots, \boldsymbol{s}_n$ denote the n spatial coordinates of the data points in $\boldsymbol{X}$, and let $\boldsymbol{s}_k^\star = \{\boldsymbol{s}_i : i \in S_k\}$. The cohesion function for a spatial PPM becomes

$$f(\rho_n) \propto \prod_{k=1}^{K_n} C(S_k, \boldsymbol{s}_k^\star).$$

In particular, we consider the following cohesion:

$$C(S_k, \boldsymbol{s}_k^\star) = \frac{M\Gamma(|S_k|)}{\Gamma(\alpha\mathcal{D}_k)\mathbb{1}\{\mathcal{D}_k \geq 1\} + \mathcal{D}_k\mathbb{1}\{\mathcal{D}_k < 1\}}\mathbb{1}\{|S_k| > 1\} + M\,\mathbb{1}\{|S_k| = 1\}, \tag{5}$$

where $\mathcal{D}_k = \sum_{i \in S_k} d(\boldsymbol{s_i}, \bar{\boldsymbol{s}}_k)$ and $d(\cdot)$ denotes the Euclidean distance. The quantity $\mathcal{D}_k$ measures the overall dispersion of the members of the k-th cluster around its centroid $\bar{\boldsymbol{s}}_k$, defined as $\bar{\boldsymbol{s}}_k = |S_k|^{-1}(\sum_{j \in S_k} s_{j,1}, \dots, \sum_{j \in S_k} s_{j,D})^\top$. In the previous formula, D is the number of recorded coordinates (equal to the ambient dimension). Joining the likelihood of ratios of NN distances and the new prior, we obtain

$$\begin{aligned} f(\boldsymbol{\mu}|\boldsymbol{z}, \boldsymbol{d}) &= \prod_{i=1}^{n} d_{z_i}\mu_i^{-d_{z_i}-1}, \quad \boldsymbol{z} = g(\rho_n), \\ p(\rho_n) &\propto \prod_{k=1}^{K_n} C(S_k, \boldsymbol{s}_k^\star), \quad d_k \sim Gamma(a_0, b_0). \end{aligned} \tag{6}$$

We call the model defined in (6) the **S**patial **P**PM for **id** **e**stimation using NNs **r**atios (**Spider**).

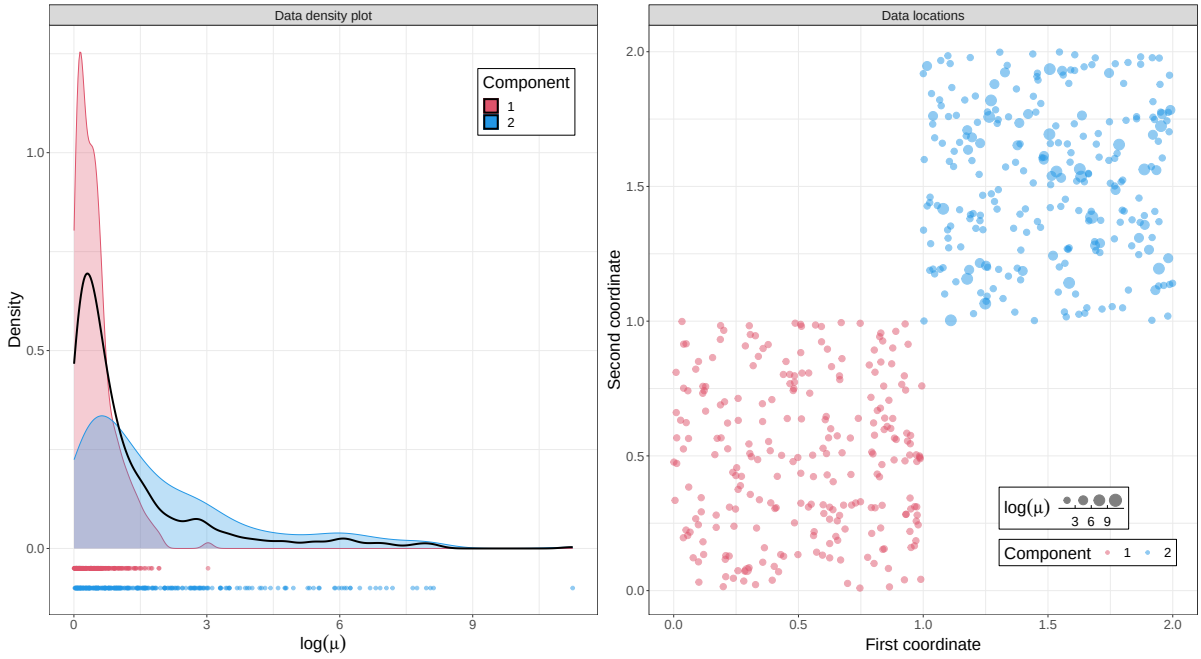

Figure 1: The left panel shows the densities and dots representing the (transformed) simulated data from the two mixture components (in red and blue), and the observed joint density (in black). The right panel shows the spatial coordinates of the data in $D = 2$ dimensions. The two simulated groups of ratios correspond to data well separated in space.

3. Applications

We show how Spider works with the help of a simple simulation scenario. We consider a mixture of two Pareto distributions, generating 500 observations each with distribution

$$\mathcal{L}(\mu_i) = \frac{1}{2} Pareto(1, 0.5) + \frac{1}{2} Pareto(1, 2). \tag{7}$$

The two distributions can originate from a dataset where the observations lie on manifolds with ids 0.5 and 2, respectively. We suppose the two manifolds are embedded in an ambient space of $D = 2$ and well-separated in space. We highlight their coordinates, generated uniformly at random, in the right panel of Figure 1. Despite the simplicity of this distribution, recovering the original clusters is highly challenging. The left panel of Figure 1 shows the true data-generating densities (after log-transforming the data to enhance the visual representation) in blue and red. Once the data are collected, what we observe is only the density function in black. This makes standard clustering algorithms dramatically fail to classify the observations correctly. The left part of Table 1 and the left panel of Figure 2 display the classification results of using a simple hierarchical clustering algorithm on the $\boldsymbol{\mu}$, thresholding the resulting dendrogram to find 2 clusters. The estimated partition is clearly off, as expected.

We then estimate Spider, employing tailored marginal Bayesian nonparametric MCMC sampling techniques. Given the Monte-Carlo chains of cluster allocation parameters, we compute the posterior similarity matrix $PSM = (v_{i,j})_{i,j=1}^{n}$, where each entry corresponds to the percentage of times the MCMC allocated observations i and j in the same cluster. We can construct a dendrogram from the dissimilarity matrix $1 - PSM$, and estimate the partition after thresholding, as we did before. The resulting partition recovers the ground truth very well (see the right part of Table 1 and the right panel in Figure 2).

	hclust		Spider	
	1	2	1	2
Component 1	250	205	248	0
Component 2	0	45	2	250
$\hat{d}_k$	1.281	0.181	2.152	0.529

Table 1: Confusions matrixes comparing the ground truth (by rows) and the clustering allocation via hierarchical clustering (columns 1 and 2) and via Spider (columns 3 and 4). The last row contains the estimated id within each cluster (the true id values are 2 and 0.5).

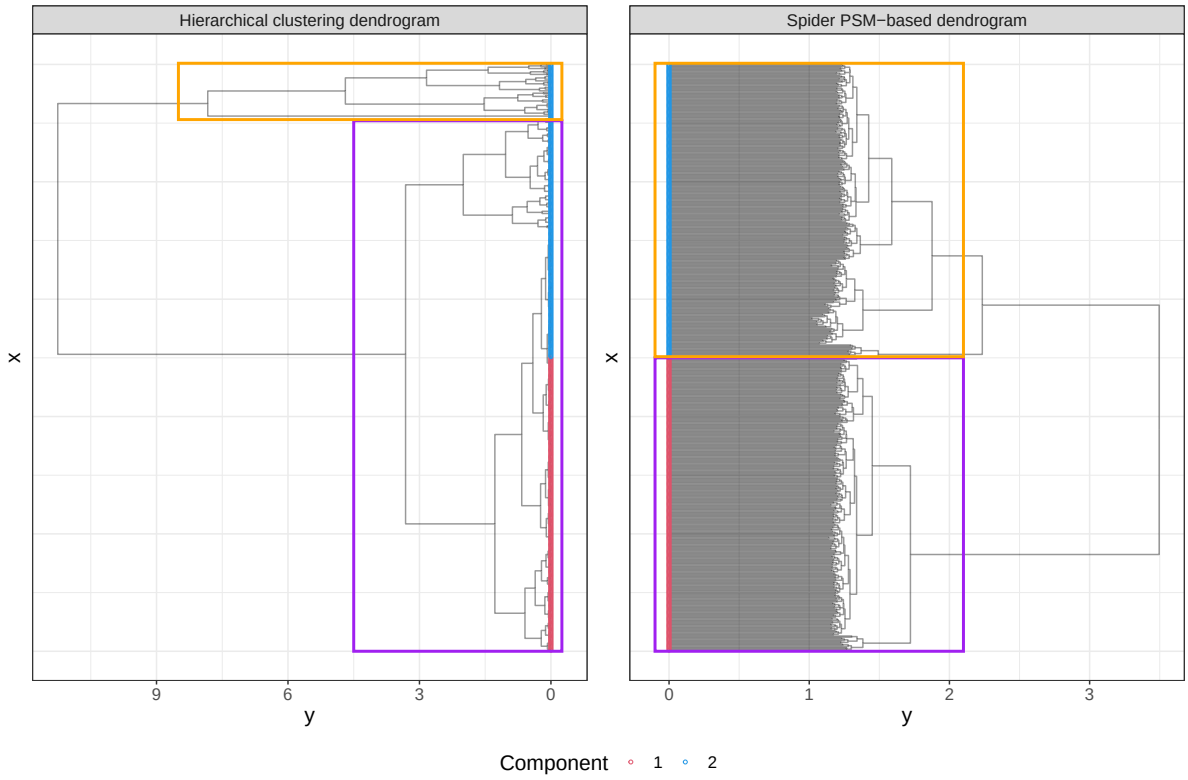

Figure 2: The figure displays the dendrograms constructed using a simple hierarchical clustering approach, using only the ratios $\boldsymbol{\mu}$ to compute the distances (left panel), and the dendrogram resulting from the PSM when applying Spider (right panel).

4. Conclusions

In this contribution, we presented some promising results concerning the application of spatial PPM to effectively identify the components of a scale mixture of Pareto distributions when spatial information is available and consequently estimate a reliable id-based partition of the data. Many interesting research directions are worth exploring. First, one could devise a novel cohesion function to use when the ambient dimension D is large to ensure the efficiency of the estimating algorithm while preserving the location information. Moreover, one can tackle the introduction of spatially informed mixtures from other perspectives. For example, one could consider Hidden Markov Random Fields to specify the distribution of the membership labels [2; 3].

Abstract

We perform change-point detection of time series of compositional data from a Bayesian nonparametric perspective. In particular, we build a model to infer change points relying on product partition models approach. We consider a combinatorial prior and an underlying diffusion process for simplex-supported time-dependent realizations. This extends one of the main approaches of Bayesian nonparametric change point detection to compositional time series, avoiding mapping the data to spaces of real numbers. An application to Italian Covid-19 data will be further investigated.

Keywords: Bayesian nonparametric, compositional data, time series, change point detection

1. Introduction

Compositonal time series are of great interest in applications and can arise in different fields, such as biology, chemistry, ecology, epidemiology and finance. The models to analyse this type of datum are targeted with respect to the purpose of the analysis. In our case, our aim is to perform (multiple) change point detection, that is, to identify the time instants when the underlying generating diffusion process changes its governing parameters and a new regime occurs. In particular, the objects of inference are both the number of change points and their location.

We rely on a popular approach introduced for the first time in (2; 3): product partition models. We assume that observations belong to the different regimes by means of the latent ordered composition induced by the unique values of their parameters, i.e.

$$\forall i \in A_j \quad \boldsymbol{\theta}_{t_i} = \boldsymbol{\theta}^*_j,$$

where the sets $A_1, \ldots, A_k$ are sets of indices representing the different regimes, $\boldsymbol{\theta}_{t_i}$ is the parameter corresponding to the observation at time t_i and $\boldsymbol{\theta}^*_j$ is the unique value of the latent parameter shared by observations in regime j. In particular, these sets are nonempty and represent a partition of $[\![n]\!] = \{1, \ldots, n\}$, where n is the number of observations, subject to a monotone increasing constraint, namely:

1. $A_l \cap A_m = \emptyset$ for $1 \leq l, m \leq n$;
2. $\cup_{i=1}^{k} A_i = [\![n]\!]$;
3. if $i \in A_l$ and $h \in A_m$, with if $l > m$, then $i > h$.

We indicate with ρ_n the vector storing such sets, i.e. $\rho_n = (A_1, \ldots, A_k)$. The observations in different groups, conditioned to the regime-specific parameter $\boldsymbol{\theta}^*_1, \ldots, \boldsymbol{\theta}^*_k$, are assumed independent. Moreover, the block-specific parameters conditioned to the particular partition are distributed a priori independently,

meaning that the behaviour of the time series in some specific regime does not depend on the change-regime process. Finally, a prior distribution is assumed on the partition ρ_n of the form

$$\mathcal{L}(\rho_n) = K \prod_{j=1}^{k} c(A_j),$$

where K is a normalization constant and $c(\cdot)$ are some cohesion functions.

Despite the authors referring to the above model as *parametric* product partition model, since we drive the change-point detection on the underlying parameters of the generating process, this suggests that we are in a Bayesian nonparametric setting. It was indeed pointed out by Quintana and Igleasias in (18) the equivalence between product partition models with a particular cohesion functions and infinite mixture models driven by the Dirichlet process (5; 6).

In this framework, in 2014 Martínez and Mena (13) proposed a multiple change-point detection product partition model for univariate time series using as cohesion function the exchangeable partition probability function arising from Pitman-Yor process (17) restricted to the suitable partition space (see Section 2). Later, Corradin et al. (4) considered a multivariate extension of such a modelling strategy. Among the different applications presented, a compositional time series of proportions of new daily cases of Covid-19 in Italy per three different macro-areas was analyzed. To be able to perform change-points detection with the developed model a log-ratio transformation was applied to proportions, in order to obtain an $\mathbb{R}^d$-supported time series. In this paper, we propose a similar model to those previous two, with the aim of avoiding mapping data to spaces of real numbers, while performing multiple change-point detection in compositional time series directly on simplex spaces.

2. Proposed model

Our data structure is a time series of compositional data: we have for $t \in \mathbb{R}_+$ an underlying random vector $\boldsymbol{Y}_t \in \Delta_{d-1} \subset \mathbb{R}^d_+$ $a.s.$, distributed as some continuous diffusion process, where $\Delta_{d-1} = \left\{(x_1, \dots, x_d) \in \mathbb{R}^d : x_i \geq 0, \sum_{i=0}^{d} x_i = 1\right\}$ denotes the $(d-1)$-dimensional simplex . The number of realizations observed are finite, hence we can index them by means of a subscript $i \in \{1, \dots, n\}$, getting finally as observed data $\boldsymbol{y}_{t_1}, \dots, \boldsymbol{y}_{t_n}$.

As anticipated, the main purpose of this paper is to adapt the model developed in (13; 4) to compositional time series, avoiding transformations of the data. With this in mind, the most natural choice is to select a diffusion process supported on the simplex. Restricting ourselves to homogeneous diffusions that are Dirichlet distributed when stationarity is reached, we chose the Wright-Fisher diffusion (7; 8; 12; 20). This process is governed by a vector of parameters $\boldsymbol{\omega} = (\omega_1, \dots, \omega_d) \in \mathbb{R}^d_+$ that corresponds to the parameter of the Dirichlet distribution reached at stationarity. The choice was driven first and foremost by the analytical tractability of the transition densities, hence, in the case of the Wright-Fisher continuous process a spectral expansion for arbitrary dimensions is available (10). We will rely on this expansion in the sampling scheme.

Following the above argumentation, we assume the diffusive process generating our data is made of an unknown number k of Wright-Fisher regimes, which are identified by unique values $\boldsymbol{\omega}^*_1, \dots, \boldsymbol{\omega}^*_k$ of the generating parameters $\boldsymbol{\omega}_{t_1}, \dots, \boldsymbol{\omega}_{t_n}$ associated to each datum. All the above-specified hypothesis underlying product partition models are assumed: observations belonging to different regimes are independent and given the partition, the group-specific parameters are independent and identically distributed according to some prior distribution P_0.

As mentioned before, we consider as prior distribution for the latent partition the exchangeable partition probability function (EPPF) arising from Pitman-Yor process (17). Note that for our purposes, the EPPF cannot be straightforwardly used, due to the fact that the class of admissible partitions in our problem are only the ones that preserve the order. In (16), the author re-weights this EPPF with respect to this new combinatorial class, naming this new function *exchangeable random order distribution*. We

report its expression

$$p_n^{(k)}(n_1,\dots,n_k) = \frac{n!}{k!}\frac{\prod_{j=1}^{k-1}(\theta+j\sigma)}{(\theta+1)_{(n-1)}}\prod_{j=1}^{k}\frac{(1-\sigma)_{n_j-1}}{n_j!},$$

for $\sigma \in [0,1)$ and $\theta \in (-\sigma,\infty)$, where k is the number of blocks and n_j is the number of observations in block j and where $(\cdot)_{(\cdot)}$ is the Pochhammer symbol. Furthermore, in order to relax the model specification, we set an hyperprior structure on the parameters (θ,σ) of the restricted Pitman-Yor EPPF.

Summing up, we can compactly write our model as

$$\{\boldsymbol{Y}_{t_i} : i \in A_j\}|\boldsymbol{\omega}_j^*, \rho_n \overset{ind}{\sim} \text{Wright-Fisher}(\boldsymbol{\omega}_j^*) \tag{1}$$

$$\boldsymbol{\omega}_j^* \overset{iid}{\sim} \mathrm{P}_0 \tag{2}$$

$$\rho_n|\theta,\sigma \sim \mathcal{L}(\rho_n|\,\sigma,\theta) \tag{3}$$

$$(\sigma,\theta) \sim \pi(\sigma,\theta). \tag{4}$$

Our underlying diffusion process is Markovian (we refer to (1; 9) for an exhaustive treatise on diffusion processes). Hence, conditioning to the block allocation, the likelihood of each datum depends on the previous one and on the group-specific parameter, except for the very first one and for any changing point. Let denote n_j the cardinality of the block A_j, and m_j the index of the last point of cluster j, where $m_1 = 0$. The integrated likelihood for each cluster can be expressed as the following product

$$\mathcal{L}(\{\boldsymbol{Y}_{t_i} : i \in A_j\}|\,\boldsymbol{\omega}_j^*,\rho_n) = p\left(\boldsymbol{y}_{t_{m_j+1}}|\boldsymbol{\omega}_j^*\right)\prod_{i=m_j+2}^{m_j+n_j} p\left(t_i - t_{i-1}, \boldsymbol{y}_{t_i}|\boldsymbol{y}_{t_{i-1}},\boldsymbol{\omega}_j^*\right), \tag{5}$$

where $p(\cdot|\boldsymbol{\omega}_j^*)$ represents the stationary density of the Wright-Fisher diffusion with parameter $\boldsymbol{\omega}_j^*$, i.e. the Dirichlet distribution, and $p(\cdot,\cdot|\cdot,\boldsymbol{\omega}_j^*)$ is the transition density of the same process. The integrated likelihood of all our data, conditioned to the partition, is just the product of all the cluster integrated likelihood (5):

$$\mathcal{L}(\boldsymbol{Y}_1,\dots,\boldsymbol{Y}_n|\boldsymbol{\omega}_1^*,\dots,\boldsymbol{\omega}_k^*,\rho_n) = \prod_{j=1}^{k}\mathcal{L}(\{\boldsymbol{Y}_{t_i} : i \in A_j\}|\,\boldsymbol{\omega}_j^*,\rho_n), \tag{6}$$

where k is the number of blocks in the conditioning partition ρ_n.

For what concerns the prior on the block parameters $\boldsymbol{\omega}_j^*$, we assume each component is distributed a priori as a gamma distribution of parameters α and β:

$$\omega_{j,\ell}^* \overset{iid}{\sim} \Gamma(\alpha,\beta), \qquad \ell = 1,\dots,d$$

whereas as hyperpriors for σ and θ, in accordance with (13), we set the following hierarchical structure

$$\sigma \sim \text{beta}(\alpha_\sigma,\beta_\sigma)$$
$$\theta|\sigma \sim s\Gamma(-\sigma;\alpha_\theta,\beta_\theta),$$

where $s\Gamma$ denotes the shifted-gamma distribution. In particular, a random variable ξ is $s\Gamma(-\sigma,\alpha,\beta)$ distributed, if $\xi+\sigma$ is gamma distributed with parameters α and β.

We underline that in (13) and (4) another likelihood form was derived. In particular, in both papers it is argued that, considering we want to perform inference on the latent partition of the data and on the number of blocks, we do not need explicitly to keep track of the values block specific parameters assume. Authors hence integrate out from the block integrated likelihoods the dependence on $\boldsymbol{\omega}_j^*$, getting finally each block-specific *marginal* integrated likelihood. In the case of the two papers this was rather convenient, since closed-forms of those marginal integrated likelihoods can be found. On the contrary, this is not the case of our model, due to the lack of conjugacy between our prior on the parameters and our block-specific likelihood on data.

2.1 Sampling algorithm

Our aim is to perform inference on the latent partition of the data and on the number of regimes. As a consequence, the target distribution is

$$\mathcal{L}\left(\rho_n|\text{rest}\right) \propto \mathcal{L}\left(\boldsymbol{Y}_1,\ldots,\boldsymbol{Y}_n|\boldsymbol{\omega}_1^*,\ldots,\boldsymbol{\omega}_k^*,\rho_n\right)\mathcal{L}\left(\rho_n|\sigma,\theta\right)\prod_{j=0}^{k} P_0\left(\boldsymbol{\omega}_j^*\right), \tag{7}$$

that is, the posterior distribution of our latent partition. In particular, the support of this distribution is, for all $k \in \{1,\ldots,n\}$, all vectors $(n_1,\ldots,n_k) \in \mathbb{N}^k$ such that $\sum_{j=1}^{k} n_j = n$, where n is the number of observed data. Due to the lack of conjugacy, the need to resort to sampling algorithms is obvious. We may think to a general fashion Markov chain Monte Carlo with target distribution the distribution (7) and with state space the above specified support. However, since the the cardinality of this space is growing rapidly as n increases, it is virtually impossible to obtain a representative sample of the posterior. Therefore, we will rely on a different Markov chain Monte Carlo method that is an adjustment to our framework of the one presented by Martínez and Mena in (13). This algorithm relies on a *split & merge* procedure.

At each iteration, we randomly choose according to some probability, except for the boundary cases in which the choice is naturally driven, either to perform a merge or to perform a split; in both cases, we propose a new value for k and a new value for ρ_n. Note that, heuristically speaking, those two moves exhaust all the possible moves, due to the ordering proviso of the data, unlike in clustering problems. Those proposed split-merge moves are accepted or rejected according to a Metropolis-Hastings step. Finally, to help the algorithm fasten convergence, at the end of each iteration we perform an additional reshuffle step, in which we reshuffle the dimension of two existing contiguous blocks, accepting this new setting still according to a Metropolis-Hastings step.

The idea underlying our algorithm will be substantially the same as in (13), under a few suitable modifications. In (13) the Metropolis-Hastings steps are driven exploiting the marginal integrated likelihood, but in our case we lack a closed form of transition densities and hence of the marginal integrated likelihood. For this reason, once we propose a new cluster-structure, we introduce a Monte Carlo integration step, in which we estimate the marginal integrated likelihood for the clusters of the new proposed setting. As anticipated, we rely on the spectral expansion available in literature (10) for the transition densities of the Wright-Fisher process.

3. Simulated data and algorithm calibration

We use model (1)-(4) with simulated with the purpose of testing it. Moreover, our sampling scheme needs the specification of the level of truncation of the series expansion of the transition densities (10) as well as the number of nodes in the MC integration of the integrated likelihood (6) to approximate the *marginal* integrated likelihood. We investigate how the choice of these two values influences the performance of the sampling algorithm.

Data are approximately simulated from a Wright-Fisher process following the approach presented in (11). We consider 150 observations in Δ_2 belonging to three different regimes of 50 observations each $\rho_{150} = (\{1,\ldots,50\},\{51,\ldots,100\},\{101,\ldots,150\})$. In particular, we set $\boldsymbol{\omega}_1^* = (0.2, 0.5, 1)$, $\boldsymbol{\omega}_2^* = (1, 0.5, 0.5)$ and $\boldsymbol{\omega}_3^* = (0.3, 0.1, 0.2)$ as parameters of the three Wright-Fisher regimes. Moreover, we assume $\alpha = 2$ and $\beta = 2$ as hyperparameters of the priors $(\omega_{j,\ell}^* \overset{iid}{\sim} \Gamma(2,2)$ for $\ell = 1,\ldots,d)$. Concerning the hyperpriors, we set $\sigma \sim \text{beta}\,(1,1)$ and $\theta|\sigma \sim s\Gamma(-\sigma;1,1)$.

The point estimate of the posterior cluster allocation is obtained by minimizing the expected value of the posterior loss. We choose the variation of information (14) as loss function and we exploit the optimization algorithm described in (19). Two different summaries are computed in order to assess the quality of the posterior estimate of the partition. From one side, we evaluate how much the posterior partition is different from the true one, using as metric the normalized variation of information (14). From the other side, we inspect the capability of the MCMC chain to produce a good sample of the posterior.

This is done by evaluating the effective sample size of the entropy of the partition that represents the state of the chain at each iteration.

Our simulation study consists in running an MCMC for a grid of the two above-mentioned hyeperparameters, which are the truncation level of the series expansion of the transition densities and the number of integration nodes in the MC integration step. In particular, we truncate the series at the first, second or third term and we consider a number of integration nodes ranging in $\{1, 20, 100, 250, 500\}$. We run 5000 iterations, where 1000 are considered burning-in iterations, on the corresponding grid expansion of the hyperparameters, setting an equal probability either to perform a split or a merge at each iteration. We average the reported results over 5 replications.

Table 1: Table showing the posterior summaries of the simulations on the grid of hyperparameters averaged over 5 replications

Truncation level	Integration nodes	VI	ESS - entropy
1	1	0.438	1.787
	20	0.047	15.491
	100	0.065	96.583
	250	0.068	114.859
	500	0.060	84.836
2	1	0.350	1.739
	20	0.049	19.280
	100	0.050	110.822
	250	0.116	110.070
	500	0.052	163.858
3	1	0.445	2.147
	20	0.126	16.559
	100	0.050	108.452
	250	0.057	130.853
	500	0.050	148.889

Posterior summaries are reported in table 1. We observe an increasing trend of precision of the estimate of the partition that is independent from the level of truncation of the series. Indeed, fixing a value of the number of nodes in MC integration, we appreciate that the normalized variation of information between the estimated partition and the true one gets comparable values with respect to the level of truncation of the series. This is not surprising since the series expansion in (10) presents a multiplicative term that decays exponentially, hence adding an extra-term does not introduce much gain in term of the approximation precision. For what concerns the effective sample size of the partition sample, we report a similar behaviour. Independently from the level of truncation of the series, there is an increasing trend where values for the same number of integration nodes have the same order of magnitude in most cases. We conclude that our model in general behaves as expected on simulated data. The posterior estimate of the partition gets fast precise and the MCMC *split & merge* sampling scheme explores efficaciously the space of possible orderings. In this sense, no advising of nonconvergent behave of the chain was detected.

As further investigation, the model will be applied to proportions of daily cases of Covid-19 by region areas in Italy, as done in (4). In particular, Italian regions are labelled as “north”, “centre” and “south/island”, according to the official grouping of the Italian *Istituto Nazionale di Statistica*, and we build the compositional time series of the proportion of daily new cases in those macro-areas, ending up with a time series in Δ_2. The purpose of this study is double. From one side, the detected change points by our model are compared with the true events that may have had an effect on the regime, enabling to test the capability of the model to perfom change point detection on real data. From the other side, we can compare this approach to the most used approach of transforming the compositional data to spaces of real numbers. For instance, in (4), authors rely on a log-transformation of the data for performing

change point detection on a similar time series.

Abstract

In this article we propose a non parametric prior for the probabilities of the Galton-Watson process based on the Dirichlet Process. After recalling the main properties of the Galton-Watson process and presenting the estimation methods already present in the literature, such as maximum likelihood and Bayesian conjugate analysis, we define the new prior by pointing out how it is more general than the Dirichlet prior used in the conjugate analysis, which is a special case of our extension. Finally, we show the results of a simulation study illustrating how our analysis leads to a more accurate classification of the process.

Keywords: Galton-Watson process, Dirichlet process, Bayesian inference, offspring distribution.

1. Background

The Galton-Watson process is a probabilistic model originally proposed to study genealogy problems, with recent applications to nuclear fission, queuing models, viral phenomena, social networks, neuroscience, and disease spread. It assumes individuals in the population reproduce independently, each individual giving rise to a random number X of descendants according to the *offspring distribution*:

$$P(X = j) = \pi_j \quad j \in \mathbb{S}(X)$$

$$\sum_{j \in \mathbb{S}(X)} \pi_j = 1$$

The offspring distribution holds for all generations, i.e, π_j does not depend on the generation number. Given Z_0 original ancestors (we always assume that $Z_0 = 1$) the evolution of the population can be described by $\{Z_i \quad i = 0, 1, \dots\}$, where Z_i denotes the total number of individuals in the i-th generation. The assumptions above imply that $Z_0, Z_1, \dots$ is a Markov chain, meaning that if we know the size of the n-th generation then the probability law of later generations does not depend on the sizes of generations preceding the n-th. In particular note that if $Z_i = 0$ for some i then $Z_r = 0 \quad \forall r \geq i$. In case $Z_i = 0$ we say that the population is *extinct* at time i.

The extinction probabilities, that is, the probability that the population becomes extinct after r generations given that each individual has $0, 1, \dots$ descendants with probabilities $p_0, p_1, \dots$ according to the offspring distribution, is often the main feature of interest of the process; see Harris (1). In fact, the model was first studied by Francis Galton to analyze the extinction of family names in England at the end of XIX century and later by A.J.Lotka, who replied the analysis using the US census (2).

Extinction probability The overall extinction probability is defined as:

$$q = P(Z_i = 0 \quad \text{for some} \quad i)$$

The following results leads to a simple classification of the process.

Theorem 1. *The extinction probability q is the smallest root of the equation $f(s) = s$ where $f(s) = \sum_{j \in \mathbb{S}(X)} \pi_j s^j \quad |s| \leq 1$ is the probability generating function of the offspring distribution.*

The theorem highlights the close connection between the extinction probability and the reproduction mean, defined as

$$m = \sum_{j \in \mathbb{S}(X)} j\pi_j$$

Indeed, by simply computing m, we can realize whether or not the extinction of the process is certain, as the reproduction mean leads to a simple classification: critical and subcritical processes lead to extinction with probability 1 while supercritical processes lead to extinction with probability $q < 1$.

1.1 Inference for Galton Watson process

Inference for GW process naturally focuses on the offspring distribution π and its average m. The minimum amount of information required to make inference is the vector of population sizes, $\{Z_i \quad i = 0, 1, \dots \ N\}$. We have a more detailed information if we can observe for each generation the number of individuals having j descendants, for all $j = 0, 1, \dots$, that is, if we observe the vector $\mathbf{Z}_c = \{Z_{ij} \quad i = 0, 1, \dots \quad j = 0, 1, \dots, k\} = \{\mathbf{Z}_1, \dots, \mathbf{Z}_N\}$ where Z_{ij} is the number of individuals in the i-th generation having exactly j descendants and $\mathbf{Z}_i = (Z_{i0}, \dots, Z_{ik})'$.
Therefore

$$Z_i = \sum_{j=0}^{k} Z_{ij} \quad \text{and} \quad Z_{i+1} = \sum_{j=0}^{k} jZ_{ij}$$

so we have

$$p(\mathbf{Z}_1, \dots, \mathbf{Z}_n | \pi) = \prod_{i=0}^{n} p(\mathbf{Z}_i | Z_i, \pi)$$

where $p(\mathbf{Z}_i | Z_i, \pi) \sim Multinomial(Z_i, \pi)$. The likelihood function is:

$$L(\pi | \mathbf{Z}_c) \propto \prod_{i=0}^{n} \prod_{j=0}^{k} \pi_j^{Z_{ij}} \propto \prod_{j=0}^{k} \pi_j^{Z_{nj}}$$

with $Z_{nj} = \sum_{i=0}^{n} Z_{ij}$ the total number of individuals giving rise to exactly j descendants.

MLE estimator The maximum-likelihood estimators of π and m are (1):

1) $\hat{\pi}_j = \dfrac{Z_{nj}}{Y_n}$
2) $\hat{m} = \frac{Z_1 + \dots + Z_n}{Z_0 + \dots + Z_{n-1}}$

where $Y_n = \sum_{j=0}^{k} Z_{nj} = \sum_{i=0}^{n} Z_i$ is the number of individuals up to the n-th generation.
These estimators are consistent conditional on the non extinction of the process. Notice that $\hat{m}$ is the

total number of children divided by the total number of parents and it is the same whether we observe only the total number of individuals in each generation or the detailed information given by $\mathbf{Z}_c$, i.e. $\hat{m}(\mathbf{Z}_c) = m(\hat{\pi}) = \sum_{j=0}^{k} j\hat{\pi}_j$.

Bayesian analysis A Bayesian conjugate analysis for the Galton-Watson process was proposed by Mendoza and Guterrez-Pena (4). These authors considered as prior distribution:

$$\pi \sim Dirichlet(\alpha_0, \ldots, \alpha_k)$$

leading to the posterior distribution $\pi|\mathbf{Z}_c \sim Dirichlet(\beta_0, \ldots, \beta_k)$

where $\beta_j = \alpha_j + Z_{nj}$. If we write $\beta = \sum_{j=0}^{k} \beta_j$, then the posterior distribution of π_j is

$$\pi_j|\mathbf{Z}_c \sim Beta(\beta_j, \beta - \beta_j) \equiv Beta\left(\alpha_j + \sum_i Z_{ij}, \sum_{i\neq j} \alpha_i + \sum_{ij} Z_{ij} - \sum_i Z_{ij}\right) \quad (1)$$

so that $E(\pi_j|\mathbf{Z}_c) = \frac{\beta_j}{\beta}$ $\quad Var(\pi_j|\mathbf{Z}_c) = \frac{\beta_j(\beta-\beta_j)}{\beta^2(\beta+1)}$ $\quad Cov(\pi_j, \pi_\ell|\mathbf{Z}_c) = -\frac{\beta_j\beta_\ell}{\beta^2(\beta+1)}$

Notice that the prior requires knowledge of the true support size, k, which is assumed finite. An appropriate choice of $\{\alpha_0, \cdots, \alpha_k\}$ can ensure neutrality with respect to either the π_j's or the reproduction mean, m. The latter is usually the inferential target as it allows the classification of the process. The first two posterior moments of m can be obtained from those of π, exploiting m is a linear combination of the entries of the vector π:

$$E(m|\mathbf{Z}_c) = \mathbf{h}'\mu = m(\mu) \quad Var(m|\mathbf{Z}_c) = \mathbf{h}'\Sigma\mathbf{h} = \sigma^2(\mu)/(\beta+1)$$

with $\mathbf{h} = (1, \ldots, k)'$, μ and Σ the posterior mean vector and the variance-covariance matrix of π. The distribution of m is not available. However, conditional on the non-extinction of the process, a normal approximations is valid for the posterior of m. In general, sampling techniques can be useful to approximate its distribution.

2. A DP prior on π

In this section we introduce a flexible prior for inference on π based on the Dirichlet Process of Ferguson (3). We recall that G is a $DP(a, G_0)$ if, for any partition $B_0, B_1, \cdots B_k$ of the real line, the vector $G(B_0), G(B_1), \cdots G(B_k)$ follows a Dirichlet distribution of parameter $(aG_0(B_0), \ldots, aG_0(B_k))$. Here $a > 0$ is a concentration parameter regulating confidence on the centering measure G_0. An important property of the Dirichlet Process (DP in the following) is that its conditional distribution given a sample from the process is still a DP, i.e., $G|x \sim DP\left(n + a, \frac{1}{n+a}\sum_{i=1}^{n} \delta_{x_i} + \frac{a}{n+a}G_0\right)$ where n is the sample size, a is the prior number of observations, and $\delta_x(\cdot)$ counts the number of x in the set $\{\cdot\}$. The posterior centering measure is thus a weighted average of the prior measure G_0 and the empirical distribution function.

We now turn back to the problem of assigning a flexible prior on the set of all possible offspring distributions of a Galton-Watson process. We can induce the prior on π by setting

$$\pi_j \sim G(A_j) \quad (2)$$

where $G \sim DP(a, G_0)$. In this context, G_0 is a distribution on the positive integers reflecting our prior guess on the offspring distribution; a is a scalar reflecting the degree of confidence on G_0 and $A_0, A_1, \cdots A_k$ is any partition such that A_j contains only the j-th natural number. It follows that, a priori

$$\pi_j \sim Beta(aG_0(j), a(1 - G_0(j))$$

and, a posteriori

$$\pi_j|x \sim Beta\left(\frac{n}{n+a}\sum_{i=1}^{n}\frac{1}{n}\delta_{x_i}(i) + \frac{a}{n+a}G_0(A_j), 1 - \frac{n}{n+a}\sum_{i=1}^{n}\frac{1}{n}\delta_{x_i}(A_j) - \frac{a}{n+a}G_0(A_j)\right) \quad (3)$$

The DP prior above generalizes the classic Dirichlet prior proposed by Guterrez-Pena (4) by allowing any offspring distribution G_0 with arbitrary degree of confidence a. In particular, comparison of posterior distributions in equations 1 and 3, shows that the distribution induced by the DP prior is the same of the classic Dirichlet prior when G_0 is a discrete distribution on $\{0, \cdots, k\}$ and a is equal to $\sum_i \alpha_i$.

For posterior inference on π_j an important role is played by the posterior average $E(\pi_j|x)$:

$$E(\pi_j|x) = E(G(A_j)|x) = \frac{n}{n+a}\sum_{i=1}^{n}\frac{1}{n}\delta_{x_i}(A_j) + \frac{a}{n+a}G_0(A_j)$$

which is a weighted mean of the prior offspring probability $G_0(A_j) = Prob(G_0 = j)$ and the empirical proportion of type j individuals.

3. Simulation

In this section we show the results of a small simulation study comparing the estimates of π and m obtained with maximum likelihood and conjugate Bayesian analysis with those obtained with our proposal. For the classic Bayesian estimator we used the Jeffreys' prior on the true support. For the flexible non parametric estimator we use a low value of the concentration parameter α and a discrete uniform distribution on the true support as centering measure G_0. In particular we consider two different estimates for m using the DP prior: the first (bayes.dp) obtained from the posterior means of π from eq.3 and the second (bayes.dp.mc) obtained as a Monte Carlo estimate by sampling from the a posteriori DP.

Table 1: Subcritical process - average and standard error over 100 MC replications

[a]	m	p_0	p_1	p_2
mle	0.836 (0.17)	0.46	0.37	0.10
bayes.dir	1.006 (0.01)	0.40	0.31	0.16
bayes.dp	0.941 (0.06)	0.42	0.33	0.14
bayes.dp.mc	0.928 (0.14)	0.42	0.33	0.14

[a] mle is maximum likelihood estimate; bayes.dir uses Jeffreys prior $(1/2, 1/2, 1/2, 1/2)$; bayes.dp uses the $DP(\alpha, G_0)$ prior with $\alpha = 1$ and G_0 discrete uniform on $\{0, 1, 2, 3\}$

In Table 1 we consider a subcritical process with probability vector ($\pi = (0.4, 0.3, 0.2, 0.1)$ leading to m=1. We replicated the generation process 100 times and we report average and standard error (in parenthesis for m) of estimates over $S = 100$ replications. The simulation shows that the bayes.dp prior performs better than mle and bayes.dir, leading to correct classification of the process.

In Table 2 we consider a supercritical process with probability vector ($\pi = (0.3, 0.3, 0.3, 0.1)$ leading to $m = 1.2$. In this situation the bayes.dp and the bayes.dir perform similarly (and both perform better than mle).

Table 2: Supercritical process - average and standard error over 100 MC replications

[a]	m	p_0	p_1	p_2
mle	0.954 (0.25)	0.40	0.29	0.24
bayes.dir	1.089 (0.10)	0.36	0.28	0.25
bayes.dp	1.038 (0.15)	0.37	0.28	0.25
bayes.dp.mc	1.052 (0.16)	0.37	0.28	0.25

[a] mle is maximum likelihood estimate; bayes.dir uses Jeffreys prior $(1/2, 1/2, 1/2, 1/2)$; bayes.dp uses the $DP(\alpha, G_0)$ prior with $\alpha = 1$ and G_0 discrete uniform on $\{0, 1, 2, 3\}$

Recall that the classic Bayesian prior bayes.dir is replied by the proposed DP prior bayes.dp when $a = \sum \alpha_i$. Setting $a = 1 < \sum \alpha_i$ leads to better estimate of m when the process is subcritical and prior sample size can heavily influence the posterior mean. Instead, for supercritical processes generating, on average, more individuals the results are very similar. Finally, preliminary results show that bayes.dp is useful also when the offspring distribution has infinite support or the support is finite but its size is unknown.

Abstract

Hierarchical processes are popular tools in Bayesian nonparametrics because of their central role within the partial exchangeable framework, which is a natural assumption for modeling different, though related, groups of observations. In this paper, we focus on neutral to the right (NTR) processes, a class of random distributions widely used as nonparametric priors in survival analysis thanks to their conjugate behavior in presence of censored data. After a brief introduction to NTR processes, we focus on their hierarchical extension by leveraging their characterization as functionals of completely random measures. We conclude by showing an example of a hierarchical NTR process, called hierarchical Beta-Stacy.

Keywords: Bayesian nonparametrics, Beta-Stacy process, completely random measures, hierarchical priors, neutral to the right processes, partial exchangeability

1. Introduction

In this work, we consider partially exchangeable data, i.e., observations coming from different (though similar) populations, and we define a general class of processes that can be used as nonparametric priors in order to carry out full Bayesian inference under this framework. Let us consider a probability space $(\Omega, \mathcal{A}, \mathbb{P})$ and a measurable space $(\mathbb{X}, \mathcal{X})$, where $\mathbb{X}$ is a Polish space with its Borel σ-algebra $\mathcal{X}$. Let us denote by $\mathbb{P}_{\mathbb{X}}$ the space of all probability measures over $(\mathbb{X}, \mathcal{X})$, and by $\mathbb{P}_{\mathbb{X}}^d$ the corresponding d-dimensional product space. Suppose we are provided with d groups of $\mathbb{X}$-valued observations, more precisely we denote by $X_{i,j}$ the ith observation of group j, for $j = 1, \ldots, d$, where N_j is the number of observations in group j. Each observation $X_{i,j}$ is a $\mathbb{X}$-valued random element defined on the common probability space $(\Omega, \mathcal{A}, \mathbb{P})$, and the infinite sequences $\mathbf{X}_j = (X_{i,j})_{i \geq 1}$ for $j = 1, \ldots, d$ are assumed to be partially exchangeable, i.e., $(\mathbf{X}_1, \ldots, \mathbf{X}_d) \stackrel{\mathrm{d}}{=} (\pi_1 \mathbf{X}_1, \ldots, \pi_d \mathbf{X}_d)$ for each set $\pi_1, \ldots, \pi_d$ of finite permutations on the natural numbers, where $\pi_j \mathbf{X}_j = (X_{\pi_j(i),j})_{i \geq 1}$.

Thanks to the de Finetti representation theorem, the partial exchangeability of the sequences $\mathbf{X}_j$'s is equivalent to the existence of the so-called *de Finetti measure*, that is, a probability measure Q_d over $\mathbb{P}_{\mathbb{X}}^d$ such that

$$\mathbb{P}\left[\bigcap_{j=1}^{d}\bigcap_{i=1}^{N_j}\{X_{i,j} \in A_{i,j}\}\right] = \int_{\mathbb{P}_{\mathbb{X}}^d}\prod_{j=1}^{d}\prod_{i=1}^{N_j} p_i(A_{i,j}) Q_d(\mathrm{d}p_1, .., \mathrm{d}p_d),$$

for any $(N_1, \ldots, N_d) \in \mathbb{N}^d$ and for any collection of Borel sets $A_{i,j} \in \mathcal{X}$, as $j = 1, \ldots, d$ and $i = 1, \ldots, N_j$. The de Finetti measure Q_d works as a prior distribution.

The definition and investigation of a suitable de Finetti measure Q_d in order to induce dependence across the d groups of observations is a well-studied topic, and *hierarchical processes* are highly popular Bayesian nonparametric models in this context. More precisely, the general structure of a hierarchical process is

$$\begin{aligned}(\tilde{p}_1, \ldots, \tilde{p}_d) \mid \tilde{p}_0 &\overset{\text{iid}}{\sim} \tilde{\mathcal{L}}_0, \\ \tilde{p}_0 &\sim \mathcal{L}_0,\end{aligned} \tag{1}$$

where $\tilde{\mathcal{L}}_0$ is the probability distribution of each random probability measure $\tilde{p}_i$ such that $\mathbb{E}_{\tilde{\mathcal{L}}_0}[\tilde{p}_i \mid \tilde{p}_0] = \int p\tilde{\mathcal{L}}_0(\mathrm{d}p) = \tilde{p}_0$, whereas $\mathcal{L}_0$ is such that $\mathbb{E}_{\mathcal{L}_0}[\tilde{p}_0] = \int p\mathcal{L}_0(\mathrm{d}p) = P_0$ for some fixed non-atomic probability measure P_0. The vector of random probability measures $(\tilde{p}_1, \ldots, \tilde{p}_d)$ in (1) defines a prior for the probability distributions of d partially exchangeable samples, with dependence across samples being induced by the measure $\tilde{p}_0$. A notable example is the hierarchical Dirichlet process of (13). Other instances of hierarchical models were introduced in the context of survival analysis: the work of (1) presents a class of multivariate mixtures whose distribution acts as a prior for the vector of sample-specific baseline hazard rates, whereas (11) extends (4) and introduces a nonparametric model for the survival functions of $d \geq 2$ groups of survival times, modeling the dependence structure via Lévy copulas. We refer to (12) for a complete review of dependent structures in Bayesian nonparametrics.
This manuscript aims to introduce a hierarchical generalization of the popular neutral to the right processes, as introduced in (3), to the partially exchangeable framework. Note that this model is particularly suitable in applications with a high number of groups ($d \gg 1$) and a low number of observations per group, i.e., in contexts in which the borrowing of information can be particularly appreciable.

The paper is organized as follows. In Sect. 2, we recall the definition of neutral to the right processes, focusing on their characterization via completely random measures and their relevance in survival analysis. In Sect. 3, we define a hierarchical extension of neutral to the right processes based on a d-dimensional generalization of completely random measures. Finally, in Sect. 3.1, we provide an example of hierarchical neutral to the right processes called hierarchical Beta-Stacy.

2. Neutral to the right processes

Completely random measures (CRMs), introduced by (8), are tractable probabilistic tools that allow the construction of several nonparametric priors (9). Let us denote by $M_{\mathbb{X}}$ the space of boundedly finite measures on $(\mathbb{X}, \mathcal{X})$, i.e., a measure μ belongs to $M_{\mathbb{X}}$ if and only if $\mu(A) < \infty$ for any bounded set $A \in \mathcal{X}$. Moreover, let us denote by $\mathcal{M}_{\mathbb{X}}$ the corresponding Borel σ-algebra.

Definition 1 (CRM)**.** *A measurable map $\tilde{\mu} : (\Omega, \mathcal{A}) \to (M_{\mathbb{X}}, \mathcal{M}_{\mathbb{X}})$ is a completely random measure (CRM) if the random variables $\tilde{\mu}(A_1), \ldots, \tilde{\mu}(A_k)$ are mutually independent for any finite choice of mutually disjoint events $A_1, \ldots, A_k \in \mathcal{X}$, for any $k \geq 1$.*

Kingman (8) proved that each CRM $\tilde{\mu}$ admits the following decomposition

$$\tilde{\mu} = \mu_0 + \sum_{i \geq 1} V_i \delta_{x_i} + \sum_{k \geq 1} J_k \delta_{X_k},$$

where μ_0 is a non-random measure, $(x_i)_{i \geq 1}$ are fixed elements of $\mathbb{X}$, $(V_i)_{i \geq 1}$ are positive and mutually independent random variables. In addition, $\tilde{N} = \sum_{k \geq 1} \delta_{(J_k, X_k)}$ is a Poisson process over $\mathbb{R}^+ \times \mathbb{X}$, therefore both J_k's and X_k's are random variables. In other words, each CRM is the sum of three components: a non-random measure μ_0, a sum of random jumps at fixed locations, and a sum of random jumps at random locations (*atoms*). In this paper, we focus on CRMs $\tilde{\mu}$ composed by a sequence of positive random jumps $(J_k)_{k \geq 1}$ and a sequence of random atoms $(X_k)_{k \geq 1}$, so that $\tilde{\mu} = \sum_{k \geq 1} J_k \delta_{X_k}$. Moreover, since a CRM is a transformation of a Poisson process, its distribution can be easily characterized by means of its Laplace functional. Indeed, the Laplace functional equals

$$\mathbb{E}\left[e^{-\int_{\mathbb{X}} f(x)\tilde{\mu}(\mathrm{d}x)}\right] = \exp\left(-\int_{\mathbb{R}^+ \times \mathbb{X}} \left(1 - e^{-sf(x)}\right) \nu(\mathrm{d}s, \mathrm{d}x)\right), \tag{2}$$

for any measurable function $f : \mathbb{X} \to \mathbb{R}$ such that $\int |f| \mathrm{d}\tilde{\mu} < \infty$ almost surely. In (2) the measure ν is called *Lévy intensity* of the CRM $\tilde{\mu}$.
We assume the Lévy intensity ν can be written as $\nu(\mathrm{d}s, \mathrm{d}x) = \rho_x(\mathrm{d}s)\alpha(\mathrm{d}x)$, where α is a measure on $(\mathbb{X}, \mathcal{X})$ and ρ is a *transition kernel* on $\mathbb{X} \times \mathcal{B}(\mathbb{R}^+)$, i.e., the function $x \mapsto \rho_x(A)$ is $\mathcal{X}$-measurable for any $A \in \mathcal{B}(\mathbb{R}^+)$ and ρ_x is a measure on $(\mathbb{R}^+, \mathcal{B}(\mathbb{R}^+))$ for any $x \in \mathbb{X}$. The Lévy intensity characterizes the CRM since it contains all the information about the distributions of its jumps and locations. We will write $\tilde{\mu} \sim \mathrm{CRM}(\nu)$ to denote the distribution of a CRM $\tilde{\mu}$ having Laplace functional as in (2). Note that if the jumps and the atoms of the CRM are independent, then its Lévy intensity can be written as $\nu(\mathrm{d}s, \mathrm{d}x) = \rho(\mathrm{d}s)\alpha(\mathrm{d}x)$, where ρ does not depend on $x \in \mathbb{X}$.

Neutral to the right (NTR) processes, introduced by Doksum (3), are popular nonparametric priors in survival analysis. We now recall the definition of an NTR process, in which $\mathbb{X} = \mathbb{R}^+$ since the observations are survival times.

Definition 2 (NTR). *A random probability measure $\tilde{p}$ on $(\mathbb{R}^+, \mathcal{B}(\mathbb{R}^+))$ is neutral to the right (NTR) if for any finite partition $0 \leq t_1 < t_2 < \ldots < t_k < \infty$ of $\mathbb{R}^+$, for any $k \geq 1$, the random variables*

$$\tilde{F}(t_1), \frac{\tilde{F}(t_2) - \tilde{F}(t_1)}{1 - \tilde{F}(t_1)}, \ldots, \frac{\tilde{F}(t_k) - \tilde{F}(t_{k-1})}{1 - \tilde{F}(t_{k-1})},$$

are independent, where $\tilde{F}(t) = \tilde{p}((0, t])$ for any $t > 0$.

Importantly, NTR processes are tied to completely random measures by the following result.

Theorem 1 (Doksum). *A random probability measure $\tilde{p}$ is NTR if and only if there exists a CRM $\tilde{\mu}$ on $(\mathbb{R}^+, \mathcal{B}(\mathbb{R}^+))$ such that*

$$\mathbb{P}\left[\lim_{t \to \infty} \tilde{\mu}((0, t]) = \infty\right] = 1$$

and the corresponding random distribution function $\tilde{F}(\cdot) = \tilde{p}((0, \cdot])$ satisfies

$$\{\tilde{F}(t) : t > 0\} \stackrel{\mathrm{d}}{=} \{1 - e^{-\tilde{\mu}((0,t])} : t > 0\}.$$

We will write $\tilde{p} \sim \mathrm{NTR}(\tilde{\mu})$.

Theorem 1 characterizes an NTR measure $\tilde{p} \sim \mathrm{NTR}(\tilde{\mu})$ in terms of the Lévy intensity ν of the associated CRM $\tilde{\mu}$. Moreover, NTR processes enjoy an appealing conjugacy property when used as nonparametric priors for exchangeable data, even in the presence of censored data. In particular, it can be proved (3; 5) that an NTR prior for possibly censored exchangeable data leads to an NTR posterior. For a complete discussion of the subject, see for example (6; 9).

2.1 NTR priors for survival analysis

Let us consider a set of dependent survival times $T_1, \ldots, T_n$ and a set of right censoring times $C_1, \ldots, C_n$. The observed values in survival analysis are the elements of the sequence $\{(X_i, \Delta_i) : i = 1, \ldots, n\}$, where $X_i = \min(T_i, C_i)$ and $\Delta_i = \mathbb{1}_{(0, C_i]}(T_i)$ for any $i = 1, \ldots, n$. In other words, the variable X_i represents the ith observed time, while the variable Δ_i tells us whether the ith observation is censored or not. Let us define $Y(x) = \sum_{i=1}^n \mathbb{1}_{[x, \infty)}(X_i)$ the *at risk process*, which counts the number of subjects still alive at time x. Moreover, let us also consider the distinct observations $X_1^*, \ldots, X_k^*$, where $k \leq n$, and define $\Delta_i^* = \max_{j : X_j = X_i^*} \Delta_j$. Finally, consider the counting processes $n_i = \sum_{j=1}^n \mathbb{1}_{(X_j = X_i, \delta_j = 1)}$ and $n_i^c = \sum_{j=1}^n \mathbb{1}_{(X_j = X_i, \delta_j = 0)}$. The general result that characterizes the posterior distribution of an NTR prior can be found in (5), and it is recalled here for convenience.

Theorem 2 (Ferguson and Phadia). *Let $(X_n)_{n \geq 1}$ be an exchangeable sequence of random variables in $\mathbb{R}^+$ such that*

$$\begin{aligned} X_1, \ldots, X_n \mid \tilde{p} &\stackrel{iid}{\sim} \tilde{p}, \\ \tilde{p} &\sim \mathrm{NTR}(\tilde{\mu}), \end{aligned}$$

where $\tilde{\mu} \sim \text{CRM}(\nu)$ *and* $\nu(\mathrm{d}s, \mathrm{d}x) = \rho_x(\mathrm{d}s)\alpha(\mathrm{d}x)$. *Then, the law of* $\tilde{\mu} \mid (X_i, \Delta_i)_{i=1}^n$ *coincides with the law of the random measure*

$$\tilde{\mu}^* = \tilde{\mu}_c^* + \sum_{i:\Delta_i^*=1} J_i \delta_{X_i^*},$$

where $\tilde{\mu}_c^* \sim \text{CRM}(\nu^*)$ *and* $\nu^*(\mathrm{d}s, \mathrm{d}x) = e^{-Y(x)s}\rho_x(\mathrm{d}s)\alpha(\mathrm{d}x)$. *The* J_i*'s are independent random variables, independent from* $\tilde{\mu}_c^*$*, having density on* $\mathbb{R}^+$ *proportional to* $(1-e^{-s})^{n_i} e^{-s(\overline{n}_{i+1}+\tilde{n}_i^c)}\rho_{X_i^*}(\mathrm{d}s)$, *where* $\overline{n}_r = \sum_{i=r}^k n_i$, $\tilde{n}_r^c = \sum_{i=r}^k n_i^c$ *and* $\overline{n}_{k+1} = 0$.

Theorem 2 provides a general characterization of the posterior of an NTR prior observing possibly censored data, and it holds true in the exchangeable framework. Examples are discussed in (7; 9; 14).

3. Hierarchical NTR processes

In many applications concerning survival analysis the exchangeability assumption is often inadequate. In such a setting, the characterization of NTR processes given in Theorem 1 can be extended by defining a hierarchical version of completely random measures that we introduce below. Let us consider the notation and the framework introduced in Sect. 1, 2. Following (1; 10), let $\tilde{\mu}_0 \sim \text{CRM}(\nu_0)$ be a CRM having Lévy intensity $\nu_0 = \rho_x(s)\mathrm{d}s\alpha_0(\mathrm{d}x)$. Exploiting Sect. 2. let us write $\tilde{\mu}_0$ in terms of the points $(\tilde{h}_{0,k}, \tilde{x}_k)_{k\geq 1}$ of a marked Poisson point process on $\mathbb{R}^+ \times \mathbb{X}$ as follows:

$$\tilde{\mu}_0 = \sum_{k\geq 1} \tilde{h}_{0,k}\delta_{\tilde{x}_k}. \tag{3}$$

Let $(\tilde{\mu}_1, \ldots, \tilde{\mu}_d)$ be a vector of CRMs, for $d \geq 1$, which are independent conditional on $\tilde{\mu}_0$, i.e., each CRM of the vector can be conditionally represented as

$$\tilde{\mu}_j \mid \tilde{\mu}_0 \stackrel{\mathrm{d}}{=} \sum_{k\geq 1} \tilde{h}_{j,k}\delta_{\tilde{x}_k}, \tag{4}$$

for any $j = 1, \ldots, d$, where $\tilde{x}_k$'s are the same atoms of $\tilde{\mu}_0$ and $\tilde{h}_{j,k}$ represents the kth non-negative jump of the jth random measure $\tilde{\mu}_j$. Moreover, conditionally on $\tilde{\mu}_0$, the random variables $(\tilde{h}_{j,k})_{j\geq 1, k\geq 1}$ are assumed to be independent.

Definition 3 (hCRM)**.** *The vector characterized by* (3)–(4) *is termed a vector of hierarchical Completely Random Measures (hCRMs).*

In this hierarchical approach, the baseline measure $\tilde{\mu}_0$ induces dependence between the groups of partially exchangeable observations. Moreover, each group is modeled by a different element of the hCRM vector $(\tilde{\mu}_1, \ldots, \tilde{\mu}_d)$. Exploiting this hierarchical extension of completely random measures, we are now able to extend the definition of neutral to the right processes as follows.

Definition 4 (hNTR)**.** *Let us consider a* d*-dimensional vector of hCRMs* $(\tilde{\mu}_1, \ldots, \tilde{\mu}_d)$ *as defined in Definition 3, with* $\mathbb{X} = \mathbb{R}^+$. *The vector of random distributions* $(\tilde{F}_1, \ldots, \tilde{F}_d)$ *such that*

$$\tilde{F}_j(t) = \tilde{p}_j((0,t]) = 1 - e^{-\tilde{\mu}_j((0,t])},$$

for any $j = 1, \ldots, d$ *and* $t > 0$*, is called a vector of hierarchical Neutral To the Right (hNTR) processes.*

The class of hierarchical processes in Definition 4 is a natural extension of NTR processes to the partially exchangeable framework. Therefore, they are a natural family of nonparametric priors for partially exchangeable survival times. Note that Definition 4 implies that given a vector of hCRMs $(\tilde{\mu}_1, \ldots, \tilde{\mu}_d)$, the corresponding d-dimensional vector of hNTR processes is $(\tilde{F}_1, \ldots, \tilde{F}_d)$ such that $\tilde{p}_j \sim \text{NTR}(\tilde{\mu}_j)$, where $\tilde{F}_j(\cdot) = \tilde{p}_j((0,\cdot])$ for each $j \in \{1, \ldots, d\}$. Therefore, following Definition 3, a vector of hNTR processes is completely specified choosing a base measure $\tilde{\mu}_0$ and the law of the conditional jumps $\tilde{h}_{j,k} \sim f_j(h \mid \tilde{h}_{0,k}, \tilde{x}_k, b_j)$ for each $j = 1, \ldots, d$, where b_j is an additional parameter that can be defined in order to specify the jth measure of the hCRM vector.

3.1 The hierarchical Beta-Stacy process

The Beta-Stacy process is an NTR process introduced by Walker and Muliere (14) as nonparametric prior for survival times in the exchangeable setting.

Definition 5 (Beta-Stacy)**.** *Let α be a probability measure on $\mathbb{R}^+$ which is absolutely continuous w.r.t. the Lebesgue measure, and let $c : \mathbb{R}^+ \to \mathbb{R}^+$ be a piecewise continuous function. The random probability distribution $\tilde{F}$ is a Beta-Stacy process with parameters c and α if $\tilde{F}(t) = \tilde{p}((0,t])$ for each time $t > 0$ and $\tilde{p} \sim \text{NTR}(\tilde{\mu})$, where*

$$\tilde{\mu} \sim \text{CRM}(\nu), \qquad \nu(\mathrm{d}s, \mathrm{d}x) = \frac{e^{-sc(x)\alpha((x,\infty))}}{1 - e^{-s}} c(x)\mathrm{d}s\alpha(\mathrm{d}x).$$

In such a case we say that the CRM $\tilde{\mu}$ is a log-Beta measure with parameters c and α and we write $\tilde{F} \sim \text{Beta-Stacy}(c, \alpha)$ and $\tilde{\mu} \sim \text{log-Beta}(c, \alpha)$.

It is known from (14) that in a model for exchangeable survival times, the Beta-Stacy process is a conjugate nonparametric prior, i.e., assuming a Beta-Stacy prior the posterior is a Beta-Stacy process with updated parameters. Let us now consider the hierarchical model defined in Sect. 3. A possible extension of the Beta-Stacy process to the partially exchangeable framework can be obtained by choosing a log-Beta CRM as the base measure $\tilde{\mu}_0$ in (3) and specifying dependent jumps distributed as transformations of Beta variables in (4). In particular, let us define

$$\begin{aligned} \tilde{\mu}_0 &\sim \text{log-Beta}(c, \alpha), \\ 1 - e^{-\tilde{h}_{j,k}} \mid \tilde{\mu}_0 &\sim \text{Beta}(c_j(\tilde{x}_k)F_j(\tilde{h}_{0,k}), c_j(\tilde{x}_k)(1 - F_j(\tilde{h}_{0,k}))), \end{aligned}$$

where $\tilde{\mu}_0 = \sum_{k \geq 1} \tilde{h}_{0,k}\delta_{\tilde{x}_k}$ is the usual representation of the CRM $\tilde{\mu}_0$ as functional of a Poisson process, $c_j : \mathbb{R}^+ \to \mathbb{R}^+$ is a function referring to group $j \in \{1, \ldots, d\}$, while F_j is c.d.f. which should encapsulate our prior opinion on the hazard function for the jth group. This is a noteworthy example of an hNTR process, which we will refer to as a *hierarchical Beta-Stacy process*. The specification of a particular prior of this family of hierarchical processes should allow a precise characterization of its posterior distribution as well as simulation studies, even without conjugacy property that might be lost in the partially exchangeable framework. Our aim in (2) is to study the whole class of hNTR processes, characterizing the posterior distribution with a particular focus on the hierarchical Beta-Stacy process; we are also interested to develop marginal and conditional algorithms to address posterior inference. We think that the model proposed here, that we plan to investigate in (2), can be used to solve a large variety of survival problems.

Abstract

The concept of Industry 4.0 is tightly connected with the enterprises' propensity to adopt new production technologies to increase productivity and improve product quality. For this reason, it has become an important scientific topic in the last few years. Industry 4.0 means a model of production that arises from the fourth industrial revolution, which is leading to fully automated and interconnected industrial production. The goal of the present work is to investigate the specific role of recent public policies, in the Italian framework, in enhancing the innovative capacity of companies regarding Industry 4.0 technologies. The case study concerns the analysis of original data, collected through a sample survey recently conducted, involving a sample of enterprises of the Region Emilia-Romagna, in the North of Italy. To test the effect of incentives on the adoption of 4.0 technologies, a nonparametric inferential approach based on the methodology of combined permutation tests is proposed. Such an approach assures greater flexibility and robustness with respect to the probabilistic assumptions on the underlying distribution.

Key words: combined permutation test, nonparametric inference, public policy, 4.0 technologies.

1. Introduction

This paper deals with the application of a regression analysis for count data, based on the use of a combined permutation test. The application concerns the specific role of recent public policies in enhancing the innovative capacity of companies with respect to Industry 4.0 technologies. Although several studies have been conducted on the enabling technologies of Industry 4.0, many aspects related to the implementation of these technologies still need to be explored, which may also depend on access to public funds and incentives [5]. This study was developed precisely because of this lack in the literature and grasping the need to provide empirical evidence.

The concept of Industry 4.0 has become a hotly debated topic in Italy only in the last two years and it is implemented through a combination of established and new technologies [3]. Industry 4.0 defines a methodology for generating a transformation from dominant machine manufacturing to digital manufacturing. Companies, to achieve a successful transformation, should review their positions and respective potentials with respect to the basic requirements established for the Industry 4.0 standard. However, the literature clearly indicates the lack of evaluation methodologies. Some authors provide a concrete definition of Industry 4.0, according to its six design principles: interoperability, virtualization, local and real-time talent, service orientation and modularity [8].

In general, larger (and younger) companies have a deep knowledge of business plan incentives, while SMEs have a more superficial knowledge of policy incentives because they often do not know the existence of certain incentives and/or do not know how to access them. Empirical studies show that the application of the incentives provided by the Business Plan 4.0 can facilitate the adoption of Industry 4.0 and have identified that the most used incentives are those relating to the amortization of investments

in technologies and the training of human capital. Furthermore, multiple incentives are often adopted in combination, so there is evidence to suggest that the openness of Industry 4.0 should be measured in terms of the number of technologies adopted [4].
Empirical works usually suffer from some methodological limitations. For instance, they ignore the existence of confounding factors (firm's size or firm's age for example), or they use inferential methods that assume asymptotic distributions of the sample statistics which are not valid for small samples. The main goal of this work is to carry out a regression analysis for count data in order to investigate the relationship between technology 4.0 adoption and policy incentives. In the regression model, firm's age and size take the role of control variables. To test the goodness-of-fit, we propose the application of a combined permutation test. This method is based on the combination of the permutation tests on the significance of the single regression coefficients. This is a distribution-free test valid also for small sample sizes. Hence, this work represents a contribution to the empirical literature on the effectiveness of public policy interventions on the adoption of 4.0 technologies by small and medium enterprises, through the application of an innovative approach to make inference on the model. Section 2 focuses on the presentation of the problem and of the methodological solution. Section 3 is dedicated to the application and section 4 includes results and conclusions.

2. Statistical problem and methodological solution

Let us consider a regression model where the response is a count variable. In such cases, the classical parametric approach to regression analysis is not suitable because the dependent variable takes only non-negative integer values. In literature, a typical approach to make inferences on such a model is based on the Poisson regression, the negative binomial regression, or a discrete Weibull regression [6,11,15].

Let Y_i denote the discrete random variable from which the value of the response observed on the i-th statistical unit is supposed to be generated. The i-th row of the design matrix $\boldsymbol{X}$, which includes the values of the k explanatory variables observed on the i-th statistical unit, is denoted by $\boldsymbol{x}_{(i)} = (x_{i1}, x_{i2}, \cdots, x_{ik})$. The model is represented as follows:

$$\log E\left[Y_i | \boldsymbol{x}_{(i)}\right] = \beta_0 + \sum_{q=1}^{k} \beta_q x_{iq}. \tag{1}$$

For the analysis of variance of such a model, the proposed solution is based the methodology of Combined Permutation Tests (CPTs) [1,2]. CPTs consists of a family of permutation tests, suitable for complex testing problems that can be broken down into partial tests. Such tests are robust with respect to the underlying distribution and powerful in particular (but not only) for small sample sizes. For the application of this test, the classical assumption of independence of the error terms with respect to units can be relaxed in favor of the milder condition of exchangeability of the errors with respect to units [9,10]. The nonparametric nature of the method, due to the fact that it does not assume any probability distribution for the model errors, provides flexibility with respect to the conditions of validity. For these main reasons, together with the characteristic of conceiving the test on the goodness-of-fit of the full model as a multiple test composed of the single tests on the regression coefficients, we consider the CPT method appropriate for such a problem.

The hypothesis of the testing problem can be represented as follows:

$$\begin{cases} H_0: \beta_1 = \beta_2 = \cdots = \beta_k = 0 \\ H_1: \overline{H_0} \end{cases} \tag{2}$$

The main idea of the CPT as a permutation ANOVA for the goodness-of-fit, is to carry out a permutation test for the significance of each regression coefficient and to combine the p-values of such partial tests in order to solve the overall problem. A suitable test statistic for the q-th partial test is the OLS estimator of the q-th regression coefficient $T_q = \left|\widehat{\beta}_q\right|$. For the general problem, a suitable combination of the p-values of the partial tests, based on the application of the so-called Fisher combining function, can be used as a test statistic: $T_{comb} = -2\sum_q \ln(\lambda_q)$ (see [2]).

3. Application

The regression analysis presented in the previous section was applied to original data collected in a sample survey carried out in January 2022. The survey was conducted in the northern regions of Italy by the Department of Economics and Management of the University of Ferrara, supported by a specialized company. It was aimed at manufacturing enterprises of the North Italy. The total number of interviewed companies is 3926. For the selection of the companies, a stratified random sampling (by region, size and technological intensity – by which we mean the percentage of companies that manufacture products with advanced and innovative technologies) was applied. In particular, we focused on the region Emilia-Romagna, one of the most developed and productive regions of Italy. In this region, more than a half of the companies have embraced the 4.0 paradigm and represents an important test bench to verify how much the evolution of regional institutions has favoured the creation of a system capable of promoting innovative capacity [7]. The number of companies from Emilia-Romagna considered in this study is 613.

The goal is to investigate the specific role of recent public policies, in enhancing the innovative capacity of companies regarding Industry 4.0 technologies. The response represents the number of technologies adopted by the company in the two-year period 2018-2019. The technologies included:

- advanced manufacturing solutions (interconnected and programmable robots),
- additive manufacturing (3D printers connected to digital development software),
- augmented reality (to support production processes),
- simulation (between interconnected machines for process optimization),
- horizontal integration (integration of information along the production process stages),
- vertical integration (sharing of information along the value chain/supply chain with suppliers and customers),
- industrial internet (multidirectional communication between production processes and products),
- cloud computing (data management on open systems),
- cyber-security (during network operations on open systems),
- big data/analytics (for the optimization of products and production processes).

The explanatory variables include:

- a discrete variable which represents firm's dimension (number of employees),
- a discrete variable which represents firm's age (in years),
- ten dummy variables which represent the Industry 4.0 benefits used by the company in the two-year period 2018-2019. Those benefits were:
  – hyper and super depreciation,
  – new Sabatini,
  – guarantee fund,
  – R&D tax credit,
  – development contracts,
  – innovative startups and SMEs,
  – patent box,
  – training tax credit,
  – regional incentive measures for Research and Development and innovation,
  – other.

The global p-value of the CPT on the goodness-of-fit is **0.0001**, which is less than the significance level $\alpha = 0.10$. Thus, the null hypothesis that all the regression coefficients are equal to zero must be rejected in favor of the alternative hypothesis that at least one regression coefficient is not equal to zero. Hence, there is empirical evidence that incentives imply the adoption of 4.0 technologies. From a descriptive point of view, the goodness-of-fit is not very high. In fact, the adjusted R^2 is 0.3847. This result could be due to either the exclusion of important predictors from the model, or to a non-appropriate model specification. However, since our study has an inferential perspective, the results of the tests are much more relevant than the values of the R^2. The proposed permutation solution is defined as a multiple test. Hence, in case of rejection of the null hypothesis in favour of the alternative, the overall significance could be attributed to specific partial tests, i.e. to the significance of specific regression coefficients, after adjustment of the partial p-values to control the family-wise error (FWE) [14]. The procedure adopted for the adjustment of p-values is the minP method, which controls the FWE in a strong sense [12,13].

Table 1 shows coefficients' estimates and adjusted p-values. According to this output, there is empirical evidence that the implementation of Industry 4.0 technologies is significantly influenced by the following

policy incentives: hyper and super depreciation, new Sabatini, R&D tax credit, patent box, and training tax credit.

Table 1: Estimates and adjusted p-values of the partial permutation tests on the regression coefficients of the regression model (significant estimates in bold).

	Coefficients	Adjusted p-values
Intercept	-0.0180	
Age	0.0013	0.9237
Dimension	0.0005	0.2672
Hyper and super depreciation	0.5599	**0.0011** ***
New Sabatini	0.4410	**0.0032** ***
Guarantee fund	0.2608	0.2570
R&D tax credit	0.4768	**0.0039** ***
Development contracts	1.3130	0.4822
Innovative startups and SMEs	0.0079	0.9877
Patent box	1.3256	**0.0466** **
Training tax credit	0.6427	**0.0932** *
Regional incentive measures for R&D and innovation	0.2264	0.9237
Other	0.0659	0.9868

*: weak significance ($p < 0.10$); **: moderate significance ($p < 0.05$); ***: strong significance ($p < 0.01$).

4. Results and conclusions

The combined permutation test for the goodness-of-fit of the regression model for count data and the significance of the regression coefficients is a distribution-free, robust and flexible solution. It represents a suitable approach to overcome some of the limits of the empirical studies on the effect of public policies from the methodological point of view. Its application to original dataset concerning a survey about Italian enterprises in Emilia-Romagna provides empirical evidence in favour of the hypothesis that the implementation of industry 4.0 technologies depends on some policy incentives such as hyper and super depreciation, new Sabatini, R&D tax credit, patent box, and training tax credit. These findings can be considered a small contribution and a good starting point in the study of how (and which) public policy interventions have an effect on the propensity to adopt technologies related to Industry 4.0.

Acknowledgments Authors thank University of Ferrara that funded the project entitled "Public policies, 4.0 technologies and enterprise performance. Empirical analyses on a representative sample of manufacturing enterprises of northern Italy (Politiche pubbliche, tecnologie 4.0 e performance d'impresa. Analisi empiriche su un campione rappresentativo di imprese manifatturiere del Nord Italia)" for the period 2022-2024, with the Departmental Research Incentive Fund - FIRD 2022.

Abstract

This work aims to highlight the situation of environmental indicators in Italy. The SDGs indicators relating to environmental sustainability were taken into consideration.

The analysis carried out is a spatial analysis and divides the Italian regions into groups with similar characteristics.

The method used to divide regions into groups is a Fuzzy C-Metoids clustering model.

The results speak of an Italy divided into two groups even if there is no clear difference between environmental behaviors in the two groups.

Keywords: SDGs; Environmental sustenibility; Fuzzy c-metoids

1. Introduction

The United Nations global plan of action is called the "2030 Agenda for Sustainable Development". The 2030 Agenda is a plan to support universal peace for people and the planet, the eradication of poverty through the sustainable transformation of society, the economy and the environment, promoting security, well-being and justice.

This plan is implemented by the sustainability indicators (SDGs) that the European Union collects through the member countries [1].

In Italy it is the Institute of Official Statistics (ISTAT) which has been producing and monitoring the SDGs indicators since 2016 and produces the Reports on the SDGs on an annual basis.

It is very important to monitor the situation of the indicators in the territories in order to understand the dynamics of development and the problems to be faced in this transition phase.

In this perspective, this work focuses on analyzing environmental indicators. Specifically, it classifies the Italian regions into two groups starting from the historical series of the SDGs environmental indicators [2].

In Italy, it is essential to collect and report indicators and data at the regional level, paying attention to the territory. In fact, the country has strong regional specificities and differences exacerbated by the North-South divide [3]. This work aims to analyze and monitor the Italian situation in achieving the environmental SDGs. In this regard, we have examined the regions and have highlighted any territorial differences or homogeneities. Specifically, we want to underline the existing gap between North and South for environmental indicators.

2. Material and methods

The analysis data were freely downloaded from the Istat website. The reference database is that of sustainability indicators (SDGs) [4].

Specifically, all the indicators that monitor the progress of the sustainability objective linked to the environment were considered [5]. The period considered is 2004-2020 but there are exceptions based on the available data. The indicators analysed are shown in Table 1.

Goal	Global indicator	Measured by
Goal 1. End poverty in all its forms everywhere	1.4.1 Proportion of population living in households with access to basic services	Submission of municipal waste to landfill
Goal 11. Make cities and human settlements inclusive, safe, resilient and sustainable	11.6.2 Annual mean levels of fine particulate matter (e.g., PM2.5 and PM10) in cities (population weighted)	Air quality - PM2.5
Goal 13. Take urgent action to combat climate change and its impacts	13.3.1 Extent to which (i) global citizenship education and (ii) education for sustainable development are mainstreamed in (a) national education policies; (b) curricula; (c) teacher education; and (d) student assessment	Concern about climate change
Goal 6. Ensure availability and sustainable management of water and sanitation for all	6.3.1 Proportion of domestic and industrial wastewater flows safely treated	Wastewater treatment
Goal 15. Protect, restore and promote sustainable use of terrestrial ecosystems, sustainably manage forests, combat desertification, and halt and reverse land degradation and halt biodiversity loss	15.1.2 Proportion of important sites for terrestrial and freshwater biodiversity that are covered by protected areas, by ecosystem type	Protected areas
Goal 7. Ensure access to affordable, reliable, sustainable and modern energy for all	7.2.1 Renewable energy share in the total final energy consumption	Electricity from renewable sources
Goal 15. Protect, restore and promote sustainable use of terrestrial ecosystems, sustainably manage forests, combat desertification, and halt and reverse land degradation and halt biodiversity loss	15.3.1 Proportion of land that is degraded over total land area	Soil sealing from artificial cover

Table 1: SDGs indicators related to environmental sustainability.

The method used for grouping is fuzzy c-metoids. A partition clustering algorithm related to the k-means algorithm [6].
This fuzzy c-medoids clustering algorithm is capable of partitioning objects simultaneously taking into account several dissimilarity matrices.

The algorithm is designed to provide a fuzzy partition and profile for each fuzzy cluster, as well as learn the specific weight of relevance for each dissimilarity matrix all this to optimize an objective function.
It assigns by randomly a weight of membership u_{ij} to each element x_i which belongs to each cluster j that we want to find. By means of an iterative process, an objective function composed by sum of the distances of each point from each cluster centre is minimized by moving dynamically the cluster centres c_j. This function is defined as:

$$J = \sum_{i=1}^{M} \sum_{J=1}^{N} u_{ij}^{p} \|x_i - c_j\|^2$$

where c_i is the centroid of cluster J; M is the number of instances in the dataset; N is the desired number of clusters imposed by the researcher; p is the fuzzifier parameter, a hyper-parameter that

controls the "fuzzy degree" of the cluster. We used the Euclidean distance metric to compute the distances between the cluster centres and each observation in the sample (Bezdek et al. 1974). The Fuzzy c-metoids procedure assigns membership to a particular cluster to each Italian region.

3. Results and disussion

There are a total of seven SDGs indicators linked to the environment. We illustrate below the characteristics of the two groups focusing on each individual indicator.

The first indicator: Submission of municipal waste to landfill (Percentage of municipal waste sent to landfills out of the total municipal waste produced);

The regions included in the first cluster are: Basilicata, Campania, Emilia-Romagna, Friuli-Venezia Giulia, Lazio, Lombardy, Piedmont, the autonomous provinces of Bolzano and Trento, Sardinia, Trentino-Alto Adige, Umbria, Veneto.

The group average is equal to 31.3% of urban waste sent to landfills compared to the total urban waste produced. Basilicata stands out for the highest percentage (53.8%) and Lombardy for the lowest percentage (8.1%).

The regions included in the second cluster are Abruzzo, Calabria, Liguria, Marche, Molise, Puglia, Sicily, Tuscany, and Valle d'Aosta. On average, the percentage of municipal waste sent to landfills in the second cluster is 62.4%. The highest percentage is held by Molise (94.3%) and the lowest percentage goes to Tuscany (40.7%).

The second indicator: Air quality - PM2.5 (Percentage of valid measurements above the reference value for health, defined by the WHO (10 µg/m³), out of the total valid measurements of the annual average concentrations of PM2.5);

In the first cluster, the average percentage is 86.07. The highest percentage is located in Lombardy (99.3%) and the lowest is located in Sardinia (51.5%).

In the second cluster the average is 84.3%, the highest value is reached in Puglia (94.1%) and the lowest value is reached in Sicily (70.6%).

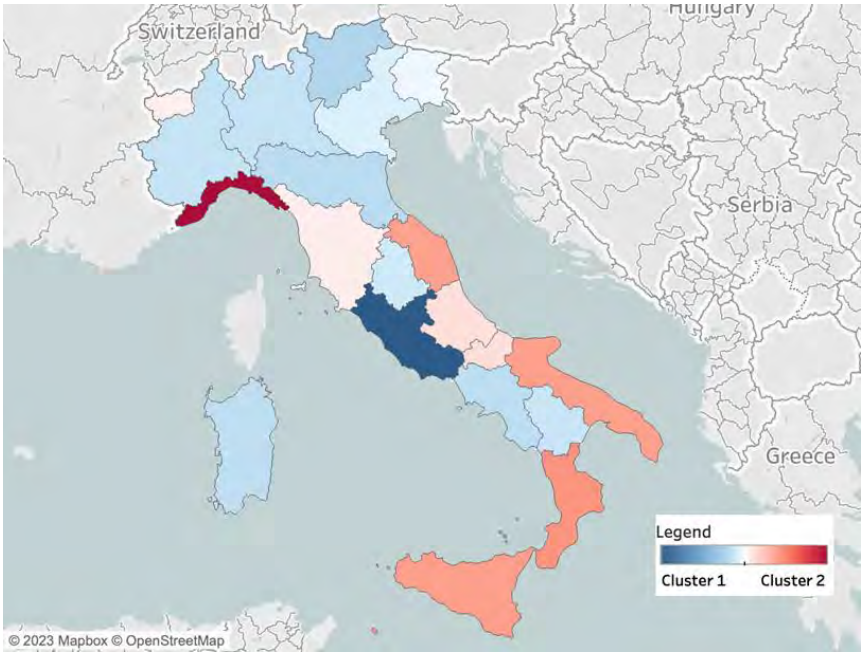

Figure 2: Composition of the clusters and the degree of memberships' Italian regions

The third indicator: Concern about climate change, (Percentage of people aged 14 and over who consider climate change or the increase in the greenhouse effect and the ozone hole among the 5 priority environmental concerns);

In the first cluster, the average percentage is 64.65. The highest percentage is in Veneto (67.1%) and the lowest in Campania (61.7%).

In the second cluster the average is 64.63%, with higher values in Abruzzo (66.2%) and lower values in Valle d'Aosta (62.7%).

The fourth indicator: Treatment of waste water (percentage of polluting loads flowing into secondary or advanced plants, in equivalent inhabitants, compared to the total urban loads generated);

In the first cluster, the average percentage is 50.7. The highest percentage belongs to the Autonomous Province of Bolzano (74.34%) and the lowest percentage belongs to Friuli-Venezia Giulia (38.5%).

In the second cluster the average is 42.6%, with higher values in Puglia (49.9%) and lower values in Sicily (31.7%).

The fifth Indicator: Protected Areas (Percentage of land area covered by terrestrial protected natural areas included in the official list of protected areas (Euap) or belonging to the Natura 2000 network.);

In the first cluster, the average percentage is 22.3. The highest percentage is from Campania 35.3 and the lowest from Emilia-Romagna 12.18.

In the second cluster the average is 25.1, the highest is 36.6 in Abruzzo and the lowest is 15.3 in Tuscany.

The sixth indicator: Electricity from renewable sources (Percentage of electricity consumption covered by renewable sources out of total gross domestic consumption. The indicator is obtained as the ratio between the gross electricity production from effective, non-normalized RES and the Gross Domestic Consumption electricity);

In the first cluster, the average percentage is 52.2. The highest percentage is in the Autonomous Province of Bolzano (184.3%) and the lowest in Veneto (19.6%).

In the second cluster the average is 58.8, with higher values in Valle d'Aosta (267.6%) and lower values in Liguria (6.4%).

The seventh indicator: Soil sealing by artificial cover (Percentage of soil sealed on the total land area);

In the first cluster, the average percentage is 6.65. The highest percentage is in Lombardy (12%) and the lowest percentage is in the Autonomous Province of Bolzano (2.7%).

In the second cluster the average is 5.6, with the highest values in Puglia (8.1%) and the lowest values in Valle d'Aosta (2.1%).

Conclusions

The subdivision of the Italian regions into groups with respect to the starting environmental SDGs indicators has highlighted a particular pattern. The north-south divide was also highlighted in this context. Furthermore, we can state that the environmental indicators would seem to be linked to the accessibility of specific regions because of their relief they do not allow human pollution to advance.

Abstract

The Delphi method is a structured communication approach used to gather and process expert judgments in order to make predictions or estimates about a specific issue. In the Futures Studies (FS) context, the Delphi method is combined with different methods, however, one of the main combinations is with the scenario method, forming the Delphi-based scenarios (DBS). Scenarios are hypothetical descriptions of the futures, adopted in different disciplines in order to prevent possible future outcomes. Nevertheless, one of the main weaknesses of DBS is the lack of spatial perspectives, where most of the time quantitative models are often used to develop spatial scenarios. To overcome this challenge, in this paper, we illustrate an enhancement of the Real-Time Spatial Delphi, through a novel web-based open platform useful to obtain, with innovative tools, a spatial convergence of opinions among a cohort of experts. We apply the method, developing spatial scenarios in the climate change context, for the city of Dublin in 2050.

Keywords: Real-Time Spatial Delphi, Futures Studies, spatial convergence

1. Introduction and Theoretical Framework

From the first application by the RAND Corporation (Linstone and Turoff, 1975) in the 1950s, the Delphi method is widely known as a structured technique for gathering and aggregating the opinions of a group of experts on a specific issue or problem. It is often used when there is a lack of data (e.g., historical data) or when the experts have diverse opinions on a complex subject. The Delphi method is generally conducted in multiple iterative rounds, where experts with high competencies, provide anonymous judgments to a series of questions (Baker et al., 2006). The judgments are carefully analysed generally with a statistical summary (e.g., mean, median, interquartile range (IQR), etc.) and the results are used to create a set of questions for the next rounds, where experts can revise their opinions based on that information. In this case, the process is repeated until there is a consensus among the experts (but is not limited to), or when we have a stability condition (Dajani et al., 1979; von der Gracht, 2012). The Delphi method is widely adopted in different disciplines and is characterized by four main features, such as anonymity, iteration, controlled feedback, and statistical group responses (Rowe and Wright, 1999).

In the Futures Studies (FS) context, scenarios are representations of possible future states and outcomes, useful to help explore and understand the potential impacts of different events, trends, and decisions that may play out over time (von der Gracht and Darkow, 2010). Scenarios can take various forms, including narrative-style descriptions, mathematical models, and visual representations (Varho and Tapio, 2013). The aim of developing scenarios is to provide a holistic and detailed picture of potential futures, considering the interactions between various factors and their effects on society, technology, economics, and the environment (Bishop et al., 2007; Hines et al., 2017). Among the many combinations

of the scenario method, one of the widest used is the Delphi method, forming the so-called Delphi-based scenarios (DBS). From what emerged, DBS constitute an interesting method to explore and empower different futures, however, one of the main weaknesses is the lack of spatial references. The conventional Delphi technique consists of multiple cyclical stages, but the surveys commonly use open-ended, closed-ended, and scaling questions which are not suitable for forecasting future territorial distributions in the form of points or polygons. To overcome this challenge, in the literature, two main methods are developed, namely the Spatial Delphi (Di Zio and Pacinelli, 2011) and the Real-Time Spatial Delphi (Di Zio et al., 2017), however, from the first applications, these two methods are still unexplored.

To overcome this challenge, we adopted Real-Time Geo-Spatial Consensus System (http://www.rtgscs.com/), a novel web-based open platform, to develop spatial scenarios for the climate change context in the city of Dublin, Ireland.

2. Materials and Methods

In this paper, we follow a modified version of the DBS, suitable to our context, starting from the Strategic Foresight approach proposed by Bishop et al., (2007): Framing, Scanning, Forecasting, Visioning, Planning and Acting integrating it with the novel platform.

The first step sees careful desk research in order to develop guidelines, acquire spatial data information and understand the territorial framework. This study is conducted in the climate change context, in the city of Dublin, where a Coastal City Living Lab, part of the SCORE H2020 EU Project, is located. Dublin faces a significant threat from coastal flooding in the coming years due to insufficient defences and a lack of public support for upgrades, such as higher flood walls. For our study, we first determine the territorial boundaries, to then select a time horizon (in this case, 2050) that is long enough to be relevant for decision-making but not too far to make accurate predictions. To define a list of key drivers, we did not involve experts in a workshop, however, we extract the main drivers from the project proposal, where experts have already defined the possible future risks. Starting from that, we have 6 hazards that may affect the climate future of Dublin in 2050, specifically: coastal flooding, land flooding, landslides, heatwave, storm surge, and coastal erosion.

From these drivers, we can now obtain the questions for our panel: $RQ1$: Thinking about 2050, what area will be most at risk of flooding? $RQ2$: Thinking about 2050, what area will be most at risk of erosion? $RQ3$: Thinking about 2050, what area will be most affected by extreme events? Once the questions have been validated by the research team (in terms of clarity), we upload them into the platform. In this study, for the selection of a suitable sample of experts we choose to include two types of experts: 1) Internal experts: part of the SCORE H2020 project, and 2) External experts: with a strong background and expertise in the topics emerged, but not part of the project. We select academics with a high level of experience, stakeholders, and representatives from companies, local authorities, and other agencies, ensuring the diversity of expertise in the panel. We reached out to 12 internal and 50 external experts by sending an introductory email about the research and requesting their participation. Out of these, 26 experts agreed to participate in the study, including 6 internal and 20 external experts. Once the experts accepted to participate in the study, we sent each panellist a registration form, including relevant attachments such as spatial data information, territorial framework, guidelines, etc.

To pursue the aim of this paper, we adopt Real-Time Geo-Spatial Consensus System (RT-GSCS, www.rtgscs.com), a novel web-based open platform adopting Real-Time Spatial Delphi (Di Zio et al., 2017) to obtain a spatial convergence of opinions among panellists in a spatial context (Fig. 1). Once all of them have registered to the platform we can start the survey. We ask the panellists to select the question and answer by placing a point on the map and electing the plausibility of the answer from 1-5. From this point, an automatic circle appears on the map and based on others' judgments it moves, shrinks, or enlarges in real-time. The experts can at any time, motivate their answers with specific comments.

Following the logic expressed by Di Zio and Pacinelli, in 2011, spatial convergence is pursued by adopting a geometric element represented by a circle C, the smallest one among all the possible circles, including the 50% of N judgments (analogue of the IQR of the traditional Delphi). If, we assume that $N = n_1, n_2, n_3, \dots, n_j$ is the number of the experts judgments on a question (points on the map), we want to find a minimum area A_i of a circle C_i covering half of those points: $A_i \supseteq T_{(N/2)}$, where $T_{(N/2)}$ denotes a set containing 50% of the N points. We take into account 50% of the points because some of the points could be placed in some locations not suitable for our research objectives. Since there are infinite circles like this, to limit the search we impose the constraint that C_i must have its centre in one of the N points.

Therefore, for each question we find a vector $A = A_1, A_2, A_3, \ldots, A_N$ where A_i is the area of a circle containing 50% of the N points and centred in point n_i. Then, $min(A)$ corresponds to the geo-consensus.

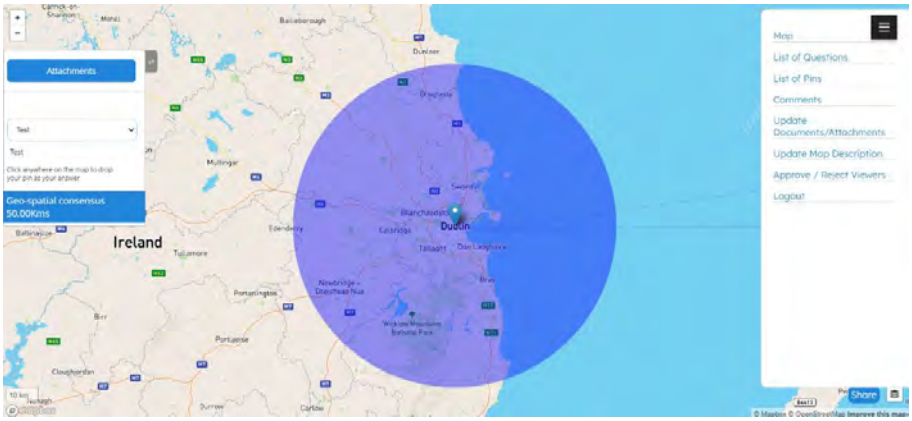

Figure 1: RT-GSCS interface

In our study, we have two types of results: geographical, with visual map outputs and non-geographical results, with spatial data and comments. In this paper, to evaluate spatial data we consider the three measures proposed by Di Zio et al., 2017, denoted by M_1, M_2 and M_3. The first measure, M_1, corresponds to the final circle area useful for the identification of outcomes. Nevertheless, this measure is absolute and does not consider the study area boundaries and the size of the initial circle. To address this challenge, we also consider $M_2 = 1 - \frac{FC}{S}$ as second indicator, obtained as the ratio between the final circle's area (FC) and the surface (S) of Dublin ($S = 117.8\ km^2$). In this case, the indicator shows the degree of geo-consensus, and the more the measure is closer to 1, the more the consensus circle is small compared to the surface. The third indicator, measures the spatial convergence dynamic process, $M_3 = \frac{FC}{IC} \cdot 100$, where IC is the initial circle area (set a priori as 50 km^2), and the more the value is higher (close to 100%), the more we have a poor convergence of opinions, the more is close to zero, the higher the convergence. Before finishing the study, we must take into consideration that convergence is not the only stopping criterion to be used to end the exercise (von der Gracht, 2012). For this reason, in our case, we also look for stability with time series analysis.

In the end, we obtain three main scenarios (one for each spatial-question) derived from value judgments and ready for decisions. Nevertheless, spatial data could be analysed in multiple ways and since we have a matrix composed of spatial data and the relative plausibility on a Likert type scale from 1 to 5 expressed by experts, we use ArcGIS PRO to represent data with a Heat Map. A Heat Map is a graphical representation of data in two dimensions that uses colour coding to represent different values, extremely useful in our case to highlight the plausibility of the judgments and possible hotspots. The final result is a map that represents the plausibility in different points of the space based on the available information and can then be used to make better decisions considering the overall territory.

3. Results

The results fully answered the research objectives, we obtain 3 main spatial scenarios. The study began officially on November 1, 2022, and concluded on December 5, 2022, after a double stability check. In our panel, out of 62 experts participating in the survey, 26 accepted by placing at least one point on the map. For $Q1$, 58 experts judgments were obtained with 13 comments. For $Q2$, 54 judgments were considered with 16 comments. At the end, for $Q3$, 40 points were recorded with 11 comments. The outputs are presented in Fig. 2.

According to the findings depicted in Fig. 2, the area most likely to face the threat of flooding by the year 2050 ($Q1$), is located in the central part of Dublin city, between the two banks of the River Liffey. The experts believe that a potential flood in this area could have devastating effects, potentially resulting in harm to buildings and infrastructure, disruption of essential services, environmental harm, and loss of life. With regards to $Q2$, the area most susceptible to erosion by 2050, is the eastern coastal

regions of Dublin. The experts believe that coastal erosion in this area could have severe impacts, including the loss of valuable real estate and infrastructure, such as roads, buildings, and homes. It could also pose a threat to public safety by destabilizing cliffs and making them prone to collapse. Furthermore, coastal erosion could lead to the loss of recreational areas and habitats for wildlife, as well as negatively impact the local economy by affecting businesses that depend on the coast for tourism or fishing. In response to $Q3$ the panellists have identified the central area of Dublin as the most likely to be impacted. The experts believe that this area could be affected by various extreme events, such as storms, floods, and heat waves, which could result in significant impacts on the city. Such events could damage or destroy buildings, infrastructure, and public facilities, disrupting daily life for residents and visitors. They could also pose a threat to public safety, causing power outages, landslides, and other hazards. Additionally, extreme events can have social implications, such as increased demand for emergency services and strain on the healthcare system. Finally, these events could also have environmental impacts, altering the local ecosystem and contributing to the degradation of natural habitats.

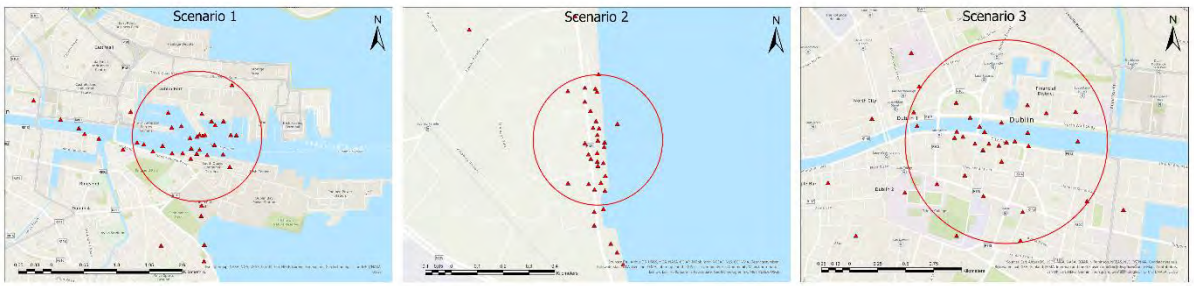

Figure 2: Spatial scenarios

The results of the indicators measuring spatial consensus are shown in Tab. 1, which highlights the convergence of the geographical data obtained from our study. Each question consists of various variables, including the area of Dublin city (S), the total number of judgments (N) the initial circle (IC), the final circle (M_1), and the convergence measures M_2 and M_3.

Table 1: Geographical results

Scenario	$S\ (km^2)$	$IC\ (km^2)$	$FC\ (km^2)\ M_1$	M_2	M_3	N
Sc.1	117.8	8.24	0.77	0.993	9.34%	58
Sc.2	117.8	3.25	0.15	0.999	4.61%	54
Sc.3	117.8	2.92	0.54	0.995	18.49%	50

The experts were able to achieve a significant reduction of the initial circles, greater than 99% in all final outputs (as indicated by M_2 in Tab. 1), reaching a high degree of convergence. For Sc.1 and Sc.2, the initial circle was reduced greatly (with M_2values of 0.993 and 0.999, respectively). The initial circle for Sc.1 was 8.24 km^2 and reduced to 0.77 km^2, while the initial circle for Sc.2 was 3.25 km^2 and reduced to 0.15 km^2. For Sc.3, the initial circle was smaller (2.92 km^2) and the final circle was 0.54 km^2 with a reduction of 0.995 (as indicated by M_2). M_2 is a measure of the efficacy of the solution with regards to the specific area of investigation, while M_3 measures the consensus dynamic among participants. In a traditional Delphi study, a common measure of consensus is the IQR, with a good consensus considered to be achieved when the IQR is less than 20% of the measurement scale used.

Similarly, in the Spatial Delphi, consensus can be reached when M_3 is less than or equal to 20%. In our case, the M_3 values of 9.34%, 4.61%, and 18.49% for the three research questions indicate that the experts reached a high level of consensus for Sc.1 and Sc.2, and a slightly lower level of consensus for Sc.3. This could mean that for extreme events it is more difficult to outline future scenarios in respect to erosion and flooding.

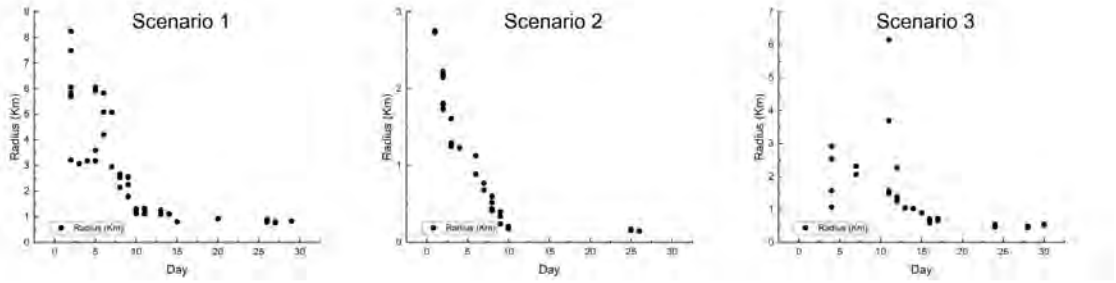

Figure 3: Time series of the sizes of the circles

From the collected data, we have time series of the size of the circles that track the stability of the results over time. Fig. 3 illustrates three-time series, one for each scenario, with the number of days from the start of the process on the horizontal axis and the radius of the circle on the vertical axis. The closer the sequence of points smoothly gets to the horizontal axis, the greater the geo-consensus among the experts. In Sc.1, the radius changed several times before reaching stability from the 18th to the 20th day. However, after we asked for validation, three additional changes took place. This means that the issue of flooding has been quite controversial, in fact, in the Dublin area, many efforts are taking action to mitigate the impacts and experts are dubious about the suitable solutions. Sc.2 had the strongest consensus, which can be seen from the sudden drop and stability from the 10th day, with only two changes made during validation. This means that experts agree on future spatial erosion dynamics finding a common consensus on the Dublin coastal area. In Sc.3, the circle underwent significant changes in the first 15 days – confirming that there has been a lot of debate about places that could be scenarios of extreme events in the future – but reached stability after the 18th day. In all scenarios, we observed stability after the validation phase with no further changes made. The results of the study that evaluated the plasuibility areas of three scenarios were analyzed to determine the scores ($X \sim U(1,5)$) assigned by participants.
The scores can be used to determine the mean (μ), median, and standard deviation (σ) of each scenario. For Sc.1, the mean score was represented as $\mu_1 = 3.86$, with a median score of $X_1 = 4$ and a standard deviation of $\sigma_1 = 0.68$. For Sc.2, the mean score was represented as $\mu_2 = 4.24$, with a median score $X_2 = 4$ and a standard deviation of $\sigma_2 = 0.57$. For Sc.3, the mean score was represented as $\mu_3 = 4.155$, with a median score $X_3 = 4$ and a standard deviation of $\sigma_3 = 0.74$. These results suggest that scenario $S2$ had the highest mean (μ_2) and median (X_2), indicating that participants considered it the most plausible of the three scenarios. At this stage, we present the results of the Heat Map, adopting the method previously illustrated. From what emerged, a noticeable association is observed between the high plausibility of occurrence and the final circle obtained. For Sc.1, the primary cluster of points identified is concentrated within the geo-consensus radius, except for a small cluster of 2-3 points outside of the radius. In Sc.2, a strong plausibility of occurrence is located within the geo-consensus radius, helping to provide a more comprehensive view of the area and highlights the selected areas. Finally, the last scenario depicts greater uncertainty among the experts. Although the strong plausibility of occurrence is located inside the final circle, there is a significant cluster of 11 points in the coastal city of Dún Laoghaire. This is why the M_3 measure is close to 20%, as the experts have identified two different plausible areas for extreme events.

Figure 4: Heat Map of the plausibility

4. Concluding remarks and future works

This paper adopted "Real-Time Geo-Spatial Consensus System", a novel web-based open platform to perform a Real-Time Spatial Delphi survey in the climate change context. The scenarios developed are a spatial representation of the experts' judgments, useful for decision-makers in empowering immediate decisions. The experts were able to achieve a significant reduction of the initial circles, greater than 99%, in all final outputs, reaching a high degree of convergence. These results suggest that the Real-Time Geo-Spatial Consensus System is a useful tool for decision-makers in the empowering of immediate decisions. The results of the Heat Map showed a noticeable correlation between the high plausibility of occurrence and the final circle obtained. Nevertheless, since the futures are multiple, these scenarios must be combined with others approaches (e.g., mathematical models, GIS analysis) in order to have an even more broad framework.

In future works, different implementations could be done as different spatial analyses (e.g., clustering) or analysis using text mining for expert comments. With regards to the results obtained, could be combined with mathematical models and submitted to a cohort of experts, part of the local authority or governmental bodies in order to develop strategies for immediate action.

Acknowledgements The work carried out in this paper was supported by the project SCORE which has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement No 101003534.

Stocks price forecasts using Stochastic Differential Equations: an empirical assessment

Dario Frisardi[a] and Matteo Spuri[a,b]

Abstract

In this analysis we investigated the reliability of Stochastic Differential Equations (SDE) in forecasting stock prices on a short time period in a simplified framework. Four different SDE models were used, each applied on stocks of companies listed on NASDAQ and validated in each month between July 2022 and January 2023. Both the coverage of the confidence intervals estimates and the reliability of the average behaviour estimates were checked. Results show an overall good reliability for stocks with a strong expected percentage increase (above 3%).

Keywords: Stochastic Differential Equations, Stochastic Processes, Forecasting, Finance

1. Introduction

Stochastic Differential Equations (SDE) models have a variety of applications and can be used in the study of many phenomena concerning different fields of science (e.g. epidemiology, geology, physics, mechanics) [3, 4, 5]. In particular, SDEs, as well as stochastic processes, are widely used for estimating and forecasting stock price trends.

Given the intrinsic uncertainty of such phenomena, progressively more complex models were developed in order to improve the estimation while accounting for several layers of variability (i.e. considering the interaction between different stocks). As a downside, their use has become increasingly complex as well.

Different papers showed how stochastic processes might yield accurate results also in much more simpler environments [8, 11], though this approach is not so well explored as of recent literature. Moreover, existing works focuses much more on intervals coverage without taking into account the trend forecasts. The goal of this study is to assess the predictive reliability in the short run of simpler models, in which each stock is evaluated individually. This was achieved by adapting different stochastic differential equations to the stock price trends. In particular, we focus on stocks with higher expected percentage increase, that was set as an expected increase of at least 3%.

The paper is structured as follows: Section 2 introduces the theoretical framework of this work, focusing on a few selected processes for stock estimation and forecasting; Section 3 reports the application and results of this procedure and Section 4 concludes.

2. Stochastic Differential Equation models for Finance

We considered four interrelated SDE models with a progressively increasing degree of complexity, thus assessing whether this leads to an improvement in the predictions. Moreover, SDE models were also chosen based on existing literature results. The four SDE models are the following:

Geometric Brownian Motion

The differential equation of Geometric Brownian Motion (GBM) is defined as follows:

$$\mathrm{d}X_t = \mu X_t \mathrm{d}t + \sigma X_t \mathrm{d}W_t \tag{1}$$

This stochastic process can be used to study the percentage increase in invested capital $\frac{\Delta S_t}{S_t}$, which is equal to the sum of a deterministic trend and stochastic fluctuations. This process is broadly used in studying and forecasting stocks price trends [9].

Ornestein-Uhlenbeck process

The Ornestein-Uhlenbeck process (OR-UH) is defined as:

$$\begin{cases} \mathrm{d}X_t = \theta(\mu - X_t)\mathrm{d}t + \sigma \mathrm{d}W_t \\ X_0 = x_0 \end{cases} \tag{2}$$

where: μ is the long-term mean; θ is the reversion speed, that is to say the tendency to fluctuate around μ (*mean reversion*); σ is the volatility term.

Cox-Ingersoll-Ross model

The Cox-Ingersoll-Ross (CIR) [1] model is defined as it follows:

$$\mathrm{d}X_t = r(\theta - X_t)\mathrm{d}t + \sigma\sqrt{X_t}\mathrm{d}W_t \tag{3}$$

This process is by construction non-negative ($X_t \geq 0 \ \forall t$) and it can be derived as the square of a OR-UH process. The r parameter corresponds to the speed of convergence of the long-term mean, while σ corresponds to the volatility.

Chan-Karolyi-Longstaff-Sanders process

The Chan-Karolyi-Longstaff-Sanders process (CKLS) [2] is defined as it follows:

$$\mathrm{d}X_t = (\theta_1 + \theta_2 X_t)\mathrm{d}t + \theta_3 X_t^{\theta_4}\mathrm{d}W_t \tag{4}$$

This process can be seen as a generalization of other stochastic processes: it corresponds to a family of stochastic processes that, for given values of the parameter, can lead to the reproduction of different behaviors.

For example, if $\theta_4 = 0$ it corresponds to a OR-UH process, while if $\theta_4 = \frac{1}{2}$ it corresponds to a CIR model and if $\theta_4 = 1$ with $\theta_1 = 0$ it returns to a GBM. [7]

The first two parameters of the CKLS process ($\alpha = (\theta_1, \theta_2)$) represent the long-term mean and the speed of convergence, while the second pair ($\beta = (\theta_3, \theta_4)$) indicate volatility and the dependence of the process on X_t, respectively.

3. Research Methods and Results

We evaluated the prediction abilities of the different SDE models described in Section 2 on the daily stocks pricing of companies listed on NASDAQ. In particular, we selected the first 750 companies by market cap. Data were retrieved through `quantmod` R package [12]. In order to have multiple periods of validation of this procedure, we used observation up to the first Friday of each of the months between July 2022 and January 2023. For each of the selected stocks, the four SDE models were adapted, deriving the parameter estimates through the maximization of the quasi-likelihood using the `yuima` R package[6].

Quasi-maximum likelihood (QML) method consists in the maximization of an approximation of the density function given that the true one is unknown (or infeasible)[13]. This allows to take into account

different properties of the parameter distribution, that might not be considered using methods such as the least squares estimation. QML estimator (QMLE), under mild assumptions, is proved to be consistent and asymptotically normal, thus granting the required properties of an estimator. In formula, it is possible to define the QMLE as:

$$\hat{\theta} = \arg\max_{\theta \in \Theta} \hat{\ell}_n \left(\mathbf{X}_n; \theta \right) \tag{5}$$

where $\hat{\ell}_n$ is the *quasi-log-likelihood function*, a function that approximate the true log-likelihood function. The quasi-log-likelihood function is, in general, a nonlinear function of θ, so its maximization has to be computed numerically using nonlinear optimization algorithms.

Forecasts were simulated on the 20 days following the last date of observation. We estimated both the empirical 90% confidence intervals and the average daily values through a bootstrap approach, simulating 10^4 forecasts.

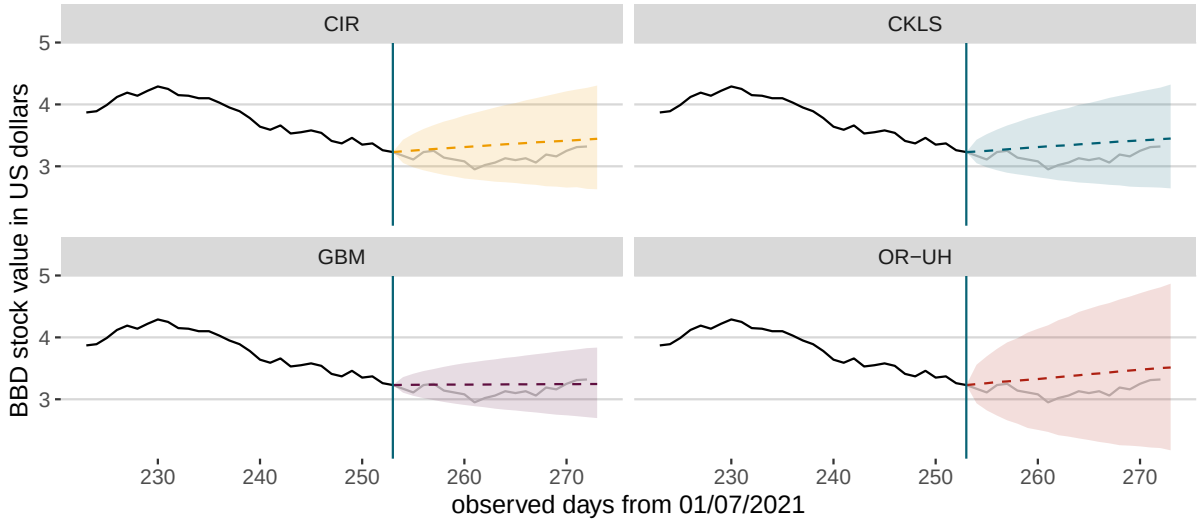

Figure 1: Forecast of average value and confidence intervals for BBD stock in July 2022.

Figure 1 shows forecast of the average daily values and confidence intervals of all four SDE models for BBD (Banco Bradesco SA) stock in July 2022. Results on BBD are reported as an explanatory example given that it is the stock with the highest forecasted increase in July 2022 concerning the CKLS model. Observation after the blue vertical line where not used in the estimation process and were used only in the following step to compute the confidence interval coverage and the average trend reliability.

For each stock we computed the expected increase as the percentage difference between the 20^{th} day forecast average value and the last observed value. We then selected stocks with an expected percentage increase of at least 3%, in order to evaluate the forecasts for stocks with a marked expected increase. Figure 2 shows the expected percentage increase of each stock in July 2022 with the CKLS process. The one selected by such method are highlighted in the green area.

On these selected stocks, we then evaluated the coverage of the empirical confidence interval, both on the first 10 days and on all the 20 predicted days. Coverage percentages are computed as the percentage of observation lying in the confidence interval region. Each model was evaluated independently.

Results, reported in Table 1, show a high coverage percentage for all four SDE models both on the 10 days forecast and the 20 days forecast (results are based on the aggregate of each month of analysis). The lowest coverage percentages, nonetheless above 87%, are those with CIR's forecasts, while GBM and OR-UH models have achieved the highest ones.

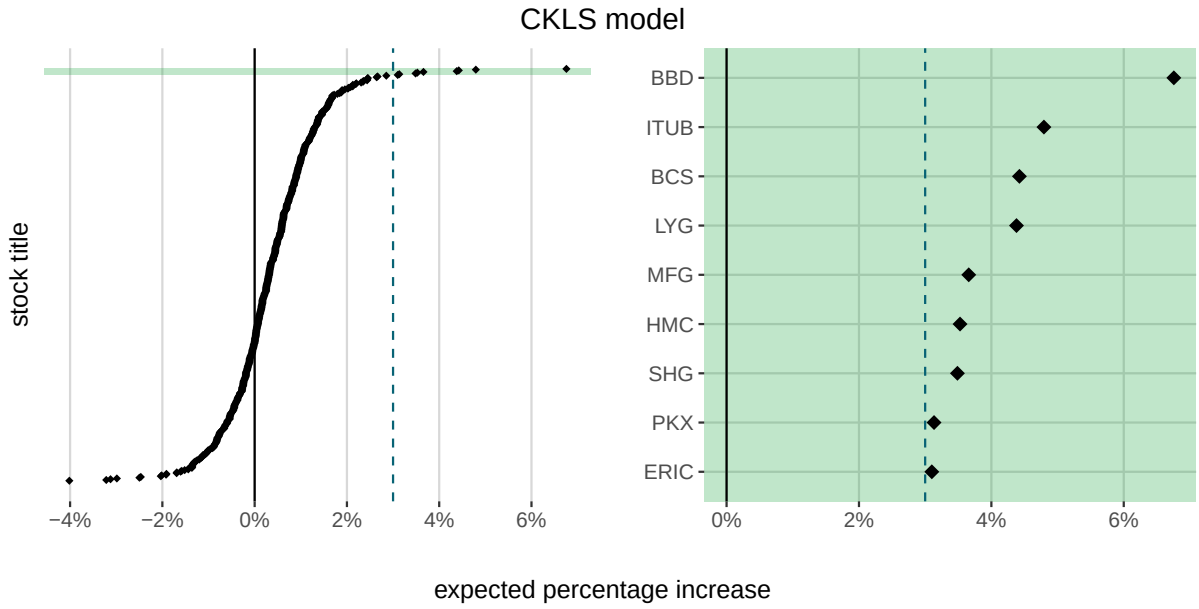

Figure 2: Expected percentage increase and selected titles with CKLS model in July 2022.

Models	20 days coverage (%)	10 days coverage (%)
CIR	87.74	89.68
CKLS	88.68	90.36
GBM	92.94	92.16
OR-UH	95.71	95.48

Table 1: Coverage percentage of the 90% empirical confidence intervals for each process of the 20 days and 10 days forecast.

Then we checked the reliability of the percentage increase estimates. For each stock and each month, we estimated an average of the percentage increase fitting a linear regression on the data in the 20 days following the last observed value used by the process, with the following formula:

$$y_t - y_0 = \beta \cdot t \tag{6}$$

where y_0 is the last observed value and y_t is the stock observed value t days after y_0. It is important to stress that this is not regarded as the true underlying model, but is just a synthetic estimate of the average increase of the process in the 20 following days. Then we derived, for each stock, the expected value 20 days after the last observation and computed the percentage increase.

Plot in Figure 3 reports the expected increase of each stock (on the x-axis) with respect to the actual observed percentage increase (y-axis). We then fitted also a linear regression to highlight whether the model were actually able to predict correctly the increasing trend for each of the four models implemented. As we can see, there is a noticeable correlation between prediction and observations, thus implying that models are predicting correctly, most of the times, the trend of the stocks.

4. Conclusions

In this study we assessed the predictive reliability of Stochastic Differential Equations applied to stocks price. We mainly focused on stocks with strong expected percentage increase and on the short term

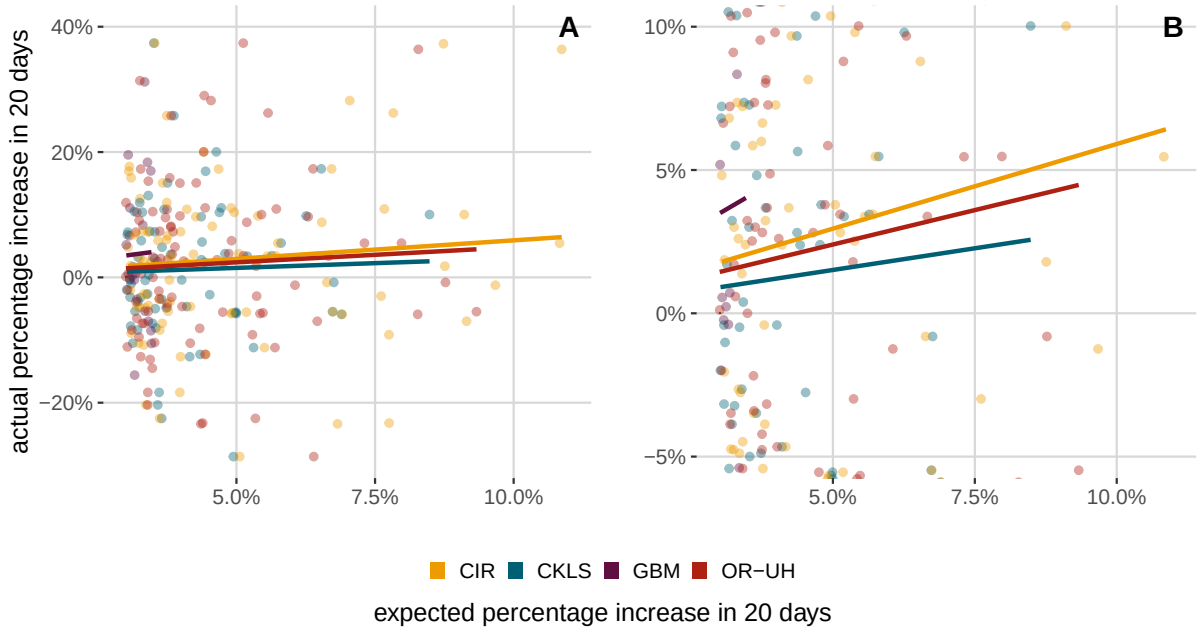

Figure 3: Expected vs. actual percentage increase for each combination of stock, month and model. Complete graph in panel **A** and zoomed graph in panel **B**.

predictions. We developed this analysis in a simplified and feasible framework, selecting four different models (Section 2) applied to each stock independently.

Results show how these SDE models are reliable from a predictive stand point and that are able to capture effectively the increasing trend on a short term analysis. These results are much more impressive if we consider that each stock is analysed individually, without accounting for possible interactions with other ones.

Confidence intervals coverage is very high both for 10 days and 20 days forecasts. It is also noticeable the correlation between the expected and actual percentage increase, as highlighted in Figure 3. Lastly, it was possible to notice how more complex models did not imply a noticeable improvement in the results.

Further developments of this analysis might be the improvement of such predictions by averaging through the different selected models, thus keeping a feasible framework. It could also be useful to take into account other types of stochastic differential equations. Another possible development that might be introduced is to account also for the interaction between different stocks, while applying a penalization to reduce the dimensionality of the adjacency matrix and, thus, of the parameters[10].

The Added-Worker Effect within Italian Households

Donata Favaro[a], Anna Giraldo[b]

Abstract

In this article, we study the relationship between female and male labour supply within Italian households. In particular, by focusing on the relationship between male transitions from employment to unemployment and—at the same time—female partner transitions from labour market inactivity to activity, we evaluate the Added-Worker Effect in Italy at the household level. The analysis is carried out over a long period of time—between 2004 and 2019—on data from the Italian Labour Force Survey (ILFS). To identify the Added-Worker Effect, we adopt a differences-in-differences methodology. By exploiting the richness of information contained in the ILFS data on unemployment status and unemployment risk, we were able to evaluate different "dimensions" of the Added-Worker Effect.

Keywords: household labour supply, differences-in-differences, female labour market participation

1. Introduction

The aim of the present article is to study the relationship between female and male labour supply within Italian households. In particular, we evaluate whether an Added-Worker Effect (AWE) exists in Italy, focusing on the transition of women from labour market inactivity to unemployment when their male partners move from employment to unemployment.

The literature on the topic goes back to the first contributions of Humphrey (1940) and Woytinsky (1940) and the empirical studies on the Added-Worker Effect (AWE) by Mincer (1962), Heckman and Macurdy (1980), Lundberg (1985). The AWE has been revived with the recent economic crisis. The latest contributions seem to agree much more on the existence of an AWE. Gong (2011), focusing on Australia, found a significant AWE in terms of increased full-time employment and working hours. Bredtmann et al. (2014) investigated the AWE across the European countries (28 countries) in the period 2004-2011 using the European Union Statistics on Income and Living Conditions survey (EU-SILC) and showed that an AWE exists, both at the extensive and at the intensive margin of labour supply. Hardoy and Schøne (2014) found no support for the AWE in Norway, although the AWE was detected in some subsamples. Starr (2014) found, for the USA, that employment rates of women whose husbands were non-employed rose significantly during the recession. Ayhan (2018) showed that the probability of participation in the labour force of Turkish women increases by 15-28% in response to their husband's unemployment. As to the Italian case, facts show that during the recent recession female employment in Italy has increased and has partially counterbalanced the increase in male unemployment (Istat, 2013). According to data from the World Bank the ratio of female to male participation rate increased in Italy over the period 2010-2020. The existing empirical analyses have already provided some evidence of this counter-cyclical trend in female employment compared to the reduction in male employment. Ghignoni and Verashchagina (2016) found that an AWE exists, even if only in cases of serious hardship. More recently, Baldini et al. (2018), studying Italy in the years 2004-2014 using EU-SILC, found a strong and robust evidence that households hit by an employment shock do respond by increasing labor supply. Then, they documented an AWE effect in Italy that affects not only wives but also

teenage children.

Our study evaluates the AWE in Italy during a long period of time—2004 to 2019—by employing the Italian Labour Force Survey (ILFS), a rotating panel provided by the Italian Statistical Institute (Istat). To identify AWE, we employ a differences-in-differences methodology (DD).

2. Data and methodology

Our study evaluates the AWE in Italy over a long period of time—between 2004 and 2019—by employing the ILFS, a rotating panel provided by the Istat. The longitudinal data of the ILFS observe individuals across couples of years (t_0, t_1): in the quarter of entrance in the panel, in the subsequent one (first two quarters of observation), and in the 5th and 6th quarter. In each quarter, new individuals enter the survey, for a share of one fourth of the total sample. The available data are from 2004-05 to 2018-19. Unfortunately, until 2012 Istat only makes available the panel data related to the first quarter of each year. Thus, for reasons of balance and comparability between samples, we carried out our analysis on the first quarter only. This means that our database is made by 15 panels of individuals observed in the first quarter of year t_0 and in the first quarter of year t_1.

Our analysis focuses on couples—married or cohabiting—with or without children, with partners not retired and not unable to work, in the age range 25-54. To our purpose, we focus on households with unchanged composition in the two occasions (t_0 and t_1). It is worth mentioning that the original longitudinal data are individual panels without information on the marital status and the relationships within the household. Thanks to the availability of a common household identifier and on the basis of individual characteristics, family relationships were reconstructed.

To identify AWE, we employ a differences-in-differences methodology (DD). Our first definition of treated women includes those women whose partners became unemployed between t_0 and t_1. Then, by exploiting the richness of the ILFS, we defined a broader group of treated, by including also those men who moved from employment to forms of job protection and those who experienced a reduction in activity or lost jobs other than the main one between t_0 and t_1. This broader definition of treatment, which is new in the literature, allowed us to consider situations that might reveal an increased risk of losing one's job or a reduction in the available income, which may affect the decision of female partners to enter the labour market.

AWE occurs when the probability of changing employment status from inactive to unemployed or employed is significantly different between treated and untreated women. Then, the equation we estimated to detect AWE is as follows[1]:

$$ES_{it} = \beta_0 + \beta_1 D_t + \beta_2 T_i + \beta_3 T_i D_t + \beta_4 X_{it_0} + \varepsilon_{it} \quad (1)$$

where ES_{it} is the employment status of female i at time t. D_t is a dummy with value equal to 0 in t_0 and 1 in t_1. T_i is a dummy that captures whether the woman is treated or not (1 if treated, 0 if not). $D_t T_i$ is our variable of interest: the parameter β_3 captures the effect of being treated, compared to not being treated, on the change of employment status of females. X_{it_0} includes several covariates, all evaluated at t_0. Among the covariates, we include: cultural proxies (female age cohort and male nationality), female educational level, male educational level, male type of job, male sector of activity, number of children, number of children who work, number of children NEET, number of children under 15 years old and dummies that capture male unemployment risk.

Equation 1 is estimated under different specifications of the treatment (T_i) and the outcome (ES_{it}).[2] The first treatment we consider is the partner's transition from employed to unemployed. In this case, T_i assumes value zero if the man is employed and 1 if he is unemployed. We then consider other categories of the man's employment status to define the treatment. The aim here is to analyse how the emergence of the partner's risk of losing his job or a change in his economic situation can influence the woman's employment choices. To capture the emergence of a risk in the partner's employment stability, we have considered men's transitions (between t_0 and t_1) from employment to CIG. CIG stands for Cassa Integrazione Guadagni (Wages Guarantee Fund) and is an institution under Italian law consisting of an economic benefit, provided by the Italian Security System, for workers suspended from the obligation to perform work or working reduced hours. CIG

[1] We follow Angrist and Pischke (2009) and employ a linear model.

[2] In the next section, we will provide a precise description of all the definitions we have adopted for *ES* and *T*.

is a cash grant the Italian Security System pays to workers when companies are in temporary difficulty. In order to capture the effects of a worsening in the economic condition of the family due to a reduction in men's work, we consider men's transitions from working full hours in t_0 to reduced hours in t_1 and men losing jobs other than the main one between the two years. To complete the analysis, we of course also consider male transitions between the two years from employment to non-employment.

With regard to women's employment transitions, the first objective is to evaluate the AWE in its traditional version, assessing the transition of women from inactive to unemployed. In this case, the outcome variable ES_{it} takes a value of 1 if the woman is unemployed, and 0 if she is out of the labour force. After that, we use further specifications of the outcome variable to capture both different 'degrees' of transition to activity and the effect on labour supply. We evaluate the transition from inactivity not searching to inactivity searching or unemployment by assigning the outcome variable the value zero if the woman is inactive and not searching for work and the value 1 if the woman is inactive but looking for work, or unemployed. Then, we assess the transition from inactivity to unemployment or employment by assigning the outcome variable value 1 if the woman is either unemployed or employed. This specification allows us to detect the extensive margin effect of treatment. Differently, to evaluate the intensive margin effect of treatment, that is the effect on labour supply, we consider only women who already work and observe the transition from part-time to full-time. In this case, the outcome variable ES_{it} takes value zero if the woman works part-time and value 1 if she has a full-time job.

3. Results

In this Section, we discuss the results of the estimates of Equation 1 for the different work transitions of women and their partners (see Table 1). Specifically, *T1* is the treatment variable that captures men's transitions from employment towards unemployment and takes on a value of 1 if the man becomes unemployed and a value of 0 if he remains employed. *T2* captures men's transitions from employment to extended CIG or transitions to reduced activity, including job losses other than their primary job. *T3* relates to men's transitions from employment to non-employment—either unemployment or inactivity.

Table 1: The AWE with different treatments and outcomes

Classes	T1	T2	T3
ES1	0.149***	0.023*	0.060***
ES2	0.123***	0.020	0.051***
ES3	0.138***	0.020	0.093***
ES4	0.038***	0.027***	0.028***
ES5	0.014	0.051***	0.023

[a] T1: men's transitions from employment to unemployment; T2: men's transitions from employment to CIG /reduced activity/lost jobs other than the main; T3: men's transitions from employment to non-employment. ES1: females' transitions from inactivity to unemployment; ES2: females' transitions from inactivity to unemployment or employment; ES3: females' transitions from inactivity "not searching" to inactivity "searching" or unemployment; ES4: females' transitions from employment "not wishing more hours" to employment "wishing more hours of work"; ES5: females' transitions from part time employment to full time employment.

For women, we adopted different definitions of the dependent variable *ES*, so as to capture different 'degrees' of exit from inactivity and changes in preferences for work involvement. *ES1* is the dependent variable definition that captures women's transitions from inactivity to unemployment; *ES1* takes on a value of 0 if women are inactive in either period and a value of 1 if they are unemployed in t_1. *ES2* evaluates transitions from inactivity to the labour force - either unemployed of employed; in this case, the dependent variable assumes a value of 1 in period t_1 if the woman enters the labour force between the two periods. *ES3* captures the intention to work and the change of the status from 'not searching' to 'searching' for work. Thus, the sample of women is restricted to the only ones who are inactive and 'not searching' for work in period t_0; then, the dependent variable *ES* assumes a value of 1 if the woman is 'searching' for work in period t_1 and a value of 0 otherwise, either in period t_0 or t_1. *ES4* assesses preferences for greater work involvement, i.e. more working hours; in this case, the sample consists of women who are already employed in t_0 and who do not wish more hours of work. The dependent variable takes the value 1 in period t_1 if women state that they wish more hours of work. We also considered a further specification to assess preferences for greater work

involvement. In this case, we selected only women with a part-time job in period t_0 and looked at the transition from part-time to full-time work between the two years; in this specification the variable *ES5* takes the value of 1 in period t_1 if women are employed full-time in that period and the value of 0 otherwise.

The results show that an AWE exists within Italian families. The classical definition of AWE, measured by women's transitions from inactivity to unemployment as their partners move from employment to unemployment, compared to women whose partners do not move to unemployment (ES1-T1), is significant and positive. The effect is also positive when the treated group includes only families whose men are "at risk of unemployment" (ES1-T2), meaning that females react to changes in the family economic situation. Interestingly, working women are willing to work more hours (ES4) when the partner loses his job or he is at risk of losing it; this effect is significant for all treatment types. However, the transition from part-time to full-time is weakly significant, only for T2 transition. Possible explanations for this result could be the existence of labour market rigidities in the transformation of part-time work into full-time work or constraints on the supply side of the labour market (due to care activities that limit women's working hours).

Acknowledgments: the authors acknowledge the financial support provided by the PRIN project «The Great Demographic Recession – GDR» financed by the Italian MIUR under the PRIN 2017 research, grant agreement n. 2017W5B55Y-003 (PI: Daniele Vignoli).

Abstract

In this work we present some preliminary results on the analysis of data collected by BreastScreen Norway to estimate the natural history of the disease. Learning about the disease occurrence and evolution is crucial to identify the optimal screening schedule, with respect to the age range of the invited women and the lag between successive examinations. The model is a multi-state semi-Markov model with a cure rate structure, where the main quantities of interest are the probability of developing the disease, the age at start of asymptomatic detectability of the disease and the sojourn time, i.e. the time interval during which the disease is screen-detectable but not yet symptomatic.

Keywords: approximate Bayesian computation (ABC), breast cancer, cure rate model, disease history, multi-state model

1. Introduction

Cancer screening is defined as the examination of asymptomatic subjects in order to detect tumours before they become evident because of symptoms (1). In the past decades screening programs have been implemented in many countries, therefore making randomized trials difficult to perform and those performed difficult to evaluate due to changes in screening techniques and diagnostic tools. As a consequence, researchers can only rely on observational data collected administratively to learn about the natural history of the disease and to identify the optimal screening policy (in terms of the age range of the women invited, and lag between consecutive examinations), and risk-based tailoring of their schedules.

In this work, we apply a multi-state semi-Markov model proposed in (2) to the breast cancer screening data from Norway (BreastScreen Norway). This model aims at reconstructing the latent process of occurrence and development of breast cancer.

All times are measured from birth of the woman. For those women who do experience the disease, we assume that after the onset of the disease there is a time interval in which not even a screening examination is able to detect the presence of the disease (see Figure 1). The two main quantities of interest are the time to the start of asymptomatic detectability (through screening) of the disease (which we denote by T_A) and the time to the symptomatic detection of the disease (denoted by T_S). Between

time T_A and T_S the tumour can only be detected through screening (the "sojourn time," denoted by Δ), while at time T_S the disease becomes evident because of symptoms. In other words we have $T_S = T_A + \Delta$. Further, we assume that symptomatic detection occurs exactly when the first symptoms appear.

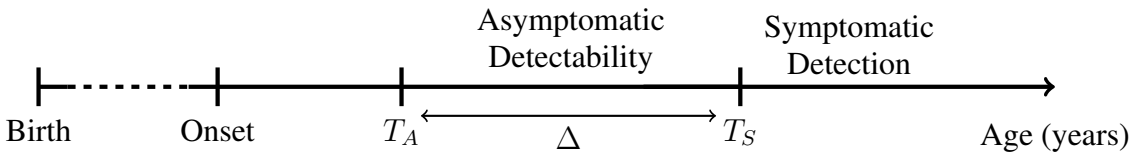

Figure 1: A graphical representation of the natural history from onset until detectability of the disease.

While studying the latent evolution of the disease, we are also interested in studying the probability of insurgence of the disease in a woman's lifetime. For this purpose, the model presents a cure rate structure, i.e. only a proportion of women, which we call the "susceptible proportion", denoted by p with $p \in (0, 1)$ will experience the event of developing breast cancer. Note that these should be considered to be latent cases and not necessarily observed cases.

Given by the limited follow-up, the lag between screening examinations and the impossibility to observe T_S when the tumour is screen-detected, this problem presents a complex missing data structure, which makes the observed data likelihood (3) of the model complicated if not intractable.

2. The Norwegian breast cancer screening data

Breast cancer screening in Norway was first introduced in 1995 (and became nationwide in 2005) and targets women aged 50-69 for biennial mammographic screening. We focus on a cohort of women born between 1948 and 1952 without any breast cancer diagnoses before entering the screening program at age 50 (with a small variability due to the invitations rounds). For these women we have information on their screening invitations, attendance and result for each examination, possible date of breast cancer diagnosis (DCIS or invasive), type of detection (in-screening or symptomatic), some additional tumour characteristics, as well as on a number of covariates collected through a questionnaire.

The screening invitations stop at age 69 but the breast cancer diagnoses are updated from the Cancer Registry until May 2022. Therefore the lentgh of follow-up is between 20 and 24 years. We focus only on invasive cancers and on three binary covariates, which divide the women in eight groups as shown in Table 1: having had at least one birth X_1 (0=no, 1=yes); level of education X_2 (0=low, 1=high); and family history of breast cancer X_3 (0=no, 1=yes). These are indeed the three non-race main risk factors for breast cancer (among women with no previous history of the disease) (4).

Table 1 also shows the sample size, the proportion of observed detections, the proportion of symptomatic detections and the mean age at asymptomatic/symptomatic detections for each covariate group.

Group	(x_1, x_2, x_3)	Size	% Dx	% Symp Dx among all Dx	Mean age Asymp Dx	Mean age Symp Dx
1	(0,0,0)	1240	5.2%	27%	63.3	65.6
2	(0,0,1)	351	7.4%	35%	63.1	63.2
3	(0,1,0)	3731	4.9%	39%	62.9	65.3
4	(0,1,1)	1329	9.0%	38%	63.1	64.0
5	(1,0,0)	16241	3.8%	28%	63.8	66.0
6	(1,0,1)	4627	5.7%	36%	64.1	66.2
7	(1,1,0)	39330	4.2%	33%	63.7	65.1
8	(1,1,1)	13252	5.7%	35%	64.0	65.0
Total		80101				

Table 1: Observed outcomes in each covariate group. Ages are measured in years. X_1= at least one child birth (0:No, 1:Yes); X_2=Education level (0:Low, 1:Medium/High); X_3=Family history of breast cancer (0:No, 1:Yes).

3. Model and preliminary results

Recall the three binary covariates described in Section 2: X_1 ="at least one birth," X_2 ="high level of education," and X_3 ="family history of breast cancer," all coded as 0 = No and 1 = Yes. The susceptible proportion is modelled as function of the observed covariates $\boldsymbol{x} = (x_1, x_2, x_3)$ through the logit link:

$$p(\boldsymbol{x}) = \frac{e^{p_0+p_1x_1+p_2x_2+p_3x_3}}{1+e^{p_0+p_1x_1+p_2x_2+p_3x_3}}.$$

For the subjects who will eventually develop the disease, the disease evolution is described through the joint distribution of the couple (T_A, Δ). The model assumes that the mean of T_A depends on the covariates linearly, and that the variance of T_A is constant across covariate groups. The distribution of Δ is defined conditionally on the observed value of T_A, and it may depend on the covariates but only indirectly (see below). The definition of the model for the disease process is as follows:

$$\begin{aligned} T_A \mid \beta_0, ..., \beta_3, \sigma &\sim 100 \cdot \text{Beta}(\alpha,\ \beta); \\ \Delta \mid \{T_A = t_A\}, \lambda_1, \lambda_2, \lambda_3 &\sim \text{Exp}(\lambda_1 \cdot 1(t_A \leq 55) + \lambda_2 \cdot 1(55 < t_A \leq 65) + \lambda_3 \cdot 1(t_A > 65)), \end{aligned}$$

where $E(T_A) = \mu(\boldsymbol{x}) = 100 \cdot \frac{\alpha}{\alpha+\beta} = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \beta_3 x_3$, $\sigma^2 = 100^2 \cdot \frac{\alpha\beta}{(\alpha+\beta)^2(\alpha+\beta+1)}$. This model, called "Rescaled beta + piecewise exponential" model, has been introduced in (2), where it was selected among ten competing models to describe breast cancer natural history. We refer to this reference for additional details on the model, such as the prior distribution for the 12 parameters $(\beta_0, \beta_1, \beta_2, \beta_3, \sigma, \lambda_1, \lambda_2, \lambda_3, p_o, p_1, p_2, p_3)$.

Approximate posterior distributions for the model parameters are obtained via likelihood-free inference. More specifically, relying on approximate Bayesian computation (ABC) allows us to avoid deriving the complex observed data likelihood of the model. Details on the metric function employed to measure the distance between the real and generated data are not shown here, but a complete description, together with a discussion of the advantages and drawbacks of ABC in this setting, can be found in (2). The results presented here are based on 200,000 generated datasets.

Figure 2 shows the boxplots of the posterior distributions for the mean of T_A, $\mu(\boldsymbol{x})$, and for the susceptible proportion $p(\boldsymbol{x})$ across the eight covariate groups. The left panel of Figure 2 highlights that women with at least one child tend to experience breast cancer later than those without children. From the right panel, instead, clearly emerges that having a family history of breast cancer is associated with an increased risk of belonging to the group of the susceptible subjects. Note that the posterior distributions of the p's are shifted toward slightly higher values than expected from previous studies (see e.g. (5)). This is likely due to the difficulties in estimating a weakly identified cure rate model with limited follow-up, i.e. little data at higher ages.

Given the posterior distributions, one can then compute the predictive distributions for the quantities of interest, T_A and Δ (see Figure 3). The median predicted values for T_A vary between 69.2 (in group 4) and 72.5 (in group 6). The standard deviation of T_A is estimated to be around 7.5 years. The predictive distributions for Δ in the three groups defined by the value of T_A have medians 2.4, 4.5 and 0.9 years, respectively. While the first two appear to be in line with what is known by previous studies, the predictive distribution for Δ in the third group does not seem very reliable. Similarly to what was highlighted when commenting the posterior distributions for the p's, this can be probably attributed to the lack of information about T_A for tumours occurring after the age of 65, given that screening examinations stop at age 69 .

4. Conclusions

We have estimated a parametric model to describe the insurgence and the evolution of breast cancer, where the main quantities of interest are the probability of developing the disease (p), the start of asymptomatic detectability of the disease and the time of symptomatic detection (T_A and T_S). Given the estimated latent disease process, it is possible to simulate the effect of different screening schedules, possibly tailored to the individual risk factors, on the number and kind of diagnoses in the populations.

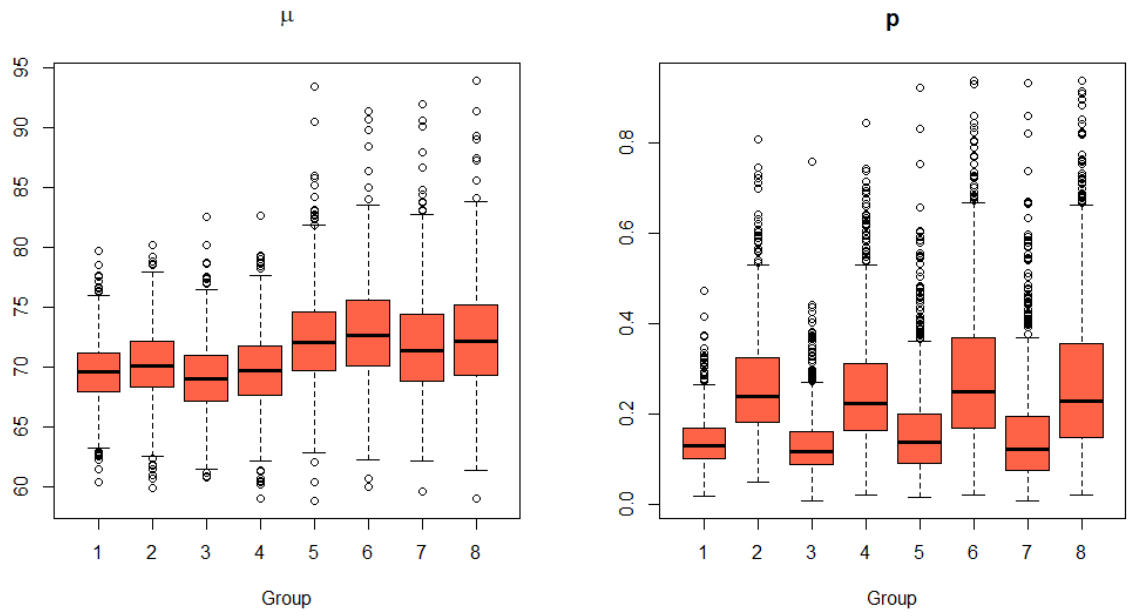

Figure 2: Approximate posterior distributions of the mean age at asymptomatic detectability $\mu(\boldsymbol{x})$ and of the susceptible proportion $\mathrm{p}(\boldsymbol{x})$ across covariate groups.

This work might be extended by including in the model a parameter for the sensitivity of the screening examinations. Indeed, the assumption of a 100% sensitivity, as we made here, corresponds to setting the probability of false negative results equal to zero, which is not realistic (6). Moreover, additional covariates, such as breast density, could be included in the model.

Other interesting analyses could be based on different cohorts of women included in the BreastScreen Norway database, which could confirm the estimated disease process or highlight differences in the occurrence between different generations.

Also, assuming a stable disease population (in which the rate of births and the distribution of ages at tumour onset are constant across calendar time (7)), one could analyse a larger cohort of women at once to exploit the information provided by women at different ages and therefore to obtain a more precise inference. This would however come with a higher computational cost and a longer time needed to perform the ABC simulations.

Future developments of this work will also involve the numerical computation of the observed data likelihood function to perform exact Bayesian inference through MCMC.

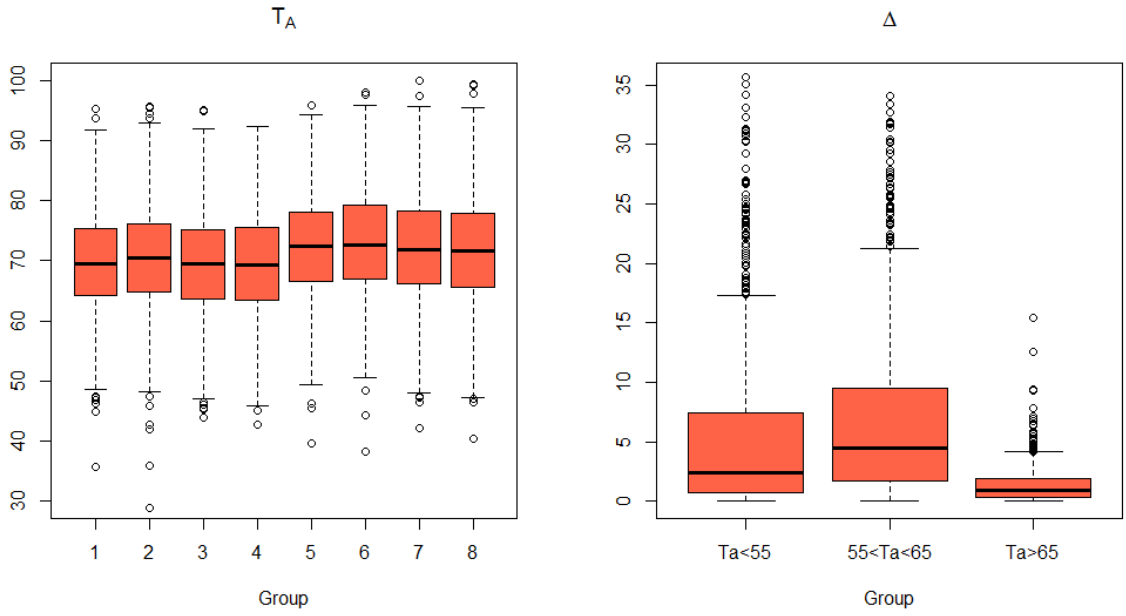

Figure 3: Approximate predictive distributions of the age at asymptomatic detectability T_A and of the sojourn time Δ across covariate groups.

Generalized Bayesian Ensemble Survival Trees: an extension to categorical variables to apply it to real data

Elena Ballante[a,b]

[a]Department of Political and Social Sciences, University of Pavia, Italy;
elena.ballante@unipv.it
[b]BioData Science Unit, IRCCS Mondino Foundation, Pavia, Italy

Abstract

Survival analysis is a common framework between different fields of application. The availability of statistical techiniques that allow to model the data at hands is a foundamental area of research. The problem is especially urgent if we consider the need of analyse small dataset, case that is extremely common in biomedical research.
In this paper, a proper Bayesian bootstrap method for ensemble survival tree models is extended to handle categorical variable, in order to apply to real data. Empirical results are shown in a simulated study that shows the potential of the method in terms of improvement of the performances and stability of results. The application on Amyotrophic Lateral Sclerosis patients shows the advantages of the application of the proposed method in real world problems.

Keywords: Survival analysis, Bootstrap, Bayesian nonparametric learning, ensemble models

1. Introduction

In a lot of different fields we can encounter problems that require the analysis of time-to-event data. This field of statistical analysis is been developed since 17th century, but still lack of the variety of models that characterize regression and classification framework. This problem especially emerge if we consider the availability of computational tools that make it easily applicable.
Moreover, a very common problem especially in biomedical application is the availability of small dataset. The use of models that can handle this kind of data obtaining stable and reliable is extremely important in that field.
The use of resempling methods to improve models is not new also in the framework of the survival analysis, as in bagging methods (1) and random forest model (2).
The most common resempling method (and the one used in applications) is Efron's bootstrap (3), but some methodological work start to apply different bootstrapping approach in bagging models and random forests. Rubin's bootstrap, also called Bayesian bootstrap, was defined in (4) and consider for this kind of model in (5) and (6). A further bootstraping method based on nonparametric Bayesian statistics, called proper Bayesian bootstrap, was defined in (7) and embedded in predictive models in (8) and (9). The models defined were applied in regression and classification problems, whilst none of these was extended to survival framework.
The aim of this paper is to fully develop the model proposed in (10), extending the bootstrap techniques

to handle categorical variable. With this addition, the model is now available for the application to real world problem.
The paper is organized as follow: Section 2. describes the methodological approach and the novelty proposed, Section 3.describes the simulation setting and the results, Section 4.shows an application to a real dataset and Section 5.contains the conclusions.

2. Methodology

The aim of this paper is to extend the proper Bayesian bootstrap bagging tree survival model (10) to manage categorical covariates in order to be able to apply to real data.
As described in more details in (9) and (10), we apply the Proper Bayesian Bootstrap in order to sample from a posterior distribution with Dirichlet distributed weights. The bootstrap resample is generated by a mixture distribution of a prior guess F_0 and the empirical distribution F_n. The weights of the prior will be referred to as w. In this work, each covariate is sampled independently from the others. The new value of the response variable associated to the observations sampled from the prior is generated by an appropriate predictive model. Then, a survival tree model is trained on each of the B bootstrap replicates. The training part of the model described so far is summarized in Algorithm 1.
The prediction step of the algorithm is defined on the basis of (1) and it is explained in Algorithm 2. Observing a new observation $\mathbf{x}_{new}$, the estimated conditional survival function $\hat{S}$ is computed aggregating all the training observation that fall in the same leaves as $\mathbf{x}_{new}$: $\hat{S}_A^B(\cdot|\mathbf{x}_{new}) = \hat{S}_{L_A^B(\mathbf{x}_{new})}(\cdot)$.

GBEST: Generalized Bayesian Ensemble Survival Trees

Input: Training set T
for *b in 1:B* **do**
  Sample $(\mathbf{x}_1^*, y_1^*), ..., (\mathbf{x}_m^*, y_m^*)$ from $(k+n)^{-1}(kF_0 + nF_n)$;
  Draw $\mathbf{w}^b$ from $D(\frac{n+k}{m}, ..., \frac{n+k}{m})$;
  Get $\phi^b = \phi(\mathbf{w}^b)$ running weighted survival tree on the new sample $\mathbf{x}_1^*, ..., \mathbf{x}_m^*$
end

Algorithm 1: Training phase of the GBEST model

Input: trained survival trees, test set T
for *i in 1:nrow(B)* **do**
  Aggregate the observations $(\mathbf{x}_k^*, y_k^*)$ in the leaves where $\mathbf{x}_{test}$ is fallen
  Predict the conditional survival function as $\hat{S}_{L_A^B(\mathbf{x}_{new})}(\cdot)$
end

Algorithm 2: Aggregation and prediction phase of the GBEST model

2.1 Categorical variables

We consider two different approaches for the bootstrap resampling of the categorical variables.
The first and most common approach is described in (11) and in this paper we will referred to it as *empirical* sampling. The prior distribution is estimated as a categorical distribution where each class has an estimated probability of $p_i = \frac{N_i}{N}$, where N_i is the number of observations of that class and N is the total sample size.
The second approach, inspired by oversampling techniques, assigns to each class the same probability $p_i = \frac{1}{n_{class}}$, without making distinction between more and less represented class in the data. This approach will be referred to as *uniform* sampling.

3. Results of the simulated study

In order to show the performances of the proposed method in a controlled setting, a simulation study is performed.
The simulated datasets contain 5 covariates with different balance between categorical and numerical variables. The numerical covariates are simulated as $U(0,1)$, while categorical covariates are sampled with different weights assigned to each categories. Survival times are simulated deploying a Weibull distribution and covariates are associated to the survival time with betas equal to 1. The censorship is fixed to 10% and the sample size is $N = 50$. The number of trees in the GBEST model is set as $B = 100$. The performances are evaluated in terms of integrated Brier score (IBS) in a train-test framework (75% and 25%) and a total number of 100 simulation is performed in order to assess the stability of the results. Mean values and non parametric confidence intervals of the resulting IBSs are presented.

3.1 Different kind of sampling

The influence of two different sampling strategies, as described in Section 2.1, is investigated. The simulated datasets are composed of five variable and only one is dichotomous and unbalanced (the probabilities of each category are 0.25 and 0.75). To stress the results, the $betas$ parameters to generate the survival times are set as 1.5 to the categorical variable and 0.5 for the others. The rest of the setting is analogue of the one described in Section 3. The results are depict in Figure 1.

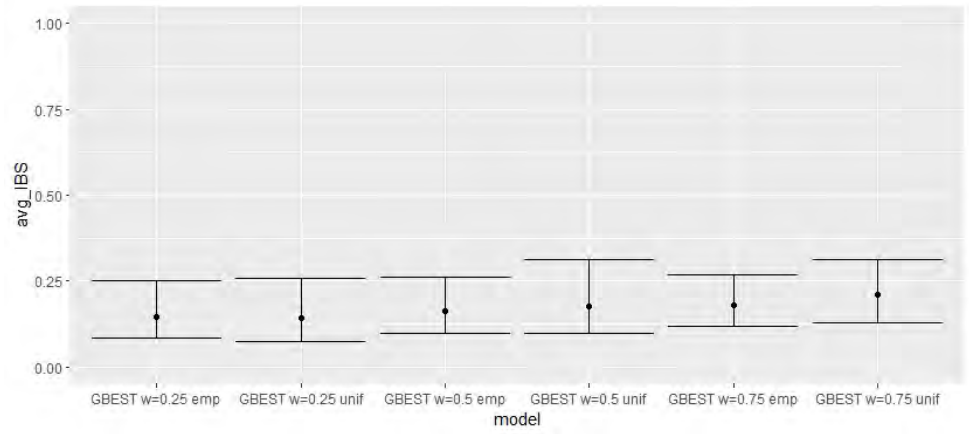

Figure 1: Comparison of mean and non parametric confidence interval of IBS between the two sampling strategies with three different choices of weight

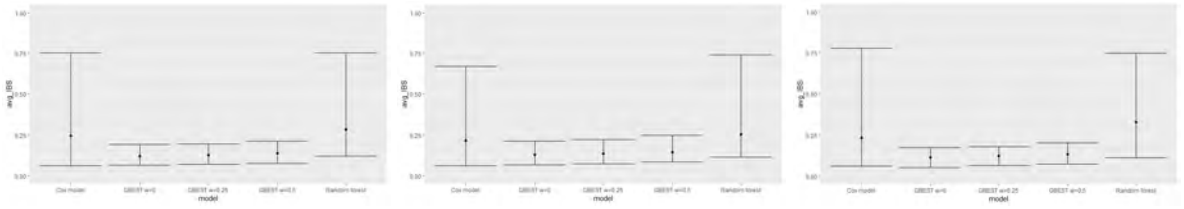
No significant differences between mean IBS values are observed, but a general is showed. The empirical sampling remains stable in terms of length of the confidence interval, instead the uniform sampling shows an increasing variability where the proportion of observation sample from the prior is high (50% and 75%). The empirical sampling is adopted in the next analysis.

3.2 Comparison with literature models

After the sensitivity analysis, the proposed model is compared with the most common models in the survival analysis: the Survival Random Forest (2) and the Cox model (12). In order to obtain more robust results, the analysis are repeated with three different setting of the original dataset.

- First scenario. One categorical variable with 3 balanced levels. The other four variables are generated as $U(0,1)$.
- Second scenario. Three categorical variables. One dichotomous and balanced, one with three balanced levels and one dichotomous and imbalanced ($prob = 0.25, 0.75$). The other variable are generated as $U(0,1)$.

- Third scenario. Five categorical variables. One dichotomous and balanced, one with three balanced levels and three dichotomous and imbalanced variables ($prob = 0.25, 0.75$, $prob = 0.4, 0.6$, $probab = 0.3, 0.7$).



(a) First scenario. (b) Second scenario. (c) Third scenario.

Figure 2: Comparison of mean and non parametric confidence intervals for IBS obtained in cross validation for the 100 simulated datasets in three different scenarios for the proposed model with difference choices of weight and literature models (Random Forest and Cox model)

The GBEST model performs better than the Random Forest and Cox model in all three scenarios, both in terms of averaged error and in terms of stability of the results. The GBEST with $w = 0.5$ seems to introduce a bit of noise with respect to $w = 0.25$ and $w = 0$ but still outperforms the most common survival models.

4. Real data application

To investigate the performances of the proposed method, we show an application to a real world problem in the context of biomedical research.
The data analyzed were collected at IRCCS Mondino Foundation. The predictive power of retinal measurement, coupled with clinical information, is investigated in terms of survival time of Amyotrophic Lateral Sclerosis (ALS) patients.
Retinal Nerve Fiber Layer (RNFL) and Ganglion Cell Layer (GCL) are measured by Optical Coherence Tomography (OCT) in 61 ALS patients.
The variables included in the model are: gender, age at onset, site of onset (bulbar/spinal), Percentage of Forced vital capacity (FVC), total score ALSFRS-r, and the OCT parameters, that are RNFL Right, RNFL Left, GCL Right mean and minimum, GCL Left mean and minimum.
Only patients without missing data are included, for a total number of 41 subjects.
The time to event outcome is represented by the survival time from the exam date and the censorship indicator (1 if the patients is dead, 0 if the subject is still alive at the follow up).
Two different settings are considered, a train-test setting where the test is randomly sample as the 25% of the dataset, and a leave one out cross validation exercise (CV). The proposed method (GBEST) with different choices of weights are compared with the most common models in survival analysis, Random Forest (RF) and Cox model (Cox). The results are reported in Table 1.

Performance	GBEST $w = 0$	GBEST $w = 0.25$	GBEST $w = 0.5$	RF	Cox
IBS	0.0859	0.0653	0.0563	0.1120	0.1621
CV IBS	0.1264	0.1223	0.1273	0.1293	0.1720

Table 1: Results in terms of Integrated Brier Score (IBS) on the OCT data.

The results show that our proposed method performs better in terms of integrated Brier score on the data at hands than classical methods. The major differences can be observed with respect to the Cox model, that performs worse in both settings. Random forest shows slightly worse results than GBEST in the cross validation setting, and the difference is more evident in the train-test setting. Regarding the

different weights assigned to the prior distribution, the best results in both settings are obtained for a weight $w = 0.25$ assigned to the prior, that corresponds to a 25% of the observation sampled from the prior and a 75% from the training data for each bootstrap replicate.

5. Conclusion

In this paper, a proper Bayesian bootstrap method for ensemble survival tree models is extended to handle categorical variable, in order to apply to real data. The model proposed has been called Generalized Bayesian Ensemble Survival Trees (GBEST).
Empirical results are shown in a simulated study that illustrates the potential of the method in terms of improvement of the performances and stability of results. The application on Amyotrophic Lateral Sclerosis patients shows the advantages of the application of the proposed method in real world problems.
Further developments include the embedding of covariance structure in the sampling process from prior distribution and the application of non parametric models to label the new generated observations.
The R functions developed for this work will be provided in the Github repository: eballante/pBBBaggTrees.

Joint modelling of hospitalizations and survival in Heart Failure patients: a discrete non parametric frailty approach

Masci Chiara[a], Spreafico Marta[b], and Ieva Francesca [a,c]

Abstract

In this work, we propose a novel joint frailty model assuming bivariate discretely-distributed non-parametric frailties, with an unknown finite number of mass points. This approach allows to detect a latent structure among subjects, clustering them in sub-populations where individuals are characterized by a common frailty value. Our method can be interpreted as an unsupervised classification tool and motivates further investigation into the reasons for similarities within the clustered subjects and dissimilarities across the clusters. This work is motivated by a study of patients with Heart Failure (HF) undergoing ACE inhibitors treatment in the Lombardia region of Italy. Recurrent events of interest are hospitalizations due to HF and terminal event is death for any cause.

Keywords: Joint models; Discrete frailties; Recurrent events; EM algorithm; Heart Failure patients.

1. Introduction

Recurrent or *repeated events* are common in many clinical and biomedical studies, as patients usually experience the same event multiple times. In the recurrent event framework, classic survival approaches are not suitable as they discard the correlation between subsequent events in the same subject. A wide literature about recurrent events modelling has hence flourished in past years [2,8]. Among others, *frailty models* handle repeated episodes by introducing a random effect which takes a common value for each group of dependent observations and can be used to describe excess risk or frailty of different individuals [2,8]. The time span of an individual's recurrent process could also depend on another terminal event, e.g., the end of the study, loss to follow-up, or death. To jointly analyse both recurrent and terminal processes over time, joint frailty models can be adopted [5,6]. Joint frailty models capture both the correlation among repeated events and the dependence between repeated and terminal processes by incorporating random effects in the two hazard functions. Last advances in this field regard the work proposed in [6], where the authors considered joint models by conditioning on a shared frailty that does not apply equivalently for the two hazard functions and the one proposed in [5], where a joint frailty model with multivariate Gaussian random effects is developed. In contrast to traditional joint shared-frailty models, the authors in [5] yield a more general model where two sets of random effects are used to account for intra-subject correlation of multivariate recurrent event times and individual differences in

mortality hazard rate. Their method allows for a positive or negative association between recurrent and terminal events, distinguishing the origin of their dependence.

We insert within this literature by proposing a joint frailty model with discrete random effects. In the last few decades, a branch of the literature is focusing on the treatment of discretely-distributed random effects [3,4]. Most of the work in this direction has been done in the context of mixed-effects regression models for continuous responses (both univariate and multivariate) and other types of responses in the exponential family. Recently, this approach has been extended in the survival analysis framework, by the introduction of discretely-distributed frailties [1]. The main advantage of modelling discrete random-effects regards the new type of treatment and interpretation of the units at the highest level of the hierarchy, that are clustered into latent subpopulations. When considering events nested within patients or patients nested within health providers, modelling discrete frailties allows to cluster patients or health providers, identifying, for example, long/short-term survivors or more/less successful health providers.

Motivated by the advantages of a discretely-distributed frailty approach in practice, in this article we propose an original extension of the general joint model in [5] to the discrete-frailty framework. In addition to handling heterogeneous susceptibility to the risk and informative censoring, this novel approach can detect a latent structure among subjects, grouping them in sub-populations where individuals are characterized by a common frailty value. Along with the model, we propose an estimation routine via Expectation-Maximization algorithm.

The approach we develop is motivated by a study on patients with Heart Failure (HF) in the Lombardia region of Italy. We face the problem of joint modelling of hospitalizations and survival of patients affected by Heart Failure, with a focus on the effect that a pharmacological treatment based on ACE Inhibitors has on these two processes. The course of HF disease is usually characterized by recurrent hospital admissions [7]. Re-hospitalization events usually herald a substantial worsening of patient's survival prognosis and are terminated by death. The application of our novel approach to this context is hence of interest.

2. ACE Inhibitors Dataset

We consider data coming from an administrative database of Regione Lombardia, which records clinical courses and pharmacological prescriptions of subjects affected by Heart Failure. We focus on patients who undergo an ACE inhibitors treatment in the period from January 1st, 2006 to December 31st, 2012. For each patient, the index date coincides with the discharge after the first hospitalization due to Heart Failure. We adopt a *gap times* timescale, i.e. each patients clinical history is declined in repeated observations, characterized by a time-to-event variable **GapEvent** which expresses the days elapsed from the previous patient's hospitalization to the next one. The last gap time of each patient expresses the time elapsed from the last known hospitalization to the terminal event, which may be death or censoring. The nature of each event is kept track of through two dummy variables, respectively **Event** and **Death**.

To assess the effect of the considered ACE inhibitors treatment on survival and hospitalizations, we design a time dependent binary classifier for adherent subjects (variable **Adherent**). At each event in a patient's history, we compute the proportion of days covered by prescriptions of ACE inhibitors since the patient index date; then, if this proportion exceeds a threshold of 80% the patient is considered adherent to treatment, otherwise not. The other three variables we consider in the model are the patient gender (**Sex**) and time-dependent variables, **AgeEvent** and **Comorbidity**, which respectively indicate the age and the number of known comorbidities of a patient at the beginning of the corresponding gap time.

Table **??** reports as an example the data table of a patient in the ACE inhibitors dataset.

3. Methods

In the proposed joint model with discrete frailty, we express the hospitalization and death hazards for each patient $i, i = 1, ...N$, as follows

ID	Sex	Adherent	AgeEvent	Comorbidity	GapEvent	Event	Death
10003004	F	0	75	5	229	1	
10003004	F	1	75	6	131	1	
10003004	F	0	76	6	168	1	
10003004	F	0	77	7	353	1	
10003004	F	1	79	7	1,153	0	1

Table 1: Data table of patient 10003004.

$$\begin{cases} h_i^R(t|u_i, \boldsymbol{x}_i^R(t)) = h_0^R(t) \exp\{u_i + \boldsymbol{\beta}^T \boldsymbol{x}_i^R(t)\} \\ h_i^D(t|v_i, \boldsymbol{x}_i^D(t)) = h_0^D(t) \exp\{v_i + \boldsymbol{\gamma}^T \boldsymbol{x}_i^D(t)\} \end{cases} \tag{1}$$

where t refers to a gap time with respect to the last known hospitalization event; h_0^R and h_0^D are the hospitalization and death baseline hazard functions, respectively; $\boldsymbol{x}_i^R(t)$ and $\boldsymbol{x}_i^D(t)$ are the observed covariates at time t; $\boldsymbol{\beta}$ and $\boldsymbol{\gamma}$ are the estimated coefficients of the two models; u_i and v_i are patient-specific additive frailties. According to our formulation, random effects u_i and v_i are distributed according to a bivariate discrete distribution P^* on $\mathbb{R}^2$

$$[u, v]_i \overset{iid}{\sim} P^* \quad \forall i = 1, \ldots, N. \tag{2}$$

Such discrete and with a finite support measure can be characterized by a vector of points in $\mathbb{R}^2$, $\boldsymbol{P}$, and a vector of weights, $\boldsymbol{w}$. Notice that each weight expresses the probability of a patient to be assigned to a certain point l, $l = 1, ..., L$ and thus the sum of the weights is constrained to be unitary. Moreover, the number of points constituting the support of the distribution, L, is assumed to be unknown a priori. By considering L as fixed, we can write each patient's contribution to the likelihood of the model as a mixture of L components. Each component coincides with the product of the individual contributions, $\mathcal{L}_i$, to the full loglikelihood $\mathcal{L}$ of two independent Cox models with fixed intercept, modelling respectively the recurrent and terminal event process

$$\mathcal{L}(\boldsymbol{\Omega}; data|z_{il}) = \prod_{l=1}^{L} \prod_{i=1}^{N} \left[\mathcal{L}_i(\boldsymbol{\Omega}; data|[u, v]_i = P_l)\right]^{z_{il}}. \tag{3}$$

where $\boldsymbol{\Omega} = [\boldsymbol{\beta}, \boldsymbol{\gamma}, \boldsymbol{w}, \boldsymbol{P}, h_0^R(t), h_0^D(t)]$. The abscissa and ordinata of each point $\boldsymbol{P}_l$ specify, respectively, the fixed intercept of the recurrent and terminal event Cox models, while z_{il} are a set of binary auxiliary random variables indicating if a patient i is assigned to the point l. In order to obtain estimates for $\boldsymbol{\Omega}$, we design a specific EM algorithm, in which at each iteration the model likelihood is firstly averaged with respect to the z_{il} variables and then maximized.
The EM algorithm is then generalized to cope with an a priori unknown number of support points L through its integration into a wrapper support reduction procedure. The first step consists in the definition of a grid of points in $\mathbb{R}^2$, which ideally covers the region in which the support of the discrete distribution is believed to lie. We evaluate two initialization procedures: the former involves sampling a high number of points from a bivariate Normal distribution, whose parameters are set according to previous knowledge (e.g., looking at the estimates of the model proposed in [5]), and initializing their weights according to the corresponding Normal density; the latter consists in defining a uniform distribution over a rectangle in $\mathbb{R}^2$, whose boundaries are set still according to available knowledge. At each iteration, we merge the couple of points with minimum distance in the actual grid whose Euclidean distance is less than a discretional threshold (*MinDist*), until convergence.

4. Results

We fit the nonparametric joint model with discrete frailty by consdiering both the gaussian and uniform initializations and we compare the results with the ones of a disjoint model and the joint models pro-

Variables	Estimate	StdDev	HR	95% CI	pvalue

Table 2: Summary of the Nonparametric Discrete Frailty model with uniform initialization. For categorical variables, the considered stratum is indicated between brackets. Points of the identified frailty discrete distribution are characterized through their abscissa (u), ordinata (v) and weight (w).

posed in [5,6]. For all models, we consider the following set of covariates: **Sex**, **Adherence**, **AgeEvent** and **Comorbidity**. The nonparametric discrete frailty models are fitted using a *MinDist* value of 0.25, which is initially believed to be suitable to spot significantly different fragility classes of patients. The trained models are compared from two perspectives: coefficients' estimation and random effects' characterization. Table **??** reports the estimates for the nonparametric discrete frailty model with uniform initialization[1] while Figure **??** displays the Hazard Ratio estimates and their respective 95% confidence of all compared models.

By looking at the hazard ratios of the covariates, we observe that male subjects are more prone to risk of hospitalization (HR=1.035) and death (HR=1.197). The covariate **Adherent** results statistically significant at any level for the two processes in all trained models. Being adherent yields a 22.9% decrease in the risk of a new hospitalization (HR=0.771) and a 33.5% decrease in the risk of death. From a clinical point of view, such results finally endorse the efficacy of the ACE inhibitors treatment for heart failure. The covariate **AgeEvent** results, for both processes, statistically significant at all levels. Its effect on the hospitalization hazard is a 1.5% reduction of the risk of hospitalization per year (HR=0.985), while on the death hazard it yields an increase of the risk of 4.1% (HR=1.040). Clinically speaking this can be explained by the fact that part of the risk of experiencing a new hospitalization is replaced by the risk to die when patients get older. The covariate **Comorbidity** results to be in all models statistically significant for both the processes. It yields an increase of 13.1% in the risk of hospitalization and a very high increase of 53.5% in the risk of death per comorbidity registered.

From the frailties characterization point of view, the nonparametric frailty model identifies the discrete distribution reported in Table **??** and visualized in the left-side panel of Figure **??**. The estimated discrete distribution consists in six points disposed in a diagonal pattern and show left skewness: point **P1** and **P2**, associated with a probability of 21% and 23%, identify respectively a *Highly Protected* and a *Protected* subpopulation; Point **P3** is related to a subpopulation *Neutral* to random effects, with almost a 20% probability for a patient to belong to it; Point **P4** identifies a relevant group of patients (*At Risk*) slightly more prone to the risk of a new hospitalization and death, with a probability of 20.5%. Point **P5** and **P6** identify two outlier subpopulations of *Fragile* and *Very Fragile* patients, associated with small probabilities (respectively, 7% and 6%). The effect of these estimated frailties can be appreciated by looking at the induced stratified baseline survival curves. As an example, right-side panel of Figure **??** reports the terminal event process induced stratified baselines.

[1]For the sake of brevity, we report results for the solely uniform initialization case.

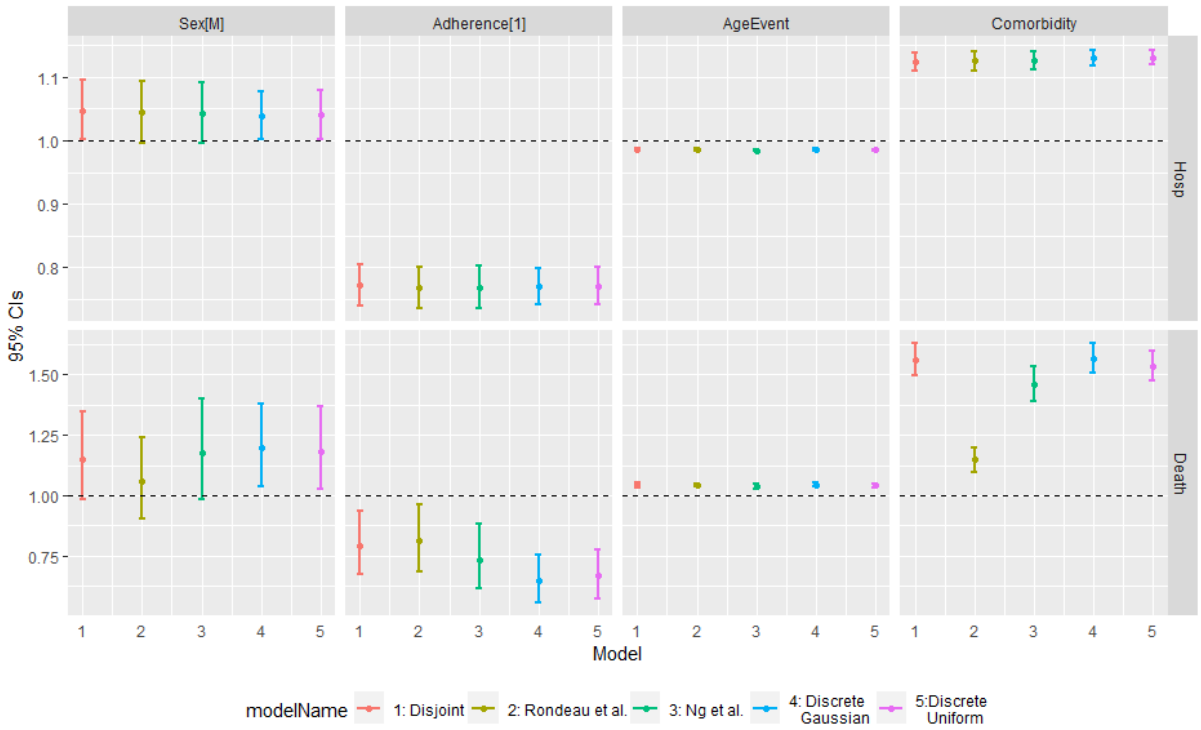

Figure 1: Comparison of estimated hazard ratios and their 95% CI in the trained models. Considered models are: disjoint (pink), Rondeau et al. (pistachio green), Ng et al. (teal), Discrete Nonparametric Frailty with Gaussian Initialization (light blue) and Discrete Nonparametric Frailty with uniform Initialization (purple).

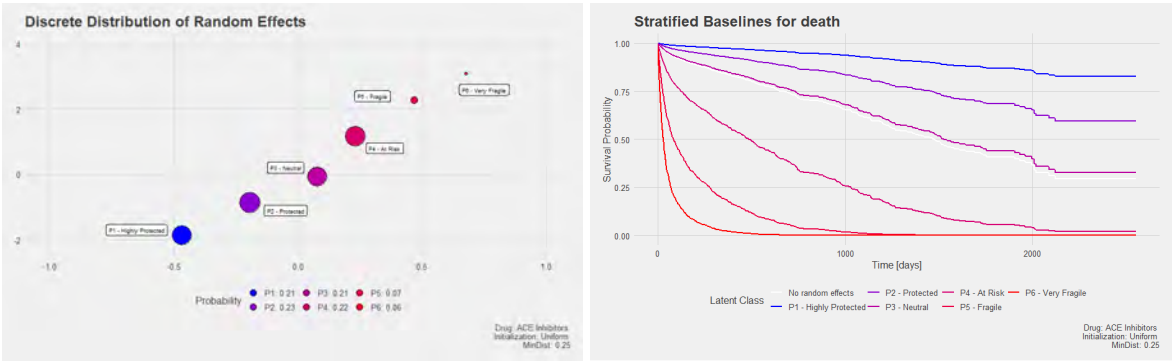

Figure 2: Left-side panel reports the estimated bivariate discrete distribution of random effects, obtained by adopting the uniform initialization case. The color of points ranges from blue (strong subjects) to red (weak subjects), while their size is proportional to the weight. Right-side panel reports the stratified survival probability baseline curves of the terminal event process.

A sensitivity analysis on the *MinDist* threshold is also conducted in order to drive the choice of this important tuning parameter.

5. Conclusions

In this work, we propose a methodology to jointly model two dependent longitudinal processes, the first being a recurrent events process, informative for the second, which instead involves events classified as terminal. In our case, the two processes are represented by hospitalizations and departure of patients affected by heart failure who undergo ACE inhibitors therapy. The work actually stems from the idea of expanding previous analyses developed in the field of pharmacoepidemiology, centered on the effect that adherence to drug prescriptions has on the survival outcome of patients, to include in the modelling the recurrent hospitalizations of a patient, in view of the renewed necessity of a proper managing of hospital beds. In this perspective, the proposed joint model with discrete random effects results to be an effective inferential tool. With respect to its counterpart methods in the literature, it yields consistent fixed-effects coefficients estimates, while providing an easy to understand but richer frailty characterization. The identification of classes of patients standing on their fragility level allows for a deeper characterization of patients' profiles. The identified profiles can be further investigated in terms of collateral patients' information.

From a methodological point of view, future work will be dedicated to the definition of a tool for driving the choice of the important tuning parameter *MinDist*.

Abstract

During Covid-19 pandemic, Governments implemented policies to reduce the spread of the virus. In Italy, policies have been implemented starting from 9th March 2020, when in the whole country lock-down policies were adopted. In this study, we analyze mobility data to understand which were the main drivers of mobility during the first pandemic wave. In particular, we analyze Google mobility reports, to study the relative changes in mobility w.r.t. a specific baseline and to analyze several different mobility drivers. In addition, we implement Multilinear Principal Component Analysis to extract relevant features from a multidimensional object. Results show good performances in terms of explained Frobenious norm and two PCs are able to synthesize the trends; finally, the reconstructed trends are also similar to the true original ones.

Keywords: Covid-19, human mobility data, mpca, three-way data

1. Introduction

At the beginning of 2020, the SARS-CoV-2 virus and its related disease, known as Covid-19, started to spread all around the world. The first cases were detected in China [1] at the end of 2019; then, on December 31st, Chinese government informed the World Health Organization (WHO) about the detection of some similar cases of respiratory disease due to an undefined agent. On 7th January the virus was identified. Then, on January 31st two Chinese citizens tested positive in Rome and on 17th February the first person affected by the disease in Italy - who has not visited China the months before - was detected. The virus started spreading and the first death occurred on February 20th in Vo' Euganeo (Veneto). In such situation, in the absence of therapies and due to the cases' fast spread, Non-pharmaceutical interventions (NPI) have been implemented by many governments. In particular, in Italy, lock-down policies and mobility restrictions were mainly adopted to reduce the spread of Covid-19. Clearly, the policies had a deep and strong impact on human behavior, especially on human mobility.

The analysis of human mobility data was deeply investigated. For example, [2] compared Covid-19 data and demographic variables with the GPS data in order to study how the restriction orders affect human mobility. In addition, the relationship between Covid-19 transmission and mobility was also analyzed by [3], who focused on 52 countries around the world. Moreover, [4] provided a comprehensive overview of human mobility data and it also compared different data sources to make the researchers and policymakers aware of the nature of the available data sets. A different study has been carried out by [5], who investigated the impact of COVID-19 on the number of people involved in crashes. Finally, [6] studied the effect of the restriction policies on mobility using the geolocalized data from 13 M Facebook users in France, Italy, and the UK.

The research focused on studying mobility data is considered as a data-driven approach which is an extremely helpful tool to support the decision-making process, as the new challenges of digitalization, innovation, and sustainability require.

In this paper, we aim to analyze mobility data provided by Google (more details in Section 2) and to find indicators able to synthesize the mobility data trends related to different categories, as also [7] did for England and Wales.

2. Data

Google Covid-19 Community Mobility Reports (GCMR) provide data on human mobility. In particular, mobility reports (GCMR link) share daily mobility data on relative changes compared to a baseline, the day that represents a 'normal' value for that day of the week. In detail, the baseline day is the median value from the 5-week period Jan 3 – Feb 6, 2020. Due to privacy reasons, the absolute values of mobility are not provided. Therefore, for any reported date, the daily relative change is estimated as the percentage change w.r.t. the corresponding baseline weekday. In addition, mobility data refer to 6 different categories which indicate the reasons why the mobility occurred: *grocery, parks, residential, retail, transit, and workplaces*.

In our analysis, the statistical units are the 20 Italian regions; for each of the 6 Google categories, mobility relative changes are provided; finally, the time frame cover from $2020-02-15$ until $2020-08-29$, for a total of 27 weeks.

Therefore, the data structure can be considered as a Three-way data array, having three ways, i.e. rows, columns, and layers, and referring to three modes, i.e. Regions, time, and Google categories, respectively. For each layer (Google category), a rows-by-columns data set provides information on the mobility relative changes during the period taken into account (week 8-week 35) for 20 Italian regions.

To explore the mobility trends, we plot them separately per Google category. In addition, we aggregate the dates referring to 'days' into 'weeks'. In Figure 1, the trends are colored differently, according to the region they refer to. As Figure 1 shows, mobility due to grocery, retail, parks, transit, and workplaces was characterized by a negative change w.r.t. the baseline period, given that lockdown restrictions mainly forbid people to move for other reason than basic needs. In particular, we notice that for transit, retail, and grocery, the relative change w.r.t. the baseline is null starting from week 28; for parks, instead, the mobility trends were set back equal to the baseline starting from week 20 and at week 25 all the regions have the same mobility as the baseline; in addition, from week 25 onward, the mobility towards parks experiences a huge increase in the relative change w.r.t. the baseline, reaching even a positive 500 % of relative change at week 33 in some regions. For what concerns workplaces, the trend, after having experienced a consistent rapid reduction from the starting week until week 15, starts increasing; however, unlike other trends, it remains below 0, meaning that during the analyzed period mobility due to reasons linked to work never came back to the level of the baseline. Totally different is the trend related to residential mobility: in the first weeks, it started a rapid increase in positive relative change w.r.t. the baseline. After that, between weeks 13 and 20, the relative change remain more or less constant at a level of 30 %, then it started slowly decreasing until reaching again level 0 between weeks 25-35, meaning that the mobility during those weeks came back to the baseline level.

3. Statistical Analysis

It can be of interest to synthesize the information on mobility data provided by GCMR, by retaining as much information as possible. However, classical techniques, such as the Principal Component Analysis (PCA), cannot be applied, since the three modes (regions, categories, and time) should be taken into account simultaneously.

As [7] noticed, for such data a multilinear PCA (MPCA) is suggested. MPCA has its origin in the well-known Tucker decomposition of a K-Tensor [8], which is used to reduce the dimension of a tensor object, or three-way data structure; the main contributor to the method is [9]. While PCA is used

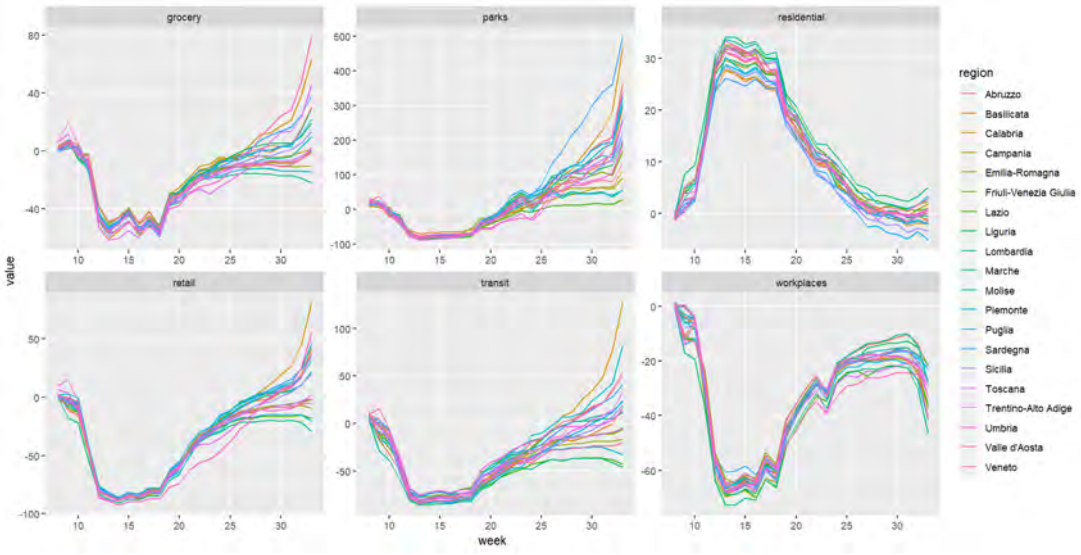

Figure 1: Mobility relative changes w.r.t. baseline separated by Italian region and reason (Google Covid-19 Community Mobility Reports (GCMR))

to reduce the dimension of the variables in a units-by-variables data set, MPCA is used to extract the relevant features of a multiway object.

It is worth mentioning that we exclude from the analysis data from parks. Indeed, on the one hand, the analysis performance, measured by the explained Frobenius norm, is significantly reduced if we include this category (less than 50%); on the other hand, the trend of mobility towards parks is very different in terms of behavior and in terms of magnitude, as aforementioned.

By applying the `mpca` function (`Rtensor` package) on the tensor (or three-way data) object (built by using `as.tensor` function in the `Rtensor` package), we obtain a good synthesis by using 2 PCs, as the percent of Frobenius norm explained by the approximation is nearly equal to 79%. In addition, the estimated data, namely the estimates of all the tensor values after compression, are quite close to the true ones. Indeed, Figure 2 shows that points (true observations) are almost gathered by the central solid lines (estimated trend), even if during the last weeks of the considered period, points spread a bit far from the estimations, meaning that the model is only nearly able to capture the variability of the trends in those weeks.

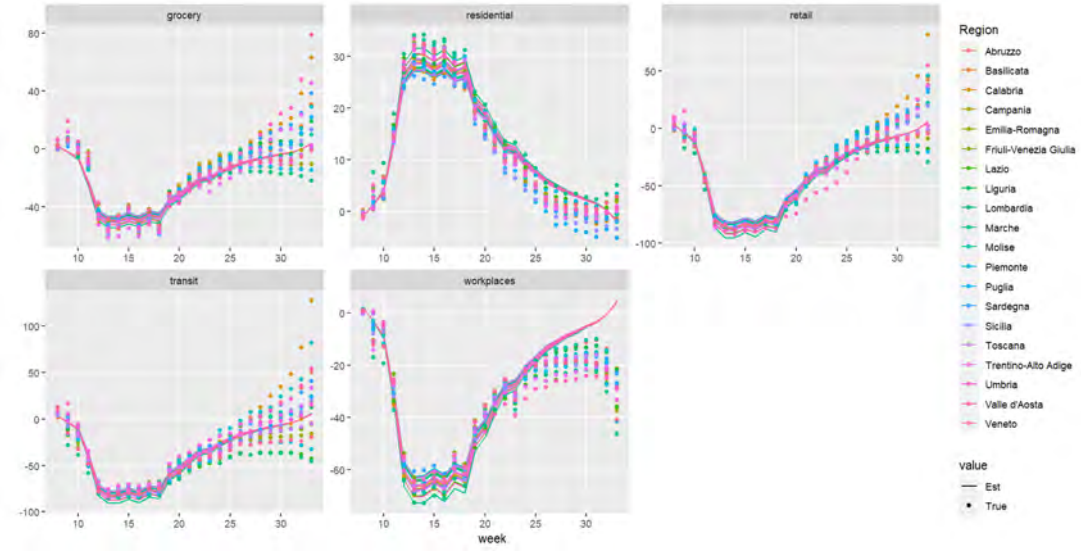

Figure 2: Estimated by mpca (2 components) and true observed mobility trends separated by Italian region and reason

By looking at the first two PCs in Figure 3, we realize that the former completely describes mobility for a residential reason, while the latter is a good synthesis of the mobility patterns for the other reasons.

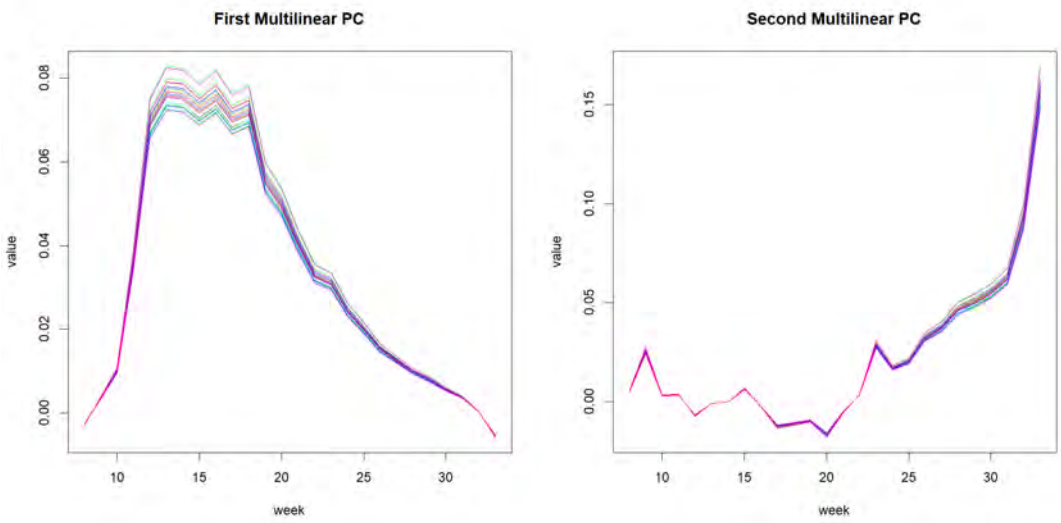

Figure 3: Mobility patterns of two PC resulting from mpca

To further describe the mobility trends, we apply the multilinear PCA with three components. By analyzing the results, we obviously obtain an increase in explained variance percentage, moving from 79% to approximately 80%. However, we realize that this gain in terms of explained variance is too small to balance the increase in model complexity. Anyway, for the sake of completeness, some details on the obtained 3 PCs are provided below. From Figure 4, we notice that the third PC allowed us to better capture the variability of the trends in the last weeks of the considered time frame, especially the trends of mobility toward workplaces.

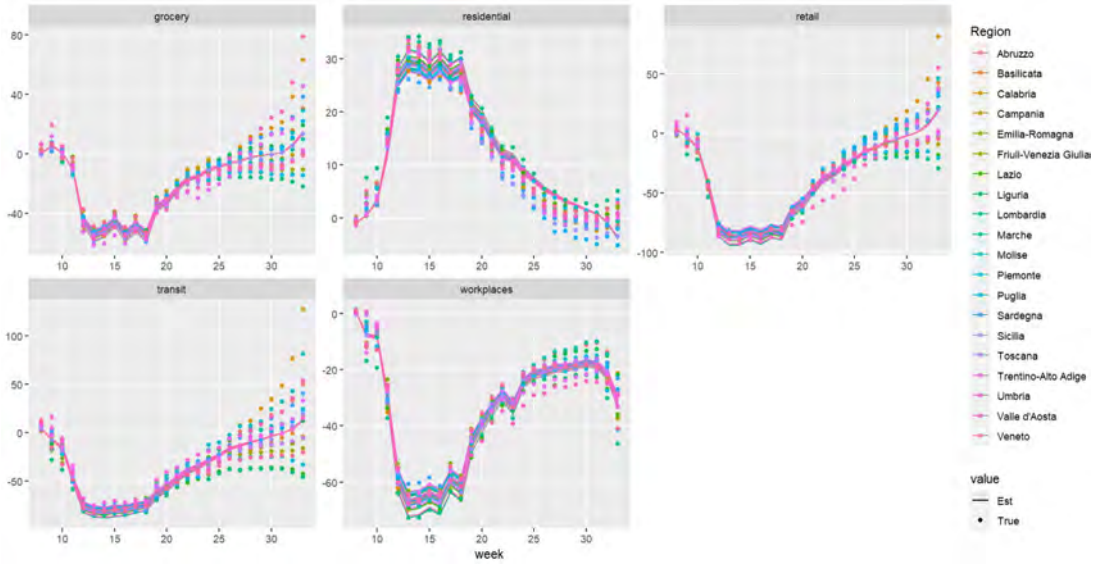

Figure 4: Estimated by mpca (3 components) and true observed mobility trends separated by Italian region and reason

In addition, by looking at the first three PC in Figure 5, we realize that the former completely describes the mobility for a residential reason, the third almost describes the mobility towards workspaces, while the second one is a good synthesis of the mobility patterns for the other reasons.

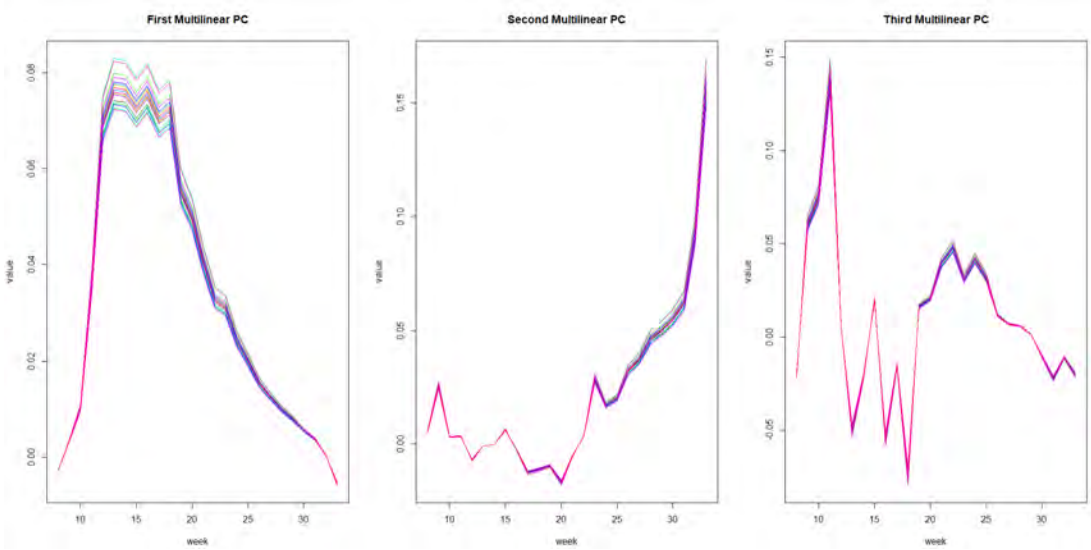

Figure 5: Mobility patterns of three PC resulting from mpca

4. Conclusion

The analysis allowed us to study how mobility during the first way of the pandemic in Italy changed with respect to the baseline period. Trends show that there was a negative relative change for mobility due to reasons other than residential, while the change was positive and rapid for residential mobility. By reducing the dimension of the three-way data object by using the Multilinear PCA, it was possible to obtain two PCs which are a good synthesis of the 5 trends (one for each mobility driver), as the percentage of Frobenious norm explained shows. In addition, the MPCA performed well also in terms of data reconstruction. Indeed, by estimating the trends and comparing them with the true ones, we experience a good model performance.

Further developments consider an analysis that involves mobility data and mortality data to study the relationship between the two.

Abstract

It is known how the social media changed our lives and the impact they have on our society today: from the general health state to thoughts on a certain topic, online users share every opinion on online platforms, especially Twitter, which provides real-time information. This article focuses the attention on the analysis of tweets in Italian language relating to an advanced stage of COVID vaccinations, from April to December 2022, with the purpose of extracting the main topics that are depicted in the considered timestamp, through the application of a new indicator, together with sentiment analysis. The results highlight the ability of the proposed analysis strategy in capturing peaks corresponding to particular events and how they were perceived on social media debates.

Keywords: SARS-CoV-2, sentiment analysis, Twitter, vaccination

1. Introduction

The outbreak of social media is certainly one of the main events that characterized the first decades of the 21^{st} century, with the aim of bringing people together, even from different parts of the globe. It is well known that online platforms have pros and cons: from the diffusion of a large amount of misinformation, to the spread of hate and other negative feelings, worldwide population is free to share whatever they want; only an internet connection is required.

From the general health state to thoughts about a particular topic, everything is shared on online discussions, especially on Twitter, that represents the perfect example of social media: it is featured by its immediacy of the data, allowing for precise information on public opinion.

A strongly debated topic during the last three years is obviously related to the outbreak of the *SARS-CoV-2* virus: the global spread of COVID-19 significantly changed customs and behaviors of the inhabitants, due to the uniqueness of the event. Indeed, this singular occurrence led political and medical institutions to find quick and effective solutions in order to prevent the diseases caused by the infection: principal resolutions consisted on lockdown measures and vaccination campaigns.

Textual analysis could be an effective monitoring tool for the epidemiological situation: it should be applied via sentiment analysis on tweets content (4) or for computing a relative increase indicator based on the amount of data at disposal (1). A further trail of predicting the evolution of the pandemic by a tool capable of providing real-time socio-economic and health crisis is proposed in (5).

In this article we focus on the analysis of Twitter posts about anti-COVID vaccines written in Italian language, from April 15^{th}, 2022 to December 31^{st}, 2022, with the purpose of understanding popular

attitudes towards the injection of Pfizer/BioNTech, Moderna, AstraZeneca/Vaxzevria and Johnson & Johnson vaccines in an advanced stage of the campaigns, when the number of infections is notably reduced. Specifically, the attention will be centered on an investigation consisting on the construction of indicators related to textual data combined with the implementation of sentiment analysis.

2. Data analysis

In this section we will discuss on the analysis that has been performed, starting from a brief illustration of the structure of the data at our disposal.

2.1 Data set description

The built data set contains 593351 tweets written in Italian language, collected day by day from mid April to the end of December 2022, each of them containing one of the following terms or bi-grams: *vaccino COVID*, *vaccinazioni COVID*, the proper vaccines names like *Pfizer*, *Moderna*, *AstraZeneca* and *Johnson & Johnson*, as also some specifics (*BioNTech*, *Vaxzevria*). Each observation consists on several variables; for instance, the type of message that users posted: original tweet (8.8% of the total), retweet (76.7%), reply or quote (14.5%). Only 1949 of them contain information about the geo-location from which the message has been posted; the most frequent ones were shared from Northern Italy (44.33%), followed by the central part (26.83%) and the Southern one (15.44%). The remaining tweets are spread across the different continents, from Australia to North America.
Nonetheless, in this work the attention will be focused only on the text. Before working on it, text has been pre-processed: indeed, punctuation marks and special ones have been dropped, as stop words, in order to obtain a more suitable information for our analysis.

A strategy consisting on the extraction of data information about mentioning vaccines is performed, through the application of two indexes, both based on the daily amount of gathered tweets. The interpretation will also be corroborated with the implementation of sentiment analysis, with the scope of describing the most important events occurred in Italy concerning the anti-COVID vaccination campaigns, and how they have been perceived by Italian citizens.

2.2 Indexes comparison

In this work we proposed a new indicator, called *Relative Count of Vaccine* i on day t, $RCV_{i,t}$, which is fashioned with the aim of indicating and highlighting how the magnitude of some specific terms can evolve over time. The $RCV_{i,t}$ is the ratio between the absolute count of the vaccine i on tweets of the day t, $ACV_{i,t}$ (hence, how many times a vaccine has been mentioned on tweets of a given day), and the number of collected posts on day t, N_t.

$$RCV_{i,t} = \frac{ACV_{i,t}}{N_t}.$$

In Figure 1 the evolution over time of the four indexes, one for each vaccine, is provided. Except for some days, the most mentioned vaccine is the Pfizer one, as the blue line shows in the plot, followed by, in magnitude order, Moderna, AstraZeneca and Johnson & Johnson, which also characterized the social media discussions in Italian language.

In addition, Table 1 reports some examples of peaks, on which date, vaccine name, respective value and event of interest are attached. For instance, the highest value reached by the RCV is 0.82 on April, 28^{th}, 2022; it should be interpreted as follows: *the 82% of tweets written on April,* 28^{th} *contained at least once the terms 'Pfizer' or 'BioNTech'*. The peak was reached after the report of the president of the Italian Drug Agency (AIFA) about the injection of the fourth dose, that appeared unnecessary; this event caused a large discussion about vaccines, due to the fact that Italian population has always been split up into two parts: from people believing on the anti-COVID vaccines effectiveness, against ones

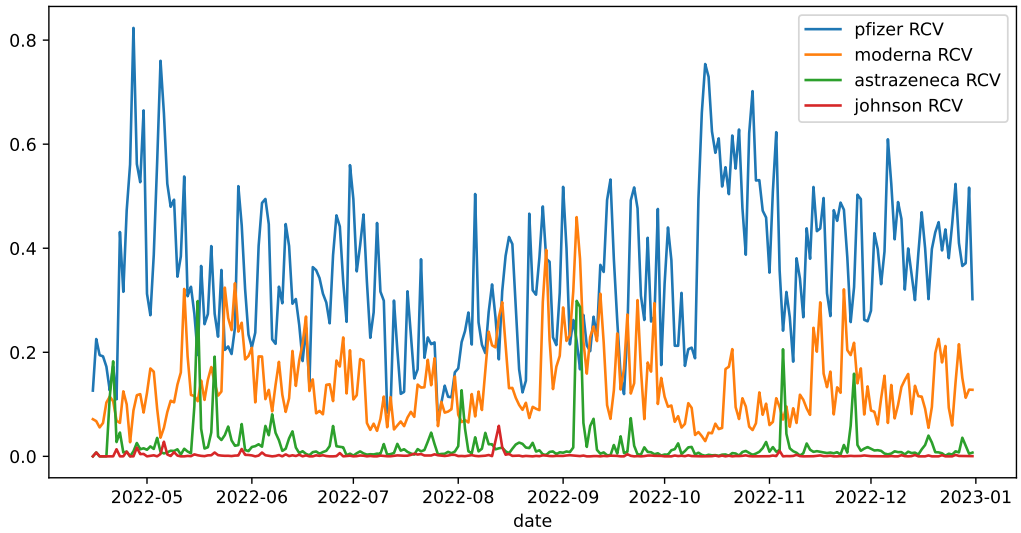

Figure 1: RCV values of Pfizer, Moderna, AstraZeneca and Johnson & Johnson vaccines.

Date	**Vaccine**	***RCV* value**	**Main debate**
April 28^{th}	Pfizer	0.82	Injection of fourth dose not necessary
May 6^{th}	J&J	0.03	Injection suspended on United States
May 16^{th}	AstraZeneca	0.29	Death of a woman after the second dose

Table 1: Description of a few main events related to RCVs peaks.

not trusting on how quickly the researchers have found a possible cure for the disease.

The literature on this specific aspect is rather scarce. Gori *et al.* (1) proposed a relative increase indicator, called for simplicity RII_t, to describe how the number of daily tweets could be affected by the happening of an event. The RII_t is equal to the the difference among the volume of tweets collected on day t, N_t, and the one of the day before, N_{t-1}, divided by the amount of tweets collected on the previous week, N_t^{t-6}, namely from day t to day $t-6$.

$$RII_t = \frac{N_t - N_{t-1}}{N_t^{t-6}}.$$

In Figure 2 a comparison among the RII (in blue) and the sum of the four RCVs (in orange) indexes is supplied. Since the two quantities are based on different concepts, there is no similarity between them; as a matter of fact, the trends are different along the timestamp. Indeed, differently from the RCV, that has a wider variation range, the RII behaves erratically, spreading around -0.11 and 0.13, suggesting that the relative amount of discussion about vaccines seems to be constant in this forward step of vaccination campaigns, so it is not so informative. Moreover, the indicator proposed in (1) exclusively depends on the amount of collected data: if the daily extraction is not constant, the result could be not informative, since the peaks are only given by a varying total of tweets collected in different days.
On the other hand, the RCVs sum, which depends on the count of mentioned terms, expresses how posts regarding vaccinations could be characterized by different peaks about more or less debates on the injection of vaccines, that mainly correspond to the event happened at the same day, or some days before, even when the number of daily tweets is constant (about 2500 per day, in the case in analysis).

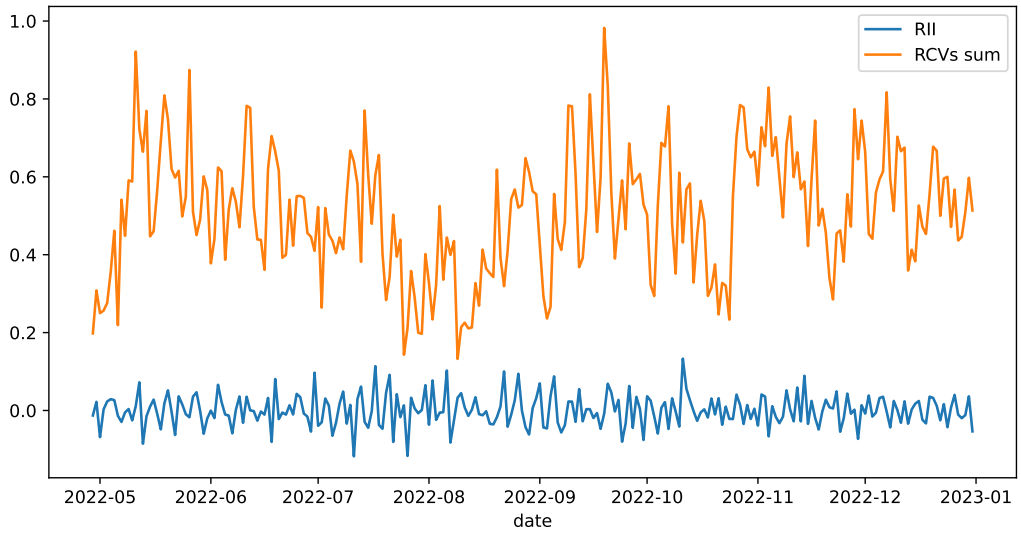

Figure 2: Comparison between the RCVs sum and RII values.

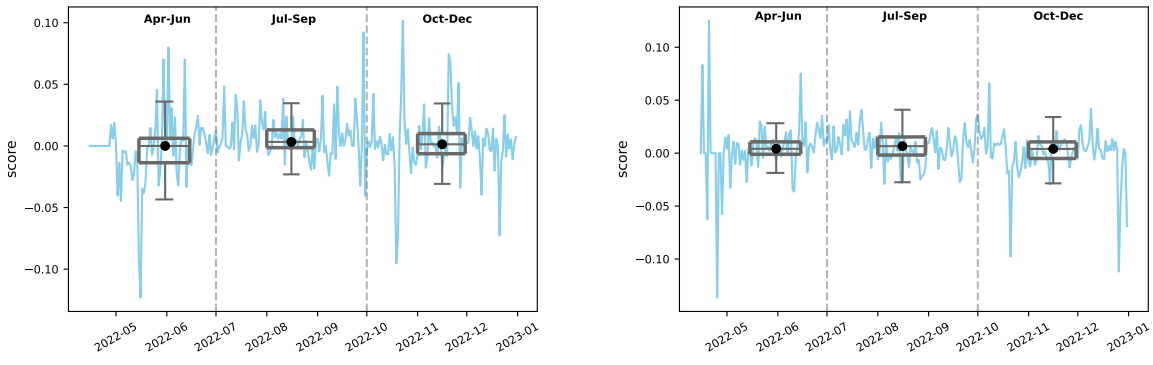
Indeed, the RCV turns out to be an interesting indicator when particular tokens wanted to be found into documents or simple texts. The strength of a simple but effective index like the one suggested in this article is highlighted in the comparison made in Figure 2, which emphasizes the way the indicator seems to adequately describe the temporal evolution of the debates about a given argument, underlining ups and downs caused by particular events that affect our society.

2.3 Sentiment analysis

Until now we have seen how an indicator based on the count of terms can be constructed and analyzed to notice whether some debates are present in a given time window and how their magnitude can change. However, social media posts report emotions and feelings, given by the attitude that the users have afterwards an event that could provoke different reactions inside them: from anger and pain, to happiness and joy. Sentiment analysis is a powerful Natural Language Processing technique that can be applied in cases when the subjectivity of a document would be extracted. Based on the implementation of an existing trained pipeline (*spaCy*), the original tweets text has been retrieved, since some emoticons that have been written as ensemble of different punctuation marks (for example the smile '*:)*', which is the most common one) could cause a meaningful variation in the message semantics. The pipeline computes a subjectivity score across -1.0 and 1.0 for each tweet, corresponding to the most positive and the most negative assessments, hence the averaged daily scores are computed, to establish the way the trend evolves.

The following analysis could be thought of as an extension of the one made in (4), where the authors considered the period from December 1^{st}, 2020 to March 31^{st}, 2021. Here we split up the timestamp into three sub-periods (April-June, July-September, October-December, 2022). Figure 3 summarizes sentiment analysis results for Pfizer and Moderna vaccines (respectively, panel (a) and (b)), along with a box plot describing the distribution of the scores for each considered sub-period. Note that, due to the limited numbers of daily tweets for AstraZeneca and Johnson & Johnson, those vaccines have been removed from the analysis.

The figure shows that the sentiment for both vaccines varies between -0.15 and 0.15 and the median value for each sub-period lies around 0. However, by looking at the box plot, it can be seen that Pfizer



(a) Sentiment score of Pfizer vaccine.

(b) Sentiment score of Moderna vaccine.

Figure 3: Averaged sentiment score across the considered timestamp for Pfizer and Moderna vaccines.

sentiment scores show a wider range across all the three-months periods, if compared to the Moderna one. This is true also for the interquartile range (IQR): for instance, the first sub-period (April-June) of Moderna has a IQR value of 0.012, whereas, for Pfizer vaccine, the respective value is 0.02.

A non-parametric Kruskal-Wallis test has been implemented in order to assess whether variations in the sentiment scores are observed across the considered time windows. Our results corroborate those obtained in (4), indeed we found a relatively stable sentiment about the Moderna vaccine in the considered period (p-value = 0.176). For Pfizer, instead, there seems to be a difference among the median level of the scores in the three periods (p-value = 0.013): more specifically, a Dunn's test (2) reveals a significant increase between the first and the second period (p-value = 0.010 with the Simes-Hochberg correction).

Despite the fact that the average sentiment seems to be somewhat neutral, the scores exhibit positive and negative peaks, that can be related to those captured by the RCV proposed in the previous paragraph. As regarding Pfizer, the maximum value reached in Figure 3 is of 0.101 on October, 23^{rd}; on the same day, the value of the related RCV (in Figure 1) is 0.628, corresponding to the period on which the discussion of Pfizer became more intense if compared to the beginning of the month. Doubts about the adverse reactions that the flu vaccine and three or more doses of Pfizer could be encountered are marked in the debates of the third October decade; however, even though the related sentiment is slightly positive, it is preceded by a strong negative peak some days before (-0.073).

Note that few peaks captured by the RCV index are not present when the sentiment analysis is applied. In most cases, the absence of a peak in the sentiment score could be due to the the fact that a large number of posts are retweets of a news posted by institutional profiles (e.g., governmental institutions, newspapers, etc.) (3). Indeed, their message content should not have subjective terms, hence the computed sentiment score should lie around 0, determining the neutral tone the tweets have; here a quantitative approach could help in understanding the magnitude of the discussion. Indeed, an effective 'quali-quantitative' analysis strategy could combine the application of the sentiment analysis along with the RCV index, since the latter has the additional ability of catching particular events.

3. Conclusion

In this article we propose an example of how social media posts could be exploited to perform several analysis related to population thoughts and feelings based on a certain event linked to the COVID-19 vaccination campaigns. A new indicator, the Relative Count of Vaccine, has been proposed, which is capable of capturing peaks of debates concerning a particular topic. A sentiment analysis is also

performed, which complements the results obtained by the RCV, by evidencing possible positive or negative emotions and hence the direction of the sentiment.
As a possible future extension of the analysis, a larger number of languages could be considered, with the aim of demonstrating if worldwide events related to SARS-CoV-2 vaccination campaigns could be recorded and in which way they were perceived and expressed on social media debates.

Abstract

In observational studies, one of the main difficulties consists in the comparison of treatment effects. In fact, receiving a treatment is not a "purely random" event, and there could be relevant differences between treatment groups. Propensity score is a popular tool to account for this source of bias. However, its use requires a careful modelization of the dependence relationships of the treatment on the covariates. In this work, we consider a general setting with multiple treatments and discrete multi-valued outcome. We propose to estimate the propensity score by using Bayesian Networks and, based on this, we develop an inferential methodology to evaluate the treatments effect. The performance of the proposed approach have been studied through a simulation study with very promising results.

Keywords: Potential outcomes, propensity score, covariate balance, observational study, Bayesian networks

1. Introduction

In medical research, there is a growing interest in evaluating the treatments effect using data from observational studies. These studies have several practical advantages compared to experimental study designs, but the lack of "purely random" treatment allocation may lead to patient characteristics unbalance between the treatment groups and thus to biased assessment of treatment effects. In this setting, several methods based on propensity score are widely adopted to account for this source of bias. In particular, statistical approaches have been developed to match, stratify or weight the samples of the treatment groups. In spite of this, much of the work on propensity score analysis has focused on the case where the treatment is binary, while the use of propensity score when examining multiple treatment conditions has received limited attention [4]. Typically, in the applications with multiple treatments the propensity score is estimated using multinomial or ordinal logistic regression model. The challenge for this approach is choosing the functional form and the correct set of interactions among the covariates to capture their relationship to treatment assignment. A misspecified propensity score may fail to achieve covariate balance between treatment groups. To overcome this issue, in the binary case of two treatments, in [5] we proposed to estimate the propensity score by using Bayesian Networks and based on it, we developed a methodology to evaluate the treatment effect. Estimating propensity score via BNs was

shown to offer substantial theoretical and practical advantages, with respect to more popular approaches such as logistic modelling and machine learning methods. Following this approach, in the present paper we propose to extend the use of the Bayesian Netwok to estimate the propensity score in the multi-level treatment case. Moreover, we consider the case where the outcomes are multi-level. In the literature, when outcomes are continuous or binary, the most commonly way to evaluate the treatment effect is the Average Treatment Effect (ATE). However, this quantity can give limited information expecially for disomogenous responses within groups; furthemore it is not well defined for categorical data with more than two categories. Then, to evaluate the treatment effect in this context we propose an appropriate test for the absence of treatment effect by using a methodology based on inverse probability weighting. A simulation study is set up for evaluating the performance of the proposed approach.

2. Method

In formal terms, consider n independent subjects, each receiving a treatment T with $K+1$ levels 0, $1, \ldots, K$. The level 0 denotes the absence of treatment (control group). Let $Y_{(k)}$ the *potential outcome* of a subject when treatment is $k = 0, 1, \ldots, K$. The *observed outcome* for a subject is then

$$Y = \sum_{k=0}^{K} Y_{(k)} I_{(T=k)} \tag{1}$$

where $I_{(T=k)} = 1$ if $T = k$, $I_{(T=k)} = 0$ otherwise. The treatment has no effect if $Y_{(0)} \stackrel{d}{=} Y_{(1)} \stackrel{d}{=} Y_{(K)}$, where $\stackrel{d}{=}$ denotes equality in distribution. Due to the presence of confounding covariates, the assignment-to-treatment mechanism is not purely at random. As an effect, there could be relevant differences among subjects receiving different treatment levels. In the present paper the assignment-to-treatment mechanism is assumed to depend only on *observed* covariates, with no unobserved confouders. Let $\boldsymbol{X} = (X_1 \cdots X_L)$ be the vector of relevant covariates, and denote by

$$p_k(\boldsymbol{x}) = P(T = k | \boldsymbol{X} = \boldsymbol{x}); \;\; k = 0, 1, \ldots, K \tag{2}$$

the propensity score, namely the probability of receiving treatment at level k conditionally on covariates. Due to the nature of the considered application, attention is focused on the case of covariates and potential outcomes that are discrete, finite random variables (r.v.). The assumptions of the analysis are listed below.

H1. *Discreteness*. Each covariate X_l is discrete, finite, and may take nominal values $x_l^1, \ldots, x_l^{s_l}$ with positive probability. The potential outcomes $Y_{(k)}$ are finite, discrete, r.v.s, too, again taking values $0, 1, \ldots, K$ with marginal probability:

$$\theta_k(h) = P(Y_{(k)} = h); \;\; h = 0, 1, \ldots, H, \; k = 0, 1, \ldots, K. \tag{3}$$

H2. *Unconfoundedness*. $T \perp\!\!\!\perp (Y_{(0)}, Y_{(1)}, \ldots, Y_{(K)}) | \boldsymbol{X}$.

H3. *Common support*. There exists a positive real δ for which $\delta \leq p_k(\boldsymbol{x}) \leq 1 - \delta$ for each $\boldsymbol{x}$ and $k = 0, 1, \ldots, K$.

For the sake of simplicity, the following vector notation is used.

$$\boldsymbol{\theta} = \begin{bmatrix} \boldsymbol{\theta}_0 \\ \boldsymbol{\theta}_1 \\ \cdots \\ \boldsymbol{\theta}_K \end{bmatrix}, \;\; \text{where } \boldsymbol{\theta}_k = \begin{bmatrix} \theta_k(0) \\ \theta_k(1) \\ \cdots \\ \theta_k(H) \end{bmatrix}, \; k = 0, 1, \ldots, K.$$

To estimate the probabilities $\theta_k(h)$, a methodology based on inverse probability weighting is used. Propensity scores $p_k(\boldsymbol{x})$ are first estimated through a Bayesian Network (BN; [1]). As shown in [5], BNs

estimators have several fundamental properties, because they are (universally) consistent and asymptotically efficient, even when the structure of the network is learnt from data. On the basis of the BN estimator $\widehat{p}_k(\boldsymbol{x})$, the estimator

$$\widehat{\theta}_k(h) = \sum_{i=1}^{n} I_{(Y_i=h)} I_{(T_i=k)} p_k(\boldsymbol{x}_i)^{-1} \Big/ \sum_{j=1}^{n} p_k(\boldsymbol{x}_j)^{-1};\ h = 0, 1, \ldots, H,\ k = 0, 1, \ldots, K \tag{4}$$

is constructed. To establish asymptotic, large sample properties of (4) we need a vector notation, similar to that introduced above. Define:

$$\widehat{\boldsymbol{\theta}}_k = \begin{bmatrix} \widehat{\theta}_k(0) \\ \widehat{\theta}_k(1) \\ \cdots \\ \widehat{\theta}_k(H) \end{bmatrix},\ k = 0, 1, \ldots, K;\ \widehat{\boldsymbol{\theta}} = \begin{bmatrix} \widehat{\boldsymbol{\theta}}_0 \\ \widehat{\boldsymbol{\theta}}_1 \\ \cdots \\ \widehat{\boldsymbol{\theta}}_K \end{bmatrix}$$

and consider the $(K+1)(H+1)$-variate r.v.

$$\sqrt{n}(\widehat{\boldsymbol{\theta}} - \boldsymbol{\theta}). \tag{5}$$

Under assumptions H1-H3,

$$\sqrt{n}(\widehat{\boldsymbol{\theta}} - \boldsymbol{\theta}) \xrightarrow{d} \boldsymbol{W} \ \text{ as } n \to \infty \tag{6}$$

where $\boldsymbol{W}$ possesses a (singular) Normal multivariate distribution, with null expectation and covariance matrix $\boldsymbol{\Sigma}$. The matrix $\boldsymbol{\Sigma}$ have a complex form, depending on unknown quantities. However, it can be consistently estimated on the basis of sample data. In other terms, it is possible to construct an estimator $\widehat{\boldsymbol{\Sigma}}$ that converges in probability to $\boldsymbol{\Sigma}$ as the sample size n tends to infinity. This result will be mainly used in the sequel to construct test-statistics for the evaluation of possible treatment effects.

2.1 Testing for the absence of treatment effect

The main hypothesis to be tested is the *absence of treatment effect*, namely

$$\begin{cases} H_0: & \boldsymbol{\theta}_0 = \boldsymbol{\theta}_1 = \cdots = \boldsymbol{\theta}_K \\ H_1: & \text{The vectors } \boldsymbol{\theta}_k \text{ do not coincide} \end{cases} \tag{7}$$

If we define the $(H+1)$-dimensional vector $\overline{\boldsymbol{\theta}} = \frac{1}{K+1}\sum_{k=0}^{K} \boldsymbol{\theta}_k$, testing for the absence of treatment effect reduces to the following hypothesis problem

$$\begin{cases} H_0: & \boldsymbol{\theta}_k = \overline{\boldsymbol{\theta}}\ \ \forall k = 0, 1, \ldots, K \\ H_1: & \boldsymbol{\theta}_k \neq \overline{\boldsymbol{\theta}} \text{ for some } k = 0, 1, \ldots, K \end{cases} \tag{8}$$

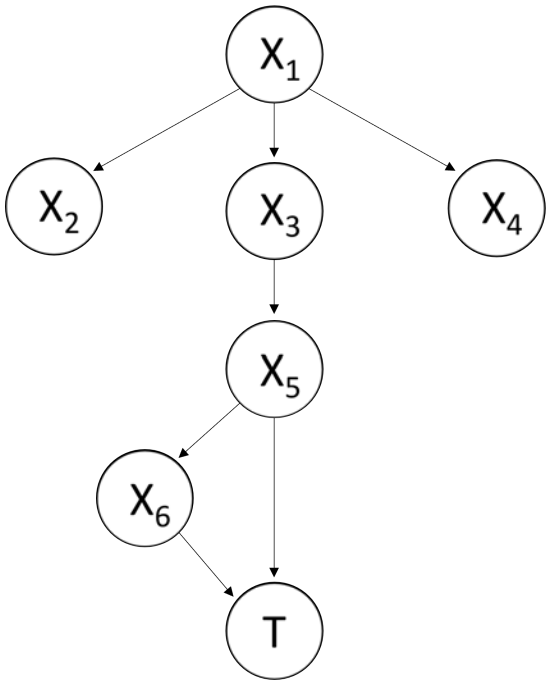
The basic idea consists in using the test-statistic

$$D_n^2 = n \sum_{k=0}^{K} \sum_{h=0}^{H} \frac{\left(\widehat{\theta}_k(h) - \widehat{\overline{\theta}}(h)\right)^2}{\widehat{\overline{\theta}}(h)}, \tag{9}$$

which is similar, in principle, to the test-statistic used in a different context by [3].
The test-statistic D_n^2 is essentially a sum of measures of divergence of the (probability) vectors $\widehat{\boldsymbol{\theta}}_k$s from $\widehat{\overline{\boldsymbol{\theta}}}$. Thus, in order to compute the rejection region of the test, the distribution of the test-statistic D_n^2 is approximated considering a technique which is essentially a combination of the approach pursued in [5], exploiting ideas in [2], with simulations.

3. Simulation study

The performance (in terms of significance level and power) of the suggested approach was evaluated through a simulation study considering both a treatment variable and an outcome variable with three levels. Following the procedure showed in [5], the data were randomly generated from the Bayesian network, displayed in Figure 1.



Event	Probability
$X_1 = 1$	0.6553
$X_2 = 1 \mid X_1 = 0$	0.9961
$X_2 = 1 \mid X_1 = 1$	0.4384
$X_3 = 1 \mid X_1 = 0$	0.2186
$X_3 = 2 \mid X_1 = 0$	0.6238
$X_3 = 1 \mid X_1 = 1$	0.2102
$X_3 = 2 \mid X_1 = 1$	0.0556
$X_4 = 1 \mid X_1 = 0$	0.1600
$X_4 = 2 \mid X_1 = 0$	0.6778
$X_4 = 1 \mid X_1 = 1$	0.4151
$X_4 = 2 \mid X_1 = 1$	0.5150
$X_5 = 1 \mid X_3 = 0$	0.4536
$X_5 = 1 \mid X_3 = 1$	0.6636
$X_5 = 1 \mid X_3 = 2$	0.9726
$X_6 = 1 \mid X_5 = 0$	0.3967
$X_6 = 1 \mid X_5 = 1$	0.7000
$T = 1 \mid X_5 = 0, X_6 = 0$	0.2
$T = 1 \mid X_5 = 0, X_6 = 1$	0.3
$T = 1 \mid X_5 = 1, X_6 = 0$	0.3
$T = 1 \mid X_5 = 1, X_6 = 1$	0.2
$T = 2 \mid X_5 = 0, X_6 = 0$	0.2
$T = 2 \mid X_5 = 0, X_6 = 1$	0.3
$T = 2 \mid X_5 = 1, X_6 = 0$	0.4
$T = 2 \mid X_5 = 1, X_6 = 1$	0.2

Figure 1: BN used for simulating the data.

Once the treatment variable and the other categorical variables were generated, the potential outcomes $Y_{(0)}$, $Y_{(1)}$ and $Y_{(2)}$ were generated from a Multinomial distribution:

$$Y_{(k)}|X_5,X_6 \sim Multinomial(P(Y_{(k)}=0|X_5,X_6),P(Y_{(k)}=1|X_5,X_6),P(Y_{(k)}=2|X_5,X_6)), \quad k=0,1,2 \tag{10}$$

and linked to the covariates through logistic models:

$$P(Y_{(k)}=0|X_5,X_6) = \frac{1}{1+e^{f_{1k}(X_5,X_6)}+e^{f_{2k}(X_5,X_6)}},$$
$$P(Y_{(k)}=1|X_5,X_6) = \frac{e^{f_{1k}(X_5,X_6)}}{1+e^{f_{1k}(X_5,X_6)}+e^{f_{2k}(X_5,X_6)}},$$
$$P(Y_{(k)}=2|X_5,X_6) = \frac{e^{f_{2k}(X_5,X_6)}}{1+e^{f_{1k}(X_5,X_6)}+e^{f_{2k}(X_5,X_6)}},$$

where

$$\begin{aligned}
e^{f_{10}(X_5,X_6)} &= \alpha_0+\beta_1X_5+\delta_1X_6,\\
e^{f_{11}(X_5,X_6)} &= \alpha_0+\alpha_1+\beta_1X_5+\delta_1X_6,\\
e^{f_{12}(X_5,X_6)} &= \alpha_0+\alpha_2+\beta_1X_5+\delta_1X_6,\\
e^{f_{20}(X_5,X_6)} &= \alpha_3+\beta_2X_5+\delta_2X_6,\\
e^{f_{21}(X_5,X_6)} &= \alpha_3+\alpha_4+\beta_2X_5+\delta_2X_6,\\
e^{f_{22}(X_5,X_6)} &= \alpha_4+\alpha_5+\beta_2X_5+\delta_2X_6.
\end{aligned}$$

The performance of the method is evaluated in three different cases: (i) there is no treatment effect; (ii) there is a treatment effect only for a treatment level ($\boldsymbol{\theta}_0 = \boldsymbol{\theta}_2 \neq \boldsymbol{\theta}_1$); (iii) there is treatment effect for all treatment levels ($\boldsymbol{\theta}_0 \neq \boldsymbol{\theta}_2 \neq \boldsymbol{\theta}_1$). For each case we explored scenarios where, except for the treatment, the potential outcomes depended on: (a) no variable among $X_1, \ldots, X_6$ (scenarios S1, S2, S3); (b) two variables X_5 and X_6 (scenarios S4, S5, S6). The simulation parameters of the different scenarios are reported in Table 1. Finally, the outcome Y was generated as in (1).

Table 1: Parameter values of the models of for simulating the six scenarios.

Scenario	α_0	α_1	α_2	β_1	δ_1	α_3	α_4	α_5	β_2	δ_2
S1 (H_0 true)	-1	0	0	0	0	-1	0	0	0	0
S2 (H_0 false - $\boldsymbol{\theta}_0 = \boldsymbol{\theta}_2 \neq \boldsymbol{\theta}_1$)	-1	1	0	0	0	-1	0.5	0	0	0
S3 (H_0 false - $\boldsymbol{\theta}_0 \neq \boldsymbol{\theta}_2 \neq \boldsymbol{\theta}_1$)	-1	2.5	1.5	0	0	-1	1.5	1	0	0
S4 (H_0 true)	-1	0	0	1	-2	-1	0	0	2	-3
S5 (H_0 false - $\boldsymbol{\theta}_0 = \boldsymbol{\theta}_2 \neq \boldsymbol{\theta}_1$)	-1	1	0	1	-2	-1	0.5	0	2	-3
S6 (H_0 false - $\boldsymbol{\theta}_0 \neq \boldsymbol{\theta}_2 \neq \boldsymbol{\theta}_1$)	-1	2.5	1.5	1	-1	-1	1.5	1	2	-3

Four sample sizes (n =500, 1000, 2500, 5000) have been explored with 1000 Monte Carlo runs for each combination of scenario and sample size. Table 2 summarizes the Monte Carlo rejection probabilities of the null hypothesis for different scenarios and sample sizes. The simulated significance level is always lower than the nominal level 5% (S1 and S4) and when the null hypothesis H_0 of absence of treatment effect is false (S2, S3, S5, S6), simulated the power is at least 0.38 when the sample size is 500 and greater than 0.8 as the sample size increases.

Table 2: Rejection probabilities (nominal significance level 0.95)

Scenario	n=500	n=1000	n=2500	n=5000
S1 (H_0 true)	0	0.01	0	0
S2 (H_0 false - $\boldsymbol{\theta}_0 = \boldsymbol{\theta}_2 \neq \boldsymbol{\theta}_1$)	0.6	0.93	1	1
S3 (H_0 false - $\boldsymbol{\theta}_0 \neq \boldsymbol{\theta}_2 \neq \boldsymbol{\theta}_1$)	1	1	1	1
S4 (H_0 true)	0.01	0	0	0
S5 (H_0 false - $\boldsymbol{\theta}_0 = \boldsymbol{\theta}_2 \neq \boldsymbol{\theta}_1$)	0.38	0.84	1	1
S6 (H_0 false - $\boldsymbol{\theta}_0 \neq \boldsymbol{\theta}_2 \neq \boldsymbol{\theta}_1$)	1	1	1	1

4. Remarks and perspectives

In the present paper, a new method to assess the treatment effect in case of multi-level treatment and multi-level outcome is presented. In particular, (i) we proposed to estimate the potential outcomes distributions applying a methodology based on the inverse probability weighting with the propensity score estimated using a Bayesian Network, and (ii) we developed a new test for the absence of treatment effect. A simulation study showed the good performance of the developed test.
In the future, the proposed approach will be also evaluated through an application to real data of prostate cancer patients. Moreover, this work will be extended developing tests for stochastic ordering among treatments effects.

Abstract

Our current food systems are not sustainable as the negative impacts on our environment, society, and individuals' health are still intense. The transition to sustainable food systems is set as one of the Sustainable Development Goals. Existing literature suggests that the true price of food regulates a more sustainable food system while building up trust in consumers and further persuading their purchase intention. Indeed, consumers play a key role to accelerate the transition to sustainable food systems. The question is to what extent consumers are willing to pay the true price for sustainable food. What is influencing consumers' Willingness to Pay? Can values which are conveyed through a true price increase purchase intention? We carried out an in-depth analysis of a large-scale survey targeting individuals' knowledge and attitudes towards food sustainability in EU-27. Our findings suggest the importance of the attitudes towards the environment, and organic products as well as of economic affordability that policymakers and stakeholders should consider.

Keywords: Willingness To Pay, true price, food sustainability, ordinal logistic regression

1. Introduction

Before buying a food product, do you check the price? Do you fully understand the information that the price label conveys? What if you would be told that 10% of the price represents the value of "green production" and the guaranteed welfare of the workers? Will you buy this product even if it is 10% more expensive than another one without any specifications on the same shelf?

In the 2021 Food Systems Summit report, the scientific group pointed out that our current food systems were still not sustainable (Hendriks et al., 2021), with a specific focus on the impacts of the current food systems on our environment, society, and health (FAO et al., 2020). A transition towards more sustainable food systems had been called to reduce the related impacts and costs while offering affordable and healthy food to all. To quantify these potential benefits, we could project a 21-37% cut of the net anthropogenic GHG emissions (IPCC, 2019), a 690 million undernourished population and more than 10 million lives saved (GBD, 2019; FAO et al., 2020).

In recent years, much research has been carried out aimed at improving the sustainability of the food system. Among the various perspectives of analysis and factors studied, "externalities" have been introduced. Indeed, the costs and the benefits of those "food" externalities are not included in the market prices, and as a result, both consumers and the stakeholders of the food systems are not aware of the negative hidden effects (Baker et al. 2020), classified into environmental, social, health, and economic externalities. The inclusion of those issues within the product prices would help realize the true cost to the stakeholders in the value chain and the true price to the consumers. Scholars have carried out studies on the True Cost Accounting (TCA) approach with the externalities to unfold the hidden impact on the environment, economy, and society to the industrial stakeholders, consumers, and policymakers; meanwhile, studies on consumer perception and potential acceptance of the "true price" are increasing, because ultimately the acceptance of the "true price" by the market (consumers) will accelerate the transition to sustainable food systems. Moreover, stakeholders in the food systems will gain the consumers' trust when they successfully demonstrate the values with the true price (Taufik, van Haaster-de Winter, and Reinders 2023).

However, previous studies carrying out comprehensive research on consumers' perception and acceptance of the true price are limited. Most of the existing studies have covered the selected typical

externalities or have targeted a specific area, for instance, the consumer's motivation and perception towards environmental and social externalities via food product labelling such as carbon footprint, fair trade, rainforest protection, and animal welfare (Grunert, Hieke, and Wills 2014a); Shao (2018) studied the consumers' Willingness To Pay (WTP) relating to the environment protection in China – an analysis on both micro (individual) factors and macro (city) influences.

The aim of this paper is to provide an in-depth analysis of the potential linkages between EU-27-country consumers' WTP for the true price of food. We consider the individual-level factors including personal habits and attitudes and conduct the first exploration of the role of heterogeneity at territorial (country) levels.

2. Data and descriptive analysis

Our study refers to the latest available Special Eurobarometer (SE) survey (93.2), carried out between 3 August to 15 September 2020 on a representative sample of approximately 28,300 individuals across 27 EU Member States (European Commission, Brussels 2021). The survey was designed to collect public opinions towards the strategy of transforming our food system set by SDGs. With the aim of capturing the individuals' appetite for change, a wide range of questions was designed around food buying and eating habits, knowledge about food sustainability and sustainable diet. Meanwhile, to engage the whole food system, citizens' attitudes and opinions towards the roles they play in sustainable food systems were examined.

The survey included a complete section dedicated to food sustainability to explore consumers' food buying and eating habits, knowledge about sustainable food and diet, and opinions of the key roles to play in food sustainability. The attitudes of the interviewees were captured by an ordinal scale of measurement ranging from *Totally Agree* to *Totally Disagree categories*. To study the sample population's WTP for sustainable food, we specifically referred to the following statement *"You are prepared to pay 10% more for agricultural products that are produced in a way that limits their carbon footprint"* as our target variable.

Our descriptive analysis on the SE 93.2 microdata shows a country-level heterogeneity towards WTP for sustainable food among 27 EU Member States (Figure 1) with overall responses identifying 22.26% of interviewees totally agree with spending more for sustainable food and 42.56% tend to agree on spending more (up to 10%) on sustainable food products, while nearly 11.66% disagreed with a firm attitude.

Among 27 EU Member States, Germany (39.5%), Denmark (39%), the Netherlands (38.9%), Sweden (34.3%), Cyprus (33.4%), Luxembourg (32.7%), and Slovenia (31.7%) showed the highest WTP when considering the individuals' opinions of *Totally Agree*. When we merged the opinions of *Tend to Agree* with *Totally Agree*, we obtained more countries in our results, for example, Ireland and Belgium. On the other hand, Lithuania (20.1%), Bulgaria (19.9%), Hungary (18.7%), Latvia (18.2%), and Slovakia (17.6%) had the highest disagreement voices when we only considered the individuals' opinions of *Totally Disagree*. Again, if we included the answers of *Tend to Disagree*, Portugal had the highest (sample) population (54.7%) who voted *Totally Disagree* and *Tend to Disagree*.

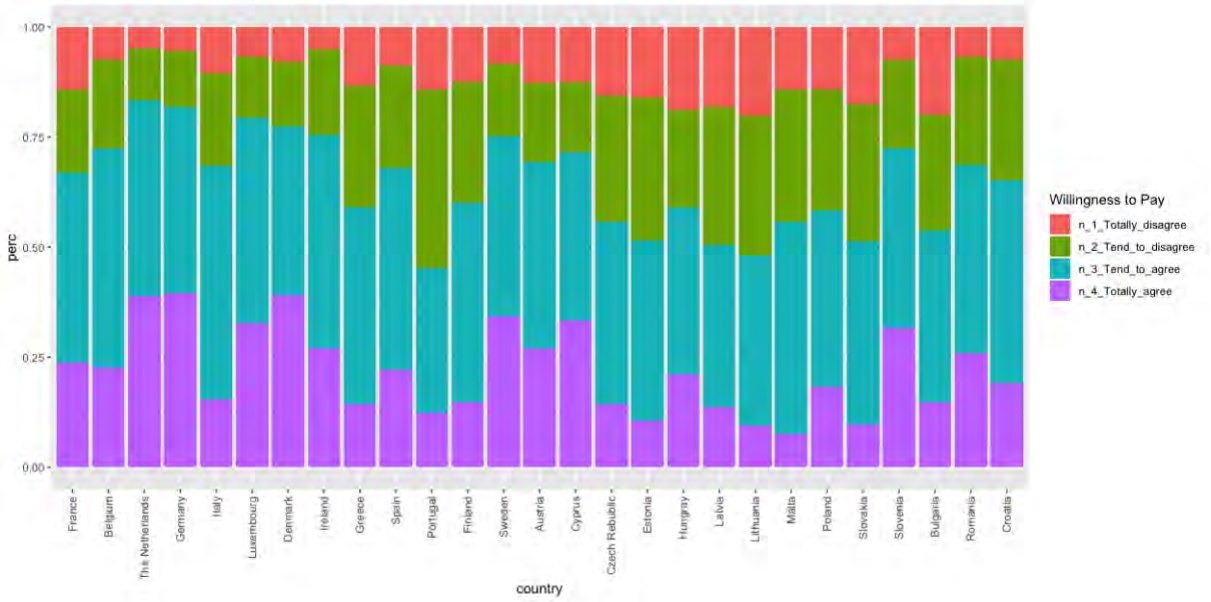

Figure 1: Willingness-to-Pay in percentage by country

Youths (those aged between 15 and 35 years old) showed higher WTP, and so did the education level. An individual's WTP rose with his/her education level. Focusing on the individual's subjective social classification which was divided into 5 categories as underlined in Figure 2, the upper middle class (36%) showed more WTP than the higher class (33%). Gender and residence areas did not display diverging patterns. People working in management positions in the companies had the highest WTP (29%), followed by self-employed (25.9%) consumers and students (25.4%). Indeed, unemployed and retired-or-unable-to-work-due-to-illness groups reported a higher disagreement rate (14.5% and 13.9% respectively), although a proportion of retired-or-unable-to-work-due-to-illness group was willing to pay more for sustainable food (21.5%), which was higher than the figures of the employed (not management roles; 21%), housewife or houseman (19%), and the unemployed (18%).

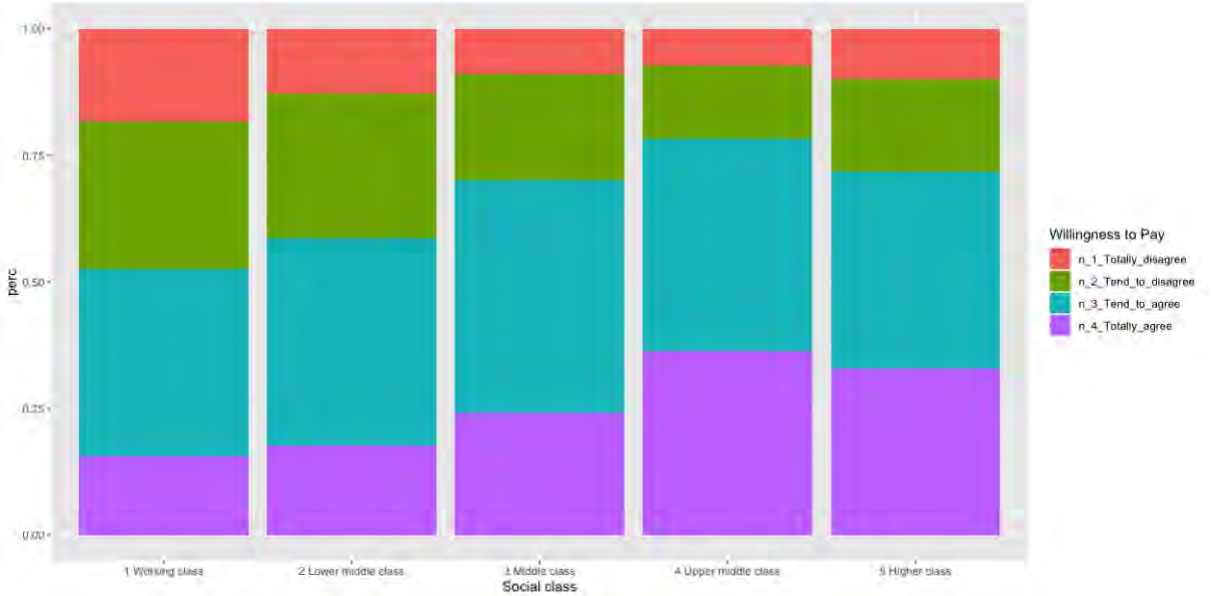

Figure 2. Willingness-to-Pay in percentage by subjective social-class

Safety, cost, nutrition, taste, and origin of the food products were important conditions when most individuals made their purchase decision. Most people connected sustainable food with three sets of descriptions: nutritious and healthy, affordable, and with little or no pesticides. Moreover, most people thought that a sustainable diet represented health and was beneficial to the local economy in the first place. Regarding individuals' opinions towards the key roles to play in a sustainable food system, 82.3%

thought food producers and manufacturers should play a key role, followed by government or NGOs (9.2%) and retailers (4.3%). Only 1.2% considered themselves an important role in food sustainability. Most interviewees believed that making sustainable food more affordable (55.3%), more accessible in the shops (48.7%), and clearer labelling (37.5%) would help them to adopt healthy and sustainable diets. More people agreed that public institutions should offer sustainable food (52.7% *Totally Agree*; 40.8% *Tend to Agree*) and 44% of the sample population strongly agreed that information about sustainability should be compulsory on food labels, and another 43.5% held the opinion of *Tend to Agree*.

8.9% and 57.5% of interviewees reported that they had a frequent sustainable diet or took a sustainable diet most of the time, respectively; only 4.3% never had a sustainable diet. Interestingly, we found out that, although sustainable-food frequenters were most willing to pay for more expensive sustainable food (33.6%), the disagreement in this group was not the least (12.2%), but people who claimed a sustainable diet most of the time had the least disagreement (8.8%).

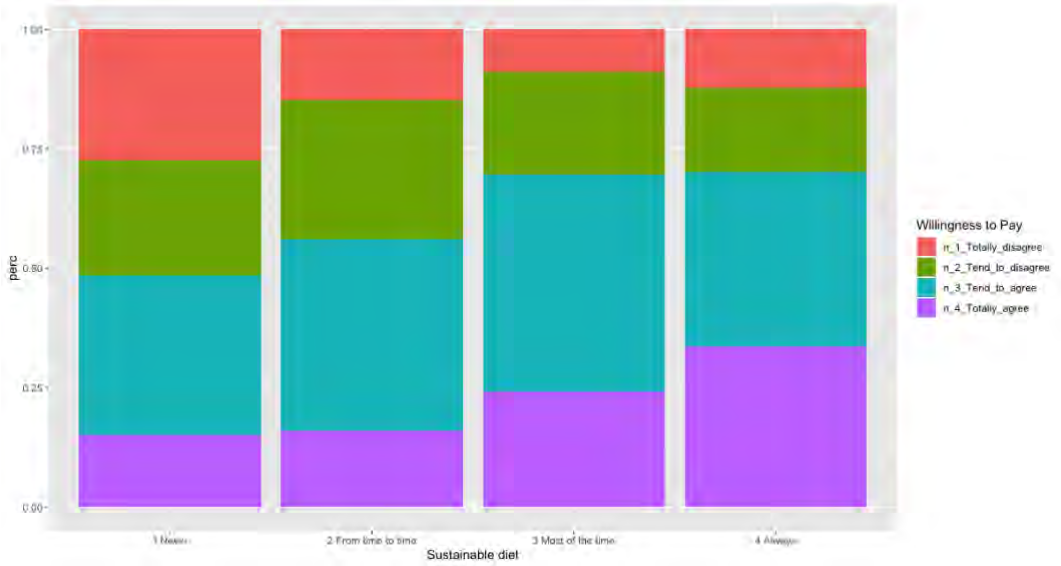

Figure 4. Willingness-to-Pay in percentage by the sustainable diet

3. Methodology

Given the above-mentioned target variable, we considered the WTP in our analysis as an ordered variable with a ranking nature. We decided to implement the Ordinal Logistic Regression (OLR) model, which has been widely used to analyze ordinal and categorical outcomes (Shao, Tian, and Fan 2018; Loan et al. 2019; Long and Freese 2006; McCullagh 1980). In our data-cleaning process, we reorganized the values of all ordinal variables, so that they shared the same rising tendency with other explanatory variables.

WTP=1 represents the lowest WTP and acceptance of the price increase (up to 10%) and WTP=4 stands for the highest WTP and the least tolerance to the price change. As the basis of the OLR model, we set up the following OLR model:

$$WTP_i^* = \boldsymbol{\beta}'\boldsymbol{x}_i + \varepsilon_i \tag{1}$$

Where $\boldsymbol{x}$ is the vector of explanatory variables; $\boldsymbol{\beta}$ is the vector of parameters; ε is the random error and i represents the individual respondents. The latent WTP for more expensive (up to 10% price increase) sustainable food, ***WTP*,*** is a linear function of the vector of explanatory variables in the OLR model.

Therefore, we used the observed responses "*Totally disagree*" (WTP=1), "*Tend to disagree*" (WTP=2), "*Tend to agree*" (WTP=3), and "*Totally agree*" (WTP=4) to construct the ordinal categories with the cut points $\boldsymbol{C_j}$ as following:

$$WTP = 1 \Rightarrow Totally\ disagree\ (0\%\ price\ increase), if\ -\infty < WTP_i^* \leq C_1$$

$$WTP = 2 \Rightarrow Tend\ to\ disagree\ (0 - 10\%\ price\ increase), if C_1 < WTP_i^* \leq C_2$$

$$WTP = 3 \Rightarrow Tend\ to\ agree\ (0 - 10\%\ price\ increase), if C_2 < WTP_i^* \leq C_3$$

$$WTP = 4 \Rightarrow Totally\ agree\ (10\%\ price\ increase), if C_3 < WTP_i^* \leq +\infty \quad (2)$$

The probability that respondent ***i*** chooses ***k*** is expressed accordingly:

$$\begin{aligned} P_{ik} &= pr(WTP_i = k|x_i) \\ &= pr(WTP_{ik} = 1|x_i) \\ &= pr(C_{k-1} < x_i'\beta + \varepsilon_i < C_k) \\ &= F(C_k - x_i'\beta) - F(C_{k-1} - x_i'\beta) \end{aligned} \quad (3)$$

4. Ordinal Logistic Regression (OLR) model: provisional results

The OLR estimation results suggested that single or married (or with a partner) individuals tended to have higher WTP than divorced, separated or widow individuals. People aged between 56 to 75 years showed the highest level of disagreement with sustainable food products with increased prices. WTP decreased among housewives or housemen. Individuals who self-reported to be from a higher social class indicated a higher WTP. Interestingly, individuals with a lower education still showed a higher WTP significantly.

Compared with the demographic factors, individuals' knowledge and attitudes towards sustainable food had more influence. The individuals who had a sustainable food diet tended to show a higher WTP. People who had strong ethics and beliefs and took convenience as an important factor for general food purchase decisions had higher WTP, but those who cared about the environment, food origin, nutrition, and safety when buying food showed lower WTP. In terms of promoting sustainable food to consumers, it might be more difficult to convince those who voted for affordability. However, sustainable food promotion through education campaigns on its health benefits, simply facilitating better menus with sustainable food choices or ensuring a clearer label and more access to sustainable food products in the shops, might potentially increase the individual's WTP.

17 countries (Total: 27 EU Member States) were found to be significantly associated with individuals' WTP. The Netherlands, Germany, Luxembourg, Denmark, Ireland, Sweden, Slovenia, and Croatia indicated a higher WTP; Italy, Greece, Estonia, Latvia, Lithuania, Malta, Poland, Slovakia, and Bulgaria showed the opposite results (lower WTP).

5. Conclusion and limitation

We find out that the younger generation tends to accept the price increase regarding sustainability, and this echoes the similar findings that students have a higher WTP as well. Higher education results in higher WTP, but the richer (higher social class) does not necessarily show a higher WTP. However, demo-social-economic factors seem less influence on individuals' WTP in comparison with an individual's knowledge and attitude towards food sustainability, which was agreed by other scholars (Laroche, Bergeron, and Barbaro-Forleo 2001).

The results suggest a positive relationship between the consumer's attention to food products' affordability and the WTP. Therefore, a true price should persuade consumers that transparent pricing from a sustainable food system indeed is affordable and responsible for our planet and society. People who relate environmental issues (pollution, carbon footprint, etc), minimal processes and short supply chains with food sustainability displayed higher WTP. Stakeholders in food systems should consider specifying the true price which underlines these extra values of producing sustainable food to win the trust of the consumers and consumers' purchase intention (Taufik, van Haaster-de Winter, and Reinders 2023). Our results show that food producers or manufacturers fail to persuade consumers to accept sustainable food products with higher prices now, and they are expected to play the most important role to promote food sustainability. In the lower stream of the food value chain, more sustainable food

choices with easier access to food outlets (retail and food service) could be helpful to increase consumers' acceptance of more expensive sustainable food products. Meanwhile, consumers with higher WTP expect better labelling to communicate the sustainable contributions or impacts of a food product, and regulations to be implemented in the value chain for food sustainability development.

Different countries display different influences on their citizens' WTP. Previous studies incline that in different nations with various GDP levels, the public concern ranges from survival and material issues to post-material values, such as welfare and environment, therefore the WTP varies; however, it is common that complex and even contrary relations exist between the motivation or concern about sustainability and its implementation (Shao, Tian, and Fan 2018; Grunert, Hieke, and Wills 2014b). The hidden factors influencing individuals in a country include many, for example, policies, living standards, traditions and so on. However, it reminds us that the influence from a country level could be more efficiently assessed. Therefore, researchers and governments should take a leading joint role in examining the food sustainability transition in depth.

Since the survey was conducted in 2020 and released in 2021, we foresee the limitation of the data, and we aim to update our analysis results when the new wave of micro-data will be released. In addition, our quantitative analysis was not completed after the implementation of the OLR model and further work is still ongoing to refine micro-level variables by considering specific country-level factors in the model selection and specification. Lastly, an extension of this analysis could be to continue our research through a TPA approach based on the latent WTP threshold values.

Abstract

In recent years, there has been a significant transformation in how important social and natural phenomena are assessed and measured, with traditional single-variable measurements being replaced by multidimensional approaches. Key to these approaches are composite indexes (CIs), which are real-value functions that synthesise multiple achievements of a group of units.
Each of the dimensions under study are typically synthesised through one or more variables, usually referred to as indicators. The reliability of CIs is affected by estimation errors, such as sampling error, that might be non-negligible when indicators are obtained through estimation processes.
In this paper, we propose a methodology based on a parametric bootstrap technique to evaluate the effect of uncertainty in indicators on the reliability of composite indexes, with a focus on indicators whose sampling error may be correlated, such as indicators obtained from a common sample survey. The aim is to apply this method to a CI proposed to evaluate Italian regions' environmental performances. The proposed methodology can be generalized to address other types of errors, such as measurement, non-response, or non-sampling errors.

Keywords: bootstrap, correlated sampling errors, ecological indicators

1. Introduction

In recent years, the way in which significant social and natural phenomena are measured and evaluated has undergone a significant transformation. This is largely due to the widespread agreement among the scientific community regarding the complex and multi-faceted nature of subjects such as well-being, poverty, and the environment, and the need to have a more comprehensive approach to defining and measuring them. Traditional methods of measurement, which were based on a single variable, are now frequently being replaced by multidimensional techniques (Sen, 1999; Chakravarty and D'Ambrosio, 2006; Alkire and Foster, 2011; Bossert et al., 2012; Nicholas et al., 2017).

These methods tackle the subject of investigation from a wider viewpoint by incorporating a large number of dimensions. Depending on the theoretical model selected, these dimensions (often referred to as "achievements" or "indicators") are either considered as outcomes of the underlying concepts under study, or as their root cause.

Many studies that are based on a multidimensional approach use composite indices (CIs) as a tool to reduce the complexity of data. In recent years, the use of CIs has significantly increased. Bandura (2009) noted the use of hundreds of CIs covering a wide range of topics, including well-being, the environment, and child poverty. The growth in both structured and unstructured data, often referred to as "big data", is a major factor that is driving the development of multidimensional frameworks. The abundance of data has increased interest in multidimensional approaches, creating at the same time new theoretical and methodological challenges.

The indicators used to define the CIs are often obtained from different datasets, or are measured on subgroups of the target population. This sometimes results in a mixed framework, where some indicators are measured from the overall population and others from samples of the population. This can cause difficulties in measuring the impact of sampling variability on the aggregated CIs.

This is particularly true for complex areas, where the variables included in the analysis can be extremely diverse and belong to different fields of study. For instance, the sustainable development index provides a one-dimensional metric to evaluate country-specific information on different dimensions like economic, environmental, and social.

Moreover, measures based on subjective processes, such as opinions or perceptions, are often derived from sample surveys, adding an additional source of heterogeneity between indicators.

Sampling variability is only one of the potential sources of error that must be taken into account. Other sources of error, such as non-response and measurement errors, can also affect the data used to calculate the individual indicators that make up the composite index (CI). In this paper, we only focus on sampling error as a source of uncertainty affecting the indicators, but our methodology can be expanded to consider other sources of error.

Traditionally, most of the literature on the development of CIs focused on the effects of normalization procedures, the combination of different indicators (linear or non-linear), and the sensitivity of CIs to methods of aggregation and weighting. Some authors examine the variability among the indicators included in the CIs, while others consider the uncertainty in the construction process of a CI. However, as Ceccarelli et al. (2020) point out, the sensitivity of CIs due to uncertainty in the indicators has often been overlooked in the literature, and finding measures of accuracy for a composite index remains an unsettled problem.

2. Estimating uncertainty in composite indicators

Mauro at al. (2021) attempted to address the issue introduced above by studying the impact of uncertainty due to the sampling error in the true values of indicators on the final aggregate score. They presented a method for obtaining estimates of confidence intervals and their variability.

The method was applied to real data indicators that were combined to create a CI that represented the environmental performance of different regions in Italy. The proposed method effectively captures how the sampling error in individual indicators affects the corresponding error in the CI. The results of the study also provided insight into how errors CIs should be interpreted, such as ranking the environmental performance of Italian regions.

Mauro at al. (2021) proposed a solution by accounting for the sampling error in the aggregation phase of CIs through the use of a parametric bootstrap technique. The sampling distribution of each indicator was replicated to obtain a distribution, which was used to determine the standard errors and confidence intervals for the CI. In order to test the results, the proposed technique was therefore applied to four aggregation methods: arithmetic mean, geometric mean, Mazziotta-Pareto index and multidimensional synthesis of indicators.

In their work, Mauro et al. (2021) rely on a three basic hypothesis, namely:

1. The sampling errors of the indicators are independent of each other within units, so that the sampling error of indicator *j* for unit *i* does not depend on the sampling errors of the other *k-1* indicators of unit *i*, where *k* is the number of indicators available for each unit.
2. The estimates are unbiased with regards to the survey design.
3. The variance, σ_{ij}^2, of the estimates is known for all *i* and *j*. Usually, σ_{ij}^2 is unknown and estimated from the sample data, but the estimator is often smoothed and treated as the true sampling variance.

The first assumption rules out potential correlations among the sampling errors of the indicators. Specifically, the approach assumes that the covariance matrix is diagonal, which may be overly restrictive: for example, if the indicators are obtained from the same surveys, they are likely to present correlated sampling errors. This case is referred to as “horizontal correlation”.

Let $\widehat{\boldsymbol{\theta}}_i = \boldsymbol{\theta}_i + \boldsymbol{e}_i$, where $\widehat{\boldsymbol{\theta}}_i = \left[\hat{\theta}_{i1}, \dots, \hat{\theta}_{ik}\right]^T$ is the vector of the estimates for the *k* indicators for unit *i*, $\boldsymbol{\theta}_i = [\theta_{i1}, \dots, \theta_{ik}]^T$ the vector of their true (unknown) values and $\boldsymbol{e}_i = [e_{i1}, \dots, e_{ik}]^T$ is the vector of

their sampling errors. Therefore, we can assume $\boldsymbol{e}_i \sim D_k(\mathbf{0}, \boldsymbol{\Sigma}_i)$, where $\boldsymbol{\Sigma}_i$ is its covariance matrix and D_k is a multivariate distribution, usually a multivariate normal of dimension k, because of the central limit theorem.

Using a parametric bootstrap, we estimate the variance of CIs, taking into account the sampling variability of single indicators and their horizontal correlation. The proposed technique is as follow:

1. Generate B bootstrap vectors $\widehat{\boldsymbol{\theta}}_i^b = \left[\hat{\theta}_{i1}^b, \dots, \hat{\theta}_{ik}^b\right]^T$ sampling from $D_k\left(\widehat{\boldsymbol{\theta}}_i, \boldsymbol{\Sigma}_i\right)$, so that $\widehat{\boldsymbol{\theta}}_i^b$ mimic a realization of the unknown sampling distribution of $\widehat{\boldsymbol{\theta}}_i$, which is $\widehat{\boldsymbol{\theta}}_i \sim D_k(\boldsymbol{\theta}_i, \boldsymbol{\Sigma}_i)$; then stack together the n vectors $\widehat{\boldsymbol{\theta}}_i^b$ to obtain the matrix $\boldsymbol{X}^b$;
2. Starting from $\boldsymbol{X}^b$, compute B standardized matrix $\boldsymbol{\Xi}^b$, where the entries of this matrix are obtained as $\xi_{ij}^b = \frac{x_{ij}^b - \min\left(x_{1j}^b, \dots x_{nj}^b\right)}{\max\left(x_{1j}^b, \dots x_{nj}^b\right) - \min\left(x_{1j}^b, \dots x_{nj}^b\right)}$ or $\xi_{ij}^b = \frac{\max\left(x_{1j}^b, \dots x_{nj}^b\right) - x_{ij}^b}{\max\left(x_{1j}^b, \dots x_{nj}^b\right) - \min\left(x_{1j}^b, \dots x_{nj}^b\right)}$ according to positive or negative polarity of the indicator respectively;
3. Using Ξ^b, obtain estimates of CIs, denoted as τ_i^b, $b = 1, \dots, B$ and $i = 1, \dots, n$;
4. Obtain estimated variance from the B-vector of CIs: $\hat{V}(\tau_i) = \frac{1}{B}\sum_{b=1}^{B}\left(\tau_i^b - \bar{\tau}_i\right)^2$, where $\bar{\tau} = \frac{1}{B}\sum_{b=1}^{B}\tau_i^b$.

Usually, when indicators are means, totals or proportions, the distribution D_k is a multivariate normal distribution. The covariance matrix of the sampling errors is considered known here, and in real applications it has to be estimated from survey data.

Our goal is to measure if and how the relaxation of the first assumption by Mauro et al. (2021) affects the overall uncertainty of the CIs obtained with different aggregation methods. In their case study, Mauro et al. (2021) analyse data from multiple sources, including administrative archives and two national sample surveys (EU-SILC and HBS), as well as the Istat sample survey on Aspects of Daily Life, to address this limitation. All the estimates were therefore calculated assuming independence between sampling errors, although this was not the case from some of the indicators coming from the same survey. In general, the hypothesis of independence may not hold for analyses where indicators are obtained from a limited number of datasets or a unique dataset. In these cases, the correlation between the variances of the indicators can significantly affect the overall uncertainty of the CIs if not properly addressed. Therefore, the uncertainty in the CIs estimates can be caused by both the variance of individual indicators and the covariance matrix, whose structure is not diagonal. The purpose of this paper is to provide a preliminary assessment of the impact of indicators' sampling errors on CIs in a more general context.

A design-based simulation has been carried out using data described in section 3. A correlation between 0.3 and 0.8 has been set among indicators coming from the same survey, and main results indicates that the proposed bootstrap perform very well, particularly for the AMPI. Detailed results of the simulation are not reported here and are available upon request to the authors.

3. Application

As already underlined, CIs are nowadays widely used to measure complex phenomena in many fields of studies. Especially in the last years, with the increase of data available from surveys, administrative archives and alternative data sources, the awareness that many phenomena can be better measured using a set of indicators, instead that as single one, is widely recognized. A noteworthy example is the Italian National Statistical Institute's (Istat) Equitable and Sustainable Well-being (BES), where 12 domains of analysis are each measured by several indicators to obtain a detailed framework for monitoring well-being in Italy. Aggregating the information of the well-being indicators into a reduced number of composite indicators, for example one indicator within each well-being domain, can be crucial for policy-making and benchmarking when the units of analysis are the Italian regions or provinces (Ciommi et al., 2017).

Based on the BES, Mauro et al. (2021) proposed a CI indicator that can be used to monitor the environmental performance of Italian regions. The CI is composed by 14 indicators (Table 1): 7 coming

from administrative archives and therefore not affected by sampling error, and seven coming from sample surveys. Specifically, four indicators come from the Istat survey on 'Aspects of daily life', two from the EU-SILC survey ('European Union - Statistics on Income and Living Conditions') and one from the HBS ('Household Budget Survey'). These indicators are affected by sampling error, and as shown by Mauro et al. (2021), this kind error also affects the corresponding CI.

Table 1: Indicators used to define the proposed CI to evaluate Italian regions' environmental performance: name, source, polarity. Indicators non affected by sampling error are in italics.

Indicator	Source	Polarity
Dissatisfaction for the landscape deterioration (%)	Istat survey on Aspects of daily life	-
Concern for landscape deterioration (%)	Istat survey on Aspects of daily life	-
Satisfaction with environmental quality (%)	Istat survey on Aspects of daily life	+
Concern for biodiversity loss (%)	Istat survey on Aspects of daily life	-
Noise from neighbours or from the street (%)	Istat survey EU-SILC	-
Pollution, grime or other environment problems (%)	Istat survey EU-SILC	-
Share of car transportation expenses on overall transportation expenses (%)	Istat survey HBS	-
Losses in drinking water supply network (%)	*Istat census on water availability for civil use*	-
Exceeding of the NO2 annual limit for the protection of human health (%)	*Istat environmental data on regional capital cities*	-
Urban green areas per inhabitant	*Istat environmental data on regional capital cities*	+
Wastewater treatment failures (%)	*Istat census on water availability for civil use*	-

However, Mauro et al. (2021) used the hypothesis of independence of the indicators' sampling errors, although this assumption is not correct in the case of the four indicators coming from the survey 'Aspects of daily life'. The aim of the current work is to remove the hypothesis of independence and to derive the corresponding effect in terms of variability of the CI.

The preliminary results obtained by relaxing the assumption of independence between errors in the estimates of the indicators still depend on some minor assumptions that could be revised, extended, or relaxed to encompass more general situations.

To our knowledge, there is no literature on estimating the impact of indicators' sampling error on CIs under this framework. The methodology proposed in this paper must therefore be considered as a first tentative to address this issue.

Initial Coin Offerings and ESG: allies or enemies?

Alessandro Bitetto[a] and Paola Cerchiello[a]

[a]University of Pavia; alessandro.bitetto@unipv.it, paola.cerchiello@unipv.it

Abstract

Initial Coin Offerings (aka ICOs) have gained a prominent interest in the FinTech world as an alternative way to fund raising for innovative and cutting edge business ideas. So far, academics have studied drivers of success without posing specific attention to the products or activities proposed by the ICOs. In this paper, we investigate the possible nexus between ICOs and Enviromental, Social and Governance (ESG) indicators, by studying a set of 621 ICOs. Specifically, we extract keywords related to ESG from whitepapers associated to each ICO and build a variable which acts as a signal of attention to sustainability topics. Our research hypothesis concerns the evaluation whether ICOs oriented towards ESG are more likely to successfully raise expected funds. Preliminary results confirm such hypothesis.

Keywords: ICO, Green, Sustainability

1. Introduction

Nowadays themes like Environment, Social Change, and Governance are becoming more and more important. Over 90% of CEOs believe that ESG indicators are critical to their company's earnings and progress. Indeed, the inclusion of environmental, social, and governance aspects are playing an important role in investment and emission processes, promoting innovation and the expansion of sustainable finance [7]. We could state that, for a company, Environmental, Social, Governance investments and reporting represent one of the ways to keep up with the market. As a matter of fact, companies with stronger ESG propositions tend to have higher growth, higher worker efficiency, lower volatility, cost decrease, and fewer institutional interventions. Furthermore, in recent years, start-ups and the most innovative businesses turn to alternative sources of capital instead of classic channels, such as Initial Coin Offerings (ICOs). An ICO is a new way to fund businesses and initiatives, it is one of the blockchain-based processes that allow the emission of an utility token rather than a security or equity token. The growing popularity of the ICOs is clearly due to several related benefits, such as the high level of offered return on investment, high liquidity, fast financing, cost minimization and high availability, which are increasingly encouraging innovative investors and businesses to abandon traditional financing methods. However, it is also a young and ever-changing market full of significant risks.

Previous literature on this topic is still scarce. Most relevant papers that consider the effect and success of environmental initial coin offerings were published in recent years, and the studies examine the success of environmental ICO measured by the total funding in the actual ICOs and the long-term survival of the projects [4]. Moreover, there are some articles that study how environmental issues have led to many new trends in technology and financial management. They analyze the relationship between Fintech and sustainability. These studies explain how, in recent years, investors' attention to environmental issues is increased and how investors, that are concerned about such issues, reduce the probability of long-term failure. Such considerations are consistent with the fact that investors concern regarding climate change influences investment decisions and resource allocation. Moreover, the trends in the fintech sector regarding the environmental, sustainable, and governance factors boost the business

performance of financial institutions [11]. As stated in the McKinsey article [6], it is proven that a strong ESG proposition can guarantee long-term success for the company. Therefore, those ESG plans are not only a feel-good exercise but they are important for the growth of the company [3]. Some studies, for example, found that a company's ESG performance is positively related to stock market returns during the financial crisis and, furthermore, they suggest that ESG may play a significant role in company success during the Covid-19 pandemic [12]. It is worth mentioning that in recent years, the obligatory tools have been enhanced based on the issuer's sustainability performance, with characteristics that may change depending on the achievement of specific goals. Green Bonds, for example, are relatively new financial instruments that have experienced extraordinary growth since 2007. They are obligations and their emission is linked to projects that have a positive impact on the environment, such as energy efficiency, renewable energy production, and sustainable land use. Moreover, since 2020, other types of instruments were going to be added. Among those there are the sustainability-linked bonds, which have amassed a total value of 120 million euros as of December 2021, equal to 12% of the annual volume of ESG emissions [1]. Sustainability-Linked Bonds (SLB) are obligations with financial and structural characteristics that vary depending on the achievement of predefined goals related to the issuer's sustainability performance [2]. However, when it comes to making a financial decision, Europe is not in the first place in terms of environmental sustainability. In Indonesia, India, and China, on the other hand, when a financial institution is selected for supporting a new product or service, it is evaluated also in terms of environmental sustainability. Although the limited literature on the nexus between ESG and ICOS, a recent paper by Guzman et al. [5] investigate whether the attention to global warming increases the total funding raised in an environmental ICO by leveraging a set of 324 ICOs and Google trends information. In this paper, we aim at improving such analysis by analysing a wider data set composed of 621 ICOs and extracting specific references to ESG pillars from whitepapers through appropriate deep learning methods.

Our paper therefore puts a special emphasis on whether ESG dimensions influence ICOs performances. Thus, we propose to investigate the role played by a ESG flag covariate, appropriately built as described in the following section, in predicting the probability of success when collecting the expected amount of funds during the funding round. To this end, we use textual analysis techniques for creating a proper sustainability flag variable; afterwords, we fit logistic models with several specifications along the ESG dimensions and controls.

2. Data

As database, we consider the Token Offering Research Database by Paul P. Momtaz [10]. Such database contains more than 6,400 ICOs. It comprises several important pieces of information. Besides the available variables, we focus on the whitepapers' links and we download and use them to gather the information we require. By examining each whitepaper, we are able to learn about the company's industry, the number of words and pages, the level of technical and financial expertise and, most importantly, whether it is a company compliant with the ESG principles or carrying a related business idea. Indeed, we analyze each document searching for the ones which are related to sustainability and environment topics, looking both at those having as final purpose the sustainability and/or the environment. After screening for available whitepapers and relative ICOs with no missing data for the other variables of interest, we end up with a database containing 621 ICOs, spanning from 2014 to 2019. Our target variable, similarly to previous literature (for example [9]), is the binary flag of ICOs success/failure, evaluated as the ratio of raised funds and the hard cap, i.e. the maximum amount of funding expected to be raised. If the ratio is above 0.5, we assign success, failure otherwise.

By using the methods previously described, we are able to collect 16 independent variables. The country variable indicates the continent of each ICO divided into America, Africa, Asia, Europe, and Oceania. The accepting variable *CRYPTOACCEPT* indicates what type of cryptocurrency each ICO accepts, i.e. Bitcoin (BTC), Ethereum (ETH) and others. Every ICO is divided into those who admit Ethereum and those who accept Bitcoin and those who accept both. The sector variable shows the type of industry that corresponds to each ICO. We have several sectors: internet publishing and entertainment

providers; IT services and software development; environmental services; healthcare industry and research services; real estate industry; investment and financial services; Civic and Social Organizations; Manufacturing and logistics; consumer services; mining; facilities services. The *ERC20* variable is a dummy one that indicates whether the token offering adheres to the technical ERC20 standard. The technical standard is known as Ethereum Request for Comment 20 (or ERC20), and it specifies a set of rules that a token built on the Ethereum blockchain must follow [8]. So, in other words, ERC-20 establishes a standard for token fungibility. These tokens have a property that makes each token identical (in type and value) to another token. The variable *RATING* indicates the overall project rating on ICObench and it is based on the consensus of industry experts. It ranges from 1 to 5 (”poor quality” to ”good quality”). The *BOUNTY* variable is a dummy one indicating whether the token offering has a bounty program that rewards individuals (usually in the form of free tokens) for marketing activities that promote the offering and the startup. Bounty programs are rewards given to groups of participants for various activities related to an ICO. The *SOCIAL* variable is a numeric one that counts how many social networks (Linkeding, Twitter, Facebook, etc.) the ICO is advertized on. The *PRESALE* variable is a dummy stating whether the ICO had a pre-sale round or not. The *DURATION* variable is a numeric one that reports the number of days the ICO lasted. The *BTCOPENING* variable records the logarithm of the Bitcoin opening price (in USD) at the ICO starting date and the *TOKENPRICE* reports he logarithm of the ICO token price (in USD).

White papers have been fully analyzed through advanced textual analysis techniques based on Bidirectional Encoder Representations from Transformers (BERT) architecture, in order to extract information about the characteristics of the proposed business idea. In particular, we use pretrained model specifically tailored on ESG indicators and financial related vocabularies. The outcome of the model is a probability score for each classification class, e.g. Environmental, Social, Governance, estimating how much pertinent the whitepaper text is. In this way, we do not perform a topic-independent analysis, but we specifically focus and elicit the possible presence of sustainability related keywords. Such step is crucial for building the *ESGFLAG* covariate used in the analysis. Other BERT models are used to extract the continuous Financial Sentiment *FINSENT* (1 for positive, 0 for neutral, -1 for negative) and the level of technical terms *TECHLVL* (from 0 to 1), defined as the frequency of occurrence of tech-related words, e.g. Block-chain, Cloud, etc. Additionally, the length of the whitepaper *PAPERLENGTH* indicates the number of pages associated each paper. The variable *WORDSNUM* indicates the number of words into each paper.

3. Methodology and Results

We start the research by analyzing the Token Offering Research Database by Paul P. Momtaz [10]. We apply BERT model to each whitepaper, extracting the ESG topic probability and creating the related flag, as well as all the other text-related variables. At the end of this analysis, 150 ICOs are flagged as ESG-compliant. Due to collinearity, we remove the variable *WORDSNUM* (positively correlated with *PAPERLENGTH*).

We then fit a logit model with OLS estimation, taking into account for year-quarter, country and sector fixed effects, as well as clustering the error by country. We divide our analysis into two scenarios: in the first we only consider the impact of ICOs technical and financial specifications and in the second we include the information extracted from the whitepapers. Both scenarios include the key variable *ESGFLAG*, in order to validate our research hypothesis. Given the imbalance in the target variable, we opt for a weighted logit model, so as to mitigate the impact of the ”failure” class. Table 1 reports the results of both scenarios. Results are stable over the two scenarios. In particular, the type of cryptocurrency and the ERC20 protocol have a positive impact on the success, as BTC and ETH are the most traded cryptocurrencies and the ERC20 guidelines ensure a robust level of security. A positive effect of the presence of a bounty schema and the amount of social platforms is confirmed by the involvement of fundraisers in advertising the ICO. The presence of a pre-sale round and a short duration of the ICO increase the probability of success because they reflect the trust of the investors and the appeal of the product. The price of BTC at the beginning of the ICO and the small price of each sold token still contribute positively

in increasing the likelihood of success, as they reflect the global crypto market trend. In the second scenario, the length of the paper, the positive financial sentiment and the technical level of the content of the whitepaper additionally increase the probability of success. In both scenarios, we observe that the the success of an ICO is promoted when the project shows an interest in ESG topic.

Thus, preliminary results appear to confirm the nexus between ICOs success and ESG. The attention towards sustainability related topics in general seem to favour fund raising activities. This in line with a public audience tendency in evaluating better every activity connected to ethic and responsible behaviour. Such analysis will be further improved and robustified by enlarging the dataset and evaluating more control variables and scenarios.

Notes: The table reports coefficients and their standard error (in parentheses). The outcome variable is the binary flag of ICO's success/failure and all variables are defined in Section 2. Data span over the period 2014-2019. Estimation method is OLS with standard errors clustered by ICO's country. The bottom part of the table reports which fixed effects are used in each model specification. First column reports the baseline model, second reports the model that includes variables extracted from whitepapers. The *, ** and *** symbols denote the p-values at 10^{th}, 5^{th} and 1^{st} significance level, respectively.

On the impact of intraclass correlation in the ANVUR evaluation of academic departments

Giorgio E. Montanari[a] and Marco Doretti[a]

[a]University of Perugia, Department of Political Science, via Pascoli 20, 06123 Perugia (Italy);
giorgio.montanari@unipg.it, marco.doretti@unipg.it

Abstract

In Italy, academic departments are ranked according to a function of the scores assigned by ANVUR (an appointed national agency) to some of their scientific products. We show how intra-department correlation among these scores affects the overall validity of currently-in-use procedures. For this correlation, we also outline an identification and estimation strategy based on the available data.

Keywords: department ranking, performance index, research output evaluation

1. Introduction

The Italian Agency for the Evaluation of Universities and Research Institutes (Agenzia Nazionale di Valutazione del sistema Universitario e della Ricerca - ANVUR) is a public institution monitored by the Ministry of University and Research. In accordance with the Italian law, one of its tasks consists in periodically producing a ranking of academic departments reflecting their overall scientific quality level. Such a ranking serves as a tool to identify a restricted set of top departments (departments of excellence), which can compete to gain access to dedicated funds. The ranking methodology is based on a standardized departmental performance index (Indice Standardizzato di Performance Dipartimentale - ISPD). For each department, ISPD is computed as a function of scores assigned to a selection of scientific products (papers) written by its scholars. Specifically, the scores of another periodic department-level evaluation process (Valutazione della Qualità della Ricerca - VQR, also conducted by ANVUR) are taken [1].

Recently, a noticeable debate around the overall soundness of the ANVUR ranking methodology has risen [2]. The main critique lies in the fact that in the 2017 and 2022 rankings (based on the 2011-2014 and 2015-2019 VQR processes, respectively), the number of departments with extremely high and low ISPD values is sensibly higher than expected. Possible causes, however, have not been deeply investigated so far. In this paper, we address this problem by considering the most likely (in our view) reason of this discrepancy: the presence of some degree of intra-department correlation among the product scores.

2. The ANVUR standardized departmental performance index

For the 2015-2019 VQR process, Italian academic departments have been asked to submit a number of scientific products equal to three times the number of staff members, with sporadic exceptions. Each product belongs to a scientific field (Settore Scientifico Disciplinare - SSD) and, after the evaluation process, it receives a VQR score equal to 0, 0.2, 0.5, 0.8 or 1, with higher scores denoting higher quality

levels. To remove heterogeneity in evaluation standards among SSDs, product scores are then standardized with the mean and standard deviation of all scores associated to products of the same SSD. Thus, for each SSD, standardized scores have null average and standard deviation equal to 1.

Let N_d be the number of evaluated scientific products for the d-th department ($d = 1, \ldots, D$). Further, denote by Z_{dji} the standardized score for the i-th product of the j-th SSD, with $i = 1, \ldots, N_{dj}$ and $j \in \text{SSD}_d$ (the set of SSDs in the d-th department), where $N_d = \sum_{j \in \text{SSD}_d} N_{dj}$. The ANVUR ranking procedure computes, for each department, the scaled average

$$Z_d \equiv \sqrt{N_d}\bar{Z}_d = \frac{\sum_{j \in \text{SSD}_d} \sum_{i=1,\ldots,N_{dj}} Z_{dji}}{\sqrt{N_d}}$$

($\bar{Z}_d$ being the sample average) and defines the standardized departmental performance index as

$$\text{ISPD}_d = 100 \cdot \Phi(Z_d),$$

where $\Phi(\cdot)$ denotes the Cumulative Density Function (CDF) of the standard normal distribution (note that published ISPD values are rounded to the nearest semi-integer). Clearly, this index ranges from 0 to 100, with higher values denoting better performances. Specifically, ISPD_d is interpreted as the percentage probability that the product set of a virtual department with the same SSD structure as d - formed by replacing each product of the department d with one selected at random from those of the SSD it belongs to - realizes a scaled average score not greater than that of d. Indeed, under such a random process, Z_{dji} is a standardized random variable. Thus, assuming the absence of correlation among the Z_{dji} variables, each department's scaled average Z_d is approximately distributed as a standard normal random variable by virtue of central limit theorem. Since N_d is typically greater than 60 (with a few exceptions), the approximation is reliable.

The ISPD is used to rank departments in the same way as an order statistic since, under the above assumptions, it has a uniform distribution on the 0-100 interval. Specifically, denoting by $F(x)$ the CDF of ISPD_d evaluated at x, we have

$$\begin{aligned} F(x) &= P(\text{ISPD}_d \leq x) = P(100 \cdot \Phi(Z_d) \leq x) = P(Z_d \leq \Phi^{-1}(x/100)) \\ &= \Phi(\Phi^{-1}(x/100)) = x/100. \end{aligned}$$

3. The impact of intra-department correlation

The approach described in Section 2. hinges on the assumption that the Z_{dji} variables are uncorrelated. However, such an assumption might be unrealistic due to the fact that scholars submit more than one product to the VQR procedure, as well as to departments' tendency to aggregate scholars with similar scientific quality levels, especially within SSDs. This generates a non-null intra-department correlation among the Z_{dji} variables, that we model as $\rho_d = \text{Cor}(Z_{dji}, Z_{dj'i'})$ for all $i = 1, \ldots, N_{dj}$, $i' = 1, \ldots, N_{dj'}$ and $j, j' \in \text{SSD}_d$ such that $ji \neq j'i'$. Hence, the variance of the scaled department average modifies to

$$V(Z_d) = 1 + (N_d - 1)\rho_d \equiv \sigma_d^2, \tag{1}$$

becoming department-specific. Since it is reasonable to assume that ρ_d is positive, we have $\sigma_d^2 > 1$, meaning that the distribution of each Z_d has heavier tails than the standard normal.

In this setting, the comparability of the ISPD_d values - if computed without a proper modification - is in doubt. To acknowledge this fact, suppose that two departments with the same number of products, say 150, but different intra-department correlations, say 0.02 and 0.05, realize the same scaled average, say 2.0. For both departments, ISPD is equal to 97.7, but the true percentage probabilities of performing better than the corresponding random virtual departments are 84.2% and 75.4%. Conversely, if the common scaled average were equal to -2.0 (*ceteris paribus*), the two true percentage probabilities would be 15.8% and 24.7%, whereas the ISPD value would be 2.3 for both departments. Clearly, analogous discrepancies would arise for departments with the same scaled average and correlation, but with different number of products. Hence, the comparison is no more unaffected by the size of the departments, as it would be if all the ρ_d values were equal to zero.

4. Identification and estimation

The heterogeneity of the σ_d^2 variances implies that the observed department scaled averages, and ISPD values in turn, cannot be treated like realizations from the same distribution as in Section 2. In fact, the former can be thought of as realizations of a stratified sample, with one observation per stratum (i.e., department). The underlying observed random variable, denoted by S, is characterized by the mixture density

$$f_S(s) = \frac{1}{D}\sum_{d=1}^{D} \phi(s; 0, \sigma_d^2), \tag{2}$$

with $\phi(x; 0, \sigma^2)$ representing the probability density function at x of a $N(0, \sigma^2)$ variate. Straightforward calculations show that $E(S) = 0$ and that

$$V(S) = \frac{1}{D}\sum_{d=1}^{D} \sigma_d^2 = 1 + \frac{1}{D}\sum_{d=1}^{D}(N_d - 1)\rho_d \equiv \sigma^2, \tag{3}$$

which is greater than 1 since all the σ_d^2 terms also are; see Section 3.

In this framework, ISPD values can be thought of as independent realizations of $100 \cdot \Phi(S)$. Thus, under the assumption that the distribution of S is approximately normal, the fact that $\sigma^2 > 1$ provides an immediate explanation as to why a surplus of departments with low and high values generates. In practice, the empirical histogram of the ISPD values, rounded to the nearest semi-integer, will approximately assume a "bath-tub shape" (or U-shape), with two peaks in correspondence of extreme values 0 and 100 as well as densities symmetrically increasing as the index moves away from the center of the distribution. Such a trend is recognizable in the right tail of both the 2017 and 2022 ISPD distributions (the only portions of data made available by ANVUR), while an U-shaped histogram appeared in an independent analysis performed on the whole 2017 data [2]. For the latter, it has been reported that 119 out of 766 departments (15.54%) had ISPD < 0.5, and exactly the same number had ISPD > 99.5 [2].

The σ^2 parameter can be identified from the ISPD distribution in a number of ways. The simplest approach relies on the aforementioned assumption that $S \approx \sigma Z$, with Z being a standard normal variate. Thus, letting for any $\alpha \in (0, 0.5)$

$$P_\alpha = P(\text{ISPD}_d \leq 100 \cdot (\alpha/2) \ \cup \ \text{ISPD}_d \geq 100 \cdot (1 - \alpha/2)),$$

simple algebra shows that $P_\alpha \approx 2\big(1 - \Phi(Z_{\alpha/2}/\sigma)\big)$ and, consequently,

$$\sigma \approx \frac{Z_{\alpha/2}}{\Phi^{-1}(1 - 0.5P_\alpha)}, \tag{4}$$

where $Z_{\alpha/2}$ is the standard normal distribution quantile leaving $\alpha/2$ probability at its right. Clearly, the goodness of the approximations in the above formulas depends on how close to normality S is. Hence, for a given α, estimation of σ can be performed via (4) after estimating P_α. In this respect, for the 2017 ANVUR data the estimated proportion $\hat{P}_{0.01} = 2 \cdot 119/766 = 31.07\%$ has been reported [2], leading to $\hat{\sigma} \approx 2.541$.

Unfortunately, this strategy for the (approximate) identification of σ does not enable identification of all department-specific correlations ρ_d, unless additional assumptions are made. For example, assuming $\rho_d = \rho$ in (3) returns

$$\hat{\rho} = \frac{\hat{\sigma}^2 - 1}{\bar{N} - 1}, \tag{5}$$

where $\bar{N} = D^{-1}\sum_d N_d$. More generally, assuming that ρ_d and N_d are (statistically) uncorrelated, it is possibile to identify the average correlation $\bar{\rho} = D^{-1}\sum_d \rho_d$, whose estimate is still given by the right-hand side of (5). For the 2017 ANVUR data, we have $\hat{\rho} = \hat{\bar{\rho}} \approx 0.042$, where $\bar{N}$ is computed starting from information in [2] and considering that in the 2011-2014 VQR process each scholar had to submit two products (again, with rare exceptions).

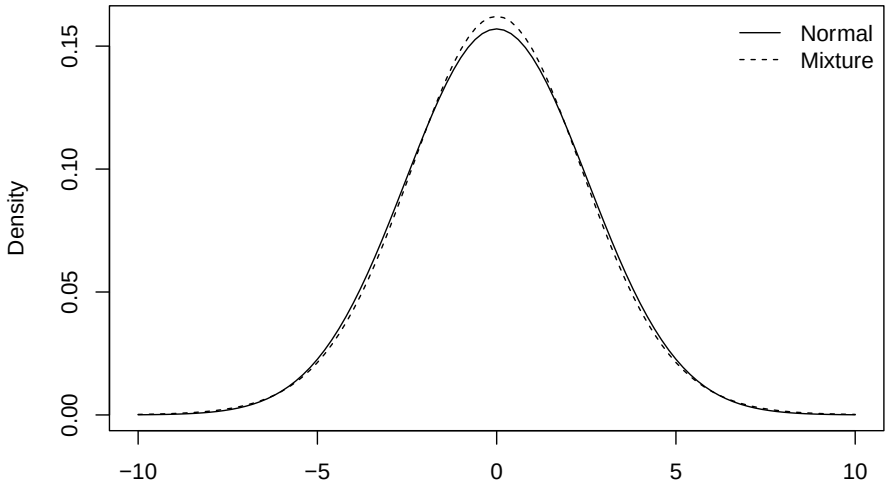

Figure 1: 2017 ANVUR data: density of the $N(0, \hat{\sigma}^2)$ distribution (undashed) and of the mixture of equally-weighted centered normal distributions with variances $\hat{\sigma}_d^2$ (dashed, $d = 1, \ldots, D$).

When the correlation level is assumed constant across departments, it is also possibile to identify and estimate all the σ_d^2 parameters by replacing ρ_d with $\hat{\rho}$ in (1). Under this approach, for the 2017 ANVUR data the estimated department-specific variances $\hat{\sigma}_d^2$ range from 1.969 to 20.499, with average $\hat{\sigma}^2 = 6.456$ and standard deviation equal to 2.090. These estimates have been plugged-in in (2) to build the estimated mixture density $\hat{f}_S(\cdot)$, which is plotted in Figure 1 together with the $N(0, \hat{\sigma}^2)$ density. As shown by the graph, the two functions are quite close, which makes the $S \approx \sigma Z$ assumption reasonable.

5. Further remarks and possible extensions

In this paper, we have motivated why ISPD values are highly concentrated in the distributions tails, with almost one third of Italian academic departments assuming the extreme values (0 or 100) in the 2017 ranking (in 2022, this phenomenon is even more pronounced). This owes to the fact that the variances of scaled averages are greater than 1, due to the correlation among the VQR scores of scientific products in the same department. Importantly, departments with (rounded) ISPD equal to 100 (as well as to 0) might severely differ in their scaled averages and, thus, in their performance. This may be unveiled by computing ISPDs with the CDF of a normal distribution with null expectation and variance equal to that of the observed scaled averages, $\hat{\sigma}^2$.

Generally speaking, the intra-department correlation is department-specific. Even if it were the same in all departments, the variances of scaled averages would not be constant because of the different size of the departments. Thus, scaled averages are not comparable, since they are drawn from distributions with different variability, and for this reason the ISPD-based department ranking might be misleading.

Access to the VQR scores assigned to each scientific product would enable direct identification and estimation of department-specific correlations ρ_d and, in turn, of variances σ_d^2 via (1). In this framework, the $Z_d/\hat{\sigma}_d$ ratio could be approximately thought of as a draw from a standard normal distribution, although some adjustments are needed because variance estimation has to be properly accounted for. The adoption of an index given by $100 \cdot \Phi(Z_d/\hat{\sigma}_d)$ would be the first step toward a fairer and more appropriate performance measure.

Future research could also deal with refinement of the ρ_d modeling, via the decomposition of this correlation level into a number of sub-components. Such an approach would allow to account more explicitly for a number of additional features as, for example, the fact that multiple scientific products belong to the same person, and that each department's scholars are further grouped into SSDs. However, sample size issues are likely to arise if N_d is not big enough.

Abstract

The aim of this work is to estimate monetary poverty indicators at provincial level in Italy taking into account the different price levels within the country. To account for the local price levels, we compute Spatial Price Indexes (SPIs) using retail scanner data on retail prices. The SPIs are used to adjust the poverty line when computing poverty indicators at provincial level that are estimated using Small Area Estimation (SAE) models.

Keywords: Poverty mapping, Spatial price indexes, Scanner data

1. Introduction

Poverty measures at sub-national and local level play an important role in setting policy actions against poverty and social exclusion.

Particularly, the local poverty indicators are relevant both for a detailed planning of the policies actions and for the citizens to evaluate their effect. However, there are still open problems to compute adequate sub-national poverty indicators. One of the main issue in estimating these indicators at sub-national level (such as Italian provinces) is the need to account for the cost-of-living differences in the comparison of poverty between different territorial areas. To assure that the poverty line(s) represent approximately the same standard of living across the different areas, Spatial Price Indexes (SPIs) are used to adjust the national poverty line at the local level. Spatial price indexes are measures of differences in price levels across areas, essential to compare economic well-being indicators. However, at the sub-national and local level, direct estimates of poverty measures are not accurate because sample surveys on income or consumption expenditures are usually designed so that direct estimators lead to reliable estimates only for larger domains (states, regions). Small area estimation (SAE) comprises the methods for obtaining more precise estimators in local areas, making use of the common features of the areas. A wide range of methods have been proposed and used in literature to obtain reliable small-area estimates (mostly model-based estimators (4)).

The costs involved for carrying out ad-hoc surveys for collecting price data and the labour-intensive analyses necessary for processing traditional price data have limited attempts to regularly produce SN-SCPIs (Sub-National Spatial Consumer Prices Indices). Because of this, using big data such as business transaction data can be a suitable solution to the challenges that National Statistical Institutes (NSIs)

encounter in comparing consumer prices at different territorial levels (2). Since 2018, Istat has included scanner data of grocery products (excluding fresh food) provided by the market research company AC-Nielsen in the production process of the consumer price indices. Due to the high coverage of transactions and the high territorial coverage, scanner data represent an useful source in order to compare price levels among geographical areas within a country at a very detailed territorial level (such as provinces).

Therefore, in this work we use scanner data to compute Spatial Price Indexes (SPIs) at provincial level in Italy. Then the poverty incidence at provincial level is estimated by using different poverty lines adjusted using the SPIs. In this way, the poverty estimates consider the different purchase power within the country. The scanner database referred to the years 2017 and 2018 were provided by an agreement between Istat and ASESD Dagum Centre signed to implement the tasks of the MAKSWELL project (www.makswell.eu) (for more details please refer to the work by Pratesi, Giusti, Marchetti, Biggeri, Bertarelli, Schirripa Spagnolo, Laureti, Benedetti, Polidoro, Di Leo, Fedeli of the Makswell "Deliverable 3.2 - Guidelines for best practices implementation for transferring methodology").

2. Estimation of Spatial Consumer Price Indexes for the Italian Provinces

Spatial Consumer Price Indexes for the Italian Provinces needs to be estimated to adjust the national poverty line and to take into account the different price levels within the country. To estimate the SN-SCPs for each of the 103 (out of 110) Italian provinces, two-step procedure has been followed, adapting the approach of (7).

In the first step, we computed the average unit price at provincial level, by considering the unit value prices from the consumer side. In applying the principle of comparability, we did not follow a very tight way by considering the comparisons of the 'like to like' items (products). Instead, we applied the principle at a different level, the level products' groups, and exactly at the level of the 102 groups of the European Classification of Individual Consumption according to Purpose (ECOICOP) 8-digit classification.

Define the weighted mean price $\bar{p}_{ij}$ for ECOICOP-8-digit j and province i. Let r_{ijk} and q_{ijk} be the annual turnover and the total quantity sold[1] respectively of item k belonging to ECOICOP-8-digit j in province i. These quantities are estimated by Istat using the scanner data of the products sold in modern distribution chains referring to the year 2017 and the sampling weights computed according to the survey design (we refer to Deliverable 3.2 of the MAKSWELL project for further details). In order to obtain, for each item the annual price per gr. or ml., the turnover per item (r_{ij}/q_{ij}) is divided by the quantity of the item ijk in terms of gr. or ml. u_{ijk}:

$$p_{ijk} = \frac{\frac{r_{ijk}}{q_{ijk}}}{u_{ijk}}.$$

Then, for each item we define its relative weights in term of turnover as

$$w_{ijk} = \frac{r_{ijk}}{\sum_{k=1}^{n_{ij}} r_{ijk}},$$

where n_j is the number of items in the jth ECOICOP-8-digit aggregation and the ith province. Finally, the weighted mean price is:

$$\bar{p}_{ij} = \frac{1}{n_{ij}} \sum_{k=1}^{n_{ij}} p_{ijk} w_{ijk}.$$

Therefore, $\bar{p}_{ij}$ is the weighted mean price per gr. or ml. for products in ECOICOP-8-digit j and province i.

The second step is devoted to the aggregation of 102 average level of prices to estimate the provincial SPI. Note that not all the ECOICOP-8-digit aggregates are present in all the provinces.

[1] Which are the expenditure and the quantity purchased by consumers.

To compute the SPIs at provincial level we adapt a Country Product Dummy (CPD) model (3). The products are aggregated by province and ECOICOP-8-digit classification, for a total of 103 provinces and 102 ECOICOP-8-digit. Note that not all the ECOICOP-8-digit aggregates are present in all the provinces. The CPD model we propose is as follows:

$$\log \bar{p}_{ij} = \alpha_0 + \alpha_i D_i + \beta_j I_j + \varepsilon_{ij}, \quad i = 1, \ldots, 103 \quad j = 1, \ldots, 102, \tag{1}$$

where D_i is a vector equal 1 if the mean price is in province i and 0 otherwise, I_j is equal 1 if the mean price belongs to jth ECOICOP-8-digits and 0 otherwise. The index i is for the provinces and the index j is for the ECOICOP-8-digit. The error $\varepsilon_{ij} \sim N(0, \sigma^2)$.

To take into account the different level of the turnover between the ECOICOP-8-digit aggregates we estimate the model (1) using weighted least squares, where the weights are computed as

$$wls_{ij} = \frac{\sum_{k=1}^{n_{ij}} r_{ijk}}{\sum_{k=1}^{n_i} r_{ijk}},$$

the ratio between the total turnover of one aggregate in one province and the total turnover in the province (n_i is the number of items in the ith province).

Model (1) – as it is specified – is not identified, because the D_is vectors are a linear combination of the constant. Therefore, we impose the constraint $\alpha_1 = 0$ so that the model is identified. Once the model is estimated, from the data we obtain the estimates of the SPIs at provincial level by $\exp(\hat{\alpha}_i)$, where $\hat{\alpha}_i$ is the estimate of α_i. The coefficient α_i is the difference of fixed effects connected with the province i compared with the base province $i = 1$. To use as a reference Italy instead of area 1, the coefficients $\hat{\alpha}_i$ has been adjusted following (6).

The aim of this work is to use the estimated SPIs to adjust the national poverty line at the province level. The SPIs estimated according to model (1) are based on mean prices of specific headings (ECOICOP-8-digit), therefore the adjustment of the national poverty line is not poor specific. As an alternative, the method can be easily extended to produce SPIs related to the first quintile of the distribution of the price of each specific product, assuming that poor purchase the cheaper items of the product. For example, figure 1 reports two choropleth maps of estimated SPIs based on model (1, left) and on an adjusted the model that considers the quantile 0.2 of the unit prices to obtain the estimates of spatial price indices related to the cheaper prices for each Italian provinces, which we denote as SPI($Q_{0.2}$)'s (right).

The results we obtained are somehow expected. Indeed, provinces in the south of Italy show SPIs smaller than 1, while provinces in the north show values greater than 1. However, there are exceptions, provinces in the north-east Alps mountains show SPIs below 1, even if they are close, both considering the mean and the quantile 0.2 of unit prices.

3. The impact of the local cost-of-living differences on the measure of the poverty incidence

To evaluate the poverty incidence at provincial level in Italy we estimate the Head Count Ratio using Household Expenditure Survey (HES) data in Italy. To take into account the different price levels, the national poverty line is adjusted for each province using the SPI($Q_{0.2}$) values opportunely weighted (adapting the idea in (5)):

$$nPL_i^* = nPL \times (\lambda_i SPI_i + 1 - \lambda_i) \tag{2}$$

where nPL is the national poverty line, nPL_i^* is the adjusted poverty line for province i, λ_i is the estimated share of food consumption in province i and SPI_i is the SPI($Q_{0.2}$) for province i. The quantities λ_i's are estimated from the HES 2017 as the provincial mean of the ratios between the food expenditure and the total consumption expenditure:

$$\lambda_i = \frac{1}{\sum_{j=1}^{n_i} w_{ij}} \sum_{j=1}^{n_i} \frac{p_{ij}}{t_{ij}} w_{ij}, \tag{3}$$

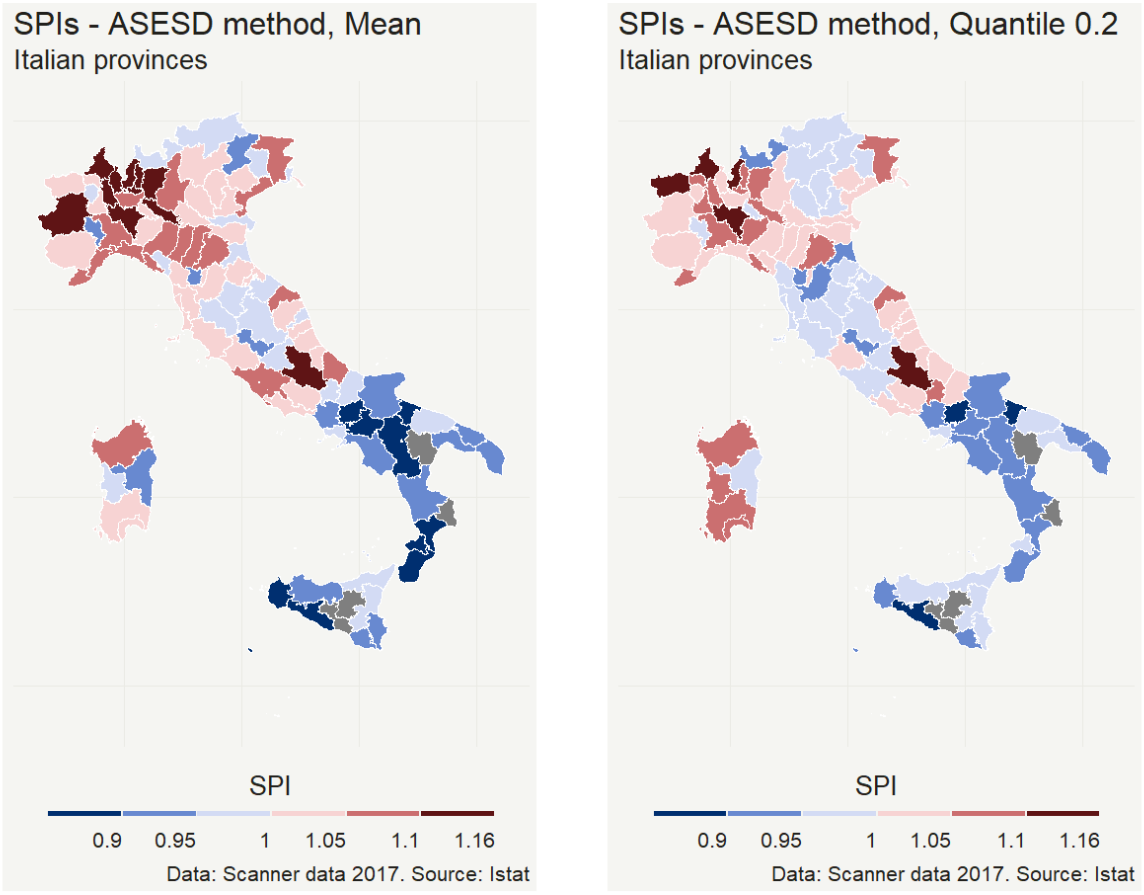

Figure 1: Choropleth map of SPIs obtained using mean unit prices (left) and quantile 0.2 of unit prices (right).

where n_i is the sample size in province i, w_{ij} is the survey weight of household j in area i, p_{ij} is the food expenditure of household j in area i and t_{ij} is the total consumption expenditure of household j in area i. The survey weights have been calibrated to sum to the total households at provincial level. Although the λ_i's are estimated at the provincial level – thus possibly unreliable because of small sample size – we judge the direct estimates suitable for our purpose.

Having computed the adjusted nPLs, we then calculated the corresponding direct estimates of the poverty rates. As the variability of the direct estimates was too high (approximately half of the provinces a CV greater than 30%) we estimated a Fay-Herriot (FH) model (1) with the following auxiliary variables: the ratio between number of taxed persons over the population, and the ratios between the number of persons with i. income coming from salary, ii. income coming from pensions and iii. income lower than 10,000 euros per year, over the number of taxed persons. These data come from the Italian tax agency database 2017.

The Empirical Best Linear Unbiased Predictor (EBLUPs) obtained with the FH model showed a gain in efficiency with respect to direct estimates. We obtained a CV smaller than 16% in 37 provinces, while half of the provinces had a CV smaller than 20%.

Figure 2 maps the Head Count Ratio (HCR) computed using the price-adjusted poverty lines referring to the Italian provinces[2]. As we can see, the results confirm the well-known north/south divide, with HCR values that are generally higher in the south of the country, lower in the north.

We also computed the EBLUPs without any adjustment of the national poverty line, using the same small area model as for adjusted EBLUPs. Figure 3 reports the comparison of the two set of EBLUPs estimates: as we can see, using the SPI($Q_{0.2}$) to adjust the poverty lines, the HCRs in northern and central

[2]The HCR value has not been estimated for out of sample provinces in the HES data. Specific predictions could be made for this provinces.

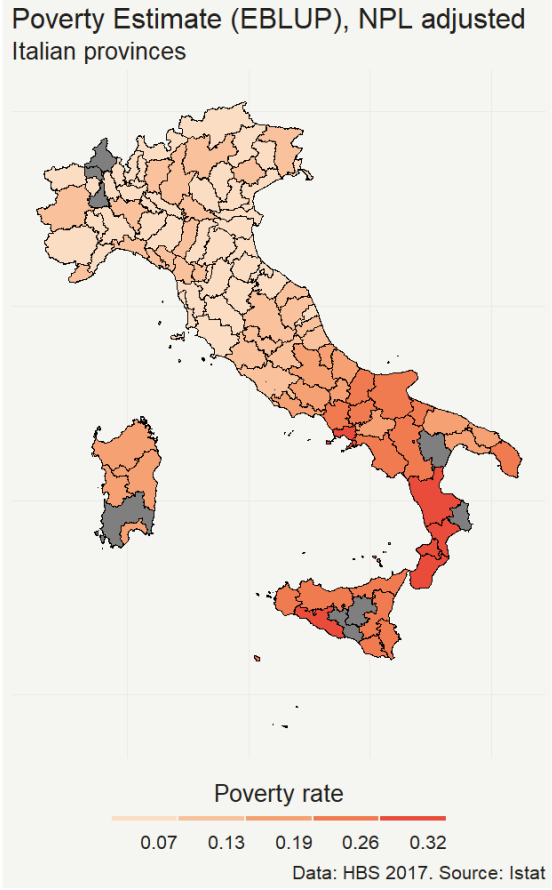

Figure 2: Poverty rate at provincial level in Italy: EBLUPs computed using the adjusted national poverty line.

provinces slightly decrease.

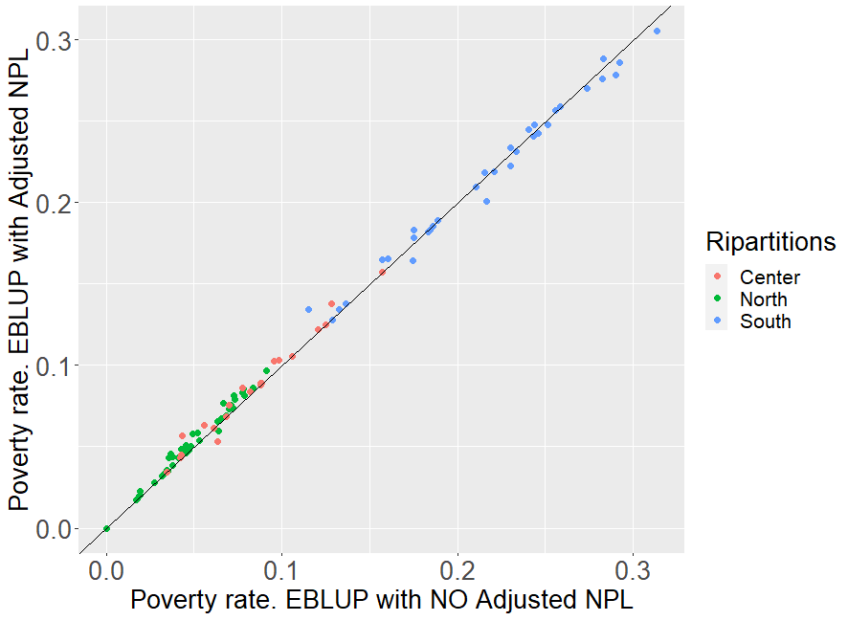

Figure 3: Poverty rate at provincial level in Italy: provincial EBLUPs estimates using the SPI($Q_{0.2}$) adjusted vs not adjusted national poverty line.

The results obtained suggest that the methodology can be extended to include other Spatial Price Indexes, therefore adjusting the national poverty line with other components of households' consumption expenditure. Indeed, our results suggest the products included in the scanner data represent a relevant but still limited share of the total household consumption expenditure, approximately equal to the 20%. Therefore, by including other consumption expenditure components, such as for example the expenditure for the rent, the national poverty line could be adjusted in a more complete manner.

Abstract

Augmenting traditional data with digital trace data is an emerging trend in statistics, as it offers the possibility to explore novel aspects not covered by traditional data sources. This study focuses on corporate sustainability and proposes to augment traditional data (from a commercial database) with social media data under a composite indicators perspective. We present and apply a modular framework for data augmentation, by building on previous research. The innovative aspect of this paper is the evaluation of the quality of the resulting indicator through a sensitivity analysis. Integrating data from different sources requires more attention than classical sensitivity analysis, where different aggregation strategies and weighting procedures are compared. It is also necessary to consider the unique nature of the innovative data source. In our study, we also test the stability of the results to different data selection strategies, data cleaning, and analytical choices for extracting relevant information from the text. We conclude with recommendations for researchers interested in augmenting traditional data with digital trace data.

Keywords: Data Augmentation, Corporate Sustainability, Social Media

1. Introduction

Measuring sustainability has become increasingly important and, in recent years, also businesses and organizations have recognized the importance of prioritizing environmental and socially responsible behaviours [7]. Measuring and evaluating the commitment of businesses towards sustainability is important to policy makers and researchers, especially with respect to the goals of the Agenda 2030. With the availability of innovative data, such as big or digital trace data, researchers can explore new aspects of sustainability phenomena, which are not covered by traditional data sources. By combining traditional and innovative data, it is possible to gain a more complete understanding of sustainability and identify areas where action is needed.

At the same time, informed decision making relies on good quality data. Traditionally, such data are represented by survey and also administrative/commercial database data. Surveys are considered the gold standard: structured, checked for quality and with well-established statistical error framework [2]. Some examples are the European Company Surveys, the Business and Consumer Surveys (BCS) and other surveys carried out by National Statistical Institutes. Alongside surveys, other popular sources for business statistics are administrative or commercial business data [6]. These are still structured data, quality is checked and improved when necessary. However, these data are not primarily collected for statistical or research purposes. For that reason, they are usually referred to as secondary data. Business registers, documents from local authorities (e.g., tax authority), and law-mandatory reporting are all examples of administrative data. Commercial business data are provided by private companies, for example, Bureau van Dijk, Bloomberg, and Refinitiv.

More recently, the digital transformation has resulted in the emergence of new sources for business and economic statistics [3]. For example, social media posts, annual reports, businesses websites and newspaper articles can be used to study new aspects or getting additional information about companies.

In this respect, the production of statistics using traditional data enhanced with new data available from online sources are referred to as smart statistics. One of the advantages of smart statistics is the ability to augment the information, thereby providing richer insights to the topic of interest.

This paper focuses on the concept of corporate sustainability, and extends on a previous study where a methodology for constructing smart composite indicators by augmenting traditional data with digital trace data has been proposed [15]. In this study quality aspects are addressed. Corporate sustainability is closely related to the notion of Corporate Social Responsibility (CSR), which involves implementing activities aimed at improving firms' reputation and positively impacting society [5]. Social media data present an opportunity for researchers and policy makers to monitor business behaviours concerning sustainable development and the Agenda 2030 by investigating online communication about CSR activities.

In Section 2, we summarize the modular framework proposed in previous papers, as well as the data used. However, the quality of the resulting indicator has not been extensively studied and evaluated before. Thus, we aim to address this topic in the current paper. Section 3 evaluates the stability of results through a sensitivity analysis, considering not only classical aspects like aggregation strategy and weighting, but also novel aspects related to the innovative data source, such as data selection, data cleaning, and analytical choices for extracting relevant information from the text. In Section 4, we conclude with recommendations for researchers interested in building composite indicators using both traditional and digital trace data.

2. The Case Study

As part of an ongoing research, this work is based on two papers where a smart composite indicator measuring corporate sustainability (SMART-INDEX) is constructed following the original modular framework proposed by Bianchi et al. [4] and Salvatore et al. [15]. It is based on the modular organization into three layers introduced by Ricciato et al. [10]. We briefly present the results of a previous work and then we move to the original contribution of this paper, the sensitivity analysis. More details about the theory of composite indicators can be found in [9,8].

The SMART-INDEX is derived from the combination of a traditional index (TRAD-INDEX), already available in a commercial database, and an original social media-based indicator (SM-INDEX). In the following paragraph we explain how to derive such indicator using the modular framework. Figure 1 presents the adaptation of the general framework to our case study.

The first layer involves digital trace data collection and their transformation into structured data. To the purpose of our analysis and as part of an ongoing research project, we consider the same data used in Salvatore et al. [14,15]. They refer to the firms included in the Dow Jones Industrial Average index, i.e., a stock market index that measures the performance of the 30 largest US listed companies as of the composition in August 2020. Following the tasks in the first layer, we identified and retrieved the data form the official Twitter accounts of the companies. Given that companies may have several Twitter accounts, we focused primarily on CSR accounts and, in case these are not available, on the news or multipurpose ones. The objective is to reduce the noise (no-CSR tweets) in the data. The Tweets refers to the 2019 year and the total number of messages retrieved is 25,148. In order to extract the relevant information from the text, the Structural Topic Model ([11]) has been applied and topics have been assigned to CSR dimensions: social, economic, environmental, and mixed. For more information about the data and the topic model methodology, please refer to Salvatore et al. [14,15]. The output of the first layer is a set of elementary indicators which are the base for the construction of the SM-INDEX.

From a theoretical point of view, social media communication differs in content (the topic discussed) and modality (the way it is conducted). Thus, we consider two dimensions to build the SM-based indicator. The first one refers to the communication content in tweets, i.e., to the text which refers to the communication of CSR activities in one of its dimensions, economic, social, environmental, and general (or mixed). The second one refers to communication modality (media richness from tweets metadata; the higher the media richness, the more effective the communication will be [1]).

The second layer involves the practical construction of the SM-INDEX (Figure 2). The composite indicator for the content dimension is constructed by considering the output of the topic model as its elementary indicators. Specifically, the proportion of text devoted to each CSR dimension for each tweet is used. We assume that these proportions are substitutes (compensatory aggregation) with the same importance (no weight). To obtain the composite indicator, we take the sum of these proportions at the

tweet level and then aggregate them at the firm level by taking the arithmetic mean (first innovative indicator).

The composite indicator for the modality dimension is based on tweets' metadata. Similar to the content dimension, we consider elementary indicators to be substitutes (compensatory aggregation) with the same importance (no weight). The elementary indicators used are the presence of hashtags, mentions, media, and links (binary variables). For each tweet, we sum these individual indicators, obtaining a score between 0 and 4. We then aggregate these scores at the firm level by computing the arithmetic mean (second innovative indicator).

Once the modality and the content indexes are constructed, it is necessary to combine them to obtain the SM-INDEX. In this case we propose to apply the Mazziotta-Pareto index (MPI) [8] which is partially compensatory recognizing that the two dimensions are equally important but partially substitute to gain efficiency in CSR communication. Indeed, a deficiency in the content can be partially compensated by effective communication (and vice versa).

For an in-depth description of the aggregation approach, please refer to Salvatore et al. [15].

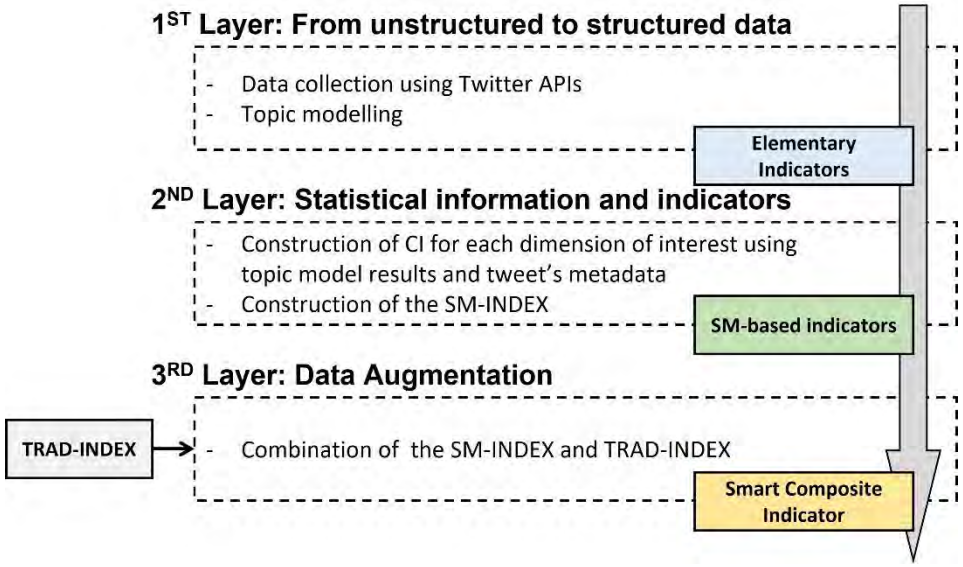

Figure 1: Modular Framework for Smart Composite Indicator adapted to our case study.

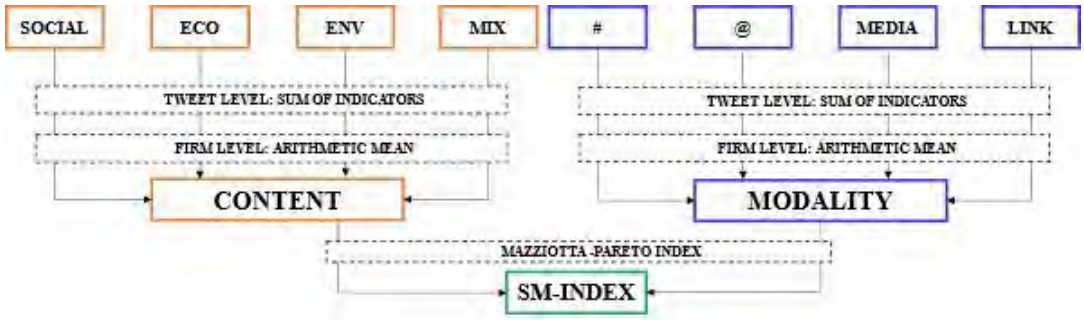

Figure 2: SM-INDEX construction strategy.

Finally, the third layer entails the data augmentation step. As TRAD-INDEX we consider the CSR-Strategy Score provided by Refinitiv, a commercial database. It reflects a company's practices to integrate economic (financial), social and environmental dimensions into its day-to-day decision-making process and it ranges between 0 and 100.

Considering the SM-INDEX and the TRAD-INDEX, it is possible to build a combined innovative smart indicator (SMART-INDEX). For the aggregation of SM-INDEX and TRAD-INDEX, we propose to apply the MPI (Figure 3). Indeed, we assume that the two dimensions are partially compensatory, i.e.,

efficient communication might compensate low effective commitment and high effective commitment might compensate scarce communication.

The SMART-INDEX measures the commitment in a more comprehensive way, considering not only the effective commitment (traditional indicator) but also the effort in online CSR communication (social media indicator).

Figure 3: SMART-INDEX construction strategy.

3. Emerging aspects of quality evaluation

Evaluating the quality of the resulting innovative indicators (SM-INDEX and SMART-INDEX) is crucial. The quality of a composite indicator depends on several factors, including the quality of the underlying data, construction procedures and its ability to produce stable and accurate measurements (robustness).

In the field of composite indicators, robustness is evaluated through uncertainty (UA) and sensitivity analyses (SA) [13]. UA focuses on how uncertainty in the input factors propagates through the structure of the composite indicators and influence its value. SA studies how much each individual source of uncertainty contributes to the output variance. For a general discussion of the procedures, please refer to [13].

However, considering the multi-source nature of the process, the evaluation of data quality and robustness is needed at each of the three layers and new aspects related to digital trace data should be considered [12]. These aspects include data retrieval (e.g., selection of social media accounts), data preprocessing and analytical methods to transform unstructured data into structured. Therefore, careful consideration of these factors is crucial to evaluate the quality of the innovative indicators.

In the next sections we present some preliminary analysis related to the influence of data retrieval and analytical choices on the SMART-INDEX. Additional results will be available in a forthcoming paper.

3. Sensitivity Analyses - Preliminary Results

In this section, we present the initial findings from a portion of our sensitivity analyses. It could be argued that the uneven selection of accounts (CSR, news, and multipurpose) may impact the results. Therefore, we conducted the first part of our sensitivity analyses to investigate the effects of various data selection strategies. Specifically, we compared the indexes derived from the complete dataset to those obtained from three distinct scenarios.

1. *Scenario 1:* all accounts but restricted to tweets for which the CSR text proportion (according to the STM model results) is higher than 50%.
2. *Scenario 2:* all accounts but restricted to tweets for which the CSR text proportion (according to the STM model results) is higher than 80%.
3. *Scenario 3:* only CSR accounts.

To facilitate summary and illustration, we limit our analysis to firms with more than 500 tweets in all scenarios (i.e., we only consider Microsoft, Verizon, Salesforce, Amgen and Cisco). Table 1 provides the values of SM-INDEX, TRAD-INDEX and SMART-INDEX considering all data and in the three scenarios considered above.

In general, we can see that the TRAD-INDEX is very similar across all companies. A rational behind this similarity is that the index is constructed considering mainly compliance to laws and regulation with respect to CSR reporting that, nowadays, is a common practice for most companies. The SM-INDEX

allows to discriminate better the communication about CSR commitment among firms. The combination of the two indicators provides an innovative measure of CSR commitment and communication effectiveness, giving additional insights to researchers.

Table 1: Sensitivity analyses results.

		All data			Scenario 1: CSR >= 50%		
Firm Name	**TRAD INDEX**	**SM INDEX**	**SMART INDEX**	**Ranking**	**SM INDEX**	**SMART INDEX**	**Ranking**
Verizon	107,30	89,61	96,87	5	91,26	97,86	5
Salesforce	99,36	98,25	98,80	4	96,45	97,99	4
Microsoft	104,44	95,18	99,38	3	94,51	98,98	3
Amgen	107,30	103,40	105,28	2	104,11	105,66	2
Cisco	107,30	110,22	108,72	1	110,24	108,73	1
		Scenario 2: CSR >= 80%			**Scenario 3: Only CSR Accounts**		
Firm Name	**TRAD INDEX**	**SM INDEX**	**SMART INDEX**	**Ranking**	**SM INDEX**	**SMART INDEX**	**Ranking**
Verizon	107,30	90,26	97,31	5	91,63	98,23	4
Salesforce	99,36	97,43	98,37	4	97,40	98,36	3
Microsoft	104,44	95,00	99,27	3	92,99	98,05	5
Amgen	107,30	103,44	105,30	2	104,46	105,84	2
Cisco	107,30	110,52	108,86	1	109,32	108,29	1

To the purpose of the sensitivity analyses, we can compare the general results with the three scenarios. When ranking the companies based on the value of the smart INDEX, it is evident that there are no differences with Scenario 1 and 2. However, the ranking in scenario 3 is different although the value of the indexes slightly differs. More precise measures of the size of the difference can be computed through the difference of the ranks and the calculation of Spearman correlation coefficient.

4. Conclusions and Future Developments

This paper demonstrated that augmenting traditional data with digital trace data offers new opportunities to better understand phenomena. In particular, the proposed SMART-IDEX allows to measure sustainability commitment in a more comprehensive way.

However, an important point to stress is the quality of the resulting indicator. This paper represents a first attempt to understand the stability of the results to different methodological choices. Future developments for the final paper include a comprehensive classical sensitivity analysis (e.g. aggregation strategies, weighting) when constructing both the SM and the SMART indexes and a more in-depth understanding of the impact of analytical choices when using innovative and unstructured data sources.

Abstract

We explore some ideas on most powerful tests in the specific case of survival data with right censoring. We carry out the test under the proportional hazards assumption, and we wish to assess whether an i.i.d. sample from the population has survival times that are generated by the known survival function $S_0(t)$ and not by $S_1(t) = [S_0(t)]^{\beta^*}$. Equivalently, the test in terms of hazard functions compares $\lambda_0(t)$ to $\lambda_1(t) = \beta^*\lambda_0(t)$. Specifically, we first discuss the test with no censoring, for a sample size equal to one and a sample size $n > 1$. Then, we obtain an explicit form of the most powerful test for a sample size equal to one with censoring.

Keywords: Most powerful test, Proportional hazards, Survival analysis.

1. Introduction

We describe some ideas on the use of Most Powerful (MP) tests in the survival framework under the proportional hazards (PH) assumption, with and without independent right censoring. In particular, we wish to test whether an i.i.d. sample has survival times that are generated by the known survival function $S_0(t)$ and not by $S_1(t) = [S_0(t)]^{\beta^*}$. In Section 2. we explore the MP test in the survival framework without censoring and in Section 3. with censoring. We close with some discussion in Section 4.

2. MP test with no censoring

In the survival setting without censoring, the observed time coincides with the value t of the time-to-event random variable T. From the PH assumption we define $\lambda_1(t) = \beta^*\lambda_0(t)$, which is equivalent to $S_1(t) = [S_0(t)]^{\beta^*}$, and the hypothesis system can be also written as

$$\begin{cases} H_0 : S(t) = S_0(t) \\ H_1 : S(t) = S_0(t)^{\beta^*} \end{cases} \iff \begin{cases} H_0 : \beta = 1 \\ H_1 : \beta = \beta^*, \end{cases}$$

with $\beta^* \neq 1$, assuming $S_0(t)$ known. The Neyman-Pearson level α MP test (see (1)), with a single observation t, rejects if and only if

$$\Lambda(t) = \frac{f_1(t)}{f_0(t)} \geq k_\alpha, \text{ with } k_\alpha : P\left(\frac{f_1(T)}{f_0(T)} \geq k_\alpha; H_0\right) = \alpha.$$

From the PH assumption, since $f(t) = -\dfrac{dS(t)}{dt}$, we have that $f_1(t) = \beta^* S_0(t)^{\beta^*-1} f_0(t)$. Therefore, the rejection rule can be rewritten as $\beta^* S_0(t)^{\beta^*-1} \geq k_\alpha$. Depending on whether $\beta^* > 1$ or $\beta^* < 1$, we have

- if $\beta^* < 1$, then $\beta^* S_0(t)^{\beta^*-1} \geq k_\alpha \iff S_0(t) \leq \left(\dfrac{k_\alpha}{\beta^*}\right)^{1/(\beta^*-1)} = \widetilde{k}_\alpha$, such that $P(\text{Reject } H_0; H_0) = P(S_0(T) \leq \tilde{k}_\alpha; H_0) = \alpha$. Since $S_0(T) \sim$Unif$[0,1]$, $\widetilde{k}_\alpha = \alpha$. Then the rejection region in terms of the time-to-event is $T \geq S_0^{-1}(\alpha)$.
- if $\beta^* > 1$, then $\beta^* S_0(t)^{\beta^*-1} \geq k_\alpha \iff S_0(t) \geq \left(\dfrac{k_\alpha}{\beta^*}\right)^{1/(\beta^*-1)} = \widetilde{k}_\alpha$, such that $P(\text{Reject } H_0; H_0) = P(S_0(T) \geq \widetilde{k}_\alpha; H_0) = \alpha$. Again, by $S_0(T) \sim$Unif$[0,1]$, $\widetilde{k}_\alpha = 1-\alpha$ follows immediately. Again, the rejection region in terms of the time-to-event is $T \leq S_0^{-1}(1-\alpha)$.

As $\widetilde{k}_\alpha$ does not depend on β^* except for its sign, the two tests are Uniformly Most Powerful (UMP) at level α for the two wider problems $H_0 : \beta = 1$ vs. $H_1 : \beta < 1$ and $H_0 : \beta = 1$ vs. $H_1 : \beta > 1$, respectively.

When dealing with an i.i.d. sample $(t_1, \ldots, t_n)$, with $n > 1$, the MP test is given by:

$$\Lambda(t_1, \ldots, t_n) = \prod_{i=1}^{n} \left[\frac{f_1(t_i)}{f_0(t_i)}\right] \geq k_\alpha, \text{ with } k_\alpha : P\left(\prod_{i=1}^{n} \left[\frac{f_1(T_i)}{f_0(T_i)}\right] \geq k_\alpha; H_0\right) = \alpha.$$

Again, this can be rewritten as $(\beta^*)^n \prod_{i=1}^n [S_0(t_i)]^{\beta^*-1} \geq k_\alpha$, and

- if $\beta^* < 1$, then $\sum_{i=1}^n [\log(S_0(t_i))] \leq \log\left(\dfrac{k_\alpha}{(\beta^*)^n}\right)^{1/(\beta^*-1)} = \widetilde{k}_\alpha$,
- if $\beta^* > 1$, then $\sum_{i=1}^n [\log(S_0(t_i))] \geq \log\left(\dfrac{k_\alpha}{(\beta^*)^n}\right)^{1/(\beta^*-1)} = \widetilde{k}_\alpha$,

with the appropriate (different) values $\widetilde{k}_\alpha$. We call $W = W(T_1, \ldots, T_n) = \sum_{i=1}^n [\log(S_0(T_i))]$, and notice that, since under H_0 $\log(S_0(T_i)) \sim$ Exp(1), then $W \sim$ Gamma$(n, 1)$. Hence, the threshold for rejection $\widetilde{k}_\alpha$ is easily found, and, as it does not depend on β^* except for its sign, the two rejection regions of the UMP tests are $W \geq$ Ga$(n,1)_{1-\alpha}$, and $W \geq$ Ga$(n,1)_\alpha$ for $H_0 : \beta = 1$ vs. $H_1 : \beta > 1$ and $H_0 : \beta = 1$ vs. $H_1 : \beta < 1$, respectively. Here the subscripts α and $(1-\alpha)$ indicate the percentiles of the Gamma$(n, 1)$ distribution.

3. MP test for independently right censored data

In the right censored survival setting, for the generic subject i, one observes the pair $\underline{\mathbf{x}}_i = (x_i, \delta_i)^T$, with $x_i = \min(t_i, c_i)$ and $\delta_i = \mathbf{I}(t_i \leq c_i)$, the observed time and the indicator of having observed the event, respectively. We follow the usual notation that has t_i indicate the survival time, and c_i indicate the (independent) censoring time both measured from the same origin.

The Neyman-Pearson most powerful test, when only one observation (x, δ) is available, rejects the null hypothesis if and only if:

$$\Lambda(x, \delta) = \frac{f_1(x)^\delta S_1(x)^{1-\delta}}{f_0(x)^\delta S_0(x)^{1-\delta}} \geq k_\alpha, \text{ with } k_\alpha : P(\Lambda(X, \delta) \geq k_\alpha; H_0) = \alpha.$$

Simple algebra shows that this is equivalent to the rejection rule $(\beta^*)^\delta S_0(x)^{\beta^*-1} \geq k_\alpha$, or $S(x)^{\beta^*-1} \geq \left(\dfrac{k_\alpha}{(\beta^*)^\delta}\right)$. We obtain the following MP test for $\alpha^* < \alpha$, based on k_α such that:

- if $\beta^* > 1$, $k_\alpha :\ S_0^{-1}\left(\left(\dfrac{k_\alpha}{\beta^*}\right)^{1/(\beta^*-1)}\right) = S_C^{-1}\left((1-\alpha) \cdot \left(\dfrac{k_\alpha}{\beta^*}\right)^{\beta^*-1}\right)$,

- if $\beta^* < 1$, $k_\alpha : \; S_0^{-1}\left(k_\alpha^{1/(\beta^*-1)}\right) = S_C^{-1}\left(\alpha \cdot k_\alpha^{\beta^*-1}\right)$.

Since β^* is fixed, these should be solved (probably numerically) for $k_\alpha^* = k_\alpha^*(\beta^*)$. The rejection regions are $\{X \leq \gamma_1, T \leq C\} \cup \{X \leq \gamma_2, T > C\}$ and $\{X \geq \gamma_1, T \leq C\} \cup \{X \geq \gamma_2, T > C\}$, respectively for $\beta^* > 1$, and $\beta^* < 1$, with $\gamma_1 = S_0^{-1}\left(\left(\frac{k_\alpha}{\beta^*}\right)^{1/(\beta^*-1)}\right)$, and $\gamma_2 = S_0^{-1}\left(k_\alpha^{1/(\beta^*-1)}\right)$. The proof follows.

We first explore the case $\beta^* > 1$. Since $\beta^* > 1$, $\frac{k_\alpha}{\beta^*} < k_\alpha$, and $\frac{1}{\beta^*-1} > 0 \Rightarrow \left(\frac{k_\alpha}{\beta^*}\right)^{1/(\beta^*-1)} < k_\alpha^{1/(\beta^*-1)} \Rightarrow S_0^{-1}\left(\left(\frac{k_\alpha}{\beta^*}\right)^{1/(\beta^*-1)}\right) > S_0^{-1}\left(k_\alpha^{1/(\beta^*-1)}\right) \Rightarrow \gamma_1 > \gamma_2$.

The rejection region is $(\beta^*)^\delta S_0(x)^{\beta^*-1} \geq k_\alpha$, with $k_\alpha : P_{(X,\Delta)}\left((\beta^*)^\Delta S_0(X)^{\beta^*-1} \leq k_\alpha; H_0\right) = 1-\alpha$, the probability of no rejection. This is

$$
\begin{aligned}
&P_{(X,\Delta)}\left((\beta^*)^\Delta S_0(X)^{\beta^*-1} \leq k_\alpha; H_0\right) = \\
&= P_{(X,\Delta)}\left((\beta^*)^\delta S_0(X)^{\beta^*-1} \leq k_\alpha, \delta = 1; H_0\right) + P_{(X,\Delta)}\left((\beta^*)^\delta S_0(X)^{\beta^*-1} \leq k_\alpha, \delta = 0; H_0\right) \\
&= P\left(\beta^* S_0(X)^{\beta^*-1} \leq k_\alpha, T \leq C; H_0\right) + P\left(S_0(X)^{\beta^*-1} \leq k_\alpha, T > C; H_0\right) \\
&= P\left(S_0(X) \leq \left(\frac{k_\alpha}{\beta^*}\right)^{1/(\beta^*-1)}, T \leq C; H_0\right) + P\left(S_0(X) \leq (k_\alpha)^{1/(\beta^*-1)}, T > C; H_0\right) \\
&= P\left(X \geq S_0^{-1}\left(\left(\frac{k_\alpha}{\beta^*}\right)^{1/(\beta^*-1)}\right), T \leq C; H_0\right) + P\left(X \geq S_0^{-1}\left((k_\alpha)^{1/(\beta^*-1)}\right), T > C; H_0\right) \\
&= P\left(X \geq \gamma_1, T \leq C; H_0\right) + P\left(X \geq \gamma_2, T > C; H_0\right) \\
&= P\left(T \geq \gamma_1, C \geq \gamma_1, T \leq C; H_0\right) + P\left(T \geq \gamma_2, C \geq \gamma_2, T > C; H_0\right) \\
&= \int_{\gamma_1}^\infty \int_t^\infty f_T(t) f_C(c) \mathrm{d}c \mathrm{d}t + \int_{\gamma_2}^\infty \int_c^\infty f_C(c) f_T(t) \mathrm{d}t \mathrm{d}c \\
&= \int_{\gamma_1}^\infty f_T(t) S_C(t) \mathrm{d}t + \int_{\gamma_2}^\infty f_C(c) S_T(c) \mathrm{d}c.
\end{aligned}
$$

Since $\gamma_1 > \gamma_2$, we have that

$$
\begin{aligned}
&\int_{\gamma_1}^\infty f_T(t) S_C(t) \mathrm{d}t + \int_{\gamma_2}^\infty f_C(c) S_T(c) \mathrm{d}c > \int_{\gamma_1}^\infty f_T(t) S_C(t) \mathrm{d}t + \int_{\gamma_1}^\infty f_C(c) S_T(c) \mathrm{d}c \\
&= \int_{\gamma_1}^\infty \left[f_T(u) S_C(u) + f_C(u) S_T(u)\right] \mathrm{d}u = -S_T(u) S_C(u)\big|_{\gamma_1}^\infty = S_T(\gamma_1) S_C(\gamma_1).
\end{aligned}
$$

We set $k_\alpha^* : S_T(\gamma_1) S_C(\gamma_1) = 1-\alpha$, so that $P(\text{Reject } H_0; H_0) = \alpha^* \leq \alpha$, i.e. we control the type I error probability. For that true P(type I error), the test is, therefore, MP with level α^*. Note that k_α^* will depend on S_C. The value of k_α^* for a given β^* is thus obtained by solving $S_T(\gamma_1) S_C(\gamma_1) = 1-\alpha$, where

$\gamma_1 = \gamma_1(k_\alpha)$, or

$$
\begin{aligned}
& S_0\left(S_0^{-1}\left(\left(\frac{k_\alpha}{\beta^*}\right)^{1/(\beta^*-1)}\right)\right) S_C\left(S_0^{-1}\left(\left(\frac{k_\alpha}{\beta^*}\right)^{1/(\beta^*-1)}\right)\right) = 1-\alpha \\
\iff & \left(\frac{k_\alpha}{\beta^*}\right)^{1/(\beta^*-1)} S_C\left(S_0^{-1}\left(\left(\frac{k_\alpha}{\beta^*}\right)^{1/(\beta^*-1)}\right)\right) = 1-\alpha \\
\iff & S_C\left(S_0^{-1}\left(\left(\frac{k_\alpha}{\beta^*}\right)^{1/(\beta^*-1)}\right)\right) = (1-\alpha)\left(\frac{k_\alpha}{\beta^*}\right)^{\beta^*-1} \\
\iff & S_0^{-1}\left(\left(\frac{k_\alpha}{\beta^*}\right)^{1/(\beta^*-1)}\right) = S_C^{-1}\left((1-\alpha)\left(\frac{k_\alpha}{\beta^*}\right)^{\beta^*-1}\right)
\end{aligned}
$$

Now, consider the case $\beta^* < 1$. Similarly to above, we have now $\frac{k_\alpha}{\beta^*} > k_\alpha$, and $\frac{1}{\beta^*-1} < 0 \Rightarrow \left(\frac{k_\alpha}{\beta^*}\right)^{1/(\beta^*-1)} > k_\alpha^{1/(\beta^*-1)} \Rightarrow \gamma_1 > \gamma_2$, like before. The rejection region is however different. Indeed, we reject $H_0 \iff (\beta^*)^\delta S_0(x)^{\beta^*-1} \geq k_\alpha$, again with $k_\alpha : P_{(X,\Delta)}\left((\beta^*)^\Delta S_0(X)^{\beta^*-1} \geq k_\alpha; H_0\right) = \alpha$. We now split the probability of rejection as

$$
\begin{aligned}
& P_{(X,\Delta)}\left((\beta^*)^\Delta S_0(X)^{\beta^*-1} \geq k_\alpha; H_0\right) = \\
& = P\left(S_0(X) \leq \left(\frac{k_\alpha}{\beta^*}\right)^{1/(\beta^*-1)}, T \leq C; H_0\right) + P\left(S_0(X) \leq k_\alpha^{1/(\beta^*-1)}, T > C; H_0\right) \\
& = P\left(X \geq S_0^{-1}\left(\left(\frac{k_\alpha}{\beta^*}\right)^{1/(\beta^*-1)}\right), T \leq C; H_0\right) + P\left(X \geq S_0^{-1}\left(k_\alpha^{1/(\beta^*-1)}\right), T > C; H_0\right) \\
& = P(X \geq \gamma_1, T \leq C; H_0) + P(X \geq \gamma_2, T > C; H_0) \\
& = P(T \geq \gamma_1, C \geq \gamma_1, T \leq C; H_0) + P(T \geq \gamma_2, C \geq \gamma_2, T > C; H_0) \\
& \leq \int_{\gamma_2}^{\infty} f_T(t) S_C(t) \mathrm{d}t + \int_{\gamma_2}^{\infty} f_C(c) S_T(c) \mathrm{d}c = S_T(\gamma_2) S_C(\gamma_2).
\end{aligned}
$$

Again, set $k_\alpha^* : S_T(\gamma_2) S_C(\gamma_2) = \alpha$, such that the probability of rejection P(Reject H_0;H_0)= $\alpha^* \leq \alpha$, and again the test is MP with level α^*. Hence, the value of k_α^* is found by setting $S_T(\gamma_2) S_C(\gamma_2) = \alpha$, such that

$$
\begin{aligned}
& S_0\left(S_0^{-1}\left(k_\alpha^{1/(\beta^*-1)}\right)\right) S_C\left(S_0^{-1}\left(k_\alpha^{1/(\beta^*-1)}\right)\right) = \alpha \iff k_\alpha^{1/(\beta^*-1)} S_C\left(S_0^{-1}\left(k_\alpha^{1/(\beta^*-1)}\right)\right) = \alpha \\
& \iff S_C\left(S_0^{-1}\left(k_\alpha^{1/(\beta^*-1)}\right)\right) = \frac{\alpha}{k_\alpha^{1/(\beta^*-1)}} \iff S_0^{-1}\left(k_\alpha^{1/(\beta^*-1)}\right) = S_C^{-1}\left(\alpha \cdot k_\alpha^{\beta^*-1}\right).
\end{aligned}
$$

When the sample size is $n > 1$, the rejection rule of the MP test is given by:

$$
\Lambda(\underline{x}, \underline{\delta}) = \frac{L_{\underline{X},\underline{\Delta}}(\underline{x}, \underline{\delta}|H_1)}{L_{\underline{X},\underline{\Delta}}(\underline{x}, \underline{\delta}|H_0)} = \prod_{i=1}^{n}\left[(\beta^*)^{\delta_i} S_0(x_i)^{\beta^*-1}\right] \geq k_\alpha, \text{ with, } k_\alpha : P(\Lambda(\underline{X}, \underline{\Delta}) \geq k_\alpha; H_0) = \alpha,
$$

with $\underline{x} = (x_1, \ldots, x_n)^T$ and $\underline{\delta} = (\delta_1, \ldots, \delta_n)^T$. No simpler description of the rejection region is currently available for this case. However, it is easily seen that the test statistic depends on $(\underline{X}, \underline{\Delta})$ only through $\left(\sum_{i=1}^n \log\left(S_0(X_i)\right), \sum_{i=1}^n \Delta_i\right)^T$, whose joint distribution is needed to obtain k_α, and thus the implementable form of the test.

Note that this reduces to $(\sum_{i=1}^n X_i, \sum_{i=1}^n \Delta_i)^T$, the sufficient statistic that appears in the maximum likelihood estimator of the parameter λ when $T_1, \ldots, T_n \sim$Exp(λ). Indeed, for the exponential model, $S_0(t; \lambda) = \mathrm{e}^{-\lambda_0 t}$, and $\sum_{i=1}^n \log\left(S_0(x_i)\right) = -\lambda_0 \sum_{i=1}^n x_i$, with λ_0 known.

4. Conclusions

As seen in Section 3, the bivariate test statistic of the last case depends on $(\underline{X}, \underline{\Delta})$ only through $(\sum_{i=1}^{n} \log(S_0(X_i)), \sum_{i=1}^{n} \Delta_i)^T$, whose joint distribution is needed to obtain the implementable form of the test. The fact that both $\sum_{i=1}^{n} \log(S_0(X_i))$ and $\sum_{i=1}^{n} \Delta_i$ are needed when dealing with censored data is of course not surprising: the very meaning of X_i depends on the value of Δ_i, and the latter is clearly dependent on the former. That dependence is such that the probability that a survival time is not (entirely) observed depends on its value so that the partial observation mechanism is not ignorable. To see that, consider for example the case of the non-parametric estimation of the survival function: one clearly cannot simply discard the observations for which $\Delta_i = 0$ and use the remaining observations to estimate $S(t)$ by, say, the empirical survival function $\widehat{S}^*(t) = \frac{\sum_{i=1}^{n} \Delta_i \cdot \mathbf{1}(X_i \geq t)}{\sum_{i=1}^{n} \Delta_i}$ without further adjustments (as is done, e.g., by the Kaplan-Meier estimator). Indeed, one can show that this estimator is consistent for the quantity $S(t)$ only in the case of a censoring random variable that is degenerate to infinity with probability one. The proof is reported in Appendix 4.

Appendix: the non-negligibility of censored observations

In what follows, we assume that the support of $f_T(t)$ is R^+. We show that one cannot simply ignore the censored cases ($\Delta_i = I(T_i \leq C_i) = 0$). We consider the empirical survival function estimator and we assess the case when it is consistent for the true survival function, for fixed t.

$$\begin{aligned}
&\widehat{S}^*(t) = \frac{\sum_{i=1}^{n} \Delta_i \cdot I(X_i \geq t)}{\sum_{i=1}^{n} \Delta_i} \\
&\widehat{S}^*(t) \xrightarrow{p} \frac{E(\Delta \cdot I(X \geq t))}{E(\Delta)} = \frac{E(I(T \leq C) I(X \geq t))}{E(I(T \leq C))} \text{ as } n \to \infty \\
&= \frac{E(I(T \leq C) I(X \geq t) I(C \geq t))}{E(I(T \leq C))} \text{ since } X = \min(T, C) \\
&= \frac{P(T \leq C, X \geq t, C \geq t)}{P(T \leq C)},
\end{aligned}$$

to be compared to $S(t) = P(T \geq t)$. Suppose that the equality holds. Since $\{T \geq t\} \cap \{C \geq T\} \subseteq \{C \geq t\}$, the equality is equivalent to

$$\frac{P(T \leq C, T \geq t)}{P(T \geq t)} = P(T \leq C) = k \quad \forall t \geq 0.$$

Hence:

$$\begin{aligned}
&P(T \leq C, T \geq t) = k \cdot P(T \geq t) \\
&\frac{\mathrm{d}}{\mathrm{d}t} \left[\int_t^{\infty} \int_u^{\infty} f_{C|T}(c|u) f_T(u) \mathrm{d}c \mathrm{d}u \right] \overset{T \perp C}{=} \frac{\mathrm{d}}{\mathrm{d}t} \left[\int_t^{\infty} S_C(u) f_T(u) \mathrm{d}u \right] \overset{Leibnitz}{=} -S_C(t) f_T(t).
\end{aligned}$$

Since $\frac{\mathrm{d}}{\mathrm{d}t} S_T(t) = -f_T(t)$, we have $\frac{\mathrm{d}}{\mathrm{d}t} P(T \leq C, T \geq t) = -S_C(t) f_T(t) = -k f_T(t)$, i.e. $S_C(t) = k \; \forall t \geq 0$, which implies $S_C(t) = 1 \; \forall t \geq 0$ since $S_C(0) = 1$. Finally, $C = +\infty$ with probability one, and immediately $\Delta = 1$ with probability one. Note that without the assumption that the censoring and the cases are independent, the censoring time does not need to be degenerate at $+\infty$.

Abstract

We consider the case of a multivariate random vector that obeys a linear mixed model when the vector itself lies in a lower dimensional subspace. This situation suggests that this subspace can be modeled by the probabilistic (random-effects) principal components. By reason of this, the random vector follows at the same time two different models. We employ a linear predictor adjusted by the residual part of the probabilistic principal components that results not explained by the linear model. The new predictor can be considered as the vector of scores that comes from that principal components, enhanced by the linear mixed model. The application to the official Italian well-being data shows some features of the method.

Keywords: multivariate random vector, principal components, linear mixed model, well-being

1. Introduction

Principal component analysis (PCA) is recognized as one of the most employed methods to reduce dimensionality, by means of the projection of a set of variables in a subspace of them. By summarizing and allowing to visualize data, and, at the same time, minimizing the loss of information in the lower dimensional space, in many cases principal components (PCs) lead to a better assessment of the bundled statistical information, seized by the original variables [2]. Because PCs are linear combinations, the interpretation of the scores by these new "data-dependent" variables is hard to give some time. In particular situations, the contribution improve understanding of some case studies may be poor and may lead to misguided or unclear findings. Furthermore, in the great majority of cases, when the interpretation stills on loadings that exceed a threshold, the linking of the variables hardly fails to provide some explanation or a bit of insight. Because of using of the common practice of ignoring the PCs affected by lower loadings, the focus shifts to the first PCs, which arise from the most correlated variables in the original set. The issue of resting on the main linearly-dependent variables is particularly relevant and becomes crucial in several instances. We may come across the trade-off between considering the retained PCs as highlighting latent phenomena, or in reproducing similar information unnecessarily. One of the recurrent ways of approaching redundancy and, in general, the recursive informative content of multivariate sample data, is given by considering a common subset of covariates that the population obeys. Two main cases in the literature are deemed representative of the joint dependence on a multivariate vector, the PCs "with covariates" or Partial PCA, and the redundancy analysis. Given a subspace spanned by the sample vectors of predictor variables, both of them rely on the common baseline of splitting the sample variance as the sum of the variance "explained" by a multivariate linear regression model, and the variance due to the regression residuals. Although these last represent a very useful tool in some cases, the deployment

of linear models to explain part of the sample variability has had a remarkable development in the last years. One of these studies brings into play the role of prediction by linear statistical models.

Tipping and Bishop [7] had already introduced the notion of prediction for PCs. They called "Probabilistic PCA" (PPCA) the model behind the PCA, which parameters are estimated with the Expectation - Maximization algorithm. The "noisy" PC model (nPC), proposed by Ulfarsson and Solo [8] has a quite similar formulation with respect to the PPC model, providing - in a similar way - the nPC prediction after giving the model estimates. Instead of a "fixed effects PCs", as the traditional linear regression PCA model, the PPC (or nPC) are random variables. This condition suggests, on the one hand, the Bayesian approach to handle the estimates for the PPC linear model and, on the other hand, to predict PCs under its meaning within random linear models theory [4]. The Bayesian approach to the estimation requires an expectation of some model parameters that are random, conditional to the observed data. Given normality of the error $\varepsilon \sim N(0, \sigma^2 I)$, for a linear model $\tau = B\lambda + \varepsilon$ - in case of the vector λ random - the likelihood is based on the conditional distribution $\lambda|\tau \sim N[E(\lambda|\tau), var(\lambda|\tau)]$.

Moreover, it is known [6] that $E(\lambda|\tau) = \widetilde{\lambda}$ is the "Best Prediction" (BP) estimate, with $var(\widetilde{\lambda} - \lambda) = E_\tau[var(\lambda|\tau)]$. This is somewhat different from the standard linear regression model prediction by $E(\tau|\lambda)$. Therefore, given a linear mixed model (LMM) [1] for τ, with $E(\tau|\lambda) = \lambda$, the model parameters are the realizations of random variables. The BP of a linear combination of the LMM fixed and random effects (i.e. linear in τ, with $E[E(\tau|\lambda)] = 0$) gives the "Best Linear Unbiased Prediction" (BLUP) estimates [5]. LMM's are particularly suitable for modeling with covariates (fixed and random) and for specifying model covariance structures [1]. They allow researchers to take in account special data, such as hierarchical, time-dependent, correlated, covariance-patterned models. Thus, given the BP estimates of the nPC λ, $\widetilde{\lambda} = E(\lambda|\tau)$, the vector $\widetilde{\tau} = B\widetilde{\lambda}$ represents the BP of the p-variate vector.

In the present paper, we introduce a multivariate LMM that considers the dependent random vector effectively represented by the subspace of the PPCs. The new predictor combines the linear model and the PPC's, carrying simultaneously the Best Linear Predictor, and the contribution given by the PPCs not "explained" by the linear predictor itself. An application to the official Well-being Italian indicators shows some of the features of the method.

2. Theory

In the sequel we report the following symbols, giving the model specification.

- $n =$ the number of subjects in the LMM model $(i = 1, ..., n)$;
- $N = \Sigma n_i =$ total sampling units considered;
- $p =$ the number of the response dependent variables;
- $l =$ the number of the linear model covariates;
- $j = 1, ..., n_i$ the within-subject (groups) units;
- $s =$ the dimension of the effective PC subspace.

Consider Θ as the $N \times p$ sample matrix of the p-variate $p \times 1$ random vector θ, with N as the total number of the units given by the sample. Moreover, consider that the vector θ obeys the linear model:

$$\theta = \beta' x + u', \tag{1}$$

where x is the $l \times 1$ vector of covariates, β is the $l \times p$ matrix of the regression effects, u is the vector of the p-variate random effect, with $u \sim N(0, \Sigma_u)$, $\Sigma_u = cov(u)$. Furthermore, we consider at the same time that the multivariate random vector θ obeys the following linear model:

$$\theta = Ab + \epsilon, \tag{2}$$

in which A is $p \times s$ a loading matrix of eigenvectors, b is the random vector of PPCs, and ϵ is a vector of isotropic error, with $\theta \sim N(\mu, A\Psi A' + \sigma_\epsilon^2 I)$, $b \sim N(0, \Psi)$, $\Psi = diag(\psi_1, \ldots, \psi_s)$, $s < p$, and $\epsilon \sim N(0, \sigma_\epsilon^2 I)$. When a sample of N observations is given, an $N \times p$ matrix Y of observations from the random vector θ is simply modeled as $Y = \Theta + E$, with the "sampling error" $Np \times Np$ covariance matrix

$cov(vec(E)) = (\Sigma_e) \otimes I_N$ ($\otimes$ is the Kronecker product), $e \sim N(0, \Sigma_e)$, $\Sigma_e = var(e)$. Thus, models (1) and (2) are rewritten as $Y = \Theta + E = X\beta + ZU + E$, with the (1) that becomes $\theta = \beta' x + u' + e'$, and $Y = \Theta + E = BA' + \Xi + E = BA' + \Gamma$, with the (2) is $\theta = Ab + \epsilon + e = Ab + \gamma$, respectively. The model errors u, ϵ, and e, are mutually independent. The matrix Z represents the $N \times n$ design matrix of random effects and E is the $N \times p$ matrix of the residual errors of the multivariate LMM, B is the $N \times s$ matrix of the PPCs that lie in the s-dimensional subspace, Ξ is the $N \times p$ matrix of the isotropic errors of the model (2). The models (1) and (2) have the following conditional expectations and variances:

$$\begin{aligned} E(\theta|y) &= \widetilde{\theta}_y = y - E(e|y) = y - cov(e,y)var(y)^{-1}y = y - var(e)Py, \\ var(\theta|y) &= var(\theta) - cov(\theta,y)var(y)^{-1}cov(y,\theta) \\ &= var(e) - var(e)Pvar(e), \end{aligned}$$

for the model in (1), where $P = \Sigma_y^{-1}(I - P_X)$, $\Sigma_y = var(y)$, and P_X is the projection matrix. For the model in (2):

$$\begin{aligned} E(b|\theta) &= E(b) + cov(b,\theta)var(\theta)^{-1}(\theta - \mu) \\ &= cov(b, \mu + Ab + \epsilon)C^{-1}(\theta - \mu) = \Psi A' C^{-1}(\theta - \mu), \\ var(b|\theta) &= var(b) - cov(b,\theta)var(\theta)^{-1}[cov(b,\theta)]' \\ &= \Psi - \Psi A' C^{-1} A\Psi \\ C &= A\Psi A' + \sigma_\epsilon^2 I. \end{aligned}$$

Based on some results on linear projections, i.e., given the random variable y, and the $1 \times j$, $1 \times k$ random vectors x, z, with positive definite covariance matrix of $(y, x, z)'$, then for the linear projection $L(y|x,z)$:

$$L(y|x,z) = L(y|x) + [z - L(z|x)]\gamma,$$

where $\gamma = var(z|x)^{-1}[cov(y,z|x)]'$, we get the following:

Proposition 1. *Given the model (2) for the p-dimensional random vector θ, with $b = \overline{F}'(\theta - \epsilon)$, and under the models in (1) and (2), the multivariate Best Predictor based on (y, b), $E(\theta|y,b)$, is:*

$$E(\theta|y,b) = \widetilde{\theta}_{y,b} = E(\theta|y) + cov(\theta,b|y)var(b|y)^{-1}\left\{\widetilde{b} - E(b|y)\right\}, \tag{3}$$

with $\widetilde{b} = E(b|\theta)$, $\overline{F}$ the $sN \times pN$ matrix $(\overline{A}'\overline{A})^{-1}\overline{A}$, and $\overline{A}$ is the $pN \times sN$ matrix $A \otimes I_N$. Then, $var(\theta|y,b) = var(\theta|y) - cov(\theta,b|y)var(b|y)^{-1}[cov(\theta,b|y)]'$.

The "hybrid" predictor $\widetilde{\theta}_{y,b}$ in (3) gives the Best Linear Unbiased Predictor $E(\theta|y)$, "embedding" the PPCs through an adjoint component. The last is due to knowing that the random vector θ lies in the s-dimensional subspace of the PPCs. In particular, the difference $\widetilde{b} - E(b|y)$ gives the multivariate vector of the PPCs "not explained" by the estimation of the linear model $E(\theta|y)$. The matrix $var(\theta|y,b)$ has rank s, and, consequently, there are $(p - s)$ linear combinations of θ for which their respective variances do not depend on the PPCs.

Proposition 2. *Given the p-dimensional random vector θ, under the models in (1) and (2), and the Best Predictor $E(\theta|y,b)$ in (3), we get:*

$$\begin{aligned} \overline{F}E(\theta|y,b) &= \overline{F}\widetilde{\theta}_{y,b} = \widetilde{b}^* \\ &= \overline{F}E(\theta|y) + \overline{F}cov(\theta,b|y)var(b|y)^{-1}\left\{\widetilde{b} - E(b|y)\right\}, \end{aligned} \tag{4}$$

where $\widetilde{b}^*$ is the s-dimensional vector of the PPCs "enhanced" (ePCs) by the linear predictor $E(\theta|y)$. As a particular case, when $\sigma_\epsilon^2 \longrightarrow 0$, $var(\epsilon) \longrightarrow 0$, $var(\gamma) \longrightarrow var(e)$, and $\widetilde{b} \longrightarrow \overline{b}$. Therefore, $\overline{F}\widetilde{\theta}_{y,b} = \widetilde{b}^* \longrightarrow \overline{b}$ with $\overline{b}$ the sample PCs $\overline{b} = A'\theta$.

The ePCs $\widetilde{b}^*$ are then the PPCs "adjusted" by the Linear BP $E(\theta|y)$, and $\widetilde{b}^*$ is then the vector of the ePC scores. Note that the ePC scores give a non-orthogonal matrix. Given $\sigma_\epsilon^2 = 0$, the vector θ in the model (2) lies in the s-dimensional subspace of the sample PCs $\overline{b}$. In fact, in this case $\widetilde{b} \equiv \overline{b}$, $cov(\theta,b|y) = var(\theta|y)\overline{F}'$, $var(b|y) = \overline{F}var(\theta|y)\overline{F}'$, $E(b|y) = \overline{F}E(\theta|y)$, and then $\overline{F}E(\theta|y,b) = \overline{b}$.

3. Application

In accordance with the recent law reforms in Italy, the Equitable and Sustainable Well-being indicators (in Italian, BES) [3] - annually provided by the Italian Statistical Institute (ISTAT) - are designed to define the economic policies which largely act on some fundamental aspects of the quality of life. In order to highlight the result of the proposed method we use 12 BES indicators relating to the years 2013-2016, collected at NUTS-2 (Nomenclature of Territorial Units for Statistics 2 level). The variables employed in the application study are in Table 1. We use the per capita adjusted disposable income variable (its logarithm, as is usually done in economics studies) - indicated with BE1 - as a unique covariate in the LMM model, while the remaining 11 variables are dependent variables (Table 1 reports the description and acronyms used for the variables). The application uses the Restricted Maximum Likelihood estimation, a Sas/IML code, and a sequence of Sas-HPMixed procedures. Table 2 shows the slope parameter estimates from the multivariate regression, with their significance level. Table 3 reports the MANOVA multivariate test statistics, based on the characteristic roots. These are the eigenvalues of the product of the sum-of-squares matrix of the regression model and the sum-of-squares matrix of the regression error. The null hypothesis for each of these tests is the same: the independent variable (LBE1) has no effect on any of the dependent variables. The four tests are all significant.

Figure 1 shows the application of Proposition 1, where all the measures are plotted in the space of the sample PCs. This plot reports simultaneously the factorial coordinates of the original variables, of the linear predictor $E(\theta|y)$, and of the hybrid predictor $\widetilde{\theta}_{y,b} = E(\theta|y,b)$. The dependent criterion variables in the application can be split into two main groups, starting from both an analysis of the plot and the correlation matrix between the sample PCs, the LMM predicted values, and the hybrid predictor values. Moreover, we have eight dependent variables for which there is accordance in terms of their mutual correlation inside the original variables, as well as the LMM predicted and the hybrid predictor. This means that the hybrid predictor $\widetilde{\theta}_{y,b}$ does not change significantly the mutual correlations, substantially because the component of the PPCs not explained by the linear predictor $E(\theta|y)$ is relatively small. For the remaining three variables - with the acronyms REL4, Q2, and BS3 - the correlation changes: in some cases it changes sign, going from positive correlation values by the sampling and predicted values, to negative correlation values between the predictor $\widetilde{\theta}_{y,b}$, and vice versa. Therefore the predictor (3) highlights the major influence of the component of the PPCs not explained by the linear predictor $E(\theta|y)$. The latter is in accordance with the sample PCs in the mutual correlations between these three criterion variables. Since the classical predictor matches the mutual correlation inside the original variables - meaning that these mutual relations in the sample are due to the disposable income (BE1), the covariate in the mixed model regression - then the different mutual correlation values of the hybrid predictor $\widetilde{\theta}_{y,b}$ can be interpreted as relationships not captured by the model. For instance, the correlation between $Q2_{E(\theta|y)}$ and $INN1_{E(\theta|y)}$ is -0.82, and becomes $+0.30$ between $Q2_{\widetilde{\theta}_{y,b}}$ and $INN1_{\widetilde{\theta}_{y,b}}$, meaning that conditionally to the model - thus looking at the correlation between the attendance of childhood services (Q2) and the percentage of R&D (INN1) in the space orthogonal to per capita income - the correlation is positive. It could be interpreted as saying that the Regions with a greater investment in R&D have a higher benefit of childhood services. In our opinion, this highlights how the "hybrid" predictor is able to grasp the relationship that actually exists between investment in research and development and the importance given to training starting from the earliest years of life, regardless of per capita income.

4. Discussion

The introduced predictor (3) can be viewed from two different perspectives. An "adjusted" linear predictor by the PPCs, and, by relation (4), as the enhanced PCs (ePCs) that modify the probabilistic PCs (PPCs) to accommodate the mixed model regression predicted values. The present work considers the probabilistic principal components like a "constraint" model, that links together the components of the multivariate random vector in a lower dimensional subspace.

While the estimation of the PPC model requests a quite simple procedure, one of the causes of concern in the estimation of the parameters of a multivariate mixed model is the number of covariance

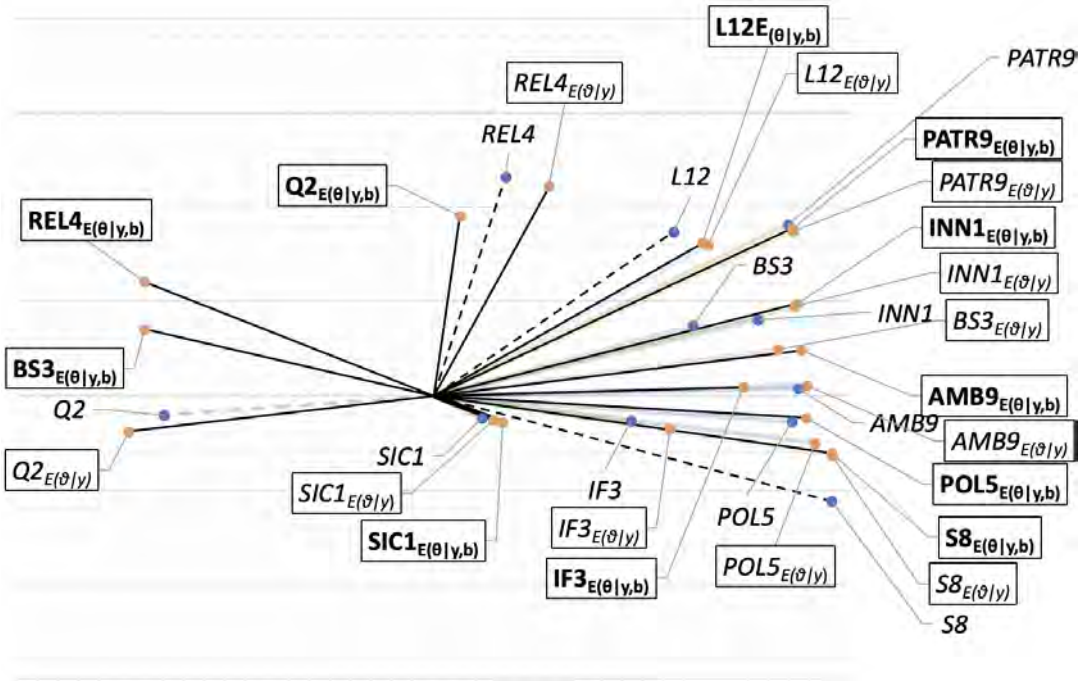

Figure 1: Plot of the application of the model (1) in the space of the sample PCs. There are represented the factorial coordinates of the original variables, of the linear predictor $E(\theta|y)$, and of the hybrid predictor $\widetilde{\theta}_{y,b} = E(\theta|y,b)$.

parameters, which may be too high for a speed software computation. Like the application presented, we suggest estimating the model covariance parameters under a uniform correlation structure among the multivariate components of the random effects. This structure is equivalent to the compound-symmetry covariance structure, with a better numerical property in terms of optimization. Indeed, some studies highlight that using uniform correlation matrices reduces the estimation noise. The model covariance matrix of random effects is then a generalized uniform correlation matrix, and works with two parameters. The "hybrid" multivariate linear predictor (3), by adjusting its standard formulation through the sample parameter vector scores in a convenient subspace, is designed to accommodate not only PPCs, but also factor models based on a random structure. In the present work, the components of the multivariate parameter among the subjects are linked by a principal components model. In order to overcome convergence problems, the method introduced can be extended to include multidimensional information from the data, through a reduced number of dependent variables in the linear model.

Abstract

The health sciences often involve survival data that may be censored and can contain correlated covariates. While there has been some research on the impact of correlated variables on survival models, there is a need for further investigation of how bootstrap methods can be used to handle correlation in survival analysis. In fact, if the variables are strongly correlated, the bootstrap samples from the prior may mask the effect of each other, making it difficult to discern the true relationship between the variables and the response, which can ultimately lead to unrealistic estimates. This article aims to extend the Proper Bayesian bootstrap ensemble tree model for analyzing survival data with highly correlated covariates. The model's performance was assessed through a simulated study, demonstrating better results compared to traditional survival models, such as the Cox model and survival random forest, with greater stability in terms of the integrated Brier score, particularly with smaller sample sizes.

Keywords: Survival analysis, Bootstrap, Bayesian nonparametric learning, Ensemble models, Correlated data

1. Introduction

Multivariate responses that are highly correlated are frequently encountered in health science studies. In such cases, a subject may have multiple related responses, and the presence of these correlated variables can have a significant impact on survival models. The adverse effects of highly correlated variables include overfitting, reduced model performance, and biased estimation of individual predictor effects.

In cases where the data comprises highly correlated variables, the survival model may exhibit bias towards splitting one of the correlated variables while disregarding information from the other correlated variables (1). This can result in overfitting of the model, leading to a reduction in its predictive performance, as the model may fail to accurately capture the true underlying relationship between the variables and the time-to-event outcome (such as the expected survival time or the probability of survival beyond a specific landmark time-point).

This paper aims to enhance the use of the Proper Bayesian bootstrap ensemble tree model for analyzing survival data by incorporating a pre-processing stage. This stage involves carefully managing the data by either removing or transforming highly correlated variables, to reduce the detrimental impact that high correlation can have on the analysis.

The model performs Bootstrap resampling techniques to approximate the posterior distribution

of a statistical function of a decision tree $\phi(F)$, where F is a random distribution function as defined in (2).
The proposed method is rooted in the family of Bayesian bootstrap procedures, starting with Rubin (1981) (3), followed by Muliere and Secchi's proper Bayesian bootstrap (1996) (2), and Lo's Bayesian bootstrap for censored data (1993) (4). The algorithm also draws upon Efron's classical bootstrap technique (5) for bagging survival trees and survival forests.
The approach inherits the advantages of Bayesian non-parametric learning such as flexibility and computational strength and considers prior opinions to overcome the drawbacks of traditional bootstrap procedures used in classical ensemble decision tree models.
The structure of the paper is as follows: Section 2. details the proposed methodology, while Section 3. and 4. provide information on the computational environment and present the initial findings, respectively. Finally, Section 5. summarizes the main outcome of the study and discusses the potential areas for future research.

2. Proposed Model

This paper aims to extend the idea of a Proper Bayesian Bootstrap Ensemble Tree model, specially tailored for survival data analysis. The model is designed to address the challenges posed by highly correlated variables and their impact on the model's performance. The proposed model is based on the initial outcomes of the Proper Bayesian Bootstrap concept, which was previously introduced by (2). However, it has been adapted and modified to suit the specific requirements of survival data analysis.
The primary metric for evaluating ensemble tree models is the decision tree $\phi(F, X)$, which depends on the underlying distribution F and the observed data X. According to a study by (6), the posterior distribution of Φ can be estimated using bootstrap procedures. This is achieved by fitting the model to a weighted dataset generated from the bootstrap process, and the resultant predictions provide an estimate of the posterior mean.
We set a prior distribution $D(kF_0)$ for F using a Dirichlet process to apply the Proper Bayesian bootstrap. To explain the response variable y based on a list of highly correlated covariates $x_1, ..., x_P$, the parameter F_0 of the Dirichlet process is established as a joint distribution that depends on both x and y.
The bootstrap sampling method from the posterior of $\phi(F, X)$ is taken from (6), where each bootstrap resample $(x_1^*, y_1^*), ..., (x_m^*, y_m^*)$ is created by combining distributions from the prior estimate F_0 and the empirical distribution F_n. Since the covariates are highly correlated, in the bootstrap resampling process, a new sample is generated from the original distribution F_0 and a new vector of covariates is produced from the original prior distributions $F_0(x_k)$ that accounts for the dependence among the covariates. The resampling process continues iteratively until the desired number of bootstrap samples is generated. This approach can help to account for the dependence among the covariates and produce more accurate estimates of the parameters of interest.
The response variable y is linked to the vector of covariates generated from the prior F_0 estimate obtained using an appropriate survival model to perform survival analysis. The method for combining the predictions should be based on the characteristics of the time-to-event data. Such as suggested in (7) the output of the model is a bootstrap aggregated version of the estimated conditional survival function S for a new observation X_{new} computed by $\widehat{S}_A^B(\cdot|x_{new}) = \widehat{S}_{L^B_{A(}x_{new})}(\cdot)$.
The distinguishing feature of the proposed method from traditional ensemble methods is its ability to generate new observations through the prior distribution F_0, which improves the prediction of the model.

Moreover, as a novelty element with respect to (8), we incorporate the correlation structure between covariates into the bootstrap resampling technique. With this modification, it takes into account the covariance matrix of the covariates which prevents the bootstrap samples coming from the prior distribution from having an unrealistic joint distribution. Incorporating this feature has the potential to produce more robust and reliable results, particularly in situations where there are strong correlations among the covariates.

3. Experimental setting

The data simulation is done using the flexible-hazard method, as outlined in (9). Also, to demonstrate the capabilities of the proposed method, we investigated the result of different weights assigned to the prior distribution F_0 with sample size $N = 50$. The simulated dataset generated for the time-to-event target variable, including 10% censored observations, comprises five highly correlated numerical covariates that are sampled from a multivariate normal distribution with adjusted parameters of mean and standard deviation. The correlation coefficients between covariates are higher than 0.85.
A total of 100 simulated datasets were produced, each consisting of $N = 50$ samples. The survival time values for observations sampled from the prior were estimated using an exponential regression model.
The proposed model was contrasted against two of the most prevalent models in survival analysis, the Survival Random Forest, and the Cox model. The performance of the predictions was evaluated using the Integrated Brier Score (IBS) through a 5-fold cross-validation process.

4. Preliminary results

The average values and nonparametric confidence intervals of the IBS results for the comparison with classical models are displayed in Figure 1. Figure 2 shows the performances of multivariate sampling with respect to the indipendent one.

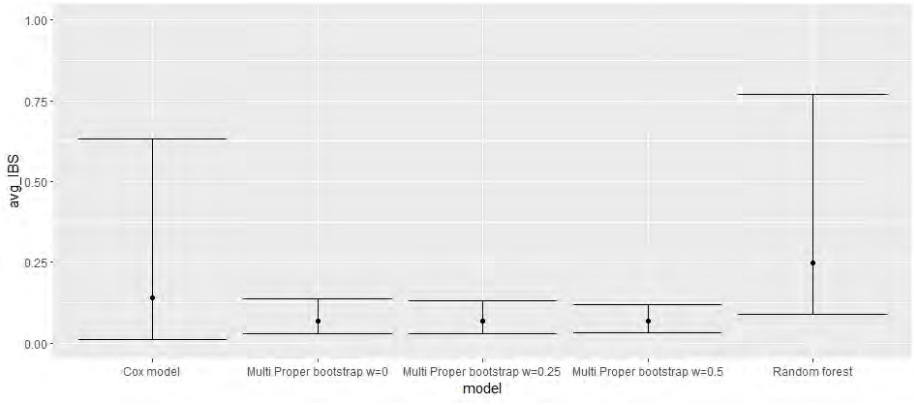

Figure 1: Comparison of mean and nonparametric confidence intervals for IBS obtained in cross-validation for the 100 simulated datasets of highly variable covariates of sample size 50. The proposed model is compared with Random Survival Forest and Cox Model

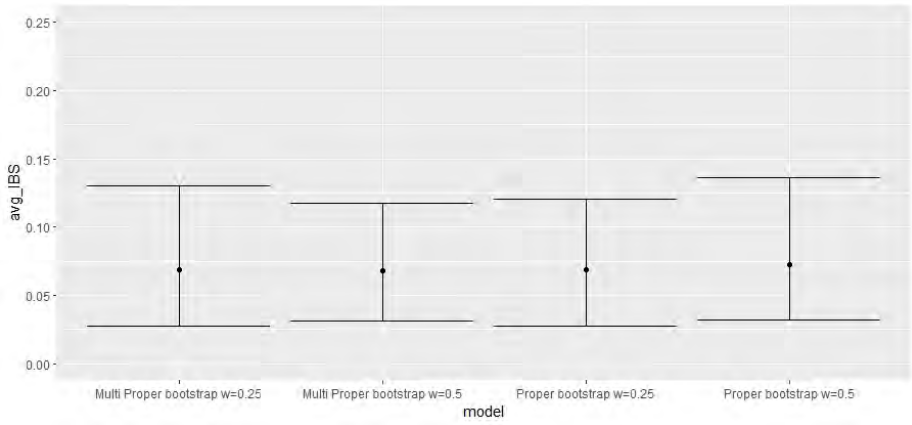

Figure 2: Comparison of mean and nonparametric confidence intervals for IBS obtained in cross-validation for the 100 simulated datasets of highly variable covariates of sample size 50. Multidimensional prior sampling is compared to the independent one

The results in Figure 1 showed that the average IBS score for the proposed Proper bootstrap model was lower, but not significantly lower when considering the width of the confidence interval for the traditional Cox and Random Forest models which is evidently large. Observing the confidence intervals of the proposed model which are significantly smaller compared to those of the traditional models, indicates that the proposed method is more consistent in its prediction performance.
The results in Figure 2 show that the application of multivariate prior sampling, that takes into account the covariance structure of the covariates, leads to slightly better results than the independent sampling when the covariates are highly correlated.

5. Conclusion

The paper introduces a novel ensemble tree modeling approach that utilizes Proper Bayesian Bootstrap, to analyze survival data while mitigating the effect of highly correlated variables to obtain increased stability and comparable results in a simulated environment.
The use of synthetic data, derived from prior distributions that are not present in the original dataset, overcomes the drawbacks of classical ensemble models which only consider the data without any prior opinion. This as a result enhances the stability of the final ensemble model, particularly for datasets with limited sample sizes. Taking into account the covariance structure of the data at hands prevent the proper Bayesian bootstrap from generating unrealistic data that could lead to more noisy results.
Further research is planned to evaluate the model's sensitivity towards varying degrees of censored data, categorical variables, and more effective techniques for sampling correlated data variables, derived from non-normal distributions.

Abstract

We present a step-wise methodology, called ROBOUT, to recover outliers in a dependent variable conditional on its predictors, to be identified from a large number of potential predictors. ROBOUT entails a preliminary imputation procedure to identify potential leverage outliers, a robust variable selection (via LASSO-penalized Huber loss regression), a robust regression (via MM) and an outlier detection step. We show in an ad-hoc simulation study that ROBOUT is the most effective methodology for what concerns outlier detection, predictor recovery, and coefficient estimation, even compared to existing integrated procedures like SPARSE-LTS and RLARS.

Keywords: conditional outlier, leverage outlier, high dimension

1. Introduction

We propose a sequential methodology, named ROBOUT, to identify the most suitable regression model for a target variable from a high number of potential predictors, and to recover anomalies in a target variable conditionally on the identified predictors. ROBOUT comprises two consecutive robust steps, one performing a variable selection and the second performing coefficient estimation. The method is shown through simulations to outperform competitive approaches in the estimation of coefficients and the identification of outliers, when the dataset is contaminated with outliers.

Although integrated methods that simultaneously perform predictor recovery, outlier detection and coefficient estimation exist in the literature, such as RLARS (2) and SPARSE-LTS (1), they may be computationally expensive or systematically ineffective when the ratio p/n is large. Differently, SNCD (Semismooth Newton Coordinate Descent) algorithm (5) provides a fast and reliable solution to the recovery of predictors, by minimizing a Huber or a least absolute deviation (LAD) loss of the residuals penalized by an elastic net (7). Its optimization problem is solved by explicitly deriving Karush-Kuhn-Tucker (KKT) conditions. At the same time, SNCD has two significant drawbacks: it provides no residual scale estimate, therefore no outlier detection can be conducted, and it is not robust to outliers in the predictors, as shown in (1).

For this reason, we provide a robust preliminary imputation procedure, that replaces anomalous values in the predictors by the median of the s closest non-outlying neighbours, identified by looking at the most (robustly) correlated variable with the predictor in question. This procedure is designed to cope with two relevant confounding factors for predictor recovery such as a high level of multicollinearity, and a high number of variables p compared to the sample size n, which actually positively impact on our leverage outlier identification procedure. In this way, SNCD may be applied with Huber loss on the clean

imputed dataset to identify the *right* predictors, on which a robust regression model like MM regression (6) can be finally employed to spot conditional outliers, by means of the robustly estimated residual scale. ROBOUT is therefore a doubly robust post-selection method, both with reference to outliers in y and in its predictors.

In order to summarize the task which we address, let us consider n numerical observations of one response variable y and p additional variables. We call the unknown set of conditional outlier indices O with $|O| = [\alpha n]$ and $\alpha \in [0, 0.5]$. The response variable vector $\mathbf{y}$ is expressed in terms of the following regression model

$$\mathbf{y} = a + \mathbf{X}_D\beta + \epsilon, \tag{1}$$

where $\mathbf{y}$ is the $n\times 1$ vector of the response variable, a is the intercept, $\mathbf{X}_D$ is the $n\times K$ matrix of predictors (whose columns are indexed by D, with $K \ll p$), β is the $K \times 1$ vector of regression coefficients and ϵ is the $n \times 1$ vector of residuals. In this context, the statistical challenge lies in identifying the set D of true predictors and correctly estimating the relative regression coefficients β in a robust way, while simultaneously recovering the outliers in the set O.

2. ROBOUT methodology

We present here our proposed conditional outlier detection method, ROBOUT, consisting of four robust steps, namely, preliminary imputation, variable selection, low-dimensional regression and conditional outlier detection.

2.1 Preliminary imputation

Let us consider the $n \times p$ matrix of potential predictors $\mathbf{X}$. First, for each $j = 1, \ldots, p$, we compute $x_{med,j} = \mathrm{med}(x_j)$ and $x_{mad,j} = 1.4826\mathrm{mad}(x_j)$. Then, relying on $x_{med,j}$ and $x_{mad,j}$, we derive a robust z-score for each entry ij of $\mathbf{X}$: $z_{ij} = \frac{x_{ij}-x_{med,j}}{x_{mad,j}}$, $i = 1, \ldots, n$, $j = 1, \ldots, p$. In the end, we flag as outliers the entries that present an outlying z_{ij}, i.e. we set $w_{ij} = 0$ if $|z_{ij}| > \phi^{-1}(0.995)$, where ϕ^{-1} is the inverse standard normal distribution function, and $w_{ij} = 1$ otherwise.

At this stage, we calculate robust rank-based pairwise correlations for each pair $j'j''$ of variables, $j', j'' = 1, \ldots, p$, $j' \neq j''$. If p is large, this can be done for a restricted number p' of randomly chosen variables, with $p' = \min(p, [300^2/p])$, for instance. We can use Spearman's rho, that is $\hat{\rho}_{j'j''}$, but Kendall's tau, $\hat{\tau}_{j'j''}$, could similarly be used, because both measures are robust to leverage outliers. Then, for each entry ij, $i = 1, \ldots, n$, $j = 1, \ldots, p$, such that $w_{ij} = 0$, we apply Algorithm 1.

Algorithm 1 Algorithm for preliminary imputation.

For each ij, $i = 1, \ldots, n$, $j = 1, \ldots, p$, such that $w_{ij} = 0$:

1. derive the set of ordered variable indices D_j by sorting $\hat{\rho}_{j'j}$ (or $\hat{\tau}_{j'j}$), $j' \neq j$, in decreasing order;
2. take the first index in the ordered set D_j, j^{top}, such that $w_{ij^{top}} = 1$;
3. identify among all the points $i' \neq i$ the set $I_{i,s}$ of the s closest neighbours of $x_{ij^{top}}$ (in absolute norm) with $w_{i'j^{top}} = 1$;
4. derive the set $I_{i,3} \in I_{i,s}$ that contains the three closest neighbours of $x_{ij^{top}}$ (in absolute norm) with $w_{i'j} = 1$, $i' \in I_{i,s}$;
5. impute $x^*_{ij} = \mathrm{med}(\mathbf{X}_{I_{i,3}j})$.

Finally, we can standardize each column of the imputed matrix $\mathbf{X}^*$, by calculating the standardized imputed values $x^{**}_{ij} = \frac{x^*_{ij}-\overline{x}^*_j}{\mathrm{sd}(x^*_j)}$, $i = 1, \ldots, n$, $j = 1, \ldots, p$.

2.2 Variable selection

We aim to consistently select the relevant set of the predictors of our target response variable y_i, $i = 1, \ldots, n$, from a large set of variables under the presence of conditional outliers in mean.

The first method (5) that we consider is to use the objective function

$$\min_{\beta_0, \beta_1, \ldots, \beta_p} \sum_{i=1}^{n} \rho_{H,\delta}(\epsilon_i) + \lambda \sum_{j=1}^{p} |\beta_j|, \tag{2}$$

where $\epsilon_i = y_i - \beta_0 - \sum_{j=1}^{p} \beta_j x_{ij}^{**}$, $i = 1, \ldots, n$, $j = 1, \ldots, p$, λ is a penalization parameter, and

$$\rho_{H,\delta}(t) = \begin{cases} \frac{t^2}{2\delta}, & |t| \leq \delta \\ |t| - \frac{\delta}{2}, & |t| > \delta \end{cases}$$

is the Huber weight function, where δ is a tuning parameter. Henceforth, we call (2) SNCD-H objective function.

The other robust alternative that we consider in the simulation study substitutes $\rho_{H,\delta}(\epsilon_i)$ in (2) with the absolute loss $\rho_L(\epsilon_i)$, where

$$\rho_L(t) = t\left(\frac{1}{2} - \mathrm{I}(t < 0)\right), \; t \in \mathcal{R}.$$

We call that version the SNCD-L objective function.

Minimization 2 with $\rho_{H,\delta}(t)$ or $\rho_L(t)$ is practically performed for a decreasing sequence of values $\lambda = \lambda_t$, $t = 1, \ldots, T$, such that $\lambda_0 = \lambda_{\max}$ and $\lambda_T = \lambda_{\min}$, where $\lambda_{\max}$ returns no predictors, and $\lambda_{\min}$ returns $K_{\max}$ predictors. Predictor selection is performed by the adaptive version of the strong rule of (4), proposed in (5). At each value of λ_t, that rule exploits the coefficient estimates at λ_{t-1}. The optimal λ is then selected by cross-validation, using as Out-Of-Sample (OOS) metric the loss $\rho_{H,\delta}$ for SNCD-H and the loss ρ_L for SNCD-L.

Let us denote by $\widehat{\beta}_{\min}$ and $\widehat{\beta}_{1SE}$ the coefficient vectors obtained by setting $\lambda = \lambda_{\min}$ or $\lambda = \lambda_{1SE}$ respectively. In general, $\widehat{\beta}_{\min}$ is composed by $\widehat{K}_{\min}$ coefficients indexed by the set $D_{\min}$ and $\widehat{\beta}_{1SE}$ is composed by $\widehat{K}_{1SE}$ coefficients indexed by the set D_{1SE}, with $\widehat{K}_{1SE} \leq \widehat{K}_{\min}$ and $D_{1SE} \subseteq D_{\min}$. Let us define the difference set $D_{diff} = D_{\min} \backslash D_{1SE}$ and the corresponding estimated coefficient vector $\widehat{\beta}_{diff}$. Then, it is sufficient to formally test the hypothesis $H_0 : \beta_{diff} = \mathbf{0}_{K_{\min} - K_{1SE}}$ by a robust ANOVA test between the two nested MM regression models. If the resulting p-value is smaller than 5%, we reject H_0 and we select $\widehat{D} = D_{\min}$ as predictor set, and $\widehat{K} = \widehat{K}_{\min}$ as the number of predictors. Otherwise, we select $\widehat{D} = D_{1SE}$ and $\widehat{K} = \widehat{K}_{1SE}$.

2.3 Robust regression

In this step, we apply a robust regression method to the recovered predictors stored in matrix $\mathbf{X}_{\widehat{D}}$, in order to robustly estimate coefficients, residuals, and residual scale. To this aim, we utilise MM regression (6). In the simulation study, we also test the performance of least trimmed squares (LTS) (3). At the end of this step, we get the estimated $\widehat{K} \times 1$ vector of coefficients $\widehat{\beta}$, the estimated $n \times 1$ vector of residuals $\widehat{\epsilon}$, and the residual scale estimate $\widehat{\sigma}$.

2.4 Outlier detection

As a last step, we recover the vector $\widehat{O}$ of conditional outlier indices as the set of all the points $i \in \{1, \ldots, n\}$ with robustly rescaled residuals $\widehat{\epsilon}_i / \widehat{\sigma}$ larger than $\phi^{-1}(0.995)$ in absolute value.

3. Simulation study

In this section, we test the four possible variants of ROBOUT methodology based on the different variable selection and robust regression estimation options presented in Section 2. In the first step, either the SNCD-H or the SNCD-L objective function can be used, while in the second step either LTS or MM can be used to estimate the regression equation. We call the ensuing four versions of ROBOUT as H+LTS, L+LTS, H+MM and L+MM, where H and L refer to SNCD-H and SNCD-L, respectively.

Our simulation study aims both to compare ROBOUT to competitor methods but also to identify the optimal design of ROBOUT with respect to its constituent components. The competitor methods against which the ROBOUT versions are tested are SPARSE-LTS and RLARS.

All the methods are run with the default preprocessing step for all the potential predictors: standardization for SNCD, unit-norm normalization for SPARSE-LTS, robust standardization for RLARS. The intercept is included for all estimations.

3.1 Settings

The set of outliers O is randomly generated with outlier proportion $\alpha = 0.1$. The set of predictors D is randomly generated with $K = 3$. The intercept is $a = 10$. The coefficients are generated in the following way: $\beta_1, \beta_3 \sim U(10, 20)$, $\beta_2 \sim U(-20, -10)$, with residual variance $\sigma^2 = 1$. For each non-outlier index $i \notin O$, we assume by simplicity that $\epsilon_i \sim N(0, \sigma^2)$, $\mathbf{x}_{D,i} \sim N(\mathbf{0}_K, \mathbf{I}_K)$ and $\mathbf{x}_{D',i} \sim N(\mathbf{0}_{p-K}, \mathbf{I}_{p-K})$, where $\mathbf{x}_{D',i}$ is the vector of non-predictors (D' stores the indices of non-predictor variables). For each outlier index $i' \in O$, we assume the following:

1) conditional outliers in mean are generated as $\epsilon_{i'} \sim N((m-1)a, \sigma^2)$, $m \in \mathcal{R}$, $m > 1$;
2) the vector of predictors is generated as $\mathbf{x}_{D,i'} \sim N(\mathbf{0}_K, \mathbf{I}_K)$, then $y_{i'}$ is generated by model 3, and in the end, leverage outliers are generated by replacing *a posteriori* $x_{D,i'k}$ with the perturbed values $x_{D,i'k} + (m-1) \times \text{sgn}(x_{D,i'k})$, $k = 1, \ldots, K$, $m \in \mathcal{R}$, $m > 1$.

The parameter $m > 1$ represents the degree of perturbation. We then generate the regression model for the single observation $i \notin O$ as

$$y_i = a + \mathbf{x}'_{D,i}\beta + \epsilon_i, \tag{3}$$

where, for each non-outlier index $i \notin O$, we assume by simplicity that $\epsilon_i \sim N(0, \sigma^2)$, $\mathbf{x}_{D,i} \sim N(\mathbf{0}_K, \mathbf{I}_K)$ and $\mathbf{x}_{D',i} \sim N(\mathbf{0}_{p-K}, \mathbf{I}_{p-K})$, while, for each outlier index $i' \in O$, we consider **case 1**, with conditional outliers in mean and leverage outliers, where the outliers are generated in $y_{i'}$ according to 1) and in $x_{D,i'k}$ according to 2). We consider $m = 1, 5, 9, 13, 17, 23, 29, 37, 45, 55$. In addition, we also allow for multicollinearity by setting $COV(x_{j'}, x_{j''}) = \rho_{j'j''}$, $\forall j', j'' \in \{1, \ldots, p\}$, $j' \neq j''$, where x_j is the j-th variable in the $n \times p$ matrix $\mathbf{X}$, representing the available information set Ω.

In this paper, we consider the following scenarios by the degree of multicollinearity in the matrix $\mathbf{X}$ and the relative size of the matrix (p/n ratio). As regards the degree of multicollinearity, we set $\rho_{j'j''} = \rho$, $\forall j', j'' \in \{1, \ldots, p\}$, $j' \neq j''$, with $\rho = 0.3, 0.7$. As regards the relative size of $\mathbf{X}$, we examine two different cases for the p/n ratio:

- case a: $p = 60$, $n = 300$ (i.e. $p/n = 0.2$, $p \ll n$);
- case b: $p = 100$, $n = 200$ (i.e. $p/n = 0.5$, $p < n$).

Henceforth, we refer to scenarios by combining the number and the letter of the above cases e.g. "scenario 1a, $\rho = 0.7$" refers to a scenario with case 1, case a for the p/n ratio i.e. $p = 60$ and $n = 300$, $\rho = 0.7$. Each scenario is run 100 times for each value of m.

For each scenario, each value of parameter m and each method, we derive the F_1 score for outlier detection, the empirical probability to recover all true predictors, the minimum recovery rate of single predictors across the true ones, and the maximum mean square error across the estimated coefficients of true predictors, whenever retrieved.

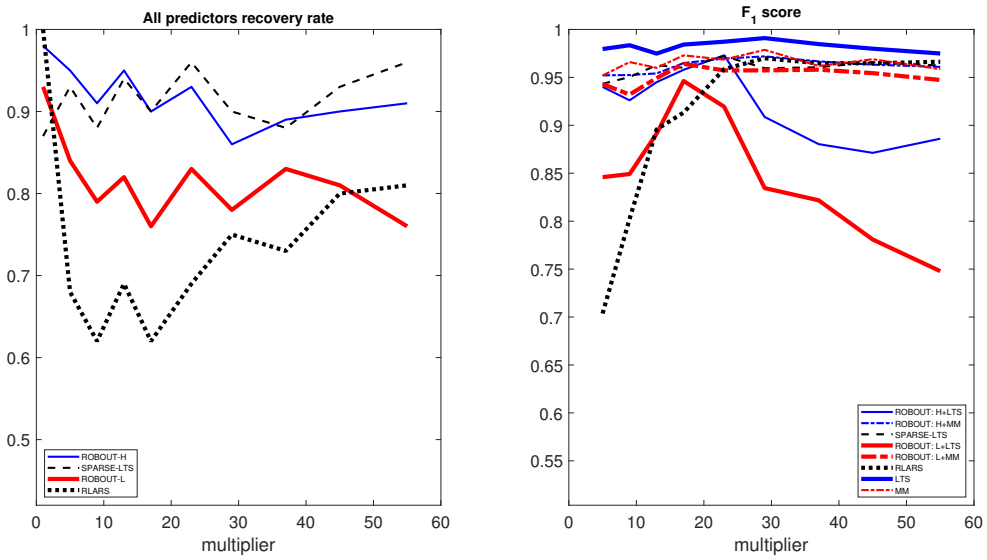

Figure 1: Average recovery proportion of all predictors (left panel) and F_1 score (right panel) of all considered methods under scenario 1a, $\rho = 0.7$.

3.2 Results

We note in Figure 1 that a clear hierarchy exists among methods under the most challenging scenario, 1a, $\rho = 0.7$. RLARS is very imprecise both concerning predictor recovery and outlier detection at small values of m. The same holds for the SNCD-L method on predictor recovery, and for H+LTS and L+LTS on outlier detection. On the contrary, H+MM, L+MM and SPARSE-LTS are doing well at outlier detection, and SPARSE-LTS and SNCD-H methods are doing reasonably well at predictor recovery.

Figure 2 shows that there are also clear levels of coefficient estimation quality: after the benchmarks, we find H+LTS and H+MM, L+LTS and L+MM, RLARS and SPARSE-LTS, which encounters difficulties in spite of the good performance in outlier detection and predictor recovery.

Under scenario 2a, $\rho = 0.7$ all ROBOUT options are doing very well both at outlier detection and predictor recovery, in comparison with competitors like SPARSE-LTS and RLARS, which are slightly less effective at small values of m. SPARSE-LTS coefficients are the worst by far; RLARS is doing reasonably well, approximately as ROBOUT options apart from H+MM, which works like the benchmarks in this case across all values of m.

Scenarios 1a, $\rho = 0.3$ and 2a, $\rho = 0.3$ present qualitatively similar results compared to their counterparts with $\rho = 0.7$.

4. Conclusions

In this paper, we have proposed a new step-wise methodology, called ROBOUT, to recover outliers in a dependent variable conditionally on its most relevant predictors retrieved from a high-dimensional dataset. ROBOUT comprises a preliminary imputation procedure, a robust predictor selection, a robust regression and an outlier detection step. The first step is designed to ensure that ROBOUT is robust against leverage outliers in the predictors.

We have shown in an ad-hoc simulation study that the combination of LASSO-penalized Huber regression to select predictors and MM regression to estimate coefficients and recover outliers is the most effective concerning predictor recovery, outlier detection, and coefficient estimation, also considering LASSO-penalized LAD regression and LTS as possible alternatives to Huber and MM regression, respectively.

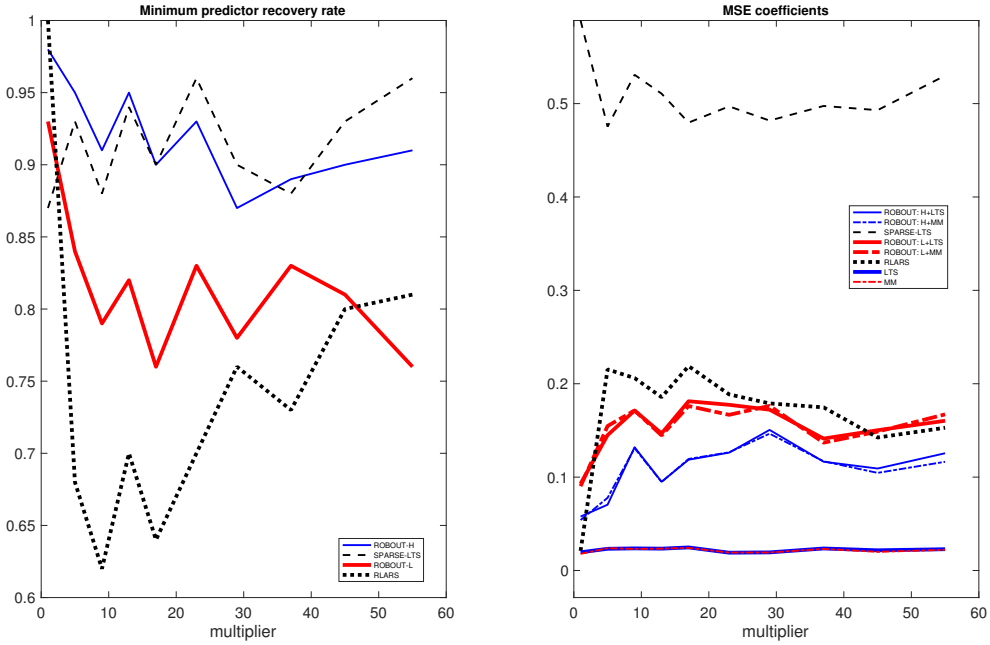

Figure 2: Minimum recovery rate of single predictors (left panel) and maximum mean square error of estimated coefficients (right panel) of all considered methods under scenario 1a, $\rho = 0.7$.

Abstract

Obtaining comparable groups in terms of the important covariates is a fundamental concern in comparative experiments. Indeed, potential imbalances of the covariates distribution across the groups could jeopardize the final inferential analysis and the validity of the study. In the sequential setting, especially within the field of clinical trials, Covariate-Adaptive randomization procedures are being increasingly used in practice, but most of them can accommodate only qualitative factors. The recently proposed Efficient Covariate-Adaptive Design [2] can incorporate also quantitative factors and it is high-order balanced. This study has the objective of exploring the robustness of this design, also in comparison with other procedures, in particular when i) some important covariates are omitted from the randomization and ii) when quantitative factors are transformed into categorical ones.

Keywords: Loss of information, Mahalanobis distance, Treatment comparisons, Unobserved covariates, Discretized variables

1. Introduction

In the field of comparative experiments, especially in clinical trials, obtaining comparable experimental groups with respect to some important covariates represents a fundamental issue in order to guarantee reliable inference about the treatment effects [14]. In this regard, several Covariate-Adaptive (CA) designs have been proposed in the literature. These are sequential randomized procedures that, by considering the allocations and the characteristics of the past subjects, as well as those of the current one, change at each step the treatment assignment probabilities with the aim of reducing possible sources of heterogeneity between the experimental arms. The so-called minimization method [18; 13], for example, is aimed at minimizing a weighted sum of the marginal imbalances of allocations, while the stratified randomization approach exploits a separate randomization sequence within each covariate stratum [4; 17].

However, most of the proposed procedures can only deal with categorical variables, so quantitative covariates are at best discretized and at worst completely discarded. This strongly affects the inferential precision of the clinical trial [15; 5]. The few available exceptions (see, e.g., [1] or [11]) present a slow rate of convergence to balance and/or exhibit poor performances as the number of considered covariates grows. This clearly conflicts with the recent increase in data availability combined with the advances in biomarkers-based personalized medicine, which has made it increasingly common to include several covariates in the analysis, especially of continuous nature [9; 16]. Recently Baldi Antognini et al. [2]

introduce a new class of CA randomization called the Efficient Covariate-Adaptive Design (ECADE), which it is high-order balanced (namely, it converges to balance with the fastest available rate among other CA procedures) and can manage both quantitative and qualitative factors with a potentially complex interaction structure. The object of the present work is to explore in depth the operating characteristics of the ECADE proposed in [2] in several 'real-life' scenarios. Moreover, through an extensive comparison with other well-known CA rules proposed in the literature, the aim is to better understand i) the impact of discretizing continuous factors and ii) the effect of unobserved covariates in terms of information loss.

2. Model and Imbalance measures

Consider an experiment in which n statistical units come sequentially and are assigned to one of two competing treatments, say A and B. Suppose that for each experimental unit a p-dimensional vector of (qualitative and/or quantitative) covariates, $\boldsymbol{X} = (X_1, \ldots, X_p)^t$, can be observed before the treatment allocation assignment is made. In what follows δ_i is the treatment indicator variable of the i-th unit, with $\delta_i = 1$ if he/she is assigned to A and 0 if B. After n steps, $\boldsymbol{\delta}_n = (\delta_1, \ldots, \delta_n)^t$ is the vector of the treatment allocations and $\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n$ are the p-dimensional vectors of observed covariates. The outcomes $\boldsymbol{Y}_n = (Y_1, \ldots, Y_n)^t$ are assumed to follow, at least approximately, a linear model

$$\mathbb{E}[\boldsymbol{Y}_n] = \boldsymbol{\delta}_n \mu_A + (\mathbf{1}_n - \boldsymbol{\delta}_n)\mu_B + \mathbb{Z}_n \boldsymbol{\beta}, \quad \text{var}(\boldsymbol{Y}_n) = \sigma^2 \mathbb{I}_n$$

where $\mathbf{1}_n$ is the n-dimensional vector of ones and $\mathbb{I}_n$ the n-dimensional identity matrix, μ_A and μ_B the treatment effects, $\boldsymbol{\beta}$ a q-dimensional vector of covariate effects, $\mathbb{Z}_n = [\boldsymbol{f}(\boldsymbol{X})^t]$ a $n \times q$ matrix of covariate effects with $\boldsymbol{f}$ being a known vector function that may include interactions among the covariates, (i.e., when $\boldsymbol{f}(\boldsymbol{X}) = \boldsymbol{X}$, $p = q$ but generally $q > p$) and σ^2 is the common variance. Let us also define $\mathbb{Q}_n = n^{-1} \begin{bmatrix} n & \mathbf{1}_n^t \mathbb{Z}_n \\ \mathbb{Z}_n \mathbf{1}_n^t & \mathbb{Z}_n^t \mathbb{Z}_n \end{bmatrix}$, a square matrix of size $q+1$.

In this set-up, Atkinson in [1] proposed a widely used measure of covariate imbalance, the so-called loss of information,

$$L_n = n^{-1} \boldsymbol{b}_n^t \mathbb{Q}_n^{-1} \boldsymbol{b}_n, \tag{1}$$

where $\boldsymbol{b}_n^t = (D_n; (2\boldsymbol{\delta}_n - \mathbf{1}_n)^t \mathbb{Z}_n)$ is the so-called *imbalance vector* and $D_n = 2\boldsymbol{\delta}_n^t \mathbf{1}_n - n$ is the difference between the assignments in the two arms. Here, L_n measures the loss of estimation precision induced by the covariate imbalance after n patients, whereas L_n/n is the corresponding loss of estimation efficiency. Under this framework, both the estimation accuracy and the power of the Wald test are strictly related to the loss and are maximized when L_n vanishes [4; 2].

By letting $\bar{\boldsymbol{z}}_{An} = \mathbb{Z}_n^t \boldsymbol{\delta}_n / \mathbf{1}_n^t \boldsymbol{\delta}_n$ and $\bar{\boldsymbol{z}}_{Bn} = \mathbb{Z}_n^t (\mathbf{1}_n - \boldsymbol{\delta}_n)/(n - \mathbf{1}_n^t \boldsymbol{\delta}_n)$ be the q-dimensional vectors collecting the sample means in the two experimental arms, in the causal inference framework, Morgan and Rubin [12] proposed the Mahalanobis distance between $\bar{\boldsymbol{z}}_{An}$ and $\bar{\boldsymbol{z}}_{Bn}$ as an alternative measure of covariate imbalance, namely

$$M_n = (\bar{\boldsymbol{z}}_{An} - \bar{\boldsymbol{z}}_{Bn})^t \, \text{var}(\bar{\boldsymbol{z}}_{An} - \bar{\boldsymbol{z}}_{Bn})^{-1} (\bar{\boldsymbol{z}}_{An} - \bar{\boldsymbol{z}}_{Bn}).$$

3. The Efficient Covariate-Adaptive Design (ECADE) and other CA procedures

The ECADE is a CA randomization procedure based on the sequential minimization of the weighted Euclidean norm of the imbalance vector $||\boldsymbol{b}_n||_{\mathbb{W}} = \sqrt{\boldsymbol{b}_n^t \mathbb{W} \boldsymbol{b}_n}$ with respect to a weight matrix $\mathbb{W}$ (symmetric and positive-definite). The n-th subject, with covariate profile $\boldsymbol{x}_n$, is assigned to treatment A with probability

$$P(\delta_n = 1 | \boldsymbol{\delta}_{n-1}, \boldsymbol{x}_1, \ldots, \boldsymbol{x}_n) = \eta((1; f(\boldsymbol{x}_n)^t) \mathbb{W} \boldsymbol{b}_{n-1}) \tag{2}$$

where $\eta : \mathbb{R} \longrightarrow (0,1)$ is a decreasing (strictly decreasing at 0) symmetric function such that $\eta(x) = 1-\eta(-x)$. Here the argument of $\eta(\cdot)$ in (2) is proportional to the difference between the squared norm of the potential imbalances that one would obtain by assigning subject n to A and B (see [2]).

Under the ECADE, for qualitative covariates, $\boldsymbol{b}_n = O_p(1)$ and the loss and the Mahalanobis distance are asymptotically equivalent with an order $o_p(1)$ of convergence to balance. The same result holds for quantitative and mixed covariates, provided that $\lim_{x\to\infty}\eta(x) = \varepsilon \in (0,1/2)$.

Several choices for the weight matrix can be adopted. The ECADE encompasses also weights that change at each step n, adopting $\mathbb{W}_n$ instead of $\mathbb{W}$ in (2). All the theoretical properties of the ECADE are preserved provided that $\mathbb{W}_n$ is a sequence of symmetric and positive-definite matrices such that $\mathbb{W}_n \longrightarrow \mathbb{W}$ almost surely, as n grows [2]. In the rest of this paper, we implement the ECADE by setting $\mathbb{W}_n = \mathbb{Q}_n^{-1}$.

With regards to the function η, we will consider i) $\eta_E(x) = 1/2 - sign(x)(\rho - 1/2)$ with $\rho \in (1/2,1)$, namely Efron's allocation function [6] and ii) $\eta_\varepsilon(x) = \varepsilon + (1-2\varepsilon)[1-\Phi(x)]$ where $\Phi(\cdot)$ is the standard normal cdf.

In the following analysis, among the CA designs that can be implemented for both qualitative and quantitative covariates, we consider the D_A-BCD by Atkinson (ATK) [1] and the CA randomization based on kernel densities by Ma and Hu (KER) [11]. With regards to the procedures that apply only to categorical covariates we consider the minimization method by Pocock and Simon [13] (PS) as well as the design by Hu and Hu [8] (HH), whose allocation probability is based on the Efron's function.

4. Numerical Comparisons

To illustrate the finite sample properties of the ECADE and to compare it to other CA procedures, we base our simulation study on the experimental setting in [7]. They report the results of the randomized clinical trial NIDA-CSP-1019 with the aim of testing the treatment effect of the *selegiline transdermal system*, a treatment of cocaine dependence, against a placebo. The trial has enrolled 300 patients and, as reported in the paper, the treatment groups were balanced with a *biased coin* procedure with respect to gender (GEN: male, female), presence of attention deficit disorder (DEFDIS: 0 absence, 1 presence), historical self-report of cocaine use in the past 30 days (COCUSE: quantitative discrete with values in 1-30) and severity of depression calculated by Hamilton Depression Rating Scale (DEPRE: quantitative discrete with values 0-44, i.e., not depressed to very severe depression). We re-design this study by also including in the randomization procedure the age of patients (AGE: measured in years) as well as the study center (CLIN, discrete with 16 levels). Thus, six covariates are considered: three qualitative, two of which are dichotomous and one with 16 levels, and three quantitative factors.

The first simulation has the aim of studying the effect of balancing the observed covariates in mitigating the potential imbalance of other covariates not observed before randomization. This issue has been recently discussed by [10], but only for categorical factors. Indeed, while for categorical covariates a possible measure to assess unobserved covariates imbalances can be based, for instance, on the marginal imbalance, when also continuous variables are included another strategy has yet to be defined [10]. In this regard, here we propose a criterion that is based on a two-step procedure described as follows. In the first step, the trial is simulated including all the six covariates in the CA randomization, obtaining L_n and M_n. In the second step, the same trial is simulated excluding CLIN and COCUSE from the randomization procedure. This results in a new treatment allocation vector $\tilde{\boldsymbol{\delta}}_n$ and then in an imbalance vector $\tilde{\boldsymbol{b}}_n$. Thus the loss in the case of unobserved covariates is $\tilde{L}_n = n^{-1}\tilde{\boldsymbol{b}}_n^t\mathbb{Q}_n^{-1}\tilde{\boldsymbol{b}}_n$; the Mahalanobis distance $\tilde{M}_n$ is computed accordingly. The rationale is that CLIN was not included in the original study and the data on the cocaine use could be unreliable or faked by the patients. For the covariate effect we restrict our attention to the case $\boldsymbol{f}(\boldsymbol{X}) = \boldsymbol{X}$. The results on the losses and Mahalanobis distances of the competing procedures, based on 10000 simulations, are displayed in Figure 1. Here ECADE$_E$ and ECADE$_{0.1}$ refer to the adoption of η_E (with $\rho = 0.8$) and η_ε (with $\varepsilon = 0.1$), respectively and the biasing probability for the KER procedure is 0.8. In addition, the superscript u refers to the unobserved covariates case and thus to $\tilde{L}_n$ and $\tilde{M}_n$ of the corresponding CA design. We first notice the severe inflation in the loss of estimation precision when two covariates are excluded from the CA randomization. More specifically,

the curves of ATK^u and KER^u do not seem to have a decreasing trend with n, while a slightly decreasing behavior is observed for the ECADE^u, which is associated with smaller values of the loss ($\tilde{L}_n$ is around 16 for the ECADE while is around 22-23 for ATK and KER). No evident differences as η changes are observed. When all the covariates are included in the randomization procedure, the KER induces a loss that essentially doubles the one under ATK for $n = 300$. The ECADE is the best performing CA procedure (for $n > 100$) with a slight difference in ECADE$_E$ and ECADE$_{0.1}$ whose L_{300} are equal to 2.2 and 1.3, respectively, against the loss of ATK which is 4.9. Similar considerations can be drawn by looking at the Mahalanobis distance.

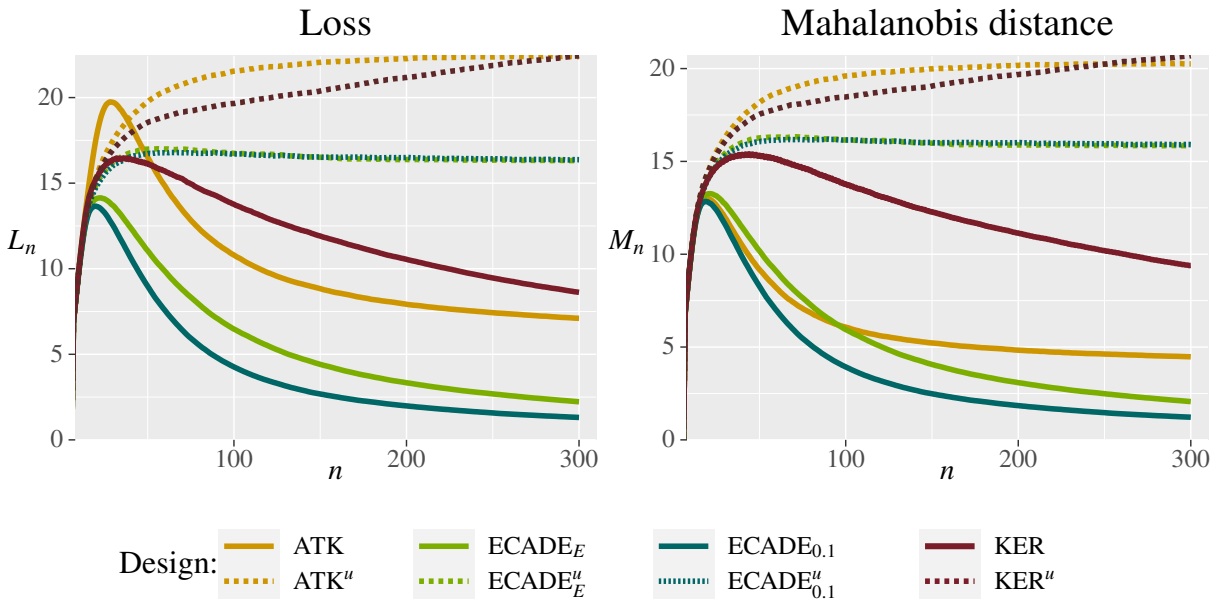

Figure 1: Loss of estimation precision L_n and Mahalanobis distance M_n for cocaine dependence clinical trial as n varies. The superscript u refers to the procedures in which two covariates have been omitted from the randomization procedure.

As most of the CA randomization procedures only deal with qualitative factors, a standard practice is to break down the numerical covariates into two or more categories. However, as it is well known [15; 5; 2], this operation does not come without a cost, as it induces a loss of information. To illustrate such an effect, we focus on the inflation in the loss of estimation precision and Mahalanobis distance induced by discretizing COCUSE into 3 categories (1:[0-10], 2:[11-20], 3:[20-30]), DEPR into 5 levels (1:[0-7], 2:[8-13], 3:[14-18], 4:[19-22], 5:[$>$ 23]) and AGE into 4 levels (1: [18-30], 2: (30-40], 3: (40-50], 4:($>$ 50)), as described in [10]. In this study, besides the D_A-BCD, the ECADE$_E$ and KER (both with $\rho = 0.85$) which can be implemented with any kind of covariates, we consider PS design and HH (with biasing probability equal 0.85). The simulation results (10000 iterations) are reported in Figure 2, where the superscript d refers to CA procedures that are implemented by discretized covariates. The PS method which is known to be strongly inadequate in the presence of a large number of covariates, has even worst performance in this setting. The HH^d presents an almost constant trend as n increases, with very large values of L_n. For discretized factors the ECADE^d is still the best choice for $n > 60$, inducing a loss even smaller than that of ATK, for n greater than 180. Finally the best procedure is the ECADE in which no subjective operation of categorization is performed and the nature of the covariates is preserved. Also in this case, L_n and M_n present very similar behavior for any procedure.

5. Discussion

Since the true relationship between study outcome and covariates is not generally known, it's fundamental to assess the performance of Covariate-Adaptive procedures when some important covariates are

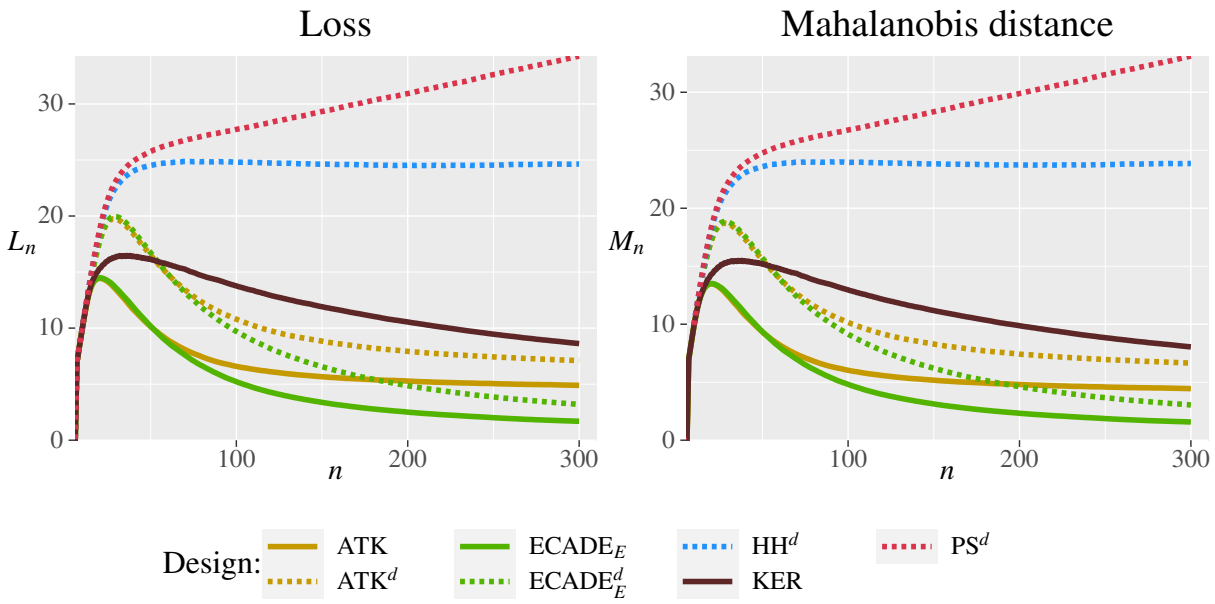

Figure 2: Loss of estimation precision L_n and Mahalanobis distance M_n for cocaine dependence clinical trial as n varies. The superscript d refers to CA procedures that are implemented by discretized quantitative covariates.

not included in the randomization procedure. In practice, this is a measure of robustness of the randomization procedure to a form of misspecification. Other forms of misspecifications can occur, for instance, when some covariates effects (e.g., quadratic or interaction terms) are not included in the randomization procedures (see [2]).

In addition, note that the impact of categorizing a continuous variable strongly depends on the chosen cutoff (see [2]). On this purpose, it is customary to take quantiles of the covariate-generating distribution to break down continuous covariates. However, we wish to point out that such distribution is generally unknown in sequential studies, making even more serious the potential consequences of categorizing quantitative variables.

Finally, it is worth noticing that methods for balancing covariates could be also successfully employed in enrichment designs, as biomarkers can be treated as covariates from a mathematical viewpoint. In an effort towards optimal designs for enrichment trials, Covariate-Adaptive randomization procedures could be suitably adjusted to fit an enrichment clinical study [3].

Separation scores: a new statistical tool for scoring and ranking partially ordered data

Marco Fattore[a]

[a]Department of Statistics and Quantitative Methods - University of Milano-Bicocca, Piazza dell'Ateneo Nuovo, 1 - 20126; marco.fattore@unimib.it

Abstract

We introduce a new statistical procedure for scoring and ranking partially ordered data derived from ordinal multi-indicator systems, improving over approaches based on so-called "dominance scores". The procedure draws upon a novel matrix representation of partial order relations ("separation matrix") that provides a fuzzy measure ("separation score") of the number of elements in-between two given elements of a partially ordered set. We introduce the new procedure through a real example pertaining to Political Pluralism and Participation in Middle East countries, showing how the new scores effectively reflect the differences in the political freedom levels of the statistical units.

Keywords: Multi-indicator system, Partial order, Politics; Ranking, Synthetic indicators.

1. Introduction

The problem of computing synthetic indicators and building rankings from multidimensional systems of ordinal indicators is still an open issue, although some advances have been made in the last years, in particular by using partially ordered sets (*posets*) as the basic data structure and by exploiting concepts and tools from *order theory* (5; 11), to design and implement proper scoring algorithms. Most of the proposals available in the literature employ, in different ways, so-called *dominance scores*, which can be seen as a way to measure to what extent an element of the input poset "tends" to globally dominate the other elements (2; 8; 9). Dominance scores are usually computed as the *mutual ranking probabilities* (6) between the poset elements; these, in turn, require the linear extensions (11) of the poset to be built, somehow limiting the complexity of the partially ordered sets that can be effectively treated, although some smart algorithms and approximation formulas, reducing the computational burden, are available in the literature (3; 4; 6; 7). Although the final ranking produced by dominance scores is in many cases reasonable and reliable, the numerical differences between the ranking scores are not that effective in revealing the corresponding differences between the overall achievement levels of the compared units. This motivates the construction of *separation* scores which exploit more effectively the information comprised in the indicator system, incorporating a kind of "metric" information (speaking with some language abuse) on the relative positions of the elements of the poset. Interestingly, separation scores can be easily obtained from the same inputs used to build the dominance scores, so adding just a small computational overhead to the scoring and ranking process. The short paper is organized as follows. Section 2 describes the data on Political Pluralism and Participation, used to introduce the new scores; Section 3 briefly recalls the essentials behind the computation of dominance scores; Section 4 motivates and develops the computation of separation scores; Section 5 concludes and provides some hints for future research.

2. The Political Pluralism & Participation poset

We introduce separation scores by working out a real example, based on data extracted from the *Freedom in the World 2022* dataset (available on https://freedomhouse.org) on the rights and freedoms enjoyed by individuals, across the world. The dataset assesses 195 countries and 15 territories on three pillars relative to political rights, namely (A) *Electoral Process*, (B) *Political Pluralism and Participation* and (C) *Functioning of Government*, and on four pillars relative to civil liberties, i.e. (D) *Freedom of Expression and Belief*, (E) *Associational and Organizational Rights*, (F) *Rule of Law* and (G) *Personal Autonomy and Individual Rights*. Here we focus on the *Political Pluralism and Participation* (PP&P) pillar, which is evaluated by considering the following four variables, each scored on a 0-4 ordinal scale: (V1) *Right of people to organize in different political parties*, (V2) *Opportunity for the opposition to increase its support or gain power through elections*, (V3) *Freedom of people's political choices from domination by external forces* and (V4) *Full political rights and electoral opportunities for relevant social groups and population segments*. For the sake of simplicity, and to allow for simpler graphical representations, here we consider only the 15 Middle East countries/territories. Each of them is attached a 4-component PP&P profile, comprising the scores on the V1-V4 variables; the set of profiles is then turned into a partially ordered set, denoted by π, by comparing each of them to the others componentwise. The Hasse diagram depicted in Figure 1 provides a visual representation of the resulting partially ordered set, together with country/territory labels. As it can be seen, some countries share the same score configuration, so that only 11 unique profiles are realized in the dataset, out of 15 units. The PP&P poset has both *top* (profile 3442, that dominates all of the other profiles) and *bottom* (profile 0000, which is dominated by all of the other profiles), comprises 42 comparabilities and 13 incomparabilities (i.e. pairs of profiles that cannot be reciprocally ordered, due to conflicting scores); its *height* (number of edges in the longest *chain*) is equal to 6 and its *width* (cardinality of the largest *antichain*) is equal to 3.

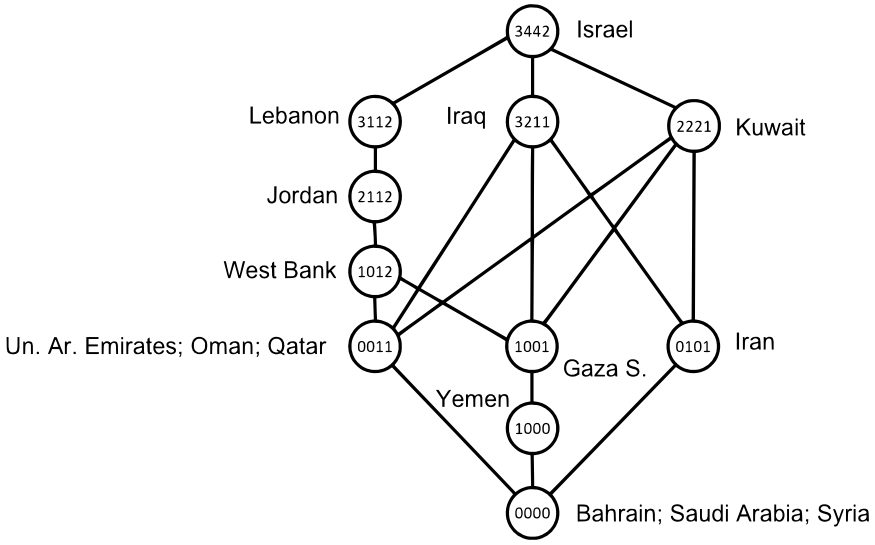

Figure 1: Hasse diagram of the PP&P profiles ordered componentwise, with country labels. Profile components refer to the variables V1-V4, each scored on a 0-4 ordinal scale, introduced in the main text (the higher the score, the better the achievement on the corresponding variable).

3. Dominance and incomparability scores

Our goal is to turn the PP&P partial order into a ranking, i.e. into a *linear order* ℓ respecting the dominances of the input poset π, so that $x_i < x_j$ in $\pi \Rightarrow x_i < x_j$ in ℓ, for any pair of comparable profiles x_i and x_j. The procedure to achieve this, fully respecting the ordinal nature of the variables and avoiding the inconsistent aggregation of ordinal scores, is described in (8; 9) and will be only sketched

here. At its heart is the computation of so-called *pairwise dominance scores* ($pdom_{ij}$) between all pairs of profiles x_i and x_j expressing, in a fuzzy spirit, the degree of dominance of x_j over x_i. In principle, these scores are computed as the fraction of linear extensions of π (i.e. linear orders preserving the dominances in π (11)), where x_i is dominated by x_j, i.e. as

$$pdom_{ij} = \frac{|\{\lambda \in \Omega(\pi) : x_i <_\lambda x_j\}|}{|\Omega(\pi)|}. \tag{1}$$

where $\Omega(\pi)$ is the set of linear extensions of π. In practice, however, this is computationally unfeasible, but for very simple posets, and alternative formulas must be employed, to compute the dominance scores directly based on some simpler quantities describing the mutual "relational positions" of the compared elements, in the poset. Here, in particular, we use the Brueggemann-Lerche-Sørensen (*bls*) formula proposed in (1), defined by:

1. For $x_i < x_j$, $pdom_{ij} = 1$ and $pdom_{ji} = 0$;
2. For x_i incomparable with x_j, $pdom_{ij} = a_{ij}/(a_{ij} + a_{ji})$ where

$$a_{ij} = \frac{|Up(i,j)| + 1}{|Down(i,j)| + 1} \tag{2}$$

with

$$Up(i,j) = \{x_h : x_i < x_h\} \cap \{x_h : x_j < x_h\}^c \tag{3}$$

and

$$Down(i,j) = \{x_h : x_h < x_i\} \cap \{x_h : x_h < x_j\}^c. \tag{4}$$

Pairwise dominance scores lies in the interval $[0, 1]$, equal 1 if and only if $x_i < x_j$ in the input poset and satisfy the equality $pdom_{ij} = 1 - pdom_{ji}$. They are collected in the *dominance* matrix D, whose main diagonal is by definition set to 0. The pairwise dominance scores associated to each element x_j can then be aggregated (e.g. by simple or weighted means) into a synthetic dominance score dom_j, used to build the final ranking. Looking at the Hasse diagram of π, however, one notices that profile 3211 directly dominates (technically, *covers*) profile 1001, since no intermediate profiles are observed in the dataset, and that this occurs although the former represents a much better configuration score than the latter. An analogous situation involves, for example, profiles 2221 and 0101. To avoid making the dominance scores of such pairs of profiles too similar, we embed the observed PP&P poset into the componentwise poset π^{all} composed of all possible $5^4 = 625$ profiles, built upon the variables V1-V4, and compute the pairwise, and the synthetic dominance scores, taking into account the existence of both observed and non-observed profiles, so better discriminating the units. Clearly, turning a partially ordered set into a linearly ordered one, i.e. turning incomparabilities into comparabilities, can indeed be forcing because incomparable profiles get put on the same "low-high" axis, notwithstanding their inherently different structure. To account for this, dominance scores are complemented with incomparability scores inc_j in the $[0, 1]$ interval, assessing to what extent profiles tend to be non-comparable to the others, in the input partial order (10). These additional scores are computed by first defining *pairwise incomparability scores* as $inc_{ij} = min(dom_{ij}, dom_{ji})$ and then aggregating and normalizing them, analogously to the dominance case. Table 1 reports the synthetic incomparability and dominance scores for the PP&P profiles, also graphically shown in the left panel of Figure 2. As it can be seen, PP&P profiles are spread along the vertical dominance axis, with Israel at the top and Bahrain, Saudi Arabia and Syria at the bottom, as expected. Notice also that profiles are in general only "moderately" incomparable (the highest incomparability score is 0.235), so that the final ranking can be taken as quite meaningful.

4. Separation matrix and separation scores

The generic entry D_{ij} of the dominance matrix D can be interpreted as a measure of the strength of the statement $x_i < x_j$ i.e., in a fuzzy spirit, as the membership of element x_i to the downset $x_j{\downarrow}$ of x_j,

Table 1: Synthetic incomparability, dominance and separability scores, for the PP&P profiles (aggregated by simple averages and normalized to [0,1]).

Profile	3442	2221	3211	3112	2112	1012	0101	1001	0011	1000	000
inc	.000	.231	.231	.199	.058	.015	.235	.200	.226	.052	.000
dom	1.000	.783	.784	.801	.629	.498	.292	.300	.287	.126	.000
sep	.783	.245	.247	.247	.164	.050	.007	.007	.007	.001	.000

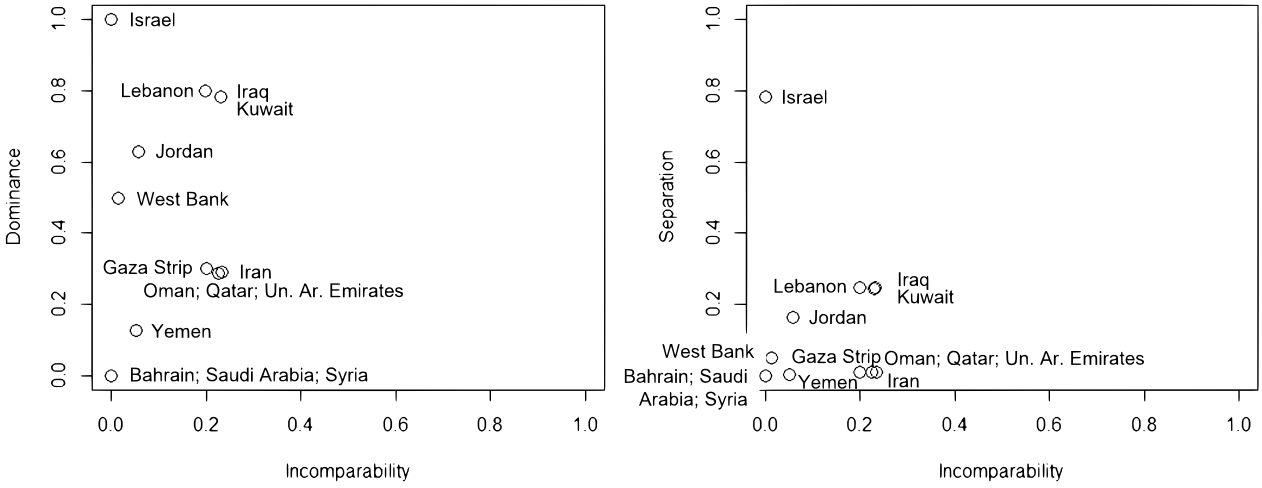

Figure 2: Scatterplot of the incomparability and dominance (left panel) and separation (right panel) scores, given in Table 1, with country labels

in the poset π. As a consequence, the sum of the entries of the j-th column of D can be interpreted as the fuzzy cardinality of $x_j{\downarrow}$ and the dominance score dom_j as a measure of the "effective" number of elements below x_j, normalized to [0,1]. As it can be observed in the left panel of Figure 2, the distribution along the vertical axis of the dominance scores of the countries is quite homogeneous, notwithstanding the fact that some profiles, although "near" in the Hasse diagram of the input poset, express very different PP&P levels. This is the case, for example, of Israel and Kuwait which are both placed in the upper part of the scatterplot. The non-complete effectiveness of the dominance scores to fully account for the "distance" (informally speaking) between observed PP&P profiles, even if embedded in the complete poset π^{all}, can be understood by observing that the pairwise scores $pdom_{ij}$ do not account, explicitly, for the number of profiles of π^{all} in-between x_i and x_j in the linear extensions of π^{all}, but only for the number of these where x_i is dominated by x_j. This "metric" information is recovered, only partially, when pairwise dominance scores $pdom_{ij}$ are summed (or averaged) into dom_j and in fact the latter can be proved to be linked to the average height of x_j, in the set of linear extensions of π^{all} (6). To increase the discriminating power of the final ranking scores, we thus want them to directly incorporate the information on the quantity of profiles separating the compared elements. In a poset, however, the concept of "in-betweeness" is not trivial to define, since two incomparable elements x_i and x_j have no element x_k such that $x_i < x_k < x_j$ (otherwise, by transitivity, $x_i < x_j$ would hold, as well). In a fuzzy spirit, however, we can attach to any x_k a score inb_{ikj} of in-betweeness given x_i and x_j, by observing that dom_{ik} and dom_{kj} express the strengths of the statements $x_i < x_k$ and $x_k < x_j$ respectively, and by taking their product, i.e. by putting $inb_{ikj} = dom_{ik}dom_{kj}$. As a consequence, the *pairwise separation score*

$$psep_{ij} = 1 + \sum_{k=1}^{n} inb_{ikj} = 1 + \sum_{k=1}^{n} dom_{ik}dom_{kj} \tag{5}$$

(where n is the number of poset elements) can be seen as the "effective" quantity of elements in-between x_i and x_j (the added 1 is necessary, since by definition the diagonal pairwise dominance scores $pdom_{hh}$

are null). Notice that $psep_{ij}$ is not symmetric in i and j and that, if x_i and x_j are incomparable, both $psep_{ij}$ and $psep_{ji}$ are non-null. By computing $psep_{ij}$ for each pair of poset elements and arranging them into a matrix, we get the *separation matrix* S, easily computed from the dominance matrix D as

$$S = (I + D)D. \tag{6}$$

By summing the entries of the generic j-th column of S, and normalizing, we finally get the *separation score* sep_j ($j = 1, \ldots, n$) which lies in $[0, 1]$. Formally separation scores are defined as

$$sep_j = \frac{\sum_{i=1}^{n} psep_{ij}}{(n-1) \cdot psep_{\perp\top}}. \tag{7}$$

where $psep_{\perp\top}$, used for normalization, is the pairwise separation score between the top $\top$ and the bottom $\perp$ of the complete poset π^{all} (respectively, profiles 4444 and 0000, in the PP&P example). The right panel of Figure 2 shows the scatterplot incomparability vs. separability scores (reported in Table 1). Compared to the left plot, it is now evident how Israel is neatly separated from the other countries, reflecting its much better achievements on the PP&P variables. At the same time, the other countries are "compressed" into the lower part of the plot, since their achievement profiles are more similar and less discriminating, in terms of political freedom. Notice also that in the right plot Israel has a score lower than 1, because the theoretical maximum separation score is assigned to the top of the *complete* poset π^{all}, i.e. to profile 4444. This shows how the information provided by the evaluation context, i.e. by the full poset of all possible PP&P profiles, anchors the ranking scores to a kind of measurement scale, although (and interestingly) this one does not come as a linear order of scores (i.e. as a unidimensional ordinal variable), but as a partially ordered set of profiles. In summary, incomparability, dominance and separation scores provide a comprehensive toolbox for investigating ordinal multi-indicator systems, for scoring and ranking purposes, accounting for both the "horizontal" and the "vertical" dimension of the evaluation process, when set in a partially ordered context.

5. Conclusion

In this paper we have proposed a new tool for scoring and ranking units assessed against ordinal multi-indicator systems, based upon the separation matrix representation of finite partial orders. The tool allows for incorporating into the scoring and ranking process a kind of "metric" information, extracted from the evaluation context where the observed data are embedded, so as to better reflect the difference in the achievement patterns of the input profiles, complementing the information provided by the incomparability and the dominance scores. Importantly, the computation of all of these scores can be made quite light, by using proper formulas for the construction of the pairwise dominance matrix, based on simple features of the order relation, with no need to generate the set of linear extensions of the complete evaluation poset. The toolbox is currently under software implementation and will be made available, both in the `R` and Python programming languages. Some further research is indeed due. Firstly, the computations introduced in the previous paragraphs must be modified to take into account the frequency distribution of the population or sample, on the set of profiles, so providing a "weighted version" of incomparability, dominance and separation scores. Secondly, a way to introduce variable importance, without using numerical weights in an ordinal context, must be worked out, to improve the flexibility of the approach and its fit to the practical needs of decision-makers. Both research avenues are currently under investigation and their results will be integrated in the toolbox and its software implementation.

Sommario

In Social Network science, and especially in the Social Media field, the research of communities is still an open and challenging task, mostly for what concerns the reliability of the results obtained. When dealing with hashtag networks, the research of communities is related to the identification of topics, which is a challenging achievement. Moreover, when dealing with political debates, which is our study's aim, it is even more complex. In this work, we aim to look for reliable communities on a co-occurrence hashtag network related to the Italian Political campaign (2022). To achieve this goal, we applied two different procedures to compare and validate different community detection algorithms.

Keywords: social media analytics, community detection comparison, hashtag network, topic detection, political tweets, robustness

1. Introduction

In network science, the research of communities is a considerable challenge [3; 4]; moreover, there is a relevant debate around the meaning of communities, especially concerning the Social Media field [5]. In such types of networks, sometimes, not only the edge-nodes positions are used to analyze the network structure in terms of communities. Other information could be used, such as the type of link or the content itself [6; 7]. These additional attributes can lead to obtaining detailed network insights.

This contribution aims to find reliable communities of hashtags in data retrieved from Twitter concerning the Italian Political electoral campaign (2022). When dealing with political debate speeches, researching topics is an arduous task. We investigate them through a hashtags co-occurrence network. Even if many methods have been implemented, the problem of choosing the best algorithm should be addressed, especially considering how different networks can be concerning density, structure, node, and edge definitions.

To answer the problem using only edges position in the network, we used two procedures implemented in the R package `robin` [1] for comparing and validating the communities.

2. Aim and Methods: Comparison and validation of communities with `robin`

In network science, many methods for community detection have been developed. However, the statistical validation of the results still needs to be addressed. The main issue is whether the detected communities are significant or merely a result of chance due to the edge positions in the network. `Robin`

(Policastro et al., 2021 [1]) assesses the robustness of the community structure of a network found by one or more methods to give indications about their reliability. The basic idea is that if a partition is significant, it will be recovered even if the graph's structure is modified. In contrast, if a partition is not significant, a minimal modification of the graph will be sufficient to change the partition.

To address this issue, in `robin`, the network structure is studied through a perturbation strategy to assess the robustness of a community structure and to compare two selected detection algorithms on the same graph.
More precisely, two procedures are implemented:

- The first one tests the stability of the partitions found by a single community detection algorithm against random perturbations of the original graph structure named "null model" (function `robinRobust`).
- The second method helps to choose among different community detection algorithms the one that best fits the network of interest, comparing their robustness in pairs (function `robinCompare`).

The first procedure finds two partitions one for the real network C_1 and the other for the null network C_2 then it perturbs both networks and finds two new partitions $C_{1(p)}$ and $C_{2(p)}$, at this step it calculates two stability measures (e.g. VI [9], NMI [11], ARI [10]..) between the original partitions and the ones obtained from the perturbed network as $M(C_{1(p)}, C_1)$ and $M(C_{2(p)}, C_2)$. This process is repeated many times at different perturbation levels $p \in [0 : 0.05 : 0.6]$; such procedure leads to the construction of two stability curves, one for the observed network and the other for the null model. After the construction of the two stability curves to test their behaviour, two tests are defined. The first test which is implemented in the function `robinGPTest`, gives a more global information testing if the two curves came from the same process or two different processes. While the second test implemented in the function `robinFDATest` gives a more precise information as it analyses the curves by intervals.

The comparison between the two curves enables us to reconsider the problem regarding the significance of the retrieved community structure in the context of the robustness of the recovered partition against perturbations.

Moving to the second procedure, the one for the comparison of different community detection algorithms, is similar to the one just explained. However, instead of comparing the real network with the null network, it applies two different community detection algorithms on the same graph to compare them. Moreover, the R [2] package `robin` (available on CRAN: `https://CRAN.R-project.org/package=robin`) gives the flexibility to use every kind of detection algorithms, even custom external functions, and every kind of null models. For further methodological details, see Policastro et al. (2021) [1].

3. From the Data to the Network

The Data referring to Italian political leaders involved in the 2022 campaign have been collected via API Twitter in the R software environment, using packages `rtweet` and `twitteR`. We have done some qualitative assessments to select the most relevant national leaders with active Twitter accounts. In the end, we selected 15 leaders which belong to different political parties, from left to right wing. The temporal window in which tweets have been retrieved ranges from 2022-08-11 to 2022-09-20. In total, the tweets collected are 5969, as depicted in the table on the right side in 1.
From these data, we focused on the (hashtags $\times$ hashtags) relationships, excluding all the information related to the leaders. Overall, the complete network of hashtags has 1538 nodes and 4146 edges. Isolated hashtags (i.e., never appear with other hashtags in the same tweet) have been dropped. Furthermore, many co-occurrences have a weight equal to 1 (the 81.86%). Thus, such links have been deleted as well, leading to a reduced and simplified network that is easier to interpret and more informative, with fewer *noisy* links.
The final network is conceived using edge for the hashtags that appeared together at least two times, obtaining a network of 405 nodes (the hashtags) and 752 edges that now are considered binary (presence

of link or absence of link). Weights are excluded for simplicity for the community detection algorithm comparisons. The following results will refer to this *reduced* binary network.

Leaders	N of tweets	N of hashtags
Giorgia Meloni	172	186
Matteo Salvini	607	621
Silvio Berlusconi	194	22
Giovanni Toti	322	287
Luigi Brugnaro	344	477
Maurizio Lupi	42	57
Enrico Letta	493	693
Nicola Fratoianni	1465	2207
Emma Bonino	41	21
Luigi Di Maio	37	36
Giuseppe Conte	193	135
Matteo Renzi	126	135
Carlo Calenda	1215	477
Gianluigi Paragone	718	1567

Figura 1: *Reduced* Hashtags adjacency matrix as network structure-visualization; Fruchterman-Reingold Layout and node (hashtag) size proportional to degree. Table representing leaders involved in the Twitter analysis and their Social activities.

4. Analysis

The analysis of the communities will include different steps that will be described in detail below. After the construction of the hashtag network, we wondered which community detection algorithm was adequate, and to achieve this goal, we applied on it the `robinCompare` function comparing the Louvain algorithm with all other algorithms. Figure 2 shows the plots of all the comparisons in pairs with the Variation of Information measure. Analyzing the curves, we can say that the most stable algorithm, i.e., the one that creates the lowest curve, is the Infomap algorithm.

Once the most stable algorithm was found, the next step was to validate it, so we analysed the behaviour of the Infomap algorithm on a random graph and on the real graph. To do so, we first constructed the random graph with the function *random*, which rewires the edges while preserving the original graphâs degree distribution, i.e., applying the *Configuration Model* (Bender and Canfield, 1978 [8]), and second applied the function *robinRobust*. In Figure 3, it is reported the plot of the robustness procedure. Just watching the plot, we could already see by eye that Infomap behaved in the same way with the real and the random network, but also the two tests confirm that the clustering was not statistically significant. Such a result makes us reflect that even if the partitioning is stable, such partitioning is probably random at the beginning.

Since Infomap did not give reliable partitions, we went to investigate the second most stable algorithm for our network which was the Louvain algorithm (in Figure 2) as in the first steps of perturbation was the most stable algorithm (had the lowest Variation of Information, i.e. VI, measures). So we analysed the robustness of the Louvain algorithm, (see the plot in Figure 4), and we could see from the curves that the real data and the null model behaved differently.

The last step was to test the two curves with the two tests. For the Gaussian Process test, the output was a Bayes Factor equal to 82.14 which gave us strong evidence for H1, i.e., that the two curves came from two different processes. While for what concerns the Functional Data Analysis, the output was the plot in Figure 5, which explains that the two curves are statistically different as the p-values are all under

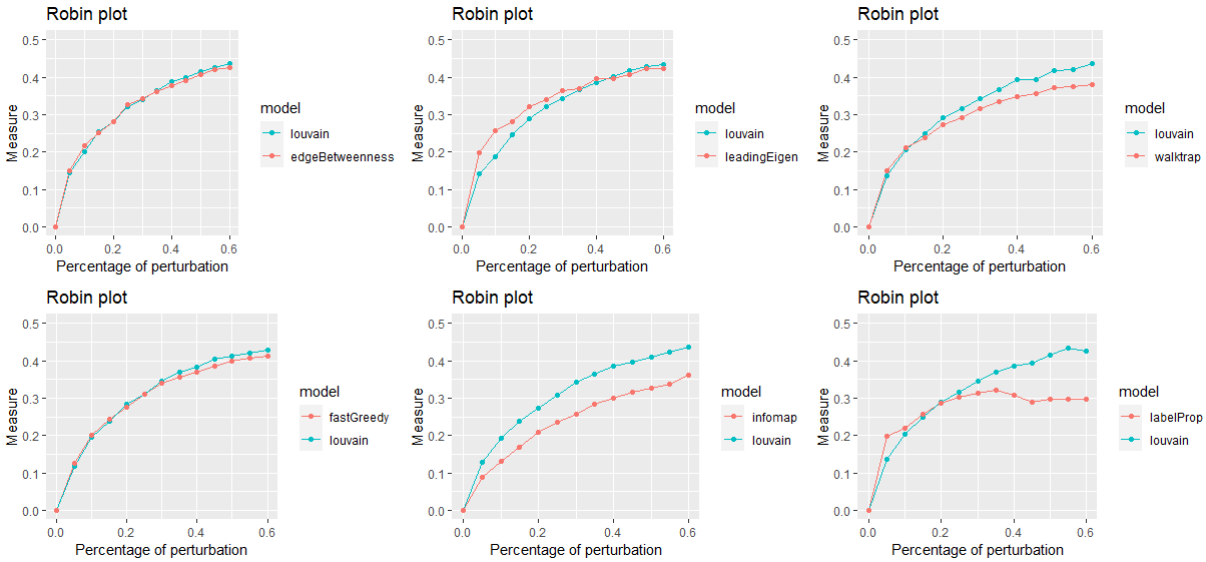

Figura 2: Comparison of all community detection algorithms versus Louvain algorithm with VI measure

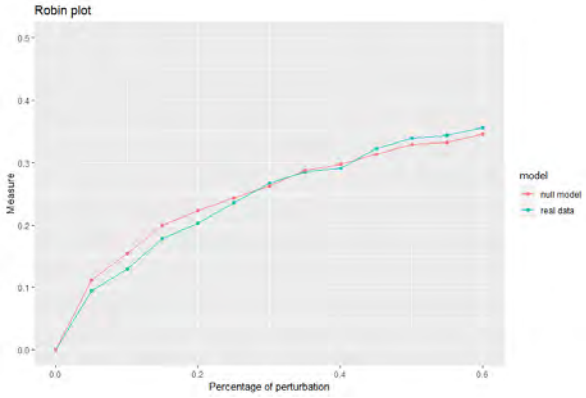

Figura 3: Infomap Validation curves

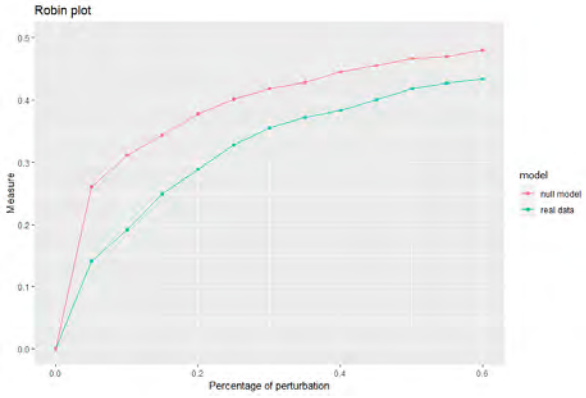

Figura 4: Louvain Validation curves

the red line (p-value=0.05) except for the first point which is only due to the constrain that both curves start from the 0.

We could conclude that Louvain algorithm had solid evidence to form the most stable and reliable clustering.

Analysing the different clusters coming from the Louvain algorithm see Figure 6, we found reliable

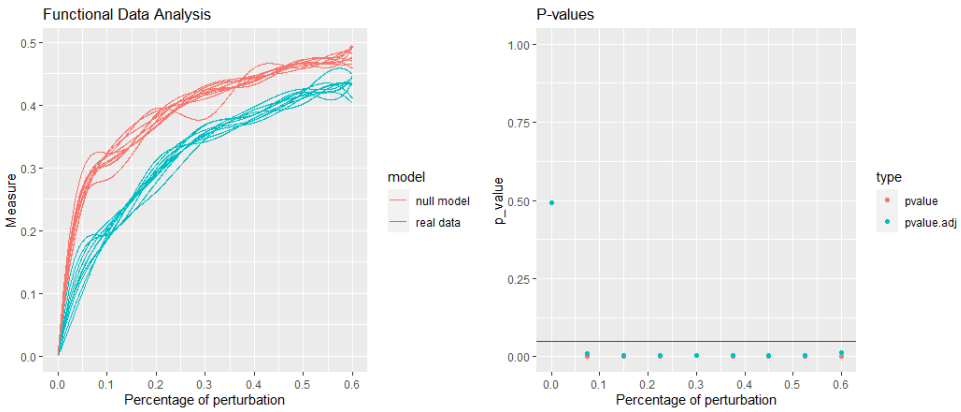

Figura 5: Functional Data Analysis Test of Louvain validation procedure

and interpretable clusters related to leaders and political parties, for example:

- pink cluster with hashtags: salvini, flattax, cristiani and lampedusa can be related to *Lega party - Matteo Salvini*
- blue cluster with hashtags: italexit, noeuro, novax and greenpass can be related to *Italexit - Gianluigi Paragone*
- grey cluster with hashtags: alleanzaverdisinistra, climateemergency, giustiviasociale, sinistra and crisiclimatica can be related to *Verdi sinistra italiana - Nicola Fratoianni*
- yellow cluster with hashtags: volontaripd, giovani, 25settembrevotopd and lettameloni can be related to *Democratic Party - Enrico Letta*

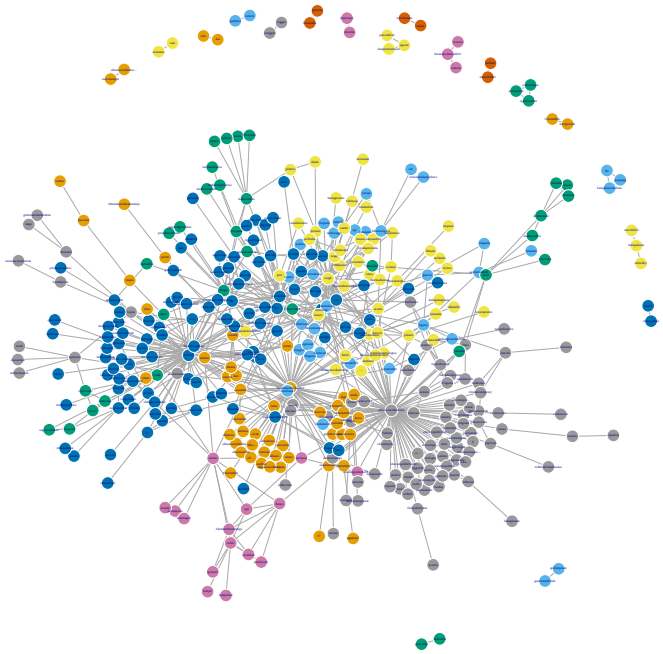

Figura 6: Louvain communities

5. Conclusions and remarks

To sum up, for the difficulty of researching topics in the political debate, we applied two procedures to our hashtag network, giving different insights into the network structure. Even if Infomap seems to be the most stable algorithm for our network (Fig:2) it has a very similar behaviour (in terms of communities discovered) when considering the random graph, indicating that the communities found are random and so not reliable. Therefore, Louvain algorithm, which is the second best for stability (as well as other methods Fig:2) identifies communities related to the real clusterization based on the network's structure, as the validation process gives significant results.

We confirmed the reliability of the partitioning of the hashtags with the Louvain algorithm as it founds different significant groups related to leaders and political parties, for example, the cluster related to *PD* or the one related to the *Lega party*.

The method applied can help to find reliable communities in social networks. However, there is not one algorithm which is the best for all types of networks, so each network must be compared and validated to find the best algorithm and both procedures must be applied to define the most stable and reliable communities.

Abstract

Motivation remains a topical issue in film tourism. However, there is no longitudinal assessment of motivation of film tourists using either survey methods or user generated comments (UGC). Online reviews, i.e., UGC contain great value as a way to understand tourist behaviour in an unstructured format and providing insights into destination marketing and management. In this study, through webscraping we extract comments from a popular global movie "The Hobbit" and "The Lord of the Rings", from Tripadvisor, and focus on selecting reviews that are related to activities and experiences available in Hinuera, New Zealand where some scenes of "The Lord of the Rings" and "the Hobbit" movies were shot. We analyse this data through Text mining techniques, Sentiment and Emotion analysis and LDA topic modelling to analyse and describe the tourist motivation to visit those locations.

Keywords: Movie set tourism, Textual data, Sentiment Analysis, Text mining, LDA

1. Introduction

Visiting a destination after watching a film is called film-induced tourism. Film-induced tourism is a highly personal experience in which each individual gives its own interpretation of media images whether they are authentic or based on fantasies. From a consumer perspective, film-induced tourism is based on different tourist behavioral aspects. For example, people may be motivated to travel to a destination they gazed on a television screen [1]. In the recent years, there has been a growing interest in understanding how movies shape visitation, destination images and tourists' expectations [2]. For example, several high-profile films have been shot in New Zealand including the Lord of the Rings (LOTR) trilogy and the Hobbit trilogy. These films have created a strong New Zealand's international image. These movies repositioned New Zealand as a Middle Earth and each trilogy publicized the destination, New Zealand, as a distinctive location, different from other landscapes in other countries. According to Connell [2], watching films such as the LOTR gives tourists an intangible experience, which can then motivate them to visit the real location. Visiting such locations where favorite films were shot gives tourists a sense of involvement and can create strong emotional bonds with the place [3]. Both quantitative and qualitative research methodologies have been used to examine the characteristics of film-induced tourists visiting different destinations from different populations and cultures ([4], [5], [6], [7]). In this study, we focus on examining both the push and pull factors for visitors wanting to visit film locations. Existing studies suggest that the push factors revolve around relaxation and fun, increasing knowledge about the film location, exemplary qualities of the scenery and attractions related to the film, cultural and social characteristics and imagery [8]. Pull factors including quality of the film locations, tourist infrastructure around the location, and other attractions in the vicinity ([8], [9]). In another study, Roesch [10] suggests that the characteristics of film locations are not the only appeal to viewers, but other factors such as film-related performances and experiences such as romance, nostalgia, and fantasy play an important role in captivating viewers to consider film destinations. Yet, only recently social media comments have been employed to understand and analyze film tourism (see [11]). For example, Gomez-Morales et al. [11] using Instagram posts for Game of thrones, found that tourists post more photographs on social media of locations that are shown longer on screen, that have more sequences of importance to the narrative structure and that characters interact with more intensely. These findings demonstrate the importance of the audiovisual text to the potential role of film in tourist destination promotion.

Social media are interactive computer-mediated tools that permit users to create or share content, such as information, ideas, career interests, and other forms of expression among virtual communities quickly and in real-time. Networks, such as Facebook, Twitter, and TripAdvisor are some of the most popular platforms among people worldwide. In this research, we focus on the analysis of reviews written on TripAdvisor, a popular American travel platform that return useful information to tourists who wants to organize their holidays, trips, and business meetings.
In this paper we apply different Natural Language Processing techniques aiming to deeply understand motivations and behaviours leading tourists to visit film locations. The key questions that this research aim to address analysing tourists' reviews written on TripAdvisor are: what tourists most frequently talk about when they visit a film location? What are they interested in? How do they feel about different topics?
Furthermore, tourists' level of satisfaction with the visited film location is investigated by means of Sentiment analysis, Emotional analysis, and Latent Dirichlet Allocation (LDA) model.
These methodologies are briefly introduced in the following section while in section 3 the case study is presented and discussed.

2. Method

2.1 Text mining

Text mining in its general definition concerns the extraction of structured and high-quality information from textual data. It usually involves the process of structuring the input text into databases and deriving patterns through statistical analysis and finally to evaluate and interpret the output.
In this work we pre-process the textual reviews to analyse them in terms of term-frequencies, bigram frequencies, terms co-occurrence and term frequencies through time, searching the reviews for some particular words, combination of words or bigrams defined by experts.
Before underlying such analysis, textual reviews need to be pre-processed, therefore the following steps have been performed:

- text lowering,
- punctuation removal,
- numbers removal,
- English stopwords removal (stopwords is a list of words that show up frequently but do not bring any valuable information as for example determiners (e.g. the, a, an) or prepositions (e.g. above, across, before)),
- white space stripping,
- tokenization: divide the document into single unit - in our case we tokenize into unigram (each single element from a string) and bigram (each sequence of two adjacent elements from a string),
- stemming: bringing each token to its root form (e.g. learning, learned, learns are stemmed into learn).

Once reviews are cleaned, a Document-Term-Matrix (DTM) can be constructed: the DTM is made up by all the documents (i.e. tourists' review) in rows and all the tokens (i.e. pre-processed words) extracted from the documents in the columns. Each cell of the matrix contains the frequency with which a token appears in a document.
This process allows us to identify the more frequent words used in the reviews, the presence of the experts' identified words, and to analyse associations among words.

2.2 Sentiment and Emotion analysis

Sentiment analysis (SA) is the process of computationally identifying and categorizing opinions expressed in a piece of text, with particular interest in determining whether writer's attitude towards a particular item (i.e. topic, product or service) is positive, neutral or negative. Through the last 15 years, different methodologies that can be grouped into 3 main approaches have been proposed in the literature to conduct a SA [12]: 1) ML based sentiment analysis; 2) lexicon-based sentiment analysis; 3) hybrid approaches.
In the present work a Lexicon based sentiment analysis has been adopted. This approach to SA requires the identification of a lexical resource called sentiment lexicon, or opinion lexicon, which is a predefined list of sentiment words associated to their semantic orientation with a positive or negative score [13], [14]. A sentiment word can be any word, i.e. adjective, noun, verb or adverb; a score can be a sentiment polarity value (for instance +1, 0 or -1 for positive, neutral or negative respectively), or a numerical value expressing

the sentiment intensity. According to Lexicon-based SA method a document is pre-processed and then a sentiment value is assigned to each token for which a match with words in the lexicon exists. In its base form, the final sentiment orientation of a document is obtained by combining (sum and average are the most frequent formulas) the semantic orientation values associated to the words that compose the whole document. The document is then classified as positive, negative, or neutral depending on whether the final score is positive negative or zero respectively.
Considering the characteristics of SA, Emotion analysis (EA) represents an extension of SA, allowing to identify emotions and not only the polarity of a text. EA allows to deeply describe the underlying consumers' feeling and emotions expressed in the text, using a much more complex system of analysis. Unlike SA, EA considers the subtleties within human emotions. In this context, lexicon-based approach to EA have been developed and its functioning is the same described for SA but the emotion lexicons are lists of words and their associated emotions (e.g. joy, sadness, fear, anger, surprise etc.). Being interested in extracting both sentiments and emotions from the reviews we adopt the NRC Word-Emotion Association Lexicon[1][2] (aka EmoLex). The NRC (National Research Council Canada) Emotion Lexicon is a list of English words and for each word two sentiments - negative and positive - and the eight basic emotions (proposed by Plutchik [15], [16], [17]) - anger, fear, anticipation, trust, surprise, sadness, joy, and disgust - are associated.

2.3 Topic modelling

Latent Dirichlet Allocation (LDA) [18], belonging to the family of topic models developed to extract topics from textual data, is an unsupervised learning topic model assuming that each document consists of a mixture of topics and each topic is a probability distribution over words. It is a document-generative model that specifies a probabilistic procedure by which documents are generated. The input to the model consists in a set of documents D while the outputs are a distribution for each document over topic (*document-topic distribution* θ), and a distribution for each topic over words (*topic-word distribution* ϕ) both following a multinomial distribution. To simplify statistical inference, it is also assumed that the 2 outputs have Dirichlet priors with α and β hyperparameters. Considering that:

- D denotes the number of documents,
- T is the number of
- topics, usually defined by the user,
- V is the number of unique words in the entire document corpus,
- N is the number of words in each document (document d is a sequence of N_d words),
- w is the bag of all observed words with cardinality,
- $|w| = \sum_d N_d$ z denotes the topic assignment of all words in all documents,
- z_i denotes the topic assignment of i -th word w_i in document d

the graphical model representation of LDA in plate notation, where θ, ϕ and z are latent variables and word w is observed is reported in Figure 1. To obtain the two distributions θ and ϕ, two main algorithms have been proposed: variational inference and Gibbs sampling. Using these algorithms, we are able to obtain the estimated distributions that are the final output of LDA model. In particular $\phi_{v,t}$ represent the predictive probability or distribution of sampling a new instance of vocabulary word v from topic t and it gives a list of words under the topic t ranked according to their probability values: these often provide good indication to label the topics and for this purpose they are adopted in the present work.

3. Case study and conclusion

Over the years, TripAdvisor became popular among tourists because it is free and easy to engage with. As a result, the number of user reviews and opinions on TripAdvisor have been increased rapidly from 200 million to 884 million from 2014 to 2020 [19]. Therefore, manually extracting emotions, sentiments, and behaviour from each review is an impossible task. To overcome the complexity of the process of extracting content and data from TripAdvisor, or any other websites, the technique called web crawling or web scraping [20] can be used.

In this study we will analyse tourists' reviews who visited New Zealand to see one of the film movie location of this destination. The web scraping process started from a web page collecting all activities available in Hinuera, New Zealand, a settlement in the Waikato Region of New Zealand's North Island, where the hobbits' village was settled for the Lord of the Rings (LOTR) and Hobbit movies, all pages of different activities have been scraped, collecting for each one all the reviews written by tourists that choose that experience, tour, or location. An automatic python script collected a total amount of 3285 textual reviews.

Experts identified a list of 8 basic motives to travel and visit such a destination: landscapes and scenery, learning about the movies and learning about the film shooting locations, technology used to make the film, fantasy world, destination image, film sets, fun and excitement and opportunity to socialise with others that have similar interests in films. Therefore, the words related to these motives that have been searched within the reviews are the following: "landscapes", "scenery", "learning", "movies", "film", "shooting", "locations", "technology", "fantasy", "world", "destination", "set", "fun", "excitement", "socialise", "interests", "experience", "memorable".

According to what explained in Section 2, term frequencies, bigram frequencies and term co-occurrence have been extracted from the reviews. The final list of unigrams has been filtered keeping only the list of interesting words listed above (once they have been properly stemmed the same way as the review, to match the unigrams). Using these words, a new DTM has been computed and analysed.

The LDA model has been applied to the pre-processed reviews, identifying 4 topics about which tourists talk the most. Observing words distribution over topics it was possible to label the topics as follows: topic 1 "On-site experience"; topic 2 "Packaged tour activities"; topic 3 "Other regional activities"; topic 4 "Movie set details". To describe the kind of emotions underlying each review, both sentiment and emotion analysis have been performed.

A lexicon-based Sentiment Analysis has been performed using the NRC Emotion lexicon which allows to extract both polarity of the comments (positive/negative) and emotions (anger, anticipation, disgust, fear, joy, sadness, surprise, trust). For each review, the SA procedure matches the words inside the review (properly pre-processed) with a list of words defining a lexicon, to which a score on each polarity and emotions is associated. In this way, a final score is computed to each review as the sum of the scores of the words belonging to the review.

To offset the possible influence of the review's length (number of words), the final review score has been weighted by the total number of words in the review.

Finally, each review has been associated to a single topic, i.e. the topic with the highest score, that represent the more likely topic the reviewer wanted to express in his/her review.

The analyses reveal that a combination of both push and pull factors over time affect decision-making to visit film locations. Tourists use both cognitive (landscape, scenery, destination) and emotive (fun, excitement) cues as motivational drivers. While previous studies [8] have examined different types of motives, they fail to identify whether these motives persist. Thus, we found through topic modelling that motives are primarily

related to the need to experience the "real" through on-site experiences. Not only tourists want to see the movie set details but they also combine their visit with other regional activities in the area. Thus, while film locations by themselves are a drawcard to the area, complementarity with other attractions is critical for destination marketing purposes. Tourists want to see a several attractions in one visit which requires destination management organizations to position film locations in relation to other attractions to visit in the region. The experience itself is also related to what is included or excluded in the package. For example, visiting Hobbiton and other areas of interest related to the films require a coordination of elements such as transport and complementary tours, which highlight value for money as being critical as well in driving visitation to the site.

Acknowledgments

We would like to thank Peter Fieger from Federation University, Australia, for the initial idea on this project. This research is part of the project titled "Fuzzy theory in Unsupervised Machine Learning algorithm and Sentiment Analysis" funded by University of Padova.

Life satisfaction and social activities in later life in Italy: a focus on the Internet use

Claudia Furlan[a] and Silvia Meggiolaro[a]
[a] Dept. of Statistical Sciences, University of Padova, Italy
claudia.furlan@unipd.it; meg@stat.unipd.it

Abstract

The study aims to provide new insights regarding the role of social activities, and in particular those connected with the use of Internet, for the wellbeing of older people in Italy, taking into account potential differences according to the living arrangements of older people and their gender. Data come from the survey "Aspects of Daily Life", undertaken in Italy in 2020 by ISTAT. Results suggest that both for older men and women, and independently from the living arrangement, the social relations have a role for the life satisfaction, but some aspects of socialization present associations with life satisfaction that are differentiated according to gender and living arrangement. In particular, even if direct social relations maintain their important role for wellbeing of older individuals, a positive association between social relations connected with Internet use and life satisfaction are emerging except for older men living alone: Internet can thus be considered a tool to strengthen the social network.

Keywords: older people, life satisfaction, social relations, Internet use, logit model

1. Introduction

With the progressive ageing of societies, increasing attention in social research and among policy makers has been directed towards older adults and the ageing process (Wilhelmson et al. 2005). Two particular areas of interest are the so-called "successful ageing" and older people's wellbeing. The term "successful ageing" was popularized by Rowe and Kahn (1987), who defined the term as including three main components: "low probability of disease and disease-related disability, high cognitive and physical functional capacity, and active engagement with life" (Rowe and Kahn 1997, p. 433). Older people's "wellbeing," meanwhile, is said to be the the subjective counterpart of successful ageing (Stanley and Cheek 2003; Adams, Leibbrandt and Moon 2011), and this explains the attention that the wellbeing of older people receives in literature as well as in policy-making processes.

Specifically, among the different aspects of subjective wellbeing (SWB) that can be distinguished (see Steptoe, Deaton, and Stone, 2015 for a discussion), the evaluative dimension measured by life satisfaction (LS) is usually considered a key indicator of wellbeing and is one of the most commonly used measures of successful aging too (Tate, Lah, and Cuddy 2003). This explains the interest in life satisfaction by social research.

Previous studies have suggested that SWB is influenced by many factors (see, for example, Gaymu and Springer, 2010) and, in particular, it is positively associated with social contact and social integration (Golden et al., 2009; Meggiolaro and Ongaro, 2015); however, social networks in later life decrease due to retirement, potential health problems and death of family member and friends (Bergland et al., 2016). As a consequence, social isolation and loneliness can increase, leading to a deterioration of wellbeing.

In recent years, Internet use has become an important tool for social activities and leisure time among people, and it may be important also among older people to reduce loneliness and increase their wellbeing (Boz and Karatas, 2015). In fact, research on the association between Internet use and wellbeing among older people showed that two opposite effects can be observed (see studied cited by

Khalaila and Vitman-Schorr, 2018): Internet use can be associated, indeed, with decreased time spent with friends, and in social activities, thus decreasing wellbeing (Veena et al., 2012, Yang et al., 2021); but, on the other hand, it can be associated with social involvement in new personal friendships, and with family and friends, but also with new forms of entertainments (Chen and Schulz, 2016; Chopik, 2016; Du and Wang, 2020).

Thus, even if the literature emphasized the importance of Internet use for wellbeing among older adults, empirical results are mixed. The aim of the current study is to provide new insights regarding the role of social activities, and in particular those connected with the use of Internet, taking into account potential differences in these roles according to the living arrangements of older people and their gender. The reference is a country such as Italy, which represents an interesting case study for various reasons. Italy's population is ageing at an unprecedented rate, with a rapid rise in the numbers of older people, along with persistently low fertility and high life expectancy (Tommasini and Lamura 2009). Since the Italian context is characterized by strong family ties (Dalla Zuanna and Micheli 2004), social relationships may play a crucial role in the SWB of the elderly. Italy also offers an interesting context to study the gender differences, being characterized by a still relatively unbalanced gender system (Anxo et al. 2011), and thus differences in socialisation of old men and women could be particularly strong in shaping expectation and behaviour in later life (and thus, SWB). Lastly, in Italy the percentage of individuals using the Internet is above the EU average[1], suggesting that potential role of social activities in Internet may be particularly strong.

2. Data and methods

We use data from the survey "Aspects of Daily Life", undertaken in Italy in 2020 by ISTAT; it is based on a nationally representative sample of approximately 25,000 households, with a total of 42,831 individuals. In our study, we focused on 10,946 individuals aged 65 and above. The survey collected information on several dimensions of life. Besides socio-demographic and socio-economic characteristics, information on health, lifestyle, religious practices, and social integration for each household member were recorded.

As regards the focus of our study, life satisfaction was assessed with the question: "How satisfied are you with your life on the whole at present?", with answers ranging from 0 (not satisfied at all) to 10 (very satisfied). The main explanatory variables of interest for our study are those describing social relations, and we consider both direct and Internet social relations. Direct social relations were referred to social network integration and active lifestyles. Social network integration was measured on how often individuals met their friends (every day, at least once a week, less often than once a week, never or without friends) and whether they participated at meetings of cultural association. Moreover, the social network was measured by considering if individuals can count on friends, relatives, or neighbours. Active lifestyles were measured considering physical activity, volunteering, and attendance at cultural activities. Physical activity can be, at least indirectly, connected with a form of social integration and, in the following analyses, we distinguished individuals who played sports regularly or occasionally or engaged in physical activity at least once a week, those who were rarely physically active and those without any physical activity. Volunteering is measured considering whether individuals carried out free activities for voluntary or not-voluntary associations. Cultural activities considered whether individuals had gone to some cultural or entertainment venues (theatre, cinema, museum or exhibitions, classical music concerts, other music concert, monuments, or archaeological sites) in the last year before the interview. In particular, one variable was created reporting the highest frequency of attendance among the six considered activities.

As regards Internet social relations, the survey investigates if the individuals who have used Internet in the last three months, have had video calls or have texted through Internet (for example with WhatsApp or Skype), participated or expressed opinions in social networks, or uploaded self-created content on web sites or through apps. The use of social media was included in the models as the number of these activities than the individual has used.

Another important variable being connected with social relations is the family in which older people live. In fact, in our study, separate analyses by gender and living arrangement are performed to take into account potential differences in the roles of social relations for different groups of individuals. In this context, the variable describing the family in which individuals live is differentiated for those living alone and those living with other people: specifically, for the former group, the marital status is considered (never married, separated or divorced, widowed); for individuals living with other people, we distinguished those living with partners without children, those living with partners and at least one child, those living without a partner but with at least one child, and those living with other persons.

Several variables are considered in the analyses as control and they may be grouped into four main domains: socio-demographic characteristics, socio-economic conditions, health status, and contextual aspects.

Socio-demographic characteristics controlled for in the analyses are the age (65-74 and 75 or more years) and religiosity (attendance at religious services: at least once a week, sometimes in a month, sometimes in a year, never).

Education and a subjective evaluation of family's economic resources were used to describe the socio-economic background of individuals. Education has four categories: low (no schooling or primary school), middle low (junior high school), middle (secondary school), high (degree or more). Economic situation is determined through a subjective evaluation of the family's economic resources: a dichotomous variable was built distinguishing whether the family had poor or insufficient resources (as opposed to very good or good).

Health was described by three covariates. The first refers to a subjective perception of health. Individuals were asked how their health is, in general (excellent or good, fair and poor health). A second variable referring to the self-reported presence of limitations in usual activities distinguishes three categories: severe limitations, only mild limitations, no limitations. The third variable refers to an indicator of mental health, where bigger values (from 0 to 100) indicate a better wellbeing.

Contextual aspects are measured considered the geographical area of residence (northern, central, and southern Italy), and some variables on the characteristics of the neighbourhood (presence of problems and availability of services).

Multivariate analyses were applied to study the association between older people's life satisfaction and their living circumstances. Life satisfaction is measured through a 0-10 anchored scale with fixed endpoints (Saris, 1988; Corbetta, 2003), which generates an "almost cardinal" variable. Since treating it as a cardinal variable is a controversial issue (Corbetta, 2003), we estimated logistic regression models dichotomizing the scores in life satisfaction. Specifically, we considered one binary categorization, using a threshold of 7, which corresponds to the mean and the median satisfaction score in our sample of the older people[2].

3. Results

Table 1 present the coefficients of the logistic regression models used to estimate the determinants of the probability of being satisfied with life (PLS) for men and women aged 65 and over in different living arrangements by gender. Results suggest that both for older men and women, and independently from the living arrangement, the social relations have a role for the life satisfaction of individuals, but some aspects of socialization present associations with the PLS that is differentiated according to gender and living arrangement.

Specifically, whereas an active lifestyle represented by physical activity has a positive role for both men and women and both for those living alone or not, other forms of active lifestyles are connected with higher PLS only for some individuals. In particular, volunteering is connected with a higher PLS for men living with others and for women living alone: for the women, this is probably due because it is a good way to find new social networks to reduce the sense of loneliness, and to satisfy the need of caring typical among lone women. Instead, older people participating in cultural activities are more likely to be satisfied with their life and this is true for all groups of older people except for men living alone.

[2] The results provided by the logistic model with the threshold of 7 are similar to the ones obtained with a threshold of 8, which is the threshold value used by Istat (2022) to identify the satisfied people.

As regards the role of social network integration, meeting friends have a positive association with the PLS again for all groups of older people, expect for men living alone. Only among the latter ones, those who can count on relatives are more likely to be satisfied with their life, probably because for them having someone to can count in case of need might be particularly important being alone.

Table 1: Results of logit models for being satisfied with life for men and women aged 65 and over, living alone or with others. β coefficients.

	Living alone		**Living with others**	
	Men	*Women*	*Men*	*Women*

Meet friends (Ref. never or without friends)				
Less often than once a week	0.240	0.142	0.164	0.173
At least once a week	0.291	0.299’	0.363*	0.439***
Every day	-0.301	0.464*	0.274	0.633**
Cultural meetings (Ref. no): Yes	-0.001	0.001	0.001	0.003
Physical activity (Ref. sedentary)				
Rarely	1.141***	0.463**	0.143	0.336**
More than once a week	0.750***	0.523***	0.317**	0.452***
Volunteering (Ref. no): Yes	-0.664*	0.847**	0.332*	0.170
Cultural activities in one year (Ref. never)				
1-3 times	0.027	0.068	0.268*	0.521***
4 or more times	0.504	0.801**	0.377*	0.553**
Number of Social networks (Ref. none)				
1	-0.695	-0.096	0.408*	-0.155
2	0.247	0.315	0.475**	0.160
3 or more	0.041	0.577*	0.504**	0.346*

Significance level: *’ p<0.1, * p<0.05, ** p<0.01, *** p<0.001.*
The logistic regression models also control for age, religiosity, education, family’s resources, health, presence of limitations, mental health, geographical area of residence, characteristics of neighbourhood.

The social relations defined by the family is important among men living alone, and, in particular, those having had a marriage are more likely to be satisfied with life than their never married counterpart, but the same variable has no role for the PLS of women living alone. For women living with others, those in a couple without children are more likely to be satisfied with life than those living in couple with children.

As regards Internet social relations, the Internet use has a positive role on LS for women both living alone and with others to maintain (or create) connections with people of their social network. The Internet use has a positive effect as well for men living with other persons; instead, it is not significant for men living alone, confirming how the connection between social relations and the PLS is weak for this group, as before seen with the direct social relation.

It is undoubtedly that the direct social relations maintain their important role for the PLS of older people; however, some signals of positive effects of the Internet social relations are emerging and suggest that Internet social relations can be seen as a tool to strengthen the social network for some group

of people. This can suggest health campaigns and social programs to encourage older people to learn computer skills and use the Internet in their daily life as a mean to reduce loneliness and increase their wellbeing.

Abstract

This paper aims at disentangling the effect of parents' fertility and education on children's educational outcomes by means of social capital endowment. We use parents' social capital endowment as exogenous factor predicting parents' education and fertility, and children's social capital values. We apply an ordered Probit to estimate children's probability to acquire a certain educational level, using the predicted instrumental variables. We use a sample of respondents aged 18-60 years old from the cross-sectional Bank of Italy's Survey on Household's Income and Wealth (SHIW) 2010. We found that parents' social capital endowment is a good predictor of parents' education, fertility, and children's own social capital. All these aspects affect differently the probability of a child to acquire a tertiary degree.

Keywords: education, intergenerational transmission, social capital, fertility

1. Introduction

Children's school outcomes are often a consequence of enduring inequalities of opportunities [5]. Substantial social stratification research converges on the fact that parental educational background is an important determinant of children educational outcomes [3,8]. Highly educated parents have more economic and cultural resources to sustain their children during education, and to motivate them to continue schooling.

Social stratification literature has emphasized the role of parental socio-economic background, and hence, children's social capital, for their educational outcomes [1,6]. Bourdieu [1] sees social capital as a tool of reproduction for the dominant class, whereas Coleman [6] emphasizes the social control aspect, where trust, information channels, and norms are characteristics of the community. In this latter framework, the family is responsible to adopt certain norms to advance children's life chances.

Recently, a strand within the social mobility and stratification literature paid attention to the role of demographic pathways in the transmission of education from one generation to the other. For instance, it has been found that for highly educated women there is no effect of (own) education on the probability to have a highly educated child, because of the negative effects of tertiary education on women's likelihood to marry and have children [5,13].

In this paper, we combine the two strands of research, aiming at disentangling the effect of parents' fertility and education by means of the social capital endowment. Previous research on the role of social capital on the level of education of the individual is vast. Differently from previous studies, we consider the complexities of the relationship between education and fertility in the parents' generation, using parents' social capital endowment as exogenous factor predicting parental background. In addition, we

also identify the effect of social capital endowment of children on their own education goal as a result of the transmission of social capital values by their parents. In doing this, we assume the components of parents' social capital endowment as exogenous predictors of children's social capital endowment. To evaluate the individual endowment of social capital, which can be defined as the values related to individuals' networks and communities, we use the categorization suggested by the Social Capital Benchmark Study (see, among others, Saguaro Seminar, 2001). This approach provides a broad conceptualization by examining indices that also relate to the pre-requisites necessary to build social capital, the aspects considered are: social trust, trust in legal system and public institutions, membership and group participation; altruism; informal interaction among individuals [12]. Furthermore, we have considered the aspect of "shared norms" ([7]), which lies outside the Saguaro Benchmark Study's approach. (

To this aim, we use the cross-sectional Bank of Italy's Survey on Household's Income and Wealth (SHIW) 2010, which retrospectively reports, in addition to sociodemographic information, a section regarding questions on the individual endowment of social capital. This information can also be traced back to the parents of the respondent. Using these data, it is possible to empirically derive associations between endowment of parents' social capital and the intergenerational transmission of education.

We expect that social capital endowment is an important component which predicts the level of education of the parents and their fertility behavior. We expect that a positive inclination of parents towards norms and attitudes about the relevance of the family and having children impacts positively parents' fertility and, indirectly, negatively affects children's probability to obtain a tertiary degree. This is in line with the so-called dilution theory and siblings' effects on individuals' human capital [9]. Next, we hypothesize that the relevance of family and having children is negatively associated with the educational level of the parents and, indirectly, reduces the positive impact of parents' education on the children's probability to obtain a tertiary degree.

2. Data and Methods

We used a sample of males and females aged between 18 and 60 years, drawn from the second "rotation" of the Italian cross-sectional SHIW survey of the Bank of Italy 2010. Dropping out the students in the sample, we finally analysed a sample of 2773 subjects. .. Information on the parents who do not live in the household of the respondents is collected with retrospective questions. At first, we correctly identify the associations between social capital endowment of the parents, their educational level and fertility, and children's social capital endowment. Predicted parents' education and fertility, as well as predicted social capital endowment of children, are then used as instrumental variables to predict children's education level.

We use answers to specific questions included in the questionnaire to obtain information on proxy variables that reasonably fall into the categories of social capital (following Putnam's Saguaro Seminar benchmark [11]). The SHIW 2010 survey contains information on various proxy variables of the individual endowment of social capital, in the questionnaire the respondent has to evaluate each social capital aspect with a score that ranges between 1 and 10: 1) tolerance, 2) compliance with authority (parents, educators), 3) respect of laws, 4) norms related to the relevance of the family and having children, 5) norms regarding being successful at work 6) being careful in trusting people. These questions are asked to the respondent in two different fashions. At first, it is asked, to what extent, in the education received by the respondent, the family of origin insisted on transmitting the values listed above. Then, it has been asked to the respondent how much himself/herself insisted (or thought it is reasonable to insist) on the importance of the same values in the upbringing of children. In the first case, it is possible to retrospectively survey a proxy-measure of the values transmitted from parents to children and which we considered as part of the social capital endowment of the parents. The proxy measures of the parents' social capital endowment are adopted as exogenous instruments of parents' education and fertility, as well of children's social capital endowment. The corresponding "instrumented" variables are then jointly used in the equation that predicts children's educational attainment.

We apply a two-stage approach: at first, we estimated simultaneously the education level of both parents, adopting a two-equation seemingly unrelated regression (SUR) model, in which the two dependent variables measure the years of schooling of the father and mother of the respondents. Regressors sets of both equations include social capital components as instruments. In this first stage, we also estimated the fertility of parents through a truncated Poisson regression (see, among others, [10]) in which

the dependent count variable, given by the number of children, is truncated to zero because we cannot include in our sample individuals who did not become a parent. Furthermore, also at this stage, we estimated the components of children's social capital endowment, performing a SUR regression model and using parents' components of social capital as instruments.

In the second stage, we apply an ordered Probit regression to estimate the probability of the respondents to obtain lower secondary educational level, a high school degree, or tertiary degree. In this regression, we include as explanatory (instrumental) variables the previously predicted parents' education and fertility, and the predicted components of children's social capital endowment.

3. Preliminary Results

The results obtained at the first stage by performing SUR and truncated Poisson regressions show that the components of social capital are significant predictors of both education and fertility of the parents, as well as of social capital endowment of children. In line with our expectations, the higher the score on attitudes and norms related to the relevance of the family and having children, the lower parents' level of education. The association is reversed when the outcome is parents' fertility. Performing appropriate overidentification and weak-instruments tests, we verify the validity and utility of parents' components of social capital as instruments in a two-stage estimation procedure (testing results are omitted here for the sake of brevity but remain available upon request).

Predicted parents' education and fertility, as well as predicted respondents' social capital endowment, strongly impact children's probability to obtain a certain educational degree. In Tab. 1 we report the ordered probit estimation results, measuring the impact of some relevant explanatory variables and the predicted parents' education and fertility by means. In line with expectations, and previous literature, parents' education positively affects children's education, while parents' fertility negatively. In addition, respect to previous studies, marginal analysis results show how the (negative) percentage effect of parents' fertility on children's educational career is stronger than the positive effect of parents' education (Table 2).

Finally, marginal effects of social capital components of children (reported in Table 2) show how predicted attitude to obedience to authorities negatively impacts the probability to be graduated, while predicted respect of laws and attitude to be successful at work have a positive impact. The analysis of profiles reported in Figure 1 show different results for women and men with regards to the effect of some components of parents' social capital endowment. However, the interpretation of these results requires further deepening.

This study presents also some limitations. It should be mentioned that due to data availability, the used measures of social capital endowment transmitted from parents to children are inevitably subjective. To clean the measurement from this subjective bias, we would need parents' responses, which, unfortunately, are not available. Moreover, the proxy variables used should be interpreted as micro-level representations of the endowment of social capital, mainly constituted by the importance of intra-community links. At a macro level, a social capital endowment could be thought of as states' responsiveness to society or the institutional capacity of a community ([7]).

Abstract

One of the most interesting areas of research that has emerged since the introduction of these platforms is the analysis of material from social networks. Over the years, several studies have tried to exploit social media data to acquire information that could be useful for predicting or understanding people's opinion on political and current issues, but also for brand and product marketing purposes. Our research focuses on the analysis of Twitter data collected during the 2022 Italian general elections. A statistical learning approach has been exploited to analyse the flow of user-submitted comments that covered the political discourse. It is possible to understand public opinion trends in an electoral context using existing tools.

Keywords: statistical learning, text mining, streaming data, opinion mining

1. Introduction

Individuals often express their views on facts, current events, politics, and sports on internet platforms such as forums and web news comments. In recent years, the widespread use of social networks has attracted more people to the internet and made it easier for them to share their opinions. Opinions expressed in social media text messages are a valuable resource for extracting knowledge. Text data mining techniques are used to extract knowledge from this type of data, as text messages are unstructured data, and specific methods have been developed.

One of the most common types of text analysis is sentiment analysis, which is used to determine the sentiment of people on various topics in order to predict future events or identify emerging trends. Several studies have shown that opinions expressed on social networks are a good indicator of overall public opinion [see 8; 4; 10; 5, among others].

Our research focuses on the specific case of the 2022 Italian general election, that involves the full engagement of the entire population, and a large coverage on media. This election has been the first one occurring in late summer and it came after the resignation of Prime Minister in July. This event took the parties unprepared and forced them, not only to rashly organize a electoral campaign, but also to build alliances plan, that changed up to few weeks from the election day.

For this study we used data collected from Twitter, through the Twitter API and Socialgrabber, a custom software that collect tweets in archives. The data collected and examinated in this research span from 22 july 2022 (the day after the Prime Minister resignation) to 27 Sempteber 2022 (the day after the general election).

2. Background

Data are the base resource, but their exploitation in any application is due mainly to Data Mining techniques. *Data Mining* is the process that allows finding hidden patterns using automated or semi-automatic systems [12]. Data Mining techniques are widely used in marketing and sales, as they often can elaborate large amounts of information, providing worthy insights and a relavant competitive advantage with a direct return on profit. The evolution of methodologies for Sentiment Analysis, is particularly entangled with progresses in the Natural Language Processing (NLP) field. Wang et al. [11] present one of the earliest research about streaming sentiment analysis. The authors implemented a system with a visual dashboard for real-time analysis of public sentiment expressed on Twitter toward presidential candidates in the 2012 U.S. election. To measure the sentiment the authors trained a Naive Bayes model, considering as features the TF-IDF matrix generated from tweets. This approach required the preparation of a big corpus manually classified. The final purpose was the implementation of a visualization tool to monitor the evolution of sentiment towards specific subjects. Rahnama et al. [9] proposes Vertical Hoeffding Tree, a parallel decision tree classifier to classify tweets. Their parallelization-based solution reduces both the computing effort and the necessity to store the data stream. A study about the UK's general elections in 2015 [2] has again sought to predict electoral results through data collected on Twitter. Although it failed to properly predict the party that would have won more seats, a factor that also depends on how the votes are geographically distributed. However, the research was able to predict the order of Parties in terms of the number of votes received, even succeeding in predict the spread out of a not-important party in the previous elections, UKIP's Nigel Farage. The study in this case made use of a lexical-based sentiment software that assigns a score between +5 and -5 at each word based on whether it is considered positive or negative. A study on the referendum for the Brexit [3], the referendum launched in the United Kingdom to decide the exit from the European Union, showed how NLP (Natural Language Processing) techniques applied to a dataset of data collected on the web, social networks and forum comments and newspapers have allowed a fairly accurate prediction of election results.
Finally, text mining techniques have been shown to be relevant also to track the evolution of long-term debates on the social media platform, as in [6] where the debate of the last year before Brexit in the UK was analyzed, detecting the most relevant topics and their time collocation through Latent Dirichlet Allocation and Dynamic Topic Modelling. The analysis of big social data can be generalized to the rest of the offline world and it's useful not only for trying to predict the election results (which is still an insidious operation when the candidates are close in elector approval), but above all to interpret the feelings, opinions, and issues affecting people, allowing to conduct more effective political campaigns, as well as implementing more appropriate business and marketing strategies.

3. Methodology

The first step of our research is related to the collection of data from Twitter. This process required a selection of the relevant keywords for the electoral debate. The keyword selection involved the candidates' parties and leaders and the most relevant politician and public personalities connected to them. The most critical factor was that two month before the elections parties were not yet organized for the electoral campaign and alliances was not too, due to the unexpected election. Therefore the number of parties, candidates, and alliances changed over time, and this required updating the keywords according to the changes. Over 4 millions of tweets have been collected in the time frame of two months. The data have been processed with Python scripts. To compute the sentiment, the Python Library *sent-it* was used [1]. The library contains a model based on the current state of the art for NLP, BERT [7] and fine-tuned on the Italian corpus of tweets to classify positive and negative attitude contents. The processing is run simulating a data streaming from the full collection of data. The sentiment model is trained with older tweets than the dataset used, and the data are binned by time, as this would occur in a real data stream. In this way, the implemented approach does not benefit from owning the full dataset beforehand

4. Results and Limitations

Figure 1 provides some preliminary results. Each graph shows the rate of positive tweets over the total number of tweets by day assigned to that party. Each tweet is assigned to a party based on the keywords in the text. Tweets with keywords belonging to more than a party have been removed from the dataset. Only parties with at least 1000 tweets by day have been selected to avoid unreliable time series due to the insufficent data. The overall results show how the general debates on tweets seem to feature a negative attitude towards parties: the positive rate is almost always under 30%. While for some parties, such as "Fratelli d'Italia" the tweet time trend seems to follow the one predicted by polls, others, such as "Lega" and "Movimento 5 Stelle" seem to be opposite to the trends tracked by poll. Some of the unexpected results may be explained by the limitations of the methodology adopted. First of all, is the keywords selection: that has a strong impact on the gathered tweets, for example some of the politician names used as keywords may lead to the selection of tweets with a specific attitude different from the general attitude towards the party. The second limitation is intrinsic in the model used to evaluate the attitude of tweets: the model was trained to predict attitude on a dataset of tweets not updated with the current discussion themes. This aspect is particularly relevant for textual data, as the way the attitude is expressed is particularly related to the domain of discussion. The last one is related to party positioning: Twitter is not a perfect representation of the population, and some groups of people may be more represented on social media, or more active than others, influencing social media analysis results. While the last point represents one of the main limitations of social network political analyses, in the future the second point may be addressed by building a model more tailored and able to grow and adapt together with the debate, reducing the human efforts in the construction of training datasets.

Abstract

Defined by Diagnostic and Statistical Manual of Mental Disorders (DSM-5), gender dysphoria is a psychological condition characterized by marked incongruence between the gender expressed by an individual and the gender assigned at birth. The scientific community has long debated the issue of gender dysphoria, first defining it as a gender identity disorder until now when it has been de-pathologized from mental disorders. The aim of the work, therefore, is to map the scientific production of gender dysphoria topics through bibliometric techniques in order to analyse scientific productivity and study their contents.

Keywords: gender dysphoria, bibliometric analysis, science mapping

1. Introduction

Gender dysphoria is a psychological condition in which a person subjectively feels their identity and gender does not conform to their birth-attributed sex, often causing clinically significant impairment insocial areas, affective-relational areas, and other areas of life (Frew et al. 2021). People who experience gender dysphoria may describe themselves as transgender, nonbinary, or trans+, due to the perception that their gender identity does not match their assigned sex at birth (American Psychiatric Association,2013).

Over the years, the clinical definition of gender dysphoria is changed, moving from "gender identity disorder" to "gender dysphoria" in the Diagnostic and Statistical Manual of Mental Disorders (DSM-5). According to the DSM-5, dysphoria is manifested by the following criteria: (a) the desire to be treated as the opposite gender; (b) the belief that one has the typical feelings and reactions of the opposite gender; (c) marked incongruence between an individual's experienced/expressed gender and primary and/or secondary sexual characteristics; (d) a strong desire to shed one's primary and/or secondary sexual characteristics due to a marked incongruence with one's experienced/expressed gender; (e) a condition clinically significant that provide distress or impairment in social, occupational or other functioning; (f) desire for the primary and/or secondary sexual characteristics of the opposite gender.

In 2018, the World Health Organization released a new version of the International Classification of Diseases (ICD-11) that state gender dysphoria as "gender incongruence", removing it from mental disorders.

To better understand the theme in various aspects, it is necessary to analyse and map the literature about it. Mapping the scientific knowledge of a topic means performing a comprehensive review of its relevant scientific literature. This involves synthesizing previous research findings to effectively lever-age the existing knowledge base and identify potential avenues for future research. Bibliometrics allowsimplifying

the review process by offering a systematic, transparent, and repeatable methodology based on statistical measurements of scientific production, scientists, and scientific activities (Cuccurullo et al., 2016). This methodology involves the application of quantitative methods for evaluating, tracking, and quantifying published research within one or multiple fields over time.

In several research domains, bibliometric methods are implemented to assess the impact of the field, specific researchers, individual papers, and reference journals, as well as to identify knowledge inputs, research gaps, trends, and future opportunities (Zhao, 2010). Two primary bibliometric approaches used for investigating a research domain are performance analysis and science mapping (Noyons et al., 1999). In this study, we concentrate on science mapping, as it enables the identification and visualization of themes and trends, both synchronically (Callon et al., 1983) and diachronically (Cobo et al., 2011). This work aims to present a systematic literature review about gender dysphoria to analyse its scientific productivity, in terms of the number of documents published about this topic, and to study their contents through quantitative analyses.

2. Methodology

To investigate the content of scientific documents, we map their conceptual structure by conducting two related analyses: a term co-occurrence network analysis and a strategic or thematic map. The use of these techniques allows (i) measuring the relationship among terms, (ii) detecting the main research themes, and (iii) highlighting how they are developed.

The term co-occurrence network analysis (Wang et al., 2019) identify of one or more topics represented by a set of terms (e.g., keywords, terms extracted from titles, or abstracts). To understand the themes covered by a research field, a network representation is used in order to find which are the most important and the most recent research frontiers. By considering the network approach, we perform a term co-occurrence matrix. Each cell outside the principal diagonal contains values that measure the number of times two terms appear together in the collection of documents (co-occur). Then, the association index, proposed by Van Eck and Waltman (2009), is used to normalize the co-occurrences among terms. The index, which can assume values between 0-1, reflects the strength of the association amongterms.

The co-occurrence matrix can be represented as an undirected weighted network in which terms are nodes and the associations between linked terms are reflected by edges, showing both single terms and subsets of terms frequently co-occurring together. To identify subgroups of strongly linked terms, where each subgroup corresponds to a center of interest or a theme of the concept structure of collected documents, we perform community detection (Fortunato, 2010) using the Walktrap algorithm (Pons and Latapy, 2006).

Topics identified through the community detection algorithm can be plotted on a Strategic or Thematic Map (Cobo et al., 2011). The Thematic Map is a bi-dimensional map where the axes **x** and **y** are built using Callon centrality and density measures respectively (Callon et al., 1983). Centrality quantifies the level of significance that a theme holds within a research field, whereas density serves as an indicator of the degree of the theme's development. These two measures allow identifying four typologies of topics (Cahlik, 2000) according to the quadrants of the map in which they are positioned.

The first quadrant, on the upper-right of the map, groups motor topics, characterized by both high centralityand density. This means that they are both developed and important.

The second quadrant, on the upper left, identify isolated topics or niche ones. These topics are distinguished by well-developed internal links, as evidenced by their high density. However, due to their lack of significant external links, they possess only limited importance for the broader research field, as indicated by their low centrality.

In the third quadrant, on the lower left, there are emerging or declining themes, characterized by both lowcentrality and density. These topics are weakly developed or marginal. In the fourth quadrant, on the lower-right of the map, basic and transversal topics are located. They are characterized by high centrality and low density identifying important topics transversal to the different research fields.

3. Data retrieval and main findings

The Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA- Liberati et al., 2009) model was used to retrieve the scientific production. We queried the Web of Science (WoS) indexing database – launched by the Institute for Scientific Information (ISI) and now maintained by Clarivate

Analytics – using the following query: (TS= ("gender dysphoria") OR TS= ("gender identity disorder*")). We refine our search by selecting only documents classified as Articles, Proceedings Papers, Review Articles, and Book Chapters in English published from 1985 – the starting year of indexing documents available on WoS - to 2022. The collection, consisting of 2362 records, was exported into PlainText format.

To analyze the whole collection, we used the *bibliometrix* R package, an open-source tool for quantitative research in scientometrics and bibliometrics that includes all the main statistical and visualization methods for performance analysis and science mapping (Aria and Cuccurullo, 2017). After converting the collection into a data frame, we reported some descriptive information:

- The 2362 documents were published in 815 different journals;
- The total number of references is 50191;
- The average citation per document is equal to 27;
- The number of co-authors per document is 4.

Focusing on the annual scientific production (Figure 1), the first phase - from 1985 to 2000 - included transsexualism as the first gender-related diagnostic label to be included in DSM-3 within the macro-category of psychosexual disorders (Zucker, 2015).

With the advent of DSM-4 in the early 2000s, the terminology changed to "gender identity disorder", falling under the category of sexual and gender identity disorders, developing new thinking and insights from the scientific community. The release of DSM-5 in 2013, which included a section on gender dysphoria, increased the literature on the topic. The shift towards highlighting clinical distress as opposed to treating transgender identity as inherently problematic seems to be a less stigmatizing approach, particularly given that the absence of the term "disorder" has been noted to be more inclusive (Galupo et al., 2021).

Following this, the new diagnosis introduced in 2018 has resulted in a rise in scientific output. It is defined as "incongruence" between the experienced gender and the assigned gender, which includes non-binary individuals belonging to the transgender population. Non-binary individuals do not identifywithin the traditional male-female gender binary, but rather identify outside of it (Reisner and Hughto, 2019).

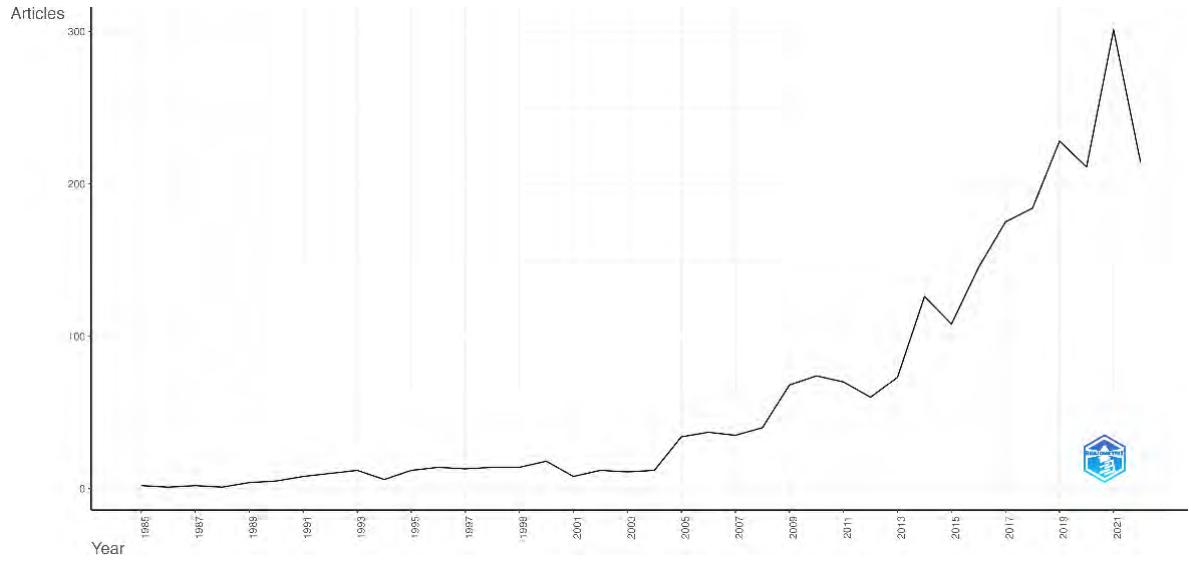

Figure 1: Annual Scientific Production of documents published from 1985 to 2022

To extract and analyse the concepts of the scientific documents collected, we perform a thematic map (Figure 2). Keywords Plus (IDs) were used as the unit of analysis to build the co-occurrence matrix and, consequently, the thematic map. IDs are words or phrases that frequently appear in the titles of anarticle's references, generated by an algorithm (Garfield, 1990) of the WoS database.

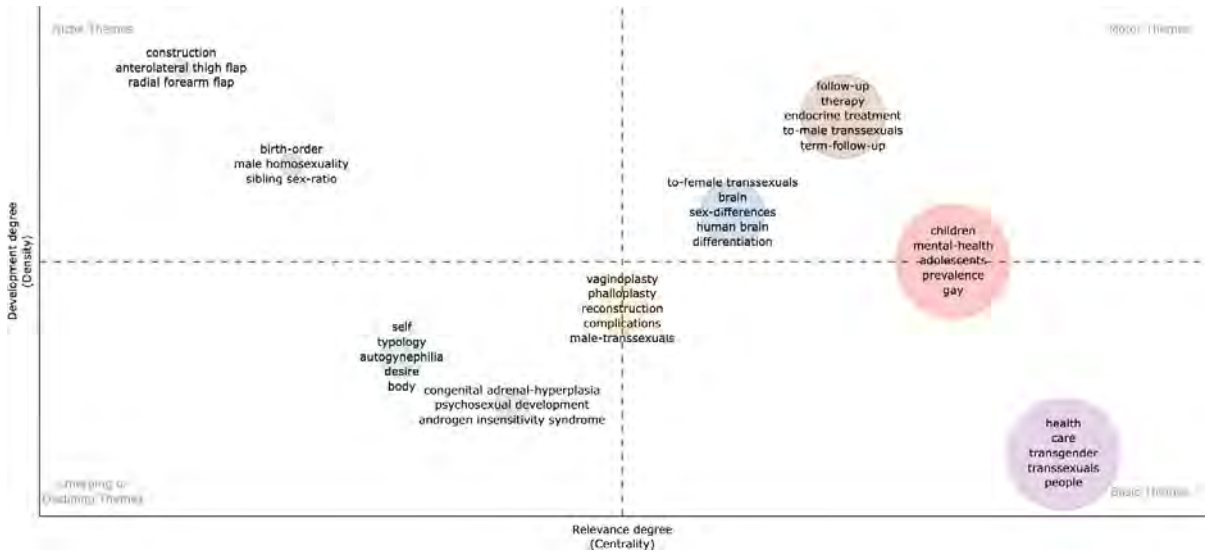

Figure 2: Thematic map of topics about gender dysphoria

Two relevant topics are highlighted as motor themes. The first one concerns the hormone therapiesthat transgender individuals receive during their transition, while the second one focuses on the biological and hormonal distinctions between male and female brains. Various studies, including Kurth et al. (2022) and Kurth et al. (2020), have suggested that the brain of a transgender person more closely resembles their gender identity rather than the gender assigned to them at birth. Straddling the motor and basic themes is a particular focus on gender dysphoria in children.

The basic theme, on the other hand, refers to health in transgender people, whose sex assigned at birth does not match their gender identity. Indeed, the scientific literature on the topic has always focused on how transgender people may experience gender dysphoria.

The emerging themes predominantly focus on medical concepts related to hormonal aspects. However, the other theme located in this quadrant pertains to the topic of transvestism, with autogynephilia being identified as the tendency of a male to experience sexual arousal from the idea of presenting as afemale and donning women's clothing (Lawrence, 2011).

Finally, the quadrant of niche themes contains topics inherent to the medicalization of sex reassignment surgeries.

4. Conclusions and future developments

The scientific production available on gender dysphoria appears to be strongly focused on medicalized aspects of gender reassignment. The literature encompasses not only the surgical procedures used to facilitate gender transition, particularly in transgender patients but also the hormonal treatments they undergo. Additionally, the study of gender dysphoria in children is an area of great significance within the field. Several studies have reported that dysphoria related to gender identity can manifest as early as two years of age. However, there is significant controversy over whether to support the social and/or medical transition of prepubertal children with gender dysphoria, as well as when to initiate such interventions. (Chen et al., 2018, Tompkins, 2019).

Future developments will be devoted to providing a bibliometric longitudinal analysis to study the evolution of gender dysphoria topics over time, dividing the reference timespan into different time slices. In addition, a specific emphasis will be placed on examining scientific literature within specific research domains (such as medicine, psychology, and social sciences) to gain insight into how the topic of gender dysphoria is approached and studied.

A hierarchical modelling approach to explain differential functioning of mathematics items by student's gender

Clelia Cascella[a] (INVALSI)

[a] INVALSI, via Ippolito Nievo, 35 00153 Roma (Italy); clelia.cascella@invalsi.it

Abstract

Understanding factors affecting students' performance in mathematics has become a priority for both policy and research agenda. In the current paper, a 2-level hierarchical model (with students nested into responses) has been employed to analyse responses given by a sample of 156 (Grade-5) students to a mathematics achievement test. Data analysis showed differential item functioning by gender. In order to interpret such a result, a hierarchical analysis was carried out. Results showed a slight, positive relationship between the length of mathematics items (i.e., word count) and gender differences, in favour of girls: the longer the text, the larger the girls' advantage. Word count has to be taken as just an example of the model's possible contribution to the study of factors affecting students' performance in mathematics. Implication for policy makers and educational practitioners have been discussed.

Keywords: Differential Item Functioning, Differential Bundle Functioning, Rasch model, Hierarchical modelling

1. Introduction

In the current paper, a Differential Bundle Functioning (DBF) analysis was proposed as a tool to bring out gender differences that may fictitiously result in negligible and often statistically not significant differences, as usually happens when we deal with large scale assessment data. Differential item functioning (DIF) analysis, often carried out within the framework of the Rasch analysis (1960/1980), has been frequently employed in educational research to disclose differences in students' performance matched on ability but differently performing on single item.

The importance of moving the focus of investigation from the overall test scores (achieved by analysing the answers given by each student to all the test items) has been already underlined by

educational scholars, such as Laeder and Forgasz (2017). The present research goes a step further by showing how Differential Bundle Functioning can be used to interpret results based on the "traditional" differential item functioning analysis.

Studies of differences between groups have been vital to concerns with equity in education (such as gender, ethnicity, class, place, nationality, language, etc.). Such studies have very often been conducted with quantitative data arising from differences in test scores by different groups, though their interpretation and the underlying causations have proved problematic (if not historically explosive, if we take the case of race and Intelligence Quotient).

One technique that has become common as a diagnostic for test inequity has been Differential Item Functioning (DIF), where DIF might speculatively be considered to be caused by explanatory, underlying group differences: thus a test item favouring girls might be due to the item having a high demand for language in its interpretation if theory / literature has shown that girls at the same age etc. have higher ability and higher success with reading and interpretation of difficult texts. In such studies the quantitative analysis stops with the calculation of DIF and a lot of work – sometimes of dubious rigour – relies on post-hoc application of theory, literature and sometimes even intuition (for example, contexts favouring boys might include football).

It is possible to consider DIF indices aggregated across bundles of items based on some item characteristics or across all *n* items in a test. The rationale is that items with DIF, which is not substantive to exhibit DIF at item-level, when aggregated across item- bundle level and test-level may show a substantive impact at bundle-level and test-level. On the other hand, groups of items exhibiting DIF at different directions at item-level might cancel each other out at item-bundle level or test-level, hence indicating the absence of DF. In fact, analysing DF at bundle-level may help to predict and explain the sources of DF - without that, we may not know whether DF is 'valid' or 'biased'.

1.1. Differential Item functioning versus Differential Bundle Functioning

Compared with Differential Item Functioning, DBF has been less frequently employed. According to a literature search carried out in ERIC, with neither time nor language constraints, and combined with a snowballing search, 34 publications were found.

A number of alternative analytical strategies have been proposed to detect DBF over time. Table 1 reports on those most frequently employed in educational research. Wainer et al. (1991), for example, proposed the employment of Differential testlet functioning parallels to IRT likelihood procedures; Oshima (1998) developed a Differential functioning of items and tests framework (DFIT) for dichotomous items, that a few years later was extended to polytomous items; Xie and Wilson (2008) proposed the employment of Differential facet functioning that is an extension of Linear Logistic Test model, whose employment was also employed by Ong; Liu et al (2008) proposed the employment of Multidimensional Rasch analysis, under the hypothesis that DIF is explained by multidimensionality. Finally, Swanson et al (2002) proposed the employment of hierarchical modelling to test interpretative hypotheses about the item-bundles.

Table 1: An overview on the analytical strategies most frequently employed in educational research

Study	**Methodology**
Wainer et al. (1991)	Differential testlet functioning parallels to IRT likelihood procedures
Oshima et al. (1998)	Differential functioning of items and tests framework (DFIT)
Xie and Wilson (2008)	Differential facet functioning, an extension of Linear Logistic Test model Multidimensional differential facet functioning
Liu et al. (2008)	Multidimensional Rasch analysis
Swanson et al (2002)	Hierarchical logistic regression model

In the present research, a three-steps quali-quantitative approach was employed. First, data were analysed via a DIF analysis to detect differential item functioning at item level. Results were used to guide the construction of bundles of items. Each bundle was interpreted from a didactical point of view. Finally, a hierarchical approach was employed to verify the statistically significance of each bundle. This model is a repeated measurement with item-person responses nested within persons (e.g., De Boeck & Wilson, 2004). This formulation is often used to describe the effect of item characteristics across groups. We have

often taken for granted that our respondents are sampled from a total possible population of persons, and we tend not to view items in measuring instruments as sampled from a total possible population of items.
Van den Noortgate and De Boeck (2005) demonstrated that logistic mixed models with random item effects can be adapted to model differential bundle functioning by including the cross-level interactions between the item characteristics variable and person explanatory variable. The authors concluded that the two-level logistic model should be preferred, because this model does not violate the independence observations, which is an important assumption of the single-level model. In other words, results of the single-level models might be spurious and may lead to invalid inferences.
Kamata (2001) has demonstrated that the marginal maximum likelihood procedure of the Rasch model can be modelled as a hierarchical two-level-logistic model. This model can be modelled as a latent regression model with person characteristic variables. In fact, this model can be extended to a three-level latent regression to model variation of student performance across classrooms and schools.
Kim (2003) extended Kamata's (2001) two-level logistic model to model DIF by including group membership and interaction effects. Kim compared the results of a two-level logistic model with the results of the LR procedure and concluded that both models produced similar results but that the two-level logistic model allows extra parameters to describe the random effects.
Employing hierarchical logistic regression makes it possible to combine results of logistic regression analyses across individual items to evaluate alternate explanations for DIF. Analytically, the coefficient representing DIF in the logistic regression equation for each item is treated as a random variable to be predicted from item characteristics, making it possible (a) to identify consistent sources of DIF across items, (b) to quantify the proportion of variation in DIF coefficients explained by those item characteristics, and (c) to evaluate alternate explanations for DIF by comparing the explanatory power of different models.

1.2. Research hypotheses and questions

Gender differences in mathematics performance are contingent upon a number of different factors. Among them, item phrasing is considered as a key factor in educational literature. The current paper aims to contribute to such a debate by analysing data from a research project aimed at exploring the possible relationship between mathematics items phrasing and their psychometric functionality. More precisely, starting from the same stem-item (that is an item showing the same mathematical content and the same question intent), alternative items phrasing was formulated to stress factors usually associated with gender differences in mathematics. In particular, it was hypothesised that (i) text length and (ii) syntactical complexity were associate with gender differences in mathematics and, in particular, that the longer and syntactically more complex the text, the better the girls' performance compared with boys. In the current paper, a focus was paid on text length.

2. Methodology

The Rasch model (1960/1980) is one of the tools most frequently used in educational research to measure students' performance. The idea underlying the model is quite easy as the probability of encountering each item successfully is a function of students' relative ability, relative because each student's ability is compared with each item's difficulty. So, when student's ability equals item's difficulty, the probability of giving a correct answer is 0.5. When student's ability is higher than item's difficulty, his or her probability of encountering that item successfully is higher than 0.5; at the opposite, when student's ability is lower than the item's difficulty, then his or her probability of encountering that

item successfully is lower than 0.5. In other words, the probability of encountering an item is function of such a difference (that it is the difference between students' ability and items' difficulty) and the role that other variables (such as students' characteristics) may have in explaining the probability of a correct answer is taken as a violation of measurement invariance, that is one of the main Rasch model's assumptions. Of course, we often observe a mismatch between the model's assumptions and reality. Empirical findings show differential items functioning even when achievement tests are constructed to be invariant across groups of students matched on same variables. Nonetheless, the differences in the test performance or in relation to specific items may represent 'real' difference in the mathematical construct being measured and may not indicate bias.

So, even though DIF must be detected, when it is within some tolerance intervals, it is not disruptive for measurement, yet it can be very informative and provide useful information to quantify, understand and fight inequalities. DIF occurs when students - matched on ability - have a different probability of encountering an item successfully depending on one or more characteristics, then we say that that item shows a Differential Functioning.

In the Item Response Theory (IRT) modelling, the absence of DIF in an item is defined as occurring when ICCs across different groups are identical (Hambleton & Rogers, 1989). In contrast, when we observe an unexpected difference among groups of examinees matched on ability, we can observe uniform or crossing DIF. In the former, the probability of answering an item correctly is consistently higher for one group than the other over all ability levels. In this case, there is no 'interaction' between ability levels and group membership. For the latter, the difference in the probabilities of answering an item correctly can vary in different directions for different ability levels.

Since DIF can indicate a real difference between students somehow grouped, then interpreting DIF from a substantive point of view is necessary. To this end, a number of qualitative, quantitative or mixed methodological approaches have been developed, such a theory-driven confirmatory approach, Multidimensionality-based DIF analysis framework and Simultaneous Item Bias Test (SIBTEST), Multidimensional Rasch analysis, Differential testlet functioning, Differential Functioning of Items and Tests, Differential facet functioning, and differential bundle functioning. The term "Differential Functioning (or DF)" may refer to item, a bundle of items or a test that functions differentially for different groups of students. The aim of the current research is to understand if (and, if yes, how) gender differences are explained by differential performances on different types or bundles of items, hence Differential Bundle Functioning. DBF is defined as the differing probability of examinees from different groups but with the same (or comparable) ability responding correctly to a bundle of items.

2.1 Analytical strategy

The model specified in [1] has been estimated in the current research.

$$\text{Logit}\,[\text{Prob}\,(Y_{ij}=1)] = b_{0j}+b_{1j}* \text{proficiency}_i + b_{2j} * \text{group}_i$$

- proficiency is an index of students′ ability in mathematics estimated on a common scale for all examinees;
- group_i =0 for "reference" and group =1 for "focal";
- b_{0j} reflects (the log odds of) item difficulty in the reference group;
- b_{1j} reflects item discrimination, constrained (in this model) to be equal in reference and focal groups;
- b_{2j} reflects the deviation of item difficulty in the focal group from the reference group.

In hierarchical logistic regression applied to DIF, level-2 equations treat the coefficients from level-1 equations as random variables with values to be predicted from item characteristics, as in the example below ([2]).

$$\begin{aligned} b_{0j} &= G_{00}+U_{0j} \\ b_{1j} &= G_{10}+U_{1j} \\ b_{2j} &= G_{20}+ G_{21}*I_1+\ldots+G_{2n}*I_n+U_{2j} \end{aligned} \qquad [2]$$

where: G_{20} reflects the grand-mean of the deviation of focal group item difficulties from reference group item difficulties, G_{21} is the coefficient for the first item characteristic in predicting DIF deviations from the grand mean, and so on; and the U_{2j} term is the residual variation in the DIF index for item *j* after its item characteristics are taken into account.

2.2 Data

Data analysed for the purposes of the present study were collected by administering a mathematics achievement test, validated within the framework of the Rasch analysis, and covering four mathematical domains, that are (i) numbers, (ii) space and figures, (iii) data and uncertainty, and (iv) functions and relationships. The sample analysed in the present study was equally distributed by gender and consisted of 156 students located in six neighbourhoods in Rome capital city (Italy) (1. Torbellamonaca; 2. San Giovanni; 3. EUR/Trastevere; 4. Parioli; 5. Talenti; 6. Cinecittà/Centocelle), selected to represent different sociocultural and economic students' family background (Table 2).

Table 2: Sample characteristics

Variable	Categories	Percentage
Gender	boys	51%
	girls	49%
Socioeconomic Background ([a])	low	39%
	medium	37%
	high	24%

[a] Socioeconomic background was measured via an index, named SC-index, and based on the combination of parental education and occupation (Author, under review)

3. Results

In this paragraph, results from the hierarchical analysis described in the previous paragraph and carried out in MLWIN (Rasbash et al., 2000) are presented. Proficiency estimates are Rasch-based but rescaled to N(0,1). The female dummy code was grand-mean centered. Taken together, these produce intercepts that are equal to the log odds of a correct response for examinees with a proficiency of zero. All fixed effects are significantly different from 0 ($p<0.005$), and all variance components are significantly greater than 0 ($p<0.001$) (Table 3). The random-effect section of Table 3 provides information about between-item variability in the regression coefficients, with error in estimation of the coefficients taken into account. The estimated (true) variance components for the intercept and for the DIF index are 1.1423 and 0.0599, respectively. Their square roots, that are 1.0688 and 0.2447, interpretable as the standard deviation of the intercept terms and as the between-item standard deviation for the DIF index, respectively.

Table 3: Hierarchical regression of students' performance in mathematics against proficiency and gender

Fixed effects	**Regression coefficient**	**SE**	**p-values**
Intercept	16.547	0.0172	
Proficiency	0.4826	0.0083	0.002
Girl (Ref: Boy)	0.0341	0.0084	0.003
Random effects	**SD**	**variance component**	
Intercept	1.0688	1.1423	
Proficiency	0.1723	0.0297	0.000
Girl (Ref: Boy)	0.2447	0.0599	0.000

In the following Table 4, 'words count' was added as an interpretative key factor of gender differences under the hypothesis that the larger the number of words, the better the female advantage at the math test compared to males. Such a hypothesis is supported by previous studies in education (e.g., Ajello et al. 2018; Author, 2022) showing a clear positive association between students' reading skills and their attainment in mathematics. item word count was used as a level-2 predictor of level-1 DIF coefficients. As with previous studies, results shown in Table 4 showed a slight positive association between words count and female advantage.

Table 4: Hierarchical regression of students' performance in mathematics against proficiency, gender and 'word count'

Fixed effects	**Regression coefficient**	**S.E.**	**p-values**
Intercept	1.5547	0.0148	
Proficiency	0.3626	0.0073	0.003
Girl (Ref: Boy)	0.0341	0.0084	0.002
Words count	0.0024	0.0001	
Random effects	**SD**	**Variance component**	
Intercept	1.0742	1.1245	
Proficiency	0.1642	0.0295	0.000
Girl (Ref: Boy)	0.1914	0.0484	0.000

4. Discussion and conclusions

In the current paper, an application of hierarchical modelling to the interpretation of differential item functioning has been proposed. A 2-level hierarchical model with persons nested into responses (rather than in classrooms or school, as frequently done in educational research) has been estimated. 'Word count' has been selected as a possible interpretative key to explain gender differences and thus added as a level-2 predictor of level-1 DIF coefficients.

Word count has to be taken just as an example of what can be done by employing a hierarchical approach to explain differential item functioning by gender (or any other variables of interest). Any other variable of interest can be used to explain DIF by gender, thus contributing to the understanding of factors explaining gender inequality in education.

Results based on such an analytical approach can be of interest to different stakeholders. Differential item functioning is to be taken as a cause of concern about data-model fit. Interpreting causes of DIF can thus be of interest to test developers (e.g., to reconnoitre and understand factors, such as word count, that explain DIF, thus to avoid DIF in future achievement test), but also to educational practitioners (e.g., to understand how they can help students) and/or to policy makers (e.g., to better channel policy interventions).

Abstract

In this paper, we consider a latent variable model for Millennials' knowledge of green finance. We draw inspiration from a survey conducted last year among students at Italian universities, as part of the COST project 'Fintech and Artificial Intelligence in Finance'. In the analysis, we consider a cumulative link model that accounts for heterogeneity in the response process. The model presented is discussed in a Bayesian framework.

Keywords: Heterogeneity of variance, MCMC, *numeracy*, ordinal responses, scale effects

1. Introduction

In the latest years, the attention devoted to climate change consequences has grown considerably together with the awareness on the need to pursue more sustainable growth and perform a transition to greener economies (16). The interest in this topic comes from many directions. Companies adopt greener practices to reduce their environmental impact to attract investors and reduce their cost of funding, also for reputational concerns, see (23) and (30) among others. Investors place a lot of emphasis on ESG performance in their investment decisions in order to drive economic growth according to their values and to achieve long-term sustainable performance; see e.g. (8), (10) and (29). Policymakers developed guidelines and action plans to promote sustainable growth and manage the risks of climate change, accompanying companies to the transition (15); (13); (27); and, in addition, civil society has become more aware and attentive to sustainability and to the impact of their choices as citizens.

Among consumers and potential investors, Millennials find themselves in the position to effectively contribute to greener growth, through their purchase and investment choices. Millennials are individuals born between 1980 and 2000 (26); they generally show a strong sensitivity towards sustainability (4) and different risk attitudes and investment habits than the older generations (3). However, as the literature shows, this focus on sustainability issues does not always translate into more sustainable purchasing (4; 25). The authors of (25) claim that the sustainable behaviour of Millennials depends on their specific characteristics, including their ecological knowledge or *eco-literacy* (20).

Starting from these findings rooted in the managerial and consumers' behaviour literature, we extend the idea to the financial sphere of decisions. As the availability of funds is crucial to the transition and to the development of a greener economic system (15), it is important that savings are redirected towards those activities that are able to pursue a more balanced and inclusive growth, also contributing to the achievement of the Sustainable Development Goals (SDGs), issued by the UN (see https://sdgs.un.org). Globally, Millennials are estimated to have contributed to a surge in the amount invested in ESG funds (24).

Nevertheless, their contribution may currently be hampered by a low level of knowledge in finance and, specifically, 'green finance'. The level of financial knowledge and education among households remains very low, especially among the young investors. Bank of Italy reports that in 2020 the average level of financial literacy in Italy was 11.2 (out of 21); see (11) and (14). Additionally, young people (less than 35 years old in the survey) show a lower level of financial literacy than their older peers. Young people scored less than the average, especially for the component 'financial attitude' that investigates the ability to plan financial decisions from a long-term perspective. In an international comparison, Italy scores poorly compared to other countries and this further underlines the critical situation of the young Italian generation in terms of financial literacy. Furthermore, the Edufin Committee provides evidence on the lack of knowledge of sustainability in finance and 'green finance' in Italy (14), reporting that around 40% of the surveyed population has never heard the word 'ESG' and 1/5 never heard about 'sustainable finance'. Similarly, Millennials perform slightly better for ESG, with about 35% having never heard of 'ESG'; 26% have never heard of 'sustainable finance'. To foster Millennials' participation as investors in the transition to sustainable growth, it is necessary to understand the factors that determine their knowledge and behaviour.

Based on the previous considerations, this paper addresses the assessment of the degree of knowledge of 'green finance' by Millennials and the factors that determine this outcome. We examine a set of data collected via a survey distributed among students at Italy's largest university. The aim of the survey was to evaluate students' financial literacy. To assess their knowledge, respondents reported scores to items on ordinal rating scales. The observed score can be considered as a discretization of an underlying unobserved (latent) continuous variable, with every possible score for the ordinal response corresponding to an interval of the latent variable. The analysis presented here has been performed by means of a latent trait model accounting for heterogeneity in the response process (22). We work in a Bayesian framework, gaining flexibility in specifying the model and enhancing richness and accuracy in providing parameter estimates, see (17) for an application in a student evaluation context. A further advantage of the Bayesian setup is the possibility to use the same framework and approach even if the sample size is small (as in the examined case). For a general discussion of the advantages of the use of a Bayesian approach for ordinal data see, e.g, (21) and references therein. For some milestones regarding Bayesian approach in the context of ordinal data see (1), (2), (12), (18) and (19).

To the best of our knowledge, no previous study investigates the degree of awareness of the existence of 'green finance' among Millennials and whether this knowledge depends on their specific characteristics and aptitudes, such as numeracy.

The paper is organized as follows. The next section provides a brief description of the considered latent trait model in its location-scale version. Section 3. introduces the examined survey data and presents the Bayesian estimates of the examined model. Section 4. presents some preliminary findings deriving from the Bayesian analysis of the examined model.

2. Latent trait model description

Let $(x_i, y_i), i = 1, \ldots, n$; be a data set of size n, where the covariates x_i's are assumed to be non-stochastic in R^p. The i-th measurement y_i is the realization of a random variable $Y \sim G(y)$ conditioned on x_i. Variable Y takes values in the finite set $\chi = \{1, \ldots, k\}$. Following (22), we assume that there exists an unobserved latent random variable Y_i^* such that when $\alpha_{j-1} < Y_i^* \leq \alpha_j$, then $Y_i = j\,, j \in \chi$. Here $-\infty = \alpha_0 < \alpha_1 < \ldots < \alpha_k = +\infty$ are the thresholds in the continuous support of the latent variable Y^*.

The i-th rating of Y^* linearly depends on $p \geq 1$ covariate(s) through $\boldsymbol{x}_i$ as $Y_i^* = \boldsymbol{x}_i\boldsymbol{\beta} + \sigma_i\epsilon_i$, $i = 1, 2, \ldots, n$, where $\boldsymbol{\beta} = (\beta_1, \ldots, \beta_p)'$ are the covariates coefficients. In the latent regression σ_i is the standard deviation of the noise variable $\epsilon \sim F_\epsilon(.)$, which may depend on covariates yielding $\sigma_i = \exp(\boldsymbol{z}_i\boldsymbol{\gamma})$. Here $\boldsymbol{z}_i$ is a row vector of the matrix $\boldsymbol{Z}$ which includes all the $q \geq 1$ relevant covariates and $\boldsymbol{\gamma} = (\gamma_1, \ldots, \gamma_q)'$ are the related covariates coefficients.

The probability mass function of Y_i, for $j = 1, 2, \ldots, k$, can be expressed as

$$\begin{aligned} Pr\left(Y_i = j \mid \boldsymbol{\theta}, \boldsymbol{x}\right) &= Pr\left(\alpha_{j-1} < Y_i^* \leq \alpha_j\right) \\ &= F_\epsilon\Big[(\alpha_j - \boldsymbol{x}_i\boldsymbol{\beta})/\sigma_i\Big] - F_\epsilon\Big[(\alpha_{j-1} - \boldsymbol{x}_i\boldsymbol{\beta})/\sigma_i\Big]. \end{aligned}$$

Among the alternative choices for $F_\epsilon(.)$ we focus on the logit link function for robustness properties.

Since we do not have relevant prior information, following the approach prosed by (6) and (7), we use non-informative priors on all parameters of interest, letting the data guide the behavior of the posterior distributions. More precisely on the covariate coefficients we assign improper uniform priors, $unif(-\infty, +\infty)$, while on the thresholds we consider Student-t priors with 3 degrees of freedom. This ensures that the tails are wide, while the distribution is still proper with finite mean and variance (here set –without loss of generality– equal to 0 and 2.5 respectively). In order to obtain posterior samples we rely on Markov Chain Monte Carlo (MCMC) method. In particular, we use `R` package `brms` (6), which implements a Hamiltonian MCMC using Stan (5). The ordering of the intercepts is ensured via the `order class` in Stan. More precisely the joint prior distribution is truncated to support over points satisfying the ordering constraints.

3. Data

The data come from the survey on 'Knowledge and Use of Fintech Products' administered as part of the European project CA19130 Fintech and Artificial intelligence in Finance. The sample consists of 385 Italian Millennials, of whom 0.511 are women, 0.563 are from Southern Italy, 0.210 are studying economics at university. The distribution of the dependent variable on the level of knowledge of green finance (ranging from 0 =I don't know to 5 =I know it perfectly) is in Figure 1.

Among the *numeracy* variables considered are the self-assessment of how good the respondent perceives himself/herself to be with fractions (0.388 Millennials give a good rating) and the correct answers to the Berlin numerical test (multiple-choice format) (9) in which the respondents who correctly formulated all answers to the four questions are indicated by *top* (0.035 respondents). Difficulties with financial language and stress in relation to financial decisions are expressed by 0.703 and 0.696 of the respondents, respectively.

The Bayesian estimates of the location and scale parameters are reported in Table 1 (posterior mean, MCMC Standard Error and 95% credible intervals). Standard convergence diagnostics have been considered. Possible interactions among covariates were tested, but they were related to not statistically significant parameters.

We run in parallel 4 chains of 2000 iteration with a burnin period of 1000 iteration each. The Bayesian estimate of the standard deviation is obtained from the posterior samples of log-disc (log-discrimination) with disc corresponding to the inverse of the standard deviation. More precisely, for every iteration t, $t = 1, 2, \ldots, T$, we transformed $\log(disc)^t$ to sd^t with $sd^t = 1/exp(log(disc))$; the Bayesian estimates of sd is then obtained as the average of all sd^t.

4. Preliminary results

Preliminary results show that the knowledge of 'sustainable finance' or 'green finance' is associated with a set of financial education items and *numeracy*. We also observe that knowledge of Fintech innovations, such as Crowdfunding, Roboadvisor and advanced technologies (AI) is associated with knowledge of 'green finance'. These two elements, financial technology, and sustainability are, in fact, often coupled together by policymakers to foster more inclusive growth. It is therefore not surprising that Millennials who are more attentive to Fintech innovations are also more aware of green finance issues.

In addition, Millennials attending university courses in the field of economics have a greater knowledge of green finance. This could be due to the inclusion of ESG and sustainability topics in courses

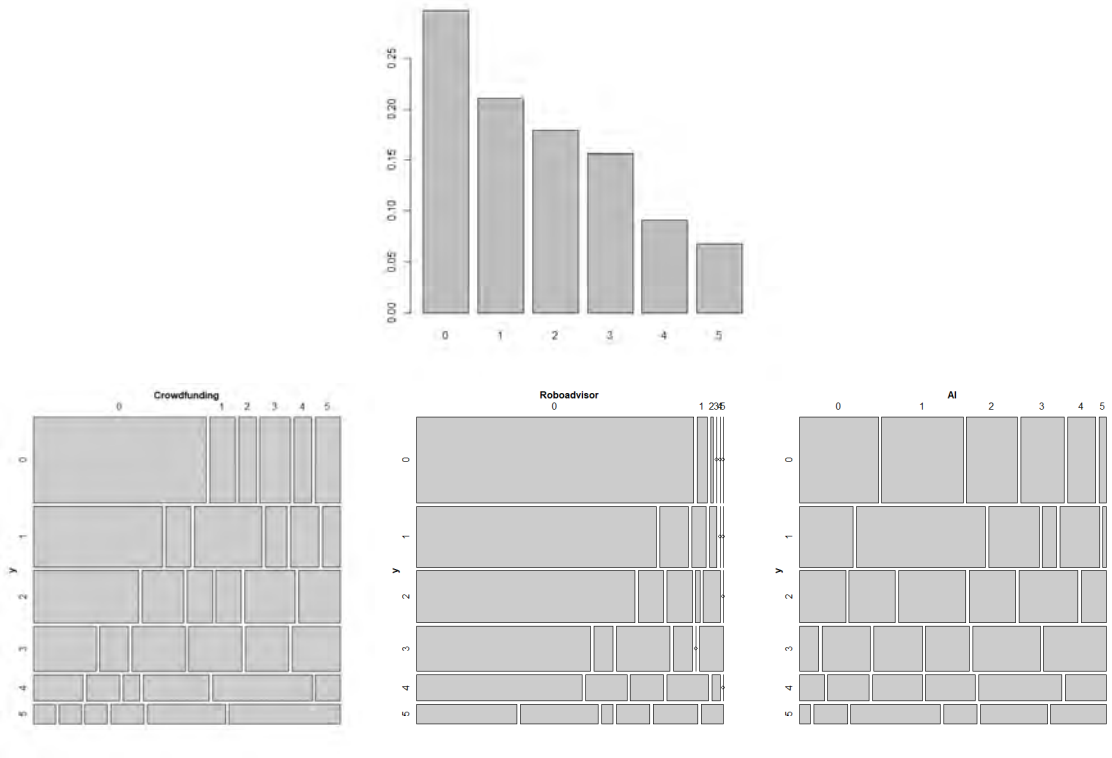

Figure 1: First row: Frequency distribution of the ordinal variable. Second row: Mosaic plot for the dependent variable vs Crowdfunding (first), Roboadvisor (second), and Artificial Intelligence - AI (third).

taken by university students in the field of finance. Numerical skills provide two seemingly counterintuitive results. Those who have a better ability to use fractions have a greater knowledge of 'green finance'. But the better performers in the Berlin numeracy test have less knowledge of our variable of interest Y.

Numeracy is a strong component of financial education and a basic skill for taking good financial decisions (28). However, in the field of 'green finance', this does not seem to be enough. In our analysis, the Millennials who score highest on *numeracy* tests have the least knowledge of green finance. This result may be determined by those Millennials studying in a STEM degree programme, who have excellent numerical skills, but have not yet encountered the topic of 'green finance'. We then evaluate the effect of financial knowledge in terms of familiarity with financial language and decisions.

Respondents who find financial language more difficult are also less knowledgeable about 'green finance'. At the same time, those who are more stressed when making financial decisions are more familiar with green finance. This could be due to the fact that stressed people might learn more before making decisions and, by doing so, become more aware of the different instruments available in the financial markets. This aspect probably deserves further investigation.

Our results are relevant for policy makers and for the design of future financial education initiatives. Further efforts should be devoted to increasing awareness of these key sustainability issues, along with general financial knowledge and *numeracy*.

Abstract

In this contribution we exploit probabilistic archetypal analysis in a three-step approach involving latent Markov models to analyze discrete latent variables with a discrete-time follow-up scheme. Archetypal analysis provides class assignments that are subsequently used as single indicators in a latent Markov model to estimate the structural part. We apply the proposed strategy to a dataset concerning responses to a statistical anxiety questionnaire administered to university students attending an introductory statistical course.

Keywords: latent Markov models, probabilistic archetypal analysis, statistical anxiety

1. Introduction

The analysis of longitudinal data (1) plays a relevant role in many fields concerning the human sciences, where many research questions concern the study across time. In general, a longitudinal data set consists of S individuals (panel), each of which a set of M items is measured at equally or unequally spaced time intervals. Various statistical models exist to analyze longitudinal data (2) and the specific application context leads to choosing the most appropriate. Among them, latent Markov models (LM, 8) play a relevant role and are considered in the present contribution. LM models basic assumptions are that the latent process follows a Markov chain process with a certain number of latent states and that the response variables, in the multivariate case, are conditionally independent (local independence). LM models are a statistical reference approach to study the state changes in individual or group characteristics over time among those considering discrete latent variables measured at different time points through a set of observed variables, while other external variables (covariates) can act as predictors of manifest or latent variables. However, this approach usually returns homogeneous groups and therefore it identifies profiles characterized by specific class response probabilities, rarely defining peculiar cases.

The goal of the present contribution is to allow for the study of an LM model that accounts for the switching between latent classes over time. According to (12), latent class (LC) analysis aims to assign individuals to a set of few discrete latent classes. The novelty of the proposal consists in the use of the archetypal analysis (AA) framework (6; 3; 11) to address the heterogeneity of the latent classes. Let Y be a $N \times M$ pooled responses matrix of S distinct subjects to M items collected to the same panel over T time intervals, where its generic element $y_{nm} \in \{1, \ldots, I\}$ is the response of the n-th individual to the m-th item. It is worth noticing that $N \leq S \cdot T$ and the equality holds in case of zero dropouts. Throughout the whole paper, the superscript (t) is used whenever it is necessary to specify the time t.

The proposed procedure consists of three steps: Step 1 exploits the AA on the pooled data, without covariates, to find homogeneous groups defining profiles characterized by specific class response probabilities; Step 2 calculates the state membership for each individual at any considered time point; Step 3

estimates an LM model to investigate individual transitions among the considered groups over time and the effect of a set of covariates on the initial classification and transitions. Because of their high feasibility, the step-wise estimation approach is considered in this work. We apply the proposed method to a dataset concerning responses to a statistical anxiety psychometric questionnaire that was administered to a convenience sample of undergraduate students attending an introductory statistics course.

The present contribution is organized as follows: in Section 2. the proposed approach is presented along with the model formulations, while in Section 3. the strategy is applied in the considered context and the main results are described. In conclusion, Section 4. outlines some final remarks.

2. A three-step PAA-LM

The vast specific literature on data clustering offers several alternative clustering approaches; in this context, we propose the Archetypal Analysis (AA), initially introduced in (6), as an alternative to the most known and used data partitioning methods. Differently from other clustering methods, AA focuses on identifying extreme points, namely archetypes, preferring the maximum heterogeneity among groups to the maximum homogeneity within groups. In its first presentation, AA deals with continuous data; more recently, different variations and algorithms have been presented for a more robust analysis (see, e.g., 7). Among them, (11) proposed a probabilistic AA model (PAA) to extend its applicability to manifest variables according to several discrete distribution families. It allows identifying a few extreme profiles corresponding to the archetypes and the related groups according to the membership degrees. In the considered application, the resulting latent classes refer to more or less severe anxiety levels and, more in particular, to statistical anxiety (SA), which is inferred through a set of items measured according to an ordinal scale. In the following, the overall method is summarized.

1. Probabilistic Archetypal Analysis. When the dataset is composed of ordinal variables, as in our case, it is possible to consider them as originating from a multinomial model. In such a case, a multinomial PAA is defined by assuming that the observed values can be reconstructed by a linear combination of the underlying multinomial probabilities. Here, the PAA is applied to the pooled dataset Y.

The goal is to find, given K the number of archetypes, two matrices W (with dimension $K \times N$) and H (with dimension $N \times K$) that solve the following optimization problem

$$\arg \min_{W,H \geq 0} - \sum_n \sum_m y_{nm} \log \left(\tilde{y}_{nm} \right), \qquad \text{where } \tilde{Y} = HWP, \tag{1}$$

subject to $\sum_j h_{nj} = 1$ and $\sum_i w_{ki} = 1$. The $\tilde{Y}$ is the reconstructed matrix of the observed values and the vector $p_{n\cdot}$ is the maximum likelihood point estimate from observation $y_{n\cdot}$. After obtaining the estimated matrices W and H, it is possible to compute the archetypal profiles $Z = WP$ and the simplex plot through the use of the membership matrix H. Moreover, it is worth remembering that even if the archetypal profiles lie in the observation space and define "extreme" profiles of responses, they can not correspond to real observations of the sample.

2. Subjects' membership assignment. Given the properties of the coefficient in H, there are different approaches allowing to cluster of the data around the archetypes, see (10). The usual method, namely the crisp allocation rule, allocates responses in a cluster based on the nearest archetype. In addition, if we consider the scores to be values of a fuzzy membership function, then it is possible to assign the data to an additional central group. The fuzzy allocation rule (FAR) is summarized as follows

$$\mathcal{C}_k = \{ y_{n\cdot} \,|\, h_{ik} > \tau \} \qquad\qquad k = 1, \ldots, K, \quad 0 < \tau < 1. \tag{2}$$

The threshold τ acts as a "purity" parameter: some respondents are assigned to the "closest" archetype, while the respondents whose membership scores do not reach the threshold are assigned to the so-called central class. In particular, if $\tau \geq 0.5$ then each data point is classified as belonging to only one group, but at the same time not all the data points will be classified. The "discarded" observations will lie in the so-called central group $\mathcal{C}_+ = \{ y_{n\cdot} | y_{n\cdot} \notin \mathcal{C}_k, k = 1, \ldots, K \}$ that, along with the other groups, will induce an augmented partition of the data consisting of $K^* = K + 1$ classes.

3. Structural model estimation. At this point, the considered LM model is applied given the latent class memberships obtained through the FAR method. LM modeling framework is used to model the change in latent class membership over time concurrently accounting for the effect of covariates on initial and transition probabilities. The latent process is assumed to follow a first-order Markov chain, where changes only depend on the previous class. According to the three-step approach, the model is specified to have the modal class assignment obtained at Step 2 as a single fixed indicator.

Denote with $g_s^{(t)}$ the vector of the considered covariates for individual s at time t. Let $X_s^{(t)}$ be the categorical latent variable for the t-th time point, taking values: $1, \ldots, K^*$. Logistic models can be used to model the effect of the covariates on initial and transition probabilities. In particular, taking the class $\mathcal{C}_+$ (corresponding to the K^*-th class) as the reference category, we have

$$\log \frac{P\big(X_s^{(1)} = k | g_s^{(1)}\big)}{P\big(X_s^{(1)} = K^* | g_s^{(1)}\big)} = \beta_{0k} + \boldsymbol{\beta}_k' g_s^{(1)}, \qquad k = 1, \ldots, K,$$

for initial probability, where β_{0k} and $\boldsymbol{\beta}_k$ are respectively the intercept and the vector of coefficients for the covariate effects, and

$$\log \frac{P\big(X_s^{(t)} = k | X_s^{(t-1)} = l, g_s^{(t)}\big)}{P\big(X_s^{(t)} = K^* | X_s^{(t-1)} = l, g_s^{(t)}\big)} = \gamma_{0k} + \gamma_{0lk} + \boldsymbol{\gamma}_k' g_s^{(t)}, \quad k, = 1, \ldots, K, \quad l = 1, \ldots, K^*,$$

for transition probabilities, where γ_{0k} is the intercept for the k-th latent class, γ_{0lk} the intercept for the considered transition, and $\boldsymbol{\gamma}_k$ the vector of covariate coefficients. Coefficients related to the last category are set to zero because the last class is taken as the reference category. Moreover, transition probabilities are assumed to be time-homogeneous. Parameter estimation for the third step of the proposed strategy is performed employing the Maximum Likelihood (MML) approach using Latent GOLD 6.0 (13).

3. Application

The proposed approach was implemented to investigate students' SA during an introductory Statistics course. SA can be defined as "an anxiety that comes to the fore when a student encounters Statistics in any form and at any level" (9). SA can cause worry and discomfort when students are exposed to evaluative contexts, instructional situations, or just Statistics content or problems. The *Statistical Anxiety Scale* (SAS, 5) aims to assess these different aspects of anxiety by means of 24 items with a 5-point Likert scale ranging from 1 (no anxiety) to 5 (very much anxiety). The instrument includes 3 subscales: *(i) Examination anxiety* (8 items), referring to the anxiety encountered during a Statistics class or a Statistics test; *(ii) Fear for asking for help* (8 items), relating to the anxiety experienced when asking a peer, a tutor, or a professor for help in understanding statistical contents; *(iii) Interpretation anxiety* (8 items), occurring when students have to interpret or make a decision about statistical data. In the literature several antecedents of SA have been proposed; herein, we consider sex, math knowledge, academic motivation, self-efficacy, test anxiety, cognitive strategy, self-regulation, students' attitude toward Statistics (dimensions: affect, cognitive, value, difficulty), engagement (dimensions: affect, cognitive, behavioral).

The study involves 196 students enrolled in the psychology degree course at the University of Naples Federico II in Italy, attending an introductory Statistics course. Participants were predominantly females (75%), with a mean age of 19.86 years (sd = 2.88). At the beginning of the course, students were invited to fill out a questionnaire including socio-demographic questions and psychometric scales assessing psychological variables related to learning Statistics and SA. In addition, SA, attitudes toward Statistics, and students' engagement were measured three times during the course, at the end of each main statistical learning module. Indeed, the course may impact students' anxiety and attitude toward Statistics and also the level of engagement can change over time. Data collection was carried out through the MOODLE platform.

3.1 Main findings

Firstly, let us look at the measurement part of the model estimated in Step 1. In Figure 1 the profiles obtained with our approach are compared with those resulting from the classical LC analysis. Dotted vertical lines divide the items according to the SA subscales that are, in order, examination, asking for help, and interpretation. The colors are intended only to distinguish the profiles within each procedure. In the top panel the resulting archetypes are depicted, basing on the optimal choice of $k = 4$ and the addition of the central class, for a total of 5 distinct profiles. At first glance, the leftmost portion of the plot shows that all the archetypes have high tendency scores on examination anxiety, evidencing that students of the considered sample generally exhibit high anxiety levels during the examination. Conversely, the profiles cover a wider range of scores for what concerns the remaining anxiety dimensions.

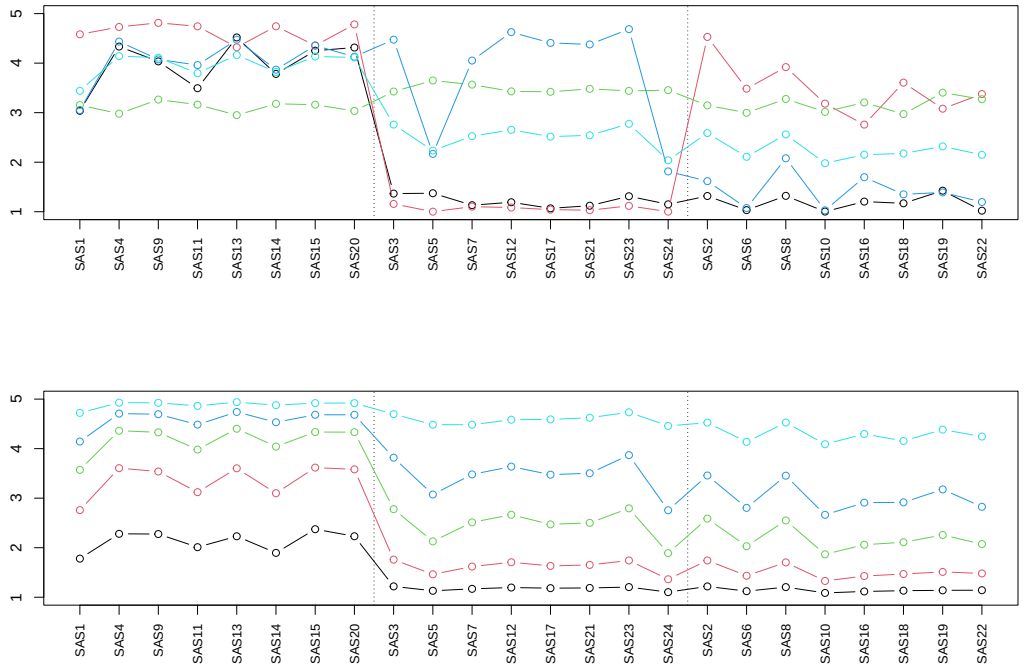

Figure 1: Archetypal (top) versus latent (bottom) class profiles.

In more detail, the archetypes A1 and A2 (colored in black and red, respectively) present a similar anxiety level for examination and asking for help dimensions, while they present different patterns for the interpretation anxiety. Specifically, the group defined by A1 encompasses the respondents with low levels of asking-for-help and interpretation anxiety, whereas A2 is representative of the group with students with the highest level of examination and interpretation anxiety. The remaining A3 (green line) and A4 (blue line) present some peculiarities. The archetype A3 describes a profile with middle scores in all the anxiety components, representing students who tend to select the intermediate category of the response scale (i.e., $i = 3$), regardless of the encountered items. This result leads us to suppose that A3 caught a specific response style. On the other hand, A4 is representative of students who experience high levels of anxiety in both examination and asking-for-help situations. Focusing on the second subscale, it can be noticed that, despite the overall high levels of anxiety, A4 is characterized by low scores related to SAS5 ("Asking a private teacher to explain a topic that I have not understood at all") and SAS24 ("Asking a private teacher to tell me how to do an exercise") items. Thus, students belonging to the group defined by A4 present a high level of asking-for-help anxiety but don't feel anxious when they request a private teacher to explain a topic. Finally, A5 (light blue line) represents the central class and is defined by averaging the scores of the respondents belonging to the central group $\mathcal{C}_+$. About the weights of the classes defined by the obtained archetypes, results show that the largest class is $\mathcal{C}_+$ (34%), followed by $\mathcal{C}_3$ (20%), $\mathcal{C}_1$ (18%), $\mathcal{C}_4$ (17%), and $\mathcal{C}_2$ (11%).

Regarding the structural part of the model, Table 1 displays the matrix of transition probabilities. Generally, students tend to remain in the same group over time, showing stability in their SA profile. For

what concern the transitions, most of them occur toward the central class, indicating gradual changes in students' anxiety over time. On the other hand, students belonging to $\mathcal{C}_+$ transit mainly towards classes defined by archetypes A1 and A3.

Table 1: Estimated transition probabilities.

Class at time $t-1$	Class at time t				
	$\mathcal{C}_1$	$\mathcal{C}_2$	$\mathcal{C}_3$	$\mathcal{C}_4$	$\mathcal{C}_+$
$\mathcal{C}_1$	0.490	0.066	0.087	0.055	0.302
$\mathcal{C}_2$	0.117	0.499	0.105	0.037	0.242
$\mathcal{C}_3$	0.096	0.026	0.532	0.126	0.220
$\mathcal{C}_4$	0.043	0.047	0.147	0.492	0.271
$\mathcal{C}_+$	0.112	0.036	0.233	0.094	0.525

In Table 2 are summarized the significant effects of the of individual covariates on initial classification and transitions, considering the central class $\mathcal{C}_+$ as reference. Statistical significance is evaluated through the Wald test. Results show that autonomous regulation in academic motivation (measured by the relative autonomy index) increases the probability of belonging to $\mathcal{C}_1$ at the beginning of the course, indicating a lower level of asking-for-help and interpretation anxiety. Math ability, instead, reduces the probability of having a high level of examination and interpretation anxiety (typical of students in $\mathcal{C}_2$).

Table 2: Regression parameters' estimates and standard errors (in parentheses)

Latent class	Initial probability			Transition probability					
	Sex	Math ability	RAI	Sex	SATS Affect	SATS Cognitive	SATS Value	ENG Cognitive	ENG Behavioral
$\mathcal{C}_1$	-0.34	0.07	**0.04**	0.27	**0.10**	-0.02	0.002	-0.48	**0.58**
(vs $\mathcal{C}_+$)	(0.50)	(0.06)	**(0.02)**	(0.38)	**(0.03)**	(0.04)	(0.02)	(0.34)	**(0.29)**
$\mathcal{C}_2$	0.03	**-0.11**	0.01	0.93	-0.01	-0.04	0.01	**-0.74**	**1.23**
(vs $\mathcal{C}_+$)	(0.66)	**(0.05)**	(0.02)	(0.71)	(0.04)	(0.04)	(0.03)	**(0.42)**	**(0.43)**
$\mathcal{C}_3$	-0.89	-0.07	0.005	-0.02	**0.12**	**-0.12**	**-0.05**	0.08	-0.08
(vs $\mathcal{C}_+$)	(0.54)	(0.05)	(0.02)	(0.33)	**(0.03)**	**(0.03)**	**(0.02)**	(0.26)	(0.24)
$\mathcal{C}_4$	-0.01	0.04	-0.01	0.13	**-0.06**	**0.07**	0.02	**-0.87**	0.23
(vs $\mathcal{C}_+$)	(0.52)	(0.05)	(0.02)	(0.42)	**(0.03)**	**(0.04)**	(0.02)	**(0.35)**	(0.27)

Note: Significant effects are reported in bold; RAI = Relative Autonomy Index, SATS = Survey of Attitudes toward Statistics, ENG = Student Engagement in Statistics.

A positive affect attitude towards Statistics (students' positive feelings concerning Statistics) increases the probability of being in $\mathcal{C}_1$ (low level of asking-for-help and interpretation anxiety) and $\mathcal{C}_3$ (students selecting the intermediate category of the response scale), whereas it reduces the probability for $\mathcal{C}_4$ (high level of asking-for-help anxiety). Conversely, the cognitive component of attitude towards Statistics (students' belief about their ability in Statistics) affects the probability of being in $\mathcal{C}_4$ positively and the probability of being in $\mathcal{C}_3$ negatively. Moreover, perceiving the relevance of Statistics in the personal and professional life (value component of attitude) reduces the probability of providing a middle-category response pattern (namely, to be in $\mathcal{C}_3$). Finally, about the effect of students' engagement in Statistics, the cognitive component (cognitive strategies to monitor their own learning of Statistics) negatively affects the probability of being in $\mathcal{C}_2$ and $\mathcal{C}_4$, both with low levels of interpretation anxiety, whereas the behavioral component (e.g., regular study, participation during lessons) influences the students' membership in $\mathcal{C}_1$ and $\mathcal{C}_2$, increasing the probability of having a low level of asking-for-help anxiety. Sex appears to be a non-significant factor for both initial and transition probabilities.

4. Concluding remarks

In many applications involving longitudinal data, the interest is focused on the evolution of a latent individual characteristic that is measured by one or more occasion-specific response variables. In such a context, LM may be usefully applied given their nature as discrete latent variable models with a discrete-time follow-up scheme. In this contribution, we exploit probabilistic archetypal analysis in a three-step approach to obtain class assignments that are subsequently used as single indicators in an LM model to estimate the structural part.

This approach could represent a helpful tool, especially in the educational context, where distinguishing peculiar profiles according to students' performance and/or psychological characteristics can drive the development of more tailored formative and motivational feedback (4). PAA also allows accounting for the ordinal nature of the observed variables, usually following a Likert-type scale when assessing motivational and emotional factors. Moreover, the use of archetypes gives better interpretability of the corresponding profiles and of the respondents belonging to their archetypal classes, thus making it easier to generate *ad hoc* recommendations for each archetypal class.

[b] Sapienza University of Rome; cristina.giudici@uniroma1.it

Abstract

This work adopts a longitudinal perspective in analysing the academic intentions and enrolment of foreign students in Italy, by citizenship. Using logistic regression models, we investigate how citizenship is associated with the academic intentions and the transition to university of a national representative cohort of foreign students and their classmates, enrolled in the last year of Italian high school in 2015. We use a unique dataset linking survey data of the "Integration of the second generation", carried out by Istat in 2015, with administrative data on students' university enrolment, from the Ministry of University registers. We found higher academic intentions among foreign students, compared to their Italian classmates, with Ecuador and Peru, China and the Philippines showing a higher probability of academic intentions and enrolment than both Italians and the other groups.

Keywords: Foreign students, Citizenship, Integration of the second generation survey

1. Background

A vast literature shows that students' educational intentions are key predictors of their future educational attainments. However, concerning foreign students, academic pathways may differ widely, depending on structural factors and individual characteristics.

Educational pathways of foreign students have been widely analysed by international literature (Zapfe & Gross 2021). Looking at the European context, several comparative studies show that the educational opportunities and school outcomes of second-generation students from the same group of origin vary considerably across countries (Crul et al. 2012, Griga & Adjar 2014, Gabrielli et al. 2022). Despite lower school results, children of immigrants generally tend to exhibit higher aspirations than ethnic majority peers. A great body of literature refer to this finding as "immigrant optimism" (Kao and Tienda 1995), or "bold choices" (Jackson 2012). Concerning school-university transition, a large sociological literature exists, showing mixed results, whereas there is a lack of statistical and demographic studies. A general finding in this field is that a stratified secondary school system reduces the educational chances of students with migrant background. Conversely,

a low-stratified secondary school system improves the probability of people with a migrant background attaining a higher education degree (Griga & Hadjar 2014, Zapfe & Gross 2021).

In this context, existing research in Italy is characterised by two major weaknesses: studies generally focus on small samples, that are not representative of the national situation and do not allow for a detailed analysis by citizenship. Moreover, existing literature in Italy rarely addresses this subject using a longitudinal perspective.

The aim of this work is to empirically contribute to this literature by investigating the academic intentions and the transition to university of a cohort of students enrolled in the last year of the Italian High school in 2015. We use a unique dataset that links survey data (the 2015 Integration of the second generation, carried out by Istat) with administrative records on university enrolment in a.y. 2015/16, 2016/17 and 2017/18.

To frame our research, we formulated three research hypotheses: (1) academic intentions of foreign students are higher than intentions of their Italian classmates; (2) despite their higher academic intentions, foreign students are less likely to enrol in university; (3) differences by citizenship exist, reflecting social and cultural specificities.

2. Data and methods

We created a pooled longitudinal dataset linking survey data of the 'Integration of the second generation' (hereafter, ISG) carried out by Istat in 2015, and administrative data on university enrolment from the Student register of the Ministry of University ("Anagrafe dello studente" hereafter, ANS-MUR).

The ISG survey collects information on a sample of 1,400 school of secondary education with at least 5 foreign students (more than 68,000 students). ISG analyses socio-demographic characteristics, behaviours and attitudes of students with a migrant background, namely those students without the Italian citizenship (Conti & Prati, 2020). In addition, this survey allows to distinguish the different models of integration of the first ten nationalities (Romania, Albania, Morocco, China, Philippines, Moldova, Peru, Ukraine, Ecuador and India) and the age at arrival, considering the age of enrolment at different levels of education in Italy (born in Italy, arrived before 6 years old, between 6 and 10 years old, and 11+)[1]. Since our work studies differences in the academic aspirations and enrolment of Italian and foreign students, from this survey we selected only students enrolled in the last year of the Italian high school in 2015.

The ANS-MUR archive contains information on students enrolled and those who obtained a degree in an Italian University.

The ISG and ANS-MUR record linkage, performed using an individual anonymised code subsequently removed, allows to follow and distinguish, among the students enrolled in the last year of the Italian high school in 2015 (previously selected from the ISG survey), those that enrolled at university within three years from 2014/2015 and those who decided not to enrol at university.

Therefore, our final sample is composed of 3,940 students (46.6% foreign students).

We used two dependent variables. The first one is the 'academic intention' of students, which is derived from the ISG survey with different possible answers including 'go to University', 'go to work', 'follow a vocationally-oriented course', 'stay at home', and 'I do not know[2]'; and the 'academic enrolment' of students derived from the ANS-MUR archive. For analysis purposes, the 'academic intention' variable takes value 1 when the student's answer is 'go to University', 0 otherwise. The 'academic enrolment' variable takes value 1 if the student enrolled within three years from 2014/2015 (i.e., within 2015/16, 2016/17 and 2017/18)[3], 0 otherwise.

[1] For further details, see Istat (2017), Conti, C., Quattrociocchi L. (a cura di), L'indagine sull'integrazione delle seconde generazioni: obiettivi, metodologia e organizzazione, 2017.

[2] The cases that answered 'I do not know' were excluded from the sample.

[3] We chose to follow students within three years from 2014/2015 because according to ad-hoc elaborations on the ANS-MUR archive, we observed that in the a.y. 2018/19, 75% of the second-generation enrolled had graduated from high

To test our research hypotheses, we applied two logistic regression models and conducted two separate analyses. In the first analysis, foreign status (foreigners vs Italians) was the main independent variable. In the second analysis, to overcome the Italians-foreigners dichotomy, we analysed any differences between Italians and foreign subgroups where we distinguished 9 communities (Romania, Albania, China, Philippines, Morocco, Moldova and Ukraine, Ecuador and Peru, Other HDC[4], Other HMPC[5]).

In all analyses, we used a set of control variables which include socio-demographic characteristics, the student's school career, the attitude towards studying of both students and their families and the relational aspects of young people with their peers.

We applied population weights provided in the dataset. First, we estimated the odds ratios. Then, to improve the readability of results we computed predicted probabilities of the outcomes with 95% confidence intervals for pairwise comparisons. In addition, confidence intervals were centred on the predictions and had lengths equal to 2 × 1.39 × standard errors. This was necessary to obtain an average level of 5% for Type I errors in pairwise comparisons of a group of means (Goldstein & Healy, 1995).

3. Preliminary results

Figure 1 shows the results of the adjusted predicted probabilities for our first dependent variable, 'academic intentions', by foreign status (Figure 1a) and citizenship (Figure 1b).

Looking at the results considering migrants as a heterogeneous group, we observed that foreign students show higher academic intentions than their Italian classmates (55.2% and 50.2%, respectively) (Figure 1a). However, the analysis by citizenship highlights differences between and among the different foreign subgroups examined. Specifically, we found that students from Ecuador and Peru, the Philippines and China register a higher probability of academic intentions than both Italians and the other groups (75.4%, 70.7% and 65.4%, respectively). Conversely, Romanian students show the lowest probability of academic intentions than all the other subgroups (43.4%). Students from Albania, Morocco, Ukraine and Moldova, and other HDC and HMPC do not show significant differences in the academic intentions with respect to Italian classmates (Figure 1b).

Figure 2 shows the adjusted predicted probabilities for our second dependent variable, 'university enrolment', by foreign status (Figure 2a) and citizenship (Figure 2b). By comparing Italians and foreigners (considering them as a single group) results show no differences between the two groups (Figure 2a), while the analysis by citizenship reveals that the subgroups that show higher academic intentions (Ecuador and Peru, China and Philippines) are the same ones that also show a higher probability of academic enrolment (60.8%, 60.2% and 57.1%, respectively). We detected that students from Romania (35.7%) and other HDC (36.0%) show the lowest probability compared to Italian classmates and the other subgroups. Finally, students from Albania, Morocco, Ukraine and Moldova, and other HMPC do not show significant differences in the university enrolment with respect to Italian classmates (Figure 2b).

school in the same year, 14% one year earlier, and 4% two years earlier, compared to values registered by Italian students of 83%, 8% and 2%, respectively.

[5] Foreigners coming from High Migratory Pressure Countries.

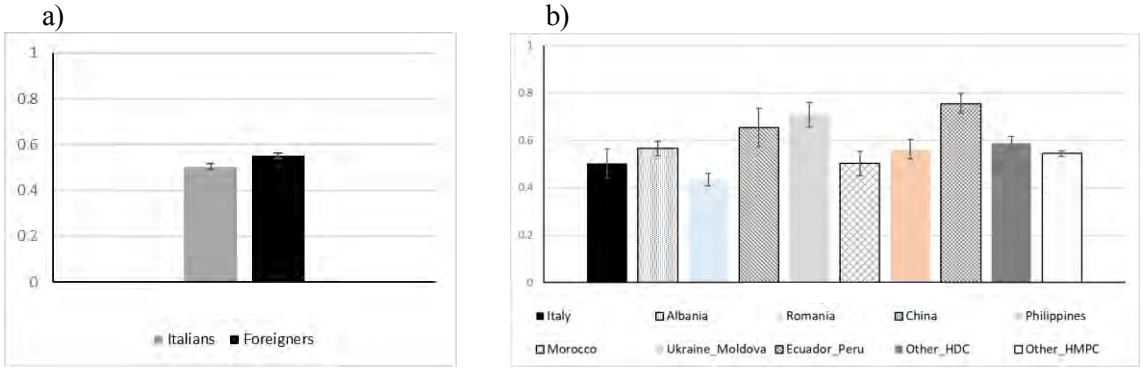

Figure 1: Adjusted predicted probabilities of the 'academic intention' by foreign status (panel a) and by foreign subgroups (panel b)

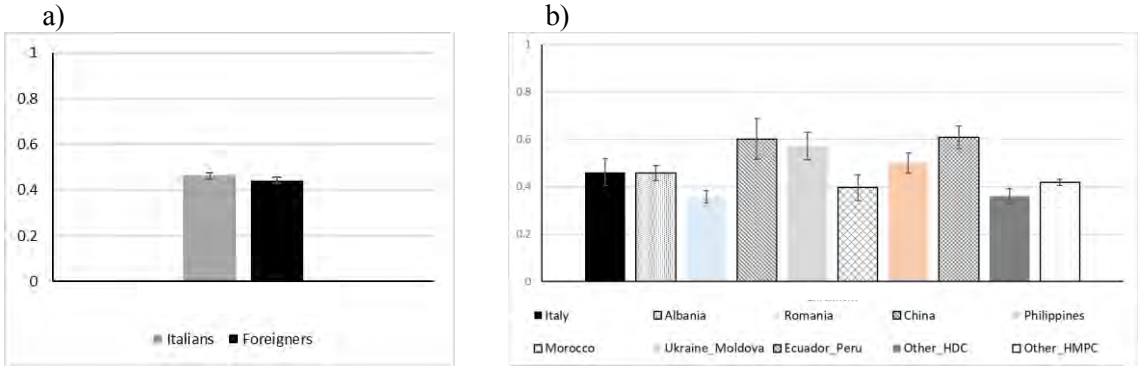

Figure 2: Adjusted predicted probabilities of the 'academic enrolment' by foreign status (panel a) and by foreign subgroups (panel b)

4. Discussion and further development

This work wants to contribute to the contemporary discussion on ethnic diversity as a major challenge for policy-makers, given the pivotal role that is played by education in the successful economic and social integration of children of immigrants.

Using a unique dataset which links the ISG survey data conducted by Istat in 2015 and the ANS-MUR archive, which contains administrative records, this is the first study which analyses academic intentions and the transition to university of foreign students in Italy. Results confirm our research hypotheses: overall, we found that academic intentions of foreign students are higher than intentions of their Italian classmates. Even though results show no differences between the two groups in terms of university enrolment, a more detailed analysis allows us to highlight differences by citizenship. Although the analysis of the factors underlying these patterns go beyond the scope of this work, we could speculate that differences by citizenship reflect social and cultural specificities of the highly heterogeneous foreign population residing in Italy. In order to deeply understand the mechanisms that explain educational choices of foreign students enrolled in Italian High School, further development of this study envisages to take into account the age at arrival, as a proxy of the social and educational integration level.

Abstract

In 2017 and 2018, for the first time in Italy, the students enrolled in Dental Schools performed a Progress test. The data available for these two years allows us to analyse the variability of students' knowledge during the course years to check the occurrence of a peak of ability. Furthermore, under certain conditions of the teaching provided by the universities, we can evaluate the coherence of the teaching results with the core curriculum. We propose an analysis of such data based on a mixed effects growth curve binomial model for the proportion of correct answers, considering fixed effects for the disciplines and random effects for the universities. We represent the trajectory of the Progress Test for each university's different fields using a polynomial time function. Using the Empirical Bayes prediction of level 2 residuals, the approach allows us to compare the trajectories of Italian universities, highlighting a substantial heterogeneity in the starting levels and growth rates.

Keywords: Binomial Growth Curves, Empirical Bayes prediction, Mixed effect model, Progress Test

1. Introduction

In 2017 a Progress Test was administered for the first time to students of 31 out of 36 Italian Universities with a degree program in Dentistry.

The tests were administered throughout Italy on the same day and consisted of 300 multiple-choice questions divided into different subject areas. This instrument gives an account of the level of knowledge achieved by students in the disciplines covered during the degree program. All students received the same test regardless of the enrollment year (from first to sixth). This feature allows us to estimate the learning curve across the 6 year of course, even in absence of longitudinal data.

The Progress Test was repeated in subsequent years. We have access to data from editions 2017 and 2018, thus we can repeat the analysis to evaluate the persistence of the findings.

We specify a growth model [3] where the response variable is the proportion of correct answers to each test item at the university level. The data have a hierarchical structure with items nested into universities, thus the growth model is multilevel with random effects for the universities. The items are also nested into disciplines, for which we use fixed effects.

The growth of knowledge over time is typically nonlinear, increasing until it reaches a peak, after which it remains constant or decreases [4]. The literature on Progress Tests reveal that base and clinical disciplines show different patterns [1], hence we will allow for distinct parameters for the two types of disciplines.

The same data have been considered in [1], who give details on the test and show the results from a linear growth model. In this contribution, we adopt a similar approach, except that we overcome the limitations of the linear model by a binomial-logit specification of the proportion of correct answers.

2. Data structure

The available dataset on the Progress Test has 11,160 records. There are 31 universities with questions covering 30 disciplines. A key feature is that all students have to answer the same questions regardless of the enrollment year (first to sixth). Therefore, there are $31 \times 30 \times 6 = 5,580$ records for each edition (2017 and 2018). We dropped 450 records with missing test results, thus the number of records per university ranges from 180 to 360. In addition, we removed universities in which the number of test takers is low [2] (less than 50% in case of more than 150 expected participants, or less than 60% otherwise). As a result, the dataset for the analysis has 8,670 records, with 24 universities in 2017 and 25 in 2018.

The percentage of correct answers tends to increase from the first to the sixth year of enrollment, showing a growth like in Progress Tests administered in the faculties of Medicine and Surgery [6; 7].

3. A growth model for the learning curve

Growth models are widely used to analyse the trajectories of individuals over time [3]. In our case, they can be used to model the learning curve across the six years of enrollment. As we do not have access to individual data, we specify a model for the proportions of correct responses for the universities, estimating the pattern at the university level. The heterogeneity among universities is accounted by random effects.

The growth model for the Progress Test is specified as follows:

$$y_{djt} \sim Bin\left(p_{djt}, n_{djt}\right) \tag{1}$$

$$logit\left[p_{djt}\right] = (\alpha_{0d} + u_{0j}) + (\alpha_{1d} + u_{1j}) \times t + (\gamma_1 + \gamma_2 \times c_d) \times t^2 \tag{2}$$

with

- $d = 1 \ldots 30$ disciplines
- $j = 1 \ldots 25$ universities
- $t = 0 \ldots 5$ enrolment years (with $t = 0$ for the first year etc.)
- c_d dummy variable for the type of discipline (1: clinic, 0: base)
- γ_1, γ_2 coefficients of the quadratic term
- α_{0d}, α_{1d} discipline fixed effects
- $[u_{0j}, u_{1j}]^T \sim N\left(\mathbf{0}, \mathbf{\Sigma}\right)$ random effects for the universities

Note that the intercepts and linear terms of the curves vary across disciplines due to the fixed effects α_{0d}, α_{1d} and vary across universities due to the random effects u_{0j}, u_{1j}. On the other hand, the quadratic term only vary across the type of discipline (base vs clinic).

The marginal likelihood of the model (1)-(2) involves an integral with respect to the random effects that is not in closed form. For this reason, we use Laplace's method to approximate the integrand function with a Normal distribution centered on the value of the random effect that maximizes the integrand. We choose to use the Laplace approximation, instead of Gauss-Hermite quadrature, because it is computationally faster while yielding similar estimates. We estimated the model using the `meqrlogit` command of `Stata`.

Once the parameters of model (1)-(2) have been estimated, we assign values to the random effects for each university by means of the Empirical Bayes method, which provides the Best Linear Unbiased Prediction (BLUP). The shrinkage property of the Empirical Bayes residuals pulls towards zero the values for the universities with a low number of respondents.

4. Results

The model's fixed and random effects in both years will be presented and discussed in this section. We will pay attention to the two types of shapes obtained from the curves of the proportions of correct answers. Since we separately estimated a model for 2017 and one for 2018, the results obtained in both years will be compared and discussed.

4.1 Fixed effects

In both editions of the Progress Test, the base disciplines have starting values higher than clinic disciplines, while the fixed effects on growth for these disciplines are among the lowest.

In contrast, the disciplines with a lower starting value are clinical. Looking at the fixed effects on growth, we see that the values of the clinical disciplines are higher than those of the basic disciplines.

In both editions of the test, the coefficient of the quadratic term is significantly different between base and clinic disciplines, leading to a different shape of trajectories. Most of the trajectories for the base disciplines are a parabola with downward concavity, which means that students' knowledge in these subjects increases until they reach a peak beyond which knowledge decreases. This pattern is expected since base disciplines are treated only early in the degree program. On the other hand, the trajectories of the clinical disciplines have a shape much closer to a straight line, pointing out that knowledge is still increasing without reaching a peak. An example of this difference can be seen in Figure 1, in which the trajectories of the predicted probabilities of correct answers for three basic disciplines (behavioral sciences, chemistry and physics) and three clinical disciplines (endodontics, plastic surgery and dentistry) are shown for an average university, i.e., with random effects equal to zero.

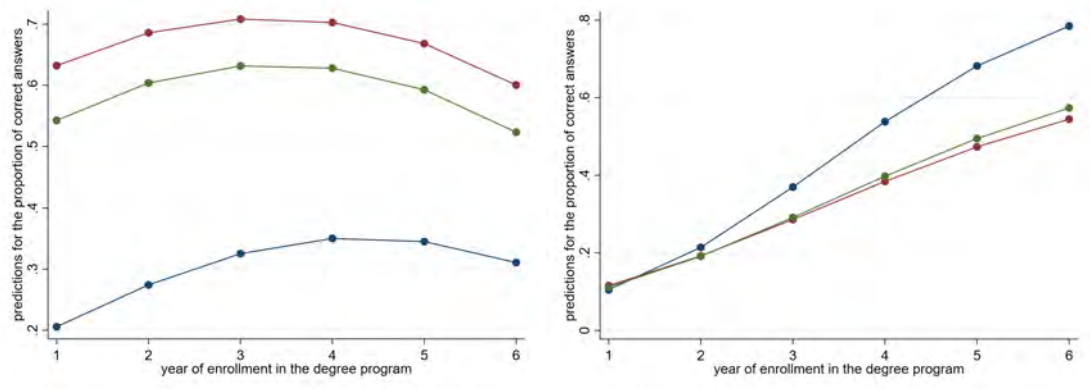

Figure 1: Predicted probabilities of correct answers for three basic disciplines (left panel) and three clinical disciplines (right panel) for an average university, 2017

4.2 Random effects

The random intercept and the random slope have statistically significant variances. Their correlation is negative, namely universities whose students have a higher knowledge at the beginning tend to grow at a lower rate. The initial gap among universities is due to the self-selection of students, who choose the universities with major reputation. In most cases, the initial gap in the knowledge is closed within the end of the degree program due to a faster learning process.

The Empirical Bayes predictions of the random effects with confidence intervals are arranged in the caterpillar plot [5] shown in Figure 2. The intervals are wider for universities with fewer respondents. In most cases the intervals do not intersect the zero, so that the corresponding random effects are significantly different from zero.

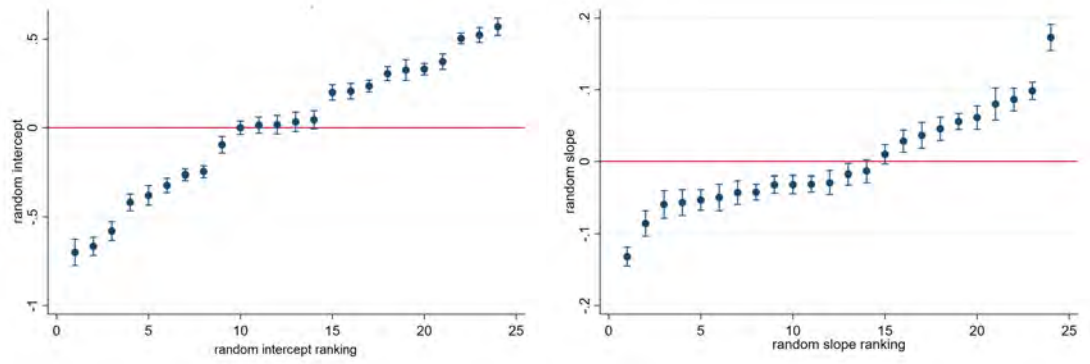

Figure 2: Caterpillar plot of Empirical Bayes predictions of random intercepts (left panel) and random slopes (rigth panel). All universities, 2017

5. Final remarks

The analysis has shown that the disciplines of the Progress Test have quite different trajectories, with the performance in the base disciplines reaching a plateau or even decreasing in the last years of the degree program. The Empirical Bayes predictions allowed us to build rankings of the universities with confidence intervals accounting for uncertainty. The results are suitable to support policy interventions.

Abstract

The term e-learning refers to a learning method involving new multimedia and internet technologies capable of totally replacing face to face meetings in academic contexts. With the advent of the COVID-19 pandemic, the closure of universities and higher education institutes forced a sudden and unexpected transition from face-to-face teaching to distance learning to mitigate the spread of SARS-CoV-2. This shift to online teaching and learning is a game changer for higher education.

The goal of this work is to identify the factors that impacted the adoption of e-learning systems within Italian universities during the period of the COVID-19 pandemic situation. Specifically, through a quantitative empirical survey and a statistical analysis with EFA method, it was possible to understand how the perceived usefulness and ease of use of e-learning platforms have influenced the online learning and teaching experience of Italian students and professors.

Keywords: e-learning, covid pandemic,exploratory factor analysis, exploratory graph analysis, digital skills

1. Introduction

The term e-learning system refers to a learning method that involves the use of new multimedia and internet technologies capable of totally replacing face to face meetings in academic contexts (Azeiteiro et al., 2015; European Commission, 2001; Guri-Rosenblit, 2005; Holmes & Gardner, 2006; Khan, 2005; Qwaider, 2011). In this sense, the use of specific technologies such as tutorials, audio, video, web pages, or games or other, provided synchronously and / or videotaped (asynchronous) also through the support of mobile devices could facilitate and improve access to e-learning systems able to completely substitute the didactic activities carried out in university classrooms (Rice & Gregor, 2016).

The forced and unprecedented shift to online teaching is seen as a game changer for education change (notably higher education) and fostering innovation (Flores et al., 2022) and has generated a different approach in students and teachers in carrying out teaching activity.

2. Design of the survey

The questionnaire was administered online. The questionnaire was disclosed in mid-March 2020, during the first lockdown period resulting from the health emergency for COVID-19, when Italy had issued a ministerial decree on guidelines and tools for implementing e-learning in universities. For the formulation of the content of the various items of the questionnaire, reference was made to the existing literature on the adoption of e-learning systems in universities (Flores et al., 2021). The questionnaire was disseminated through certain social media and online channels with some specific groups of possible participants (Kayam & Hirsch, 2012). Completion time was estimated at just under 10 minutes. Furthermore, in the initial part, based on current privacy legislation, it was indicated that the answers would be processed and managed anonymously and that participation in the questionnaire was voluntary (Kayam, & Hirsch, 2012).

The survey was aimed at professors (professors, researchers, and adjunct professors) and students (enrolled in a first- and second-level degree course or a research doctorate) from Italian universities.

A total of 473 respondents were involved in the survey. The questionnaire is divided into the 9 sections below to allow the acquisition of different information from generic to the more specific

3. Methodology and data preparation

According to the research questions of the present work, statistical methodology follows the framework of the Exploratory Factor Analysis (EFA) (Costello and Osborne, 2005; Fabrigar and Wegener, 2011). It is a statistical method used to reveal the relationships among a set of variables, i.e., to highlight the presence of a consistent structure of factors. EFA is a technique belonging to the large family of factor analysis, whose predominant aim is to identify the underlying and not necessarily explicit associations between measured variables. It is commonly conceived as a technique that identifies a set of latent constructs that are not observed, underlying a battery of measured variables that is instead observed.

When dealing with unknown factors and manifest variables with no a priori fixed constructs, this approach can assess if a few emergent latent factors are present in the data. Thus, it is handy when dealing with data about a (relative) recent topic yet to explore.

In this case, given that the sudden epidemic emergency led to a quick switch in learning strategies and the whole situation can be seen as the first time that the modern academic world has to face this kind of challenge, an exploratory approach to figure out recurrent patterns in questionnaire items can be considered a safe first multivariate picture of the COVID effect in the Italian context.

EFA is based on the principle of the common factor model (Velicer and Jackson, 1990). Within the framework of this model, a combination of common factors, unique factors, and measurement errors leads to the definition of the manifest variables (Norris and Lecavalier, 2010). Each unique factor impacts only one manifest variable and does not influence the correlation among manifest variables.

Factor loadings are measures of the weight of a given unique factor on the manifest variable.

In this case, the underlying assumption is that each item can be related only to one factor, while with the adequate rotation (not orthogonal), axes can correlate each other's. Still, the overall correlation/association structure drives the final result about the constructs.

In our case, it is interesting that it is possible to split the data in two samples: "teachers" and "students." We expect most relationships will not diverge too much from one data set to another, while a few minor differences will highlight peculiar behaviors. Overall, learning experiences can not be considered as a whole, and the two groups' expectations and challenges can differ.

3. Data description

From these data, we will focus on the questions related to the respondent's personal characteristics and items strictly associated to the e-learning process during the pandemic time, such as the type of platform, role in the university, type of degree/Ph.D., items related to behaviors and perceptions about e-learning and specific platforms, and overall effects of the pandemic context and online-distance learning.

Among the 473 respondents, students are prevalent, 351 of them. Among them, 235, the majority, is in the course of obtaining a Bachelor Degree. Among the students also, there are also 23 who are in the course of obtaining a PhD: this is because, for Italian law, PhDs are students, and also because they are more involved in learning than in teaching and researching.

The majority of respondents among professors is composed by full or associate professors (67 respondents), but there are also 55 researchers of three different types: Post-Doc, Scolarship Researchers and Researchers.

Nearly everyone among the respondents has been involved in e-learning: only two respondents still needed to have e-learning experience before responding to the survey.

To test if items are suited for Factorial Analysis, we propose results of Kaiser-Meyer-Olkin factor adequacy. Value of this KMO between 0.8 and 1 indicates a very high adequacy for factor analysis. For our data such measures is equal to 0.95.

Results indicate that data are suited for factor analysis. Similar results (0.94; 0.88) are obtained for the students data and professors data, respectively.

In the following, given the nature of the data, we will use Polychoric correlation matrix suited for ordinal data, such the Likert scale that we are using for the items involved in the analysis. The two different Polychoric correlation matrix (students and professors data) show a similar pattern, even with slight differences.

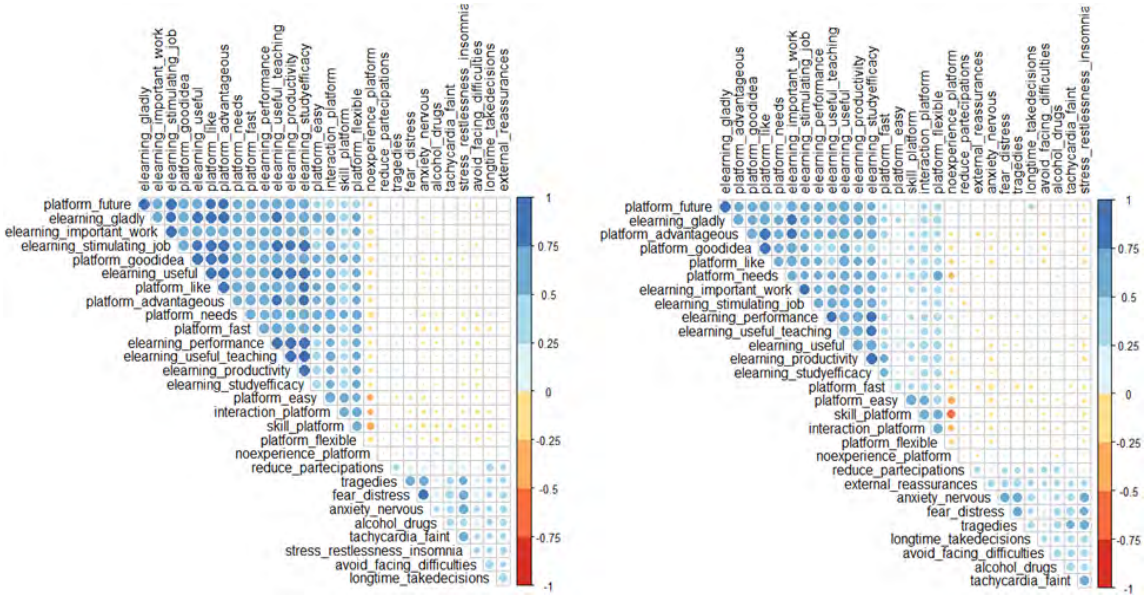

Figure 1: polychoric correlation matrix of the 29 items. Left: Students Data. Right: Professors Data.

4. Main EFA findings

Parallel Analysis (PA) (Braeken, 2017) and Exploratory Graph Analysis (EGA) (Christensen, 2020) estimate the number of dimensions in factor analysis. Results differ slightly between the two approaches (students: 3 with PA and 4 with EGA; professors, 4 with PA and 6 with EGA but with two isolated items). Thus, we propose a compromise solution with 4 factors for each data-set. As a control over such identified factors, Cronbach alpha is computed. Given the exploratory approach of the analysis, we try to understand if the observed factors can be reliable and to what extent. Most results are promising, with factor 3 in students data (0.58) and factor 3 in professors data (0.57) being the most problematic.

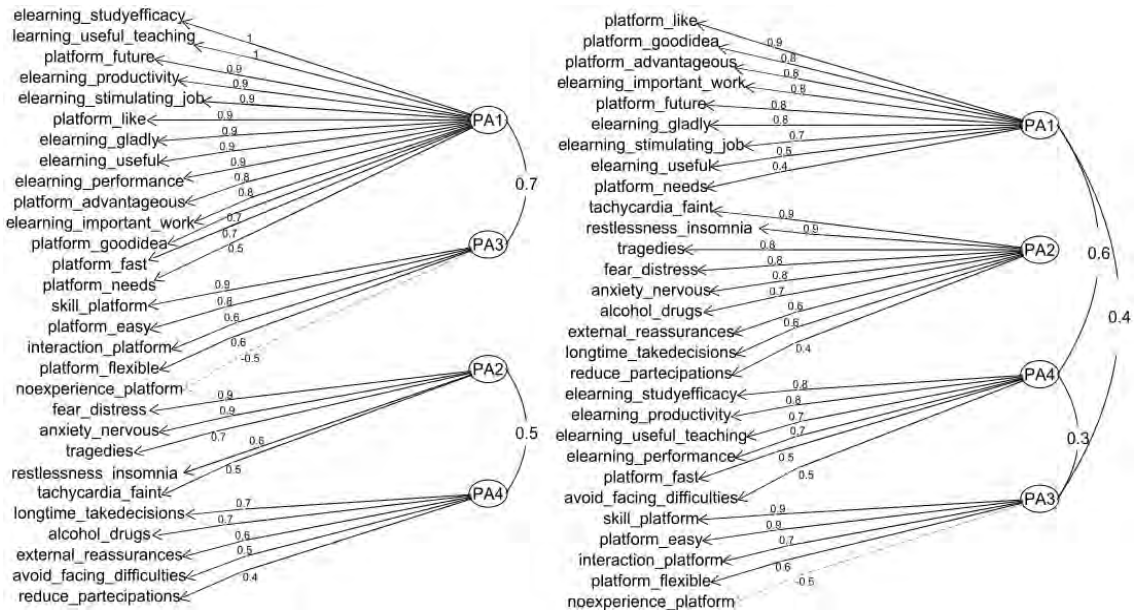

Figure 2: EFA factors identification. Both case 4 factors as best solution. Left: Students Data. Right: Professors Data.

5. Discussion and Conclusion

Students: The first factor (PA1) identifies mainly an underlying dimension tied to the efficacy and usefulness of e-learning in general, while the second (PA3) locates the relation between the individual and the e-learning platform. For factor PA1, the most influential items are "elearning_studyefficacy" and "learning_useful_teaching", both with a loading close to 1. For factor PA3, the most influential item is "skill_platform" with a loading of 0.9, representing the answers to "I believe I can soon become proficient in using the e-learning platform". The factor PA2 seems to individuate a dimension of anxiety and fear, while the last factor PA4 relates to the items pertaining to difficulties of interaction, participation, and the necessity of reassurances. For factor PA2, the most influential items are "fear_distress" and "anxiety_nervous", both with a loading of 0.9. For factor PA4, the most influential items are "longtime_takedecisions" and "alcohol_drugs", both with a loading of 0.7.

Professors: The first (PA1), third (PA4), and fourth (PA3) all correlate among them and seem to identify latent dimensions pertaining to the use of e-learning and platforms. More specifically, for factor PA1, the most influential item is "platform_like", with a loading of 0.9. For factor PA4, the most influential items are "elearning_studyefficacy" and "elearning_productivity", both with a loading of 0.8. For factor PA3, the most influential items are "skill_platform"

and “platform_easy”, both with a loading of 0.9”. The other factor (PA2), however, gathers together all the items related to fear and anxiety. The most influential items for this factor are “tachycardia_faint” and “restlessnees_insomnia”, both with a loading of 0.9. For professors, the ideal number of courses for the best teaching effort and understanding e-learning and platform is between two and three. The anxiety level tends to increase with the number of courses assigned to an individual professor: in particular, with more than four courses to dispense, the professor’s anxiety level tends to raise very significantly, and this seems the only occasion in which an influence of e-learning on anxiety level is clearly traceable.

Moreover, STEM professors seem to be less optimistic about e-learning, while medical sciences and Humanities professors have more difficulties with platform use. Professors who had their lessons in an asynchronous way (lessons were first recorded and subsequently delivered to students) have higher e-learning appreciation scores. Finally, professors who only used external platforms and not platforms provided by their universities have the worst idea of e-learning in general.

In conclusion, the results seem consistent with the Technology Acceptance Model (TAM): from the analysis, it is possible to note that the degree of satisfaction with e-learning is higher where users indicate a greater perception of reliability and ease of use of the platform. This happens for both students and professors. Nevertheless, the most evident difference between students and professors, when it comes to factors, is the difference in anxiety. This is not surprising, given the higher age and responsibilities of professors than that of the students: short-term and long-term anxiety collapse to just one dimension, while fear may be less about one’s career development and more about the health of oneself and its loved ones.

Finally, the general lack of influence of e-learning on anxiety levels should be regarded as the clearest result of this study. As shown, this lack of influence emerges from both datasets analyzed, for students and professors.

Abstract

Does having been a working student during the higher education studies matter for future job market outcomes? This article addresses this question by analysing administrative data, matching individual-level data on the career of students at the University of Florence, Italy, with records on employment contracts for the same students from the Italian Ministry of Labor. A survival analysis for ordered events is employed in order to estimate the risk of stipulating hierarchical-ranked types of employment contracts. Coherently with expectations, it turns out that former working students graduates exhibit a positive risk of being employed in a shorter time. Moreover, students from lyceums are more likely to obtain a higher-skilled contract.

Keywords: Secondary Education, Job Market Outcomes, Working students, Higher education.

1. Introduction

The present article tries to investigate the association between the fact of having been or not a working student during the tertiary education career and the labor markets outcomes for those graduates from the University of Florence. In particular, we explore the idea that the decision of being a working student may condition at a very early stage the future chances of students' social mobility. Indeed, Italy could exhibit a standstill of compulsory education in reducing inequalities (7), and even if it is included among the countries that were able to reduce inequalities for the transition to the upper secondary education, it remained behind concerning the stratification at the tertiary education level (2). Even though universal education should have helped in overcoming the classism in educational attainment, and in fostering social mobility, Italy is still characterized by mostly upper-class students that enrol in secondary school's academic tracks, such as lyceums. On the other side, students from the working class are more likely to choose technical and vocational schools; their families' investment on education turns out to be burdensome, and they need strongly to "bet" on their childrens' ability in order to allow them enrolling an academic track (14; 5). In a nutshell, Italy exhibits social origins as the main driver for educational choices after compulsory schooling, fostering a school track implicitly based on classes, which tends to mantain the status quo (8).

In this framework, focusing on the decision of working during the tertiary education path could be a useful aspect for exploiting the issue of social stratification between education and employment. Indeed, this choice should be taken by those students who need to support themselves or have at least some monetary needs to satisfy. Nonetheless, economic needs are not the only reason for getting a job in the meanwhile of a degree course; also, another motivation can be the will of anticipating the entry in the labor market, so to signal a greater experience gathered in advance with regard to not working colleagues

(12). Thus, it is still uncertain if working during studies reflects more the presence of economic difficulties, the will of signalling resourcefulness to the future recruiters, or just that tertiary education is seen as an accessory activity, as in the "parking lot" hypothesis (4).

2. Data and Model

2.1 Data

The following analysis is based on data obtained thanks to an agreement between the Italian Ministry of Labor and the University of Florence. Regarding the available data, administrative information about the student population of the University of Florence are merged with the compulsory notifications which have to be provided by every employer (public or private) who stipulates, extends, transforms or terminates any employment relationship. In particular, these data refer to 28073 graduates at the University of Florence between 2008 and 2013, who stipulated an official job contract between the 1st of January 2008 and the 30th of September 2015. For each graduate, careers were built starting from the first compulsory notification available. In this regard, it is important to notice the absence of an information about the exact graduation day, only the year being available. Thus, evaluating if certain jobs were obtained before or after the achievement of graduation is impossible: in those cases, a job is considered obtained after graduation if it is stipulated in the same calendar year of students' graduation. Coherently, the employment before graduation identifies working students. Indeed, recruiters could have some priors for evaluating positively or negatively this particular category of students.

Also, information about the Secondary Education is available: namely, the year of diploma, the final mark obtained, and the different typologies of high schools, coded according to four categories: *Lyceum*; Technical Schools; Vocational Schools; other schools. A proxy for the possibility that a student had to repeat one or more years of school is obtained through a dummy that indicates if the student graduates when s/he was older than 19 years old, which is the prescribed age at which a high school degree in Italy is supposed to be obtained.

Table 1: Descriptive Statistics: Means (for continuous variables) and proportions (for discrete) for the entire sample and sampled by job type.

	At least a Low Job	At least a Medium Job	At least a High Job	Full Sample
Secondary Ed.				
Final Grade	82.55	81.98	84.45	82.56
Fail	0.14	0.13	0.11	0.13
Type of Secondary School:				
Lyceums	0.66	0.65	0.70	0.66
Technical	0.25	0.28	0.20	0.24
Vocational	0.02	0.02	0.02	0.02
Other	0.07	0.06	0.08	0.07
Job Career				
Working Student	0.32	0.25	0.26	0.33
Prev.Job Low	0.50	0.33	0.27	0.55
Prev.Job Medium	0.17	0.31	0.15	0.30
Prev.Job High	0.10	0.14	0.37	0.30
No. Observations	15066	9608	9962	28073

Information about university performance (e.g. average mark, time-to-degree) are not used because it represents an acknowledged source of endogeneity in the analysis of working students. Indeed, the decision of working and studying at the same time affects both the performance and the speed in achieving the degree.

Finally, job contract levels are classified thanks to a framework designed by the Italian National Institute of Statistics (ISTAT), where contracts are sorted on a scale 1-8 according to a hierarchical principle. Consequently, the outcomes are classified into three categories: *Low Job*, which includes classes from 4 to 8, namely elementary workers, craftsmen, specialized workers, farmers, specialized workers in tertiary sector, executive jobs in tertiary sector; *Medium Job*, which includes class 3, that are technical professions; *High-Job*, which includes classes 2 and 1, namely intellectual and scientific high-skill professions, and legislators, businessmen, managers and entrepreneurs.

Table 1 reports some descriptive statistics for the main covariates included in the analysis by type of contract. Among the main evidences, as two thirds of the whole sample are composed by lyceum students, one third of subjects are former working students. Graduates who have obtained at least a low job exhibit a higher share of students who failed a year during secondary education (14%) and of former working students (32%). 50% of them have stipulated a low job after another low job. On the other side, graduates who have obtained one or more medium contracts show the lower average final grade (81.98) and the higher share of former students coming from technical schools. Unsurprisingly, workers in high contracts include the highest average final grade (84.45), the lower share of students who failed one or more years (11%) and the highest share of lyceum students (70%).

2.2 Model

As in the data all the information obligations were available up to the 30^{th} of September, 2015, for each individual, then the information had to be conformed to survival structure. Consequently, starting from the first employment contract for each individual and focusing on all contracts which lasted at least 30 days, we categorized each of them as as a Low, Medium or High Job. Moreover, time spells were created for the periods in which each worker had not any contract in effect, ar a contract shorter than 30 days, since we are considering a monthly time unit. Those spells start from the end date of their own previous spell, and they finish on the start date of the following one. If the last contract available for a certain person results closing before 30^{th} of September, 2015, then a spell is created up to that date[1]. Thus, we are able to consider each working spell considering its job qualification.

Consequently, we build a *Cox proportional hazard model for subdistribution* (9; 15). Given $i = 1, ..., k$, the cause-specific hazard ratio is (6):

$$h_i(t) = \lim_{\Delta \to 0} \frac{P(t \leq T < t + \Delta t, \text{failure from cause } i | T \geq t)}{\Delta t}$$

where, t is a certain point in time, T is the time to first failure, and the overall hazard rate, which is the probability that the failure occurs into the prescribed time interval, is $h(t) = \sum_i h_i(t)$, and the probability a failure occurs because of i is $h_i(t)/h(t)$.

Thus, as we can observe for each individual multiple failures for competing risks, it is necessary to control for the possibility of tied events, i.e. events with the exactly same survival time. In order to deal with this problem, the method proposed by Efron (11) is preferred since, even if fit statistics are worse than those of other methods, efficiency and parameters estimates are basically equal with others and the bias is even lower in presence of a large number of ties (3).

As already stated, in the available data events can be recurrent, and the order in which they show up for each individual matters. Accordingly, starting from the partial likelihood function by (10), the estimation is corrected for multiple failure events (1), and stratified according with the order of events (15). For the ith failure type (i = Low, Medium, High) the *hazard function* will assume the form:

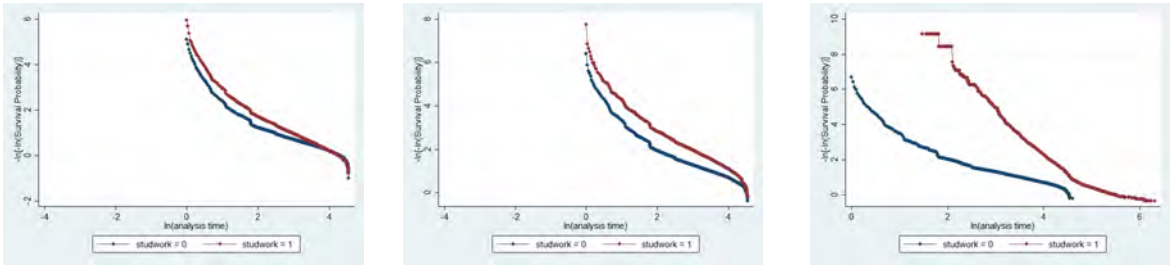
[1]Unfortunately, after this reconstruction several contracts appeared overlapping their time spells for the same individual. Maybe arbitrarily, a choice was taken of maintaining case by case only the contract with the longest time length.

$$h_i(t; \beta_i, X(t)) = h_{i0}(t) exp[X(t)^T \beta_i],$$

where h_{i0} is the latent baseline hazard function, $X(t)$ is the matrix of the covariates until time t, and β_i is the vector of the coefficients.

3. Results and Discussion

Figure 1 allow us to check graphically the proportionality of hazards for having been or not a working student, which do not seem to present a picture so much far from proportionality, with the only exception of subfigure 1(c) for high jobs.



(a) Outcome: Low job (b) Outcome: Medium job (c) Outcome: High job

Figure 1: Proportional Hazard Plot for being a Working Student: (a) Low Job; (b) Medium Job; (c) High Job.

Hence, looking at Table 2 some straightforward conclusions can be taken. First of all, the fact of having been a working student is positively associated with every kind of qualification, even if the association is very low and weak with regard to medium jobs. Probably the two stronger relationship with low and high qualifications reflect two different frameworks: on the former side, those graduates experiencing the harshest economic needs, so having worked during tertiary education studies, remain stocked in lower level jobs. On the latter side, successful working students are positively rewarded by recruiters, in the long run. Nonetheless, this emerges as a puzzling result, deserving deeper exploration of the underlying mechanisms as a further development of this study.

Moreover, we can notice how the risk of obtaining a low job is negatively associated with the final grade and positively with fails during secondary education. Moreover, students from lyceums have a lower risk of ending up in such a job level than every other high school type. The risk of obtaining a low job is also negatively associated with age, probably because this kind of contracts are more likely to be gained at the very beginning of individuals' career. As it can be seen, the classification of the previous job is never significant across the three models, with a single exception. Indeed, having had a low job is positively associated with the risk of stipulating another low job, as these contracts may cause a sort of career stagnation.

Regarding the risk of stipulating a medium job, it is negatively associated with the final grade, but it does not seem to be related with having repeated one or more years during secondary education. Graduates coming from technical schools exhibit higher risk than those from lyceums. Also in this case, the risk is negatively associated with age.

A quite different picture emerges concerning high jobs. In this case, we find a higher risk for those with a high final mark and those who did not fail during secondary education. Students from lyceum are positively associated with jobs with a high qualification more than any others. Finally, this is also the only case in which age at event is positively significant, probably because it is necessary a longer time and experience for ending up in such contracts.

Nonetheless, secondary education emerges as a strong source of social stratification. Indeed, it seems sufficient to be a well-performing student coming from a lyceum to strongly increase the chances of obtaining a high job. But, as said before, these characteristics are still devoted to upper-classes graduates.

Concluding, this article has shown a preliminary analysis about the association between the fact of having been a working students and job market outcomes. Further developments should include other socio-demographic covariates that may play a role in shaping this association, add some interaction terms that may moderate the effect, and benefit of more recent graduates' cohorts.

Abstract

The analysis of RNA data plays a crucial role in understanding cellular differentiation. One widely-used methodology for analyzing RNA data is scVelo. However, in this paper, we show that, among other issues of scVelo, the current model formalization suffers from identifiability problems. We propose a Bayesian version of scVelo with modifications that address these issues.

Keywords: scVelo, RNA, Bayesian, identifiability

1. Introduction

RNA velocity is a critical biological metric that facilitates the reconstruction of cellular differentiation at single-cell level. It provides insight into the future state of each cell, and it is closely associated with transcription from DNA to RNA, as well as the quantity of spliced mRNA in each cell. By analyzing RNA velocity, researchers can gain a deeper understanding of the underlying mechanisms driving cellular differentiation, which has important implications for fields such as developmental biology and disease research. Single-cell RNA sequencing (scRNA-seq) techniques are commonly used to measure the abundance of unspliced and spliced mRNA in each cell for each gene, which is essential for inferring RNA velocity. However, these techniques are destructive, as they permit only a single observation of gene expression for each cell before it is destroyed. In this sector, one of the most influential works is scVelo, presented in [1]. Despite its success in the scientific community, there are several criticisms when it is analyzed from a mathematical and statistical point of view.

As a primary contribution, we reframe the model under a Bayesian framework, which provides better insight into the parameters that can be estimated and identified. The use of Bayesian inference enables us to compare the posterior estimates of the parameters with their corresponding priors and compute credible intervals. In contrast, such comparisons and interval estimates are not possible with the point estimates provided by scVelo. Through simulated examples, we demonstrate that the "time" parameter is not identifiable, which, to the best of our knowledge, has not been previously identified in the literature, representing another contribution of this paper. Furthermore, we propose modifications to the model that addresses some of the criticisms of the original scVelo. Collectively, these contributions have the potential to enhance the accuracy and reliability of RNA velocity inference, as well as provide new insights into cellular differentiation.

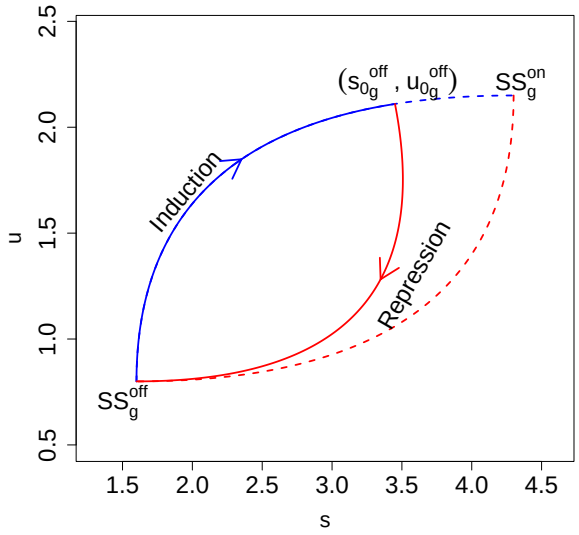

Figure 1: Solution of (2) in the space (s, u) for gene g. The solid line represents the gene's behavior if an early switch at time t_{0g}^{off} occurs, while the dashed line represents the potential behavior if the gene reaches the steady state SS_g^{on} during the inductive phase. The blue upper curve corresponds to the gene's inductive phase, characterized by the rate α_g^{on}, and the red lower curve represents the repressive phase, associated with α_g^{off}.

2. Mathematical model

Let us consider a system with n_g genes and n_c cells. The model assumes a straightforward chemical reaction network (CRN) to represent the processes of transcription, splicing and degradation, with gene-specific rates, according to mass-action kinetics. The CRN representation of the process, for a given g, is

$$\text{DNA} \xrightarrow{\alpha_g^k} \text{unspliced mRNA} \xrightarrow{\beta_g} \text{spliced mRNA} \xrightarrow{\gamma_g} \emptyset \tag{1}$$

that is associated with the following ordinary differential equation (ODE) system:

$$\begin{cases} \frac{du_g(t)}{dt} = \alpha_g^k - \beta_g u_g(t), \\ \frac{ds_g(t)}{dt} = \beta_g u_g(t) - \gamma_g s_g(t), \\ u_g\left(t_{0g}^k\right) = u_{0g}^k, \\ s_g\left(t_{0g}^k\right) = s_{0g}^k, \end{cases} \tag{2}$$

where $u_g(t)$ and $s_g(t)$ are the reads of unspliced and spliced mRNA at time t in a cell. The solution to the ODEs is

$$\begin{cases} u_g(t) = u_{0g}^k e^{-\beta_g \tau_g^k} + \frac{\alpha_g^k}{\beta_g}(1 - e^{-\beta_g \tau_g^k}) \\ s_g(t) = s_{0g}^k e^{-\gamma_g \tau_g^k} + \frac{\alpha_g^k}{\gamma_g}(1 - e^{-\gamma_g \tau_g^k}) + \frac{\alpha_g^k - \beta_g u_{0g}^k}{\gamma_g - \beta_g}(e^{-\gamma_g \tau_g^k} - e^{-\beta_g \tau_g^k}) \quad \text{with } \tau_g^k = t - t_{0g}^k. \end{cases} \tag{3}$$

It should be noted that the variable t is not the real time, but a representation of the cell position in the ODE dynamic, which is often called *pseudotime* in the literature, see, for example, [3].

RNA velocity is defined as

$$v_g(t) := \frac{ds_g(t)}{dt} = \beta_g u_g(t) - \gamma_g s_g(t).$$

Accurately estimating the model parameters is crucial for obtaining a reliable estimator of this biological quantity.

Parameters description For each gene, there exist two transcription rates, indicated as α_g^{on} and α_g^{off} with $\alpha_g^{\text{on}} > \alpha_g^{\text{off}}$, represented in (2) as α_g^k, with $k \in \{\text{on}, \text{off}\}$. The rates regulate the conversion of DNA into unspliced mRNA, as depicted in (1) (first and second components). This implies that a gene can exist in two distinct states: an inductive phase, regulated by the transcription rate α_g^{on}, and a repressive phase, where transcription either occurs at a lower rate or is absent altogether, dictated by α_g^{off}. It is assumed that each gene can be activated and then repressed only once, which is justified by the assumption that the total time length of the biological processes is sufficiently small. The rates β_g and γ_g, illustrated in (1) (from the second to the fourth component), are responsible for the splicing and degradation mechanisms of mRNA. The gene time dynamic is depicted in Figure 1.

The ODE system has two theoretical steady states, that are only gene-dependent and are identified by the coordinates

$$\text{SS}_g^{\text{off}} = \left(\frac{\alpha_g^{\text{off}}}{\beta_g}, \frac{\alpha_g^{\text{off}}}{\gamma_g} \right), \qquad \text{SS}_g^{\text{on}} = \left(\frac{\alpha_g^{\text{on}}}{\beta_g}, \frac{\alpha_g^{\text{on}}}{\gamma_g} \right),$$

in the space (s, u), see Figure 1. After the cell is created, each gene remains at SS_g^{off} for a time period of t_{0g}^{on} before being activated and entering the inductive phase, represented by the upper blue arc in Figure 1. Time t_{0g}^{on} is not identifiable (see Section 3) since there is no information in the data regarding the real time point at which the cells are observed, and hence, without loss of generality, we assume $t_{0g}^{\text{on}} = 0$. This means that $s_{0g}^{\text{on}} = \alpha_g^{\text{off}}/\beta_g$ and $u_{0g}^{\text{on}} = \alpha_g^{\text{off}}/\gamma_g$. However, before reaching the second steady state SS_g^{on}, the repressive phase is triggered at time $t_{0g}^{\text{off}} + t_{0g}^{\text{on}}$ and the dynamic follows the evolution depicted by the solid line in Figure 1.

In scVelo the pre-processed data $(Y_{u,cg}, Y_{s,cg})'$ are assumed to be normally distributed and the unspliced and spliced components to be independent, i.e.

$$Y_{u,cg} \sim \mathcal{N}(u_g(t_{cg}), \sigma^2) \qquad Y_{s,cg} \sim \mathcal{N}(s_g(t_{cg}), \sigma^2) \qquad Y_{u,cg} \perp\!\!\!\perp Y_{s,cg}. \tag{4}$$

where $t_{cg} = \tau_{cg} + t_{0g}^{k_{cg}}$ and $u_g(t_{cg})$ and $s_g(t_{cg})$ are evaluated in a time that is both cell- and gene-specific. The description of the data used to estimate the model is discussed in Section 3. The scVelo algorithm estimates the following parameters: $(\alpha_g^{\text{off}}, \alpha_g^{\text{on}}, \beta_g, \gamma_g, t_{0g}^{\text{off}})$ for each gene, and (τ_{cg}, k_{cg}) for each cell and gene.

There are several criticisms of this model, that, in our opinion, raise questions about the reliability of the results, which will be discussed in the next section.

3. Critical issues of scVelo

One of the main concerns is related to the estimation of the cell- and gene-specific τ_{cg}. Since single-cell data only provides a single observation for each cell, inferring τ_{cg} is inherently difficult, if not impossible. Despite this, the authors did not acknowledge this issue. As a first contribution, we demonstrate in Section 4. that τ_{cg} is at best weakly identifiable by showing that, the posterior distribution of τ_{cg} closely resembles the one of $\tau_{c'g}$, for $c \neq c'$, and they are both very similar to the prior.

Single-cell RNA-sequencing dataset contains discrete counts, describing the number of measured RNA molecules in each cell. In scVelo, a series of pre-processing steps are applied to the raw data. This includes filtering out genes that are not expressed, normalizing the counts to account for differences in sequencing depth across cells, and smoothing the gene expression profiles among groups of cells with similar genetic expressions. Additionally, the logarithm of the pre-processed counts is taken. The variables $(Y_{u,cg}, Y_{s,cg})'$ in equation (4), are the results of this pre-processing. While these pre-processing steps are common in many biological pipelines, they significantly alter the nature of the data by transforming them from discrete counts to continuous values. This transformation can be problematic, especially in real data applications where the original counts are often very low (often in the range [0,10]). The pipeline introduces dependence across genes which are not taken into account in the model, that assumes independence, see (2) and (4). Additionally, the use of a logarithmic transformation is questionable since ODE equations and solutions are not invariant under a non-linear transformation.

Despite time-dynamic being dependent on four parameters $(\alpha_g^{\text{off}}, \alpha_g^{\text{on}}, \beta_g, \gamma_g)'$, only three of them are identifiable due to the lack of information on t_{cg} and its scale in the data. We can easily see that, if $r \in \mathbb{R}^+$, then the parameters $(\alpha_g^{\text{off}}, \alpha_g^{\text{on}}, \beta_g, \gamma_g)'$ and $(\alpha_g^{\text{off}}/r, \alpha_g^{\text{on}}/r, \beta_g/r, \gamma_g/r)'$ produce the same likelihood if τ_{cg} is substituted with $r\tau_{cg}$. This is because under both sets of parameters, the same value $(u_g(t_{cg}), s_g(t_{cg}))$ is obtained. While some of the issues discussed here have been previously addressed in the literature (e.g., [2; 5]), the non-identifiability of τ_{cg} and its impact on other parameter estimates has not been adequately emphasized to the scientific community.

In conclusion, scVelo has a further drawback in that it only provides point estimates of the parameters and does not compute any measure of their precision. This absence reduces the reliability of the results as it is not possible to assess the statistical differences among the parameters accurately.

4. The Bayesian Implementation

In our model formulation, we choose to use the original data without the non-linear pre-processing steps applied in scVelo. The only step we keep is the filtration of the genes that are not sufficiently expressed. As a result, our data $(Y_{u,cg}, Y_{s,cg})'$ is discrete, and $(u_g(t_{cg}), s_g(t_{cg}))'$, obtained as solution of (2), represents the mean of the original count data. A natural choice for modeling $(Y_{u,cg}, Y_{s,cg})'$ is the Poisson, because this distribution arises from the chemical master equation (CME) associated with the CRN (1). Specifically, in the steady state, the Poisson distribution is the distribution of mRNA counts of a single gene in a single cell, and in the transient part, CME distribution can be expressed as the convolution of multinomial and product Poisson distributions [4]. On the other hand, to increase the model flexibility and to take into account extra sources of variability we use Negative Binomial distribution, which is an overdispersed version of the Poisson. Specifically, we assume that

$$Y_{u,cg} \sim \mathcal{NB}(u_g(t_{cg}), \eta_g) \qquad Y_{s,cg} \sim \mathcal{NB}(s_g(t_{cg}), \eta_g) \qquad Y_{u,cg} \perp\!\!\!\perp Y_{s,cg}$$

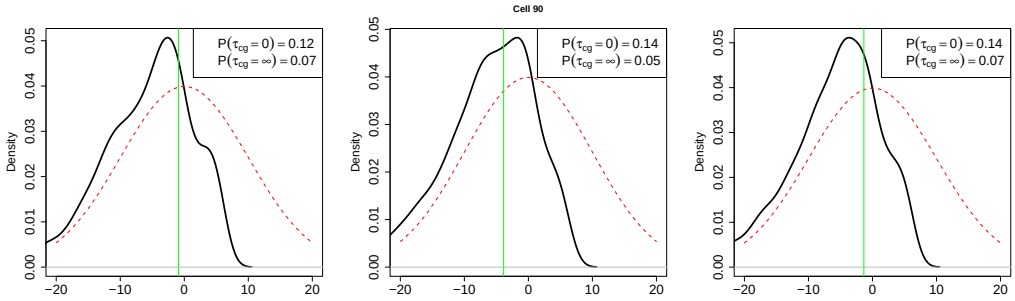
Here the Negative-Binomial is parameterized in terms of its mean μ and the overdispersion parameter η, such that if $X \sim \mathcal{NB}(\mu, \eta)$, then $\mathbb{V}(X) = \mu(1+\mu\eta)$. As prior distributions we define $\alpha_g^{\text{off}}, \alpha_g^{\text{on}}, \gamma_g, \eta_g \sim \mathcal{N}_{[0,+\infty)}(0, 10000)$, where $\mathcal{N}_{[a,b]}$ is a truncated Normal distribution with support in $[a, b]$, and $P(k_{cg} = \text{on}) = 0.5$. For τ_{cg} we define a mixed-type distribution with two masses of value 0.1 on $\tau_{cg} = 0$ and $\tau_{cg} = \infty$, respectively, and with probability 0.8 we have $\log \tau_{cg} \sim N(0, 100)$. The two masses are used to locate the cell in the steady states. The prior on t_{0g}^{off} must depend on the set $\{\tau_{cg}, k_{cg}\}_{c=1}^{n_c}$ since

$$t_{0g}^{\text{off}} \geq \max\{\tau_{cg} | k_{cg} = \text{on}, c = 1, \ldots, n_c\} = \tau_{g,\max}^{\text{on}} \tag{5}$$

hence, we assume the following: $\log t_{0g}^{\text{off}} | \{\tau_{cg}, k_{cg}\}_{c=1}^{n_c} \sim N_{[\log \tau_{g,\max}^{\text{on}}, \infty)}(0, 100)$ To avoid identifiability issue, parameter β_g is fixed to 1.

Simulation setting We simulate data with $n_g = 5$, $n_c = 3600$, and γ_g randomly generated in $[0.5, 0.8]$, α_g^{off} in $[0.05, 1]$, α_g^{on} in $[2, 5]$, and η_g in $[0.01, 0.1]$. These intervals have been chosen such that the empirical distribution of the raw data mimics the one of the real pancreatic dataset used in [1]. There are different issues when simulating parameters τ_{cg}, t_{0g}^{off}, and k_{cg}. Indeed, we have to satisfy equation (5) and, to have realistic and diversified locations of $(s_g(t_{cg}), u_g(t_{cg}))$, as well as $(s_g(t_{0g}^{\text{off}}), u_g(t_{0g}^{\text{off}}))$ close to SS_g^{on}, SS_g^{off} or in between. To achieve this, a sequence of if/else conditions were implemented, however for the sake of brevity these details are omitted. We run the model for 100000 iterations, with thin 40 and burning 10000, having then 2250 posterior samples.

Discussion of the results The posterior distributions of different τ_{cg}, as shown in Figure 2, reveal that there are minimal differences between them. Additionally, the posterior distribution is similar to the prior distribution. Comparable results are obtained when changing the prior distribution, which are not presented for the sake of brevity. It should be pointed out that, under this setting, for $\log \tau_{cg} < -5$ and $\log \tau_{cg} > 5$ the coordinates $(s_g(t_{cg}), s_g(t_{cg}))$, for all $c = 1, \ldots, n_c$ and $g = 1, \ldots, n_g$, are approximately equal to the steady states with a difference of order 10^{-3}.



(a) (b) (c)

Figure 2: Gene- and cell-specific τ_{cg} model. Prior (red dashed line) and posterior (black solid line) of the logarithm of τ_{cg} for three cells. The vertical line represents the true value.

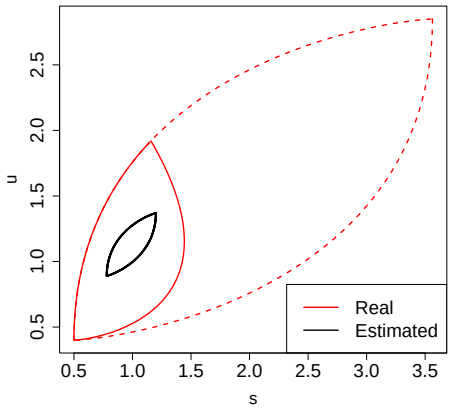


Figure 3: Phase plot in the space (s, u) for a given gene. The solid lines show the solutions (3) obtained with the real parameters (red) used to simulate the data and the posterior means (black). The dashed lines correspond to the potential dynamic if the steady state $\mathrm{SS}_g^{\mathrm{on}}$ is reached. For the estimated solution, the dashed and the solid line coincide.

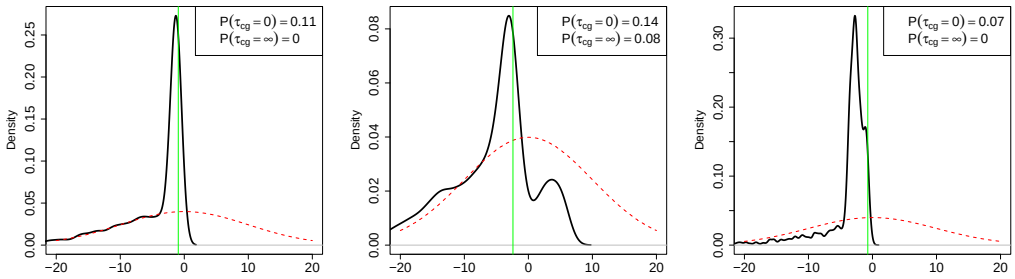
This illustrates the difficulty in estimating these parameters and emphasizes the importance of considering the full distribution rather than just point estimates. This issue cannot be detected with the original scVelo implementation, which only provides point estimates as output. As a consequence of this weak identifiability, all the other parameters are wrongly estimated, i.e., the associated 95% credible intervals do not contain the true value, and the entire structure in the space (s, u) describing the time dynamic, is very different from the real one, as shown in Figure 3.

Simulated examples demonstrate that estimating the parameter τ_{cg} and other unknowns in the model is feasible when we have repeated measures for each (c, g). The results obtained with $n_c = 8$, $n_g = 5$ and 450 repetitions are shown in Figure 4 as an example. However, in the case of single-cell data, it is not possible to have true repetitions since the variable t_{cg} is unobservable/unknown. Instead of repetitions, a mixture model can be used where data share a common coordinate in the space (s, u). These results suggest that this approach may be a viable direction.

5. Conclusions and further developments

This study highlights the issues present in the current formalization of the scVelo model. Specifically, we focus on the weak identifiability of the variable τ_{cg} and its impact on the estimation of other parame-



(a) (b) (c)

Figure 4: Repeated measurements model. Prior (red dashed line) and posterior (black solid line) of the logarithm of τ_{cg} for a three genes. The vertical lines represent the true values.

ters. To address this, we introduce a new Bayesian version of scVelo and evaluate its performance using synthetic data. Upon inspection of the posterior distribution of τ_{cg}, we observe that, for a given gene, all distributions are comparable and closely resemble the prior distribution, indicating weak identifiability of the parameters.

In addition, we propose a potential solution to overcome the identifiability problem, which shows promising results in our initial investigations. We are pursuing this direction as a possible way forward in improving the performance of scVelo.

Abstract

Damage identification analyses are fundamental to guarantee the safety of civil structures. They are often formalised as inverse problems whose solution ignores any source of uncertainty that could be accounted for by using appropriate statistical models. Unfortunately, these models often exhibit an intractable likelihood function. We propose quantifying uncertainty through a fully Bayesian approach based on Approximate Bayesian Computation (ABC), a class of methods that overcome the evaluation of the likelihood and only require the ability to simulate from the model. Furthermore, we suggest a strategy to reduce ABC computational burden using Neural Networks. Finally, we test the method at work on a damaged beam to discuss its strengths and weaknesses.

Keywords: Damage Identification, Uncertainty Quantification, Approximate Bayesian Computation, Neural Networks

1. Introduction

In the civil engineering field, structural monitoring and damage detection techniques have received growing attention since they are paramount for tasks of control and preservation. Damages modify the mechanical properties of a civil structure and can cause changes in the dynamic behaviour of the system described by natural frequencies and modal shapes. Thus, these quantities can be exploited to infer the existence of structural damages, their location and their entity. A common practice is addressing the issue as an inverse problem: optimal values of the parameters describing the properties of the system are found by minimising a distance measure between the experimental data (e.g., observed frequencies) and data produced by a Finite Element Model (FEM) - i.e. a numerical method for solving the differential equations that describe the dynamic behaviour of the system as a function of the mechanical parameters and the structural configuration. Once solved the inverse problem, one can evaluate whether there have been variations of the mechanical properties carrying pieces of information on the location and the entity of the damage. However, such a procedure ignores all the sources of uncertainty - e.g. unobserved characteristics of the system, variations of the material properties as well as measurement errors. It follows that predictions about future dynamics are taken as assured. A probabilistic damage assessment allows for taking into account different sources of uncertainty. More specifically, a Bayesian probabilistic damage identification procedure provides posterior distributions over the location and the entity of the

damage, thus avoiding a false sense of confidence. Moreover, posterior predictive distributions enable an evaluation of the uncertainty around the prediction of the future dynamic behaviour.

In the literature, there are few works addressing the problem of incorporating uncertainty in damage identification (7; 9, among others). They rely on strong assumptions and describe the relationship between observed data and mechanical properties through simple models that imply tractable likelihood functions. Implementing likelihood-free methods is a possible strategy to provide a finer description of reality. They allow a straightforward integration of the uncertainty induced by latent variables and variables having complex dependence structures. In (4; 3) the authors resort to Approximate Bayesian Computation (ABC), a likelihood-free approach, however, they do not adopt a fully Bayesian perspective and aim only at finding point estimates of the model parameters.

This paper is aimed at giving a formal statistical definition of the probabilistic model for damage's location identification building upon a proper framework for uncertainty quantification (5; 2). Furthermore, we describe a strategy to get fully Bayesian estimates using a suitable ABC algorithm. In particular, we propose a procedure based on a surrogate generative model derived via Neural Networks. We speculate that this approach will provide a flexible tool that allows straightforward integration into the model of many sources of uncertainty.

2. Bayesian Inference in models for uncertainty quantification

Let us denote by θ the variable object of our inference, that is the location of a damage in a structure, and by y_0 some observed characteristics related to its dynamic (e.g., the frequencies). Our aim is to derive the posterior distribution $\pi(\theta \mid y_0) \propto \pi(\theta)p(y_0 \mid \theta)$, given the prior distribution, $\pi(\cdot)$, and the likelihood function, $p(\cdot \mid \theta)$. [1] In this framework, the evaluation of posterior quantities requires a simulated inference approach because many unobserved variables interact with the damage's location and affects its relation with the frequencies. These variables must be included in the model as latent variables.

Let x be the latent variables and $\xi = (\theta, x)$ the vector of all the unknown quantities. In principle, Monte Carlo (MC) or Markov Chain Monte Carlo (MCMC) methods allow us to get samples from a posterior distribution defined on an augmented space: $\pi(\xi \mid y_0) = \pi(\theta, x \mid y_0) \propto \pi(\theta, x)p(y_0 \mid \theta, x)$. However, here even the likelihood function $p(y_0 \mid \theta, x)$ is analytically intractable and its evaluation may be computationally demanding. To give insights into the reasons for this intractability, we provide a formal statistical definition of the model for uncertainty quantification (2). The key elements of the model are:

- $y^R(\theta)$: the vector of real values of the frequencies when the damage's location is θ;
- $y^M(\xi)$: the output of a simulator that reproduces the real process. The simulator may be a numerical model for partial differential equations (e.g. the FEM) and takes both θ and x as inputs;
- $b(\xi) = y^R(\theta) - y^M(\theta, x)$: the discrepancy between the model and the reality. It may come from incorrect or missing physical characteristics, as well as the simplification of the problem needed to put it in a digital framework (e.g. space discretisation in FEM).
- $y^E(\xi) = y^M(\xi) + \eta(\xi)$: the emulator. It is an approximation of the simulator and $\eta(\xi)$ is the discrepancy between the simulator and the emulator.
- $y_0(\theta) = y^M(\xi) + b(\xi) + e$: the observed data. They typically differ from the real process for some measurement errors e.

In this scenario, the probability $p(y_0 \mid \xi)$ can be retrieved from $p(y_0, b, e \mid \xi)$ via marginalisation:

$$p(y_0 \mid \xi) = \int\int p(y_0 \mid e, b, \xi)p(e, b \mid \xi)de\,db = \int\int \delta_{y_0}(y^M + b + e)p(e)p(b \mid \xi)de\,db \qquad (1)$$

where $\delta_{y_0}(\cdot)$ is the Dirac measure. Note that Eq (1) comes from the assumption that measurement errors

[1] For the sake of simplicity, our notation does not discriminate between probability density functions and mass functions that can be distinguished from the context.

are independent of ξ and b, and from the fact that the simulator is a deterministic numerical model that, once a vector ξ is given as input, always returns the same output $y^M(\xi)$.

MC and MCMC algorithms for the computation of the $\pi(\xi \mid y_0)$ would involve multiple point-wise evaluations of $p(y_0 \mid \xi)$ and each of them requires the solution of the integrals in Eq (1). The computation of $y^M(\xi)$ makes exact calculations infeasible and numerical approximations are computationally demanding: a single evaluation of the integrals would require many runs of the FEM. This motivates the choice of simulation-based methods, such as Approximate Bayesian Computation (ABC).

3. ABC for probabilistic damage identification

The origin of ABC methods can be traced back to (11; 8) but, in the last twenty years, huge progress has been made in this field. For a comprehensive description of the method, we refer the reader to (10). The key idea of the basic ABC algorithm is to get samples from an approximate posterior distribution by converting samples from the prior into samples from the posterior in three steps: 1) generate N parameter values from the prior distribution $\pi(\cdot)$; 2) generate simulated processes $y_i \sim p(\cdot \mid \theta_i)$ for $i \in \{1, ..., N\}$; 3) retain only parameter values θ_i such that $d(y_i; y_0) \leq \epsilon$, where $d(\cdot\,;\,\cdot)$ is a distance function and $\epsilon \geq 0$ is a tolerance threshold.

The algorithm avoids the evaluation of the likelihood function. It only requires the ability to produce samples from $p(\cdot \mid \theta)$ using a *generative model* that can be thought of as a computer code which takes parameters θ as inputs, performs stochastic calculations that involve latent variables x, and outputs simulated data y. However, this solution to the problem of the intractability of the likelihood comes at the cost of introducing at least one source of approximation in the estimate of the posterior distribution. In particular, the quality of the approximation depends on the tolerance threshold ϵ: the approximate posterior distribution converges to the true posterior distribution as $\epsilon \to 0$.

Besides the basic ABC algorithm, many other sampling schemes have been proposed – see (10, Ch 4). Here, we resort to a sampling scheme inspired by the Population Monte Carlo ABC (PMC-ABC) presented in (1). It is displayed in Algorithm 1 where $K_j(\cdot \mid \theta_i^{j-1})$ is a Normal distribution with mean θ_i^{j-1} and variance equal to twice the weighted empirical variance of $(\theta_1^{j-1}, ..., \theta_N^{j-1})$, and α is a tuning parameter between 0 and 1. The output of the algorithm is a sample from the following approximate posterior distribution

$$\pi_\epsilon(\theta \mid y_0) = \pi(\theta) \int \mathbb{1}\{d(y; y_0) \leq \epsilon\} p(y \mid \theta) dy$$

where $\mathbb{1}\{\cdot\}$ denotes the indicator function and $\epsilon = \epsilon_M$ is the value of the threshold adaptively chosen.

Algorithm 2 describes the generative model used to get samples from $p(\cdot \mid \theta)$. Note that each run of the generative model involves a call to the FEM. Here we propose a strategy to reduce the computational cost of this procedure. In particular, we replace the simulator with a less expensive emulator based on Neural Networks.

Algorithm 1 ABC-PMC

Sample $\theta_1^0, ..., \theta_N^0$ from $\pi(\cdot)$.
Sample y_i using Alg. 2 giving θ_i^0 as input for each $i \in \{1, ..., N\}$.
Let $d_i = d(y_i; y_0)$ for each $i \in \{1, ..., N\}$.
Put ϵ_1 equal to the α-quantile of the distribution of $(d_1, ..., d_N)$.
for $j = 1, 2, \ldots, M$ **do**
  Set $i = 0$
  while $i < N$ **do**
    Sample θ^* from $q_j(\cdot) = \frac{\sum_{i=1}^{N} w_i^{j-1} K_j(\cdot|\theta_i^{j-1})}{\sum_{i=1}^{N} w_i^{j-1}}$.
    Sample y^* using Alg. 2 giving θ^* as input.
    Compute $w^* = \frac{\pi(\theta^*)}{q_j(\theta^*)} \mathbb{1}\{d(y^*; y_0) \leq \epsilon_j\}$.
    if $w^* > 0$ **then**
      Let $\theta_i^j = \theta^*$, $d_i^j = d(y^*; y_0)$, $w_i^j = w^*$ and $i = i + 1$.
    end if
  end while
  Put ϵ_{j+1} equal to the α-quantile of the distribution of $(d_1^j, ..., d_N^j)$.
end for

Algorithm 2 Generative model

Take θ as an input.
Sample x from its prior distribution.
Compute $y^M(\theta, x)$ using the simulator (FEM) or the emulator (ANN).
Sample $b(\xi)$ and e from their distributions.
Return $y = y^M(\xi) + b(\xi) + e$.

Approximating the simulator using Neural Networks Artificial Neural Networks (ANN) are computational models that use experience to learn functions. We resort to *feedforward neural networks* which process information from inputs to outputs through intermediate computations and without feedback connections. The basic processing unit of an ANN is the *neuron* that receives inputs from other neurons and computes its own output using a linear combination based on previously defined weights and bias, and an *activation function*. Neurons are then arranged in layers: the first layer is called the input layer, the last layer is the output layer and in between layers are the hidden layers that determine the depth of the network. The network learns by adjusting weights and biases to minimise the prediction error, which is the value of the loss function that quantifies the difference between the output of the network and the output taken from a training set.

In the case of the probabilistic damage identification, the relation that links the unknowns, ξ, to the simulated process, y^M, is specified by a deterministic function reproduced using the FEM. Thus, an ANN can be used as an emulator that replaces FEM in Algorithm 2. The ANN takes as input layer ξ and gives as output layer an emulated process $y^E(\xi)$. To train the ANN we need a training set built by considering S vectors, $\xi^1, ..., \xi^S$, giving them as input to the FEM, and taking S simulated process as output. It follows that our approach gives a computational advantage as long as S is smaller than the number of simulations from the generative model in Algorithm 1.

4. Simulation study

To illustrate the proposed method, we considered the example of a simply supported beam modelled by using the commercial code ANSYS®. The total length of the structure is 5000 mm and the cross-section is a IPE240 steel profile – see Figure 1.

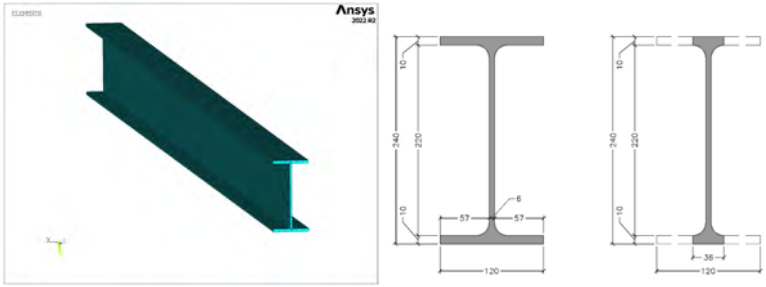

Figure 1: Discretisation in ANSYS®(left) and cross-section (right) of the beam without and with damage.

The induced localised damage is imposed by cutting the beam flanges. This damage is reproduced in ANSYS®by reducing the section shown in Figure 1. The effects, in terms of observable dynamic characteristics of the beam, are a reduction of the frequencies and changes in modal shapes. Here, we want to infer the location of the damage, $\theta \in (0, 5000)$, using three observed frequencies, $y_0 = (f_1, f_2, f_3)$ expressed in Hz. The latent variable X represents the uncertainty on the restraint conditions of the beam, in particular on its location. We assumed $\theta \sim \text{Uniform}(0, 5000)$ and $\frac{X}{100} \sim \text{Exponential}(\lambda = 1.5)$. Measurement errors $e = (e_1, e_2, e_3)$ are distributed as a Multivariate Normal with mean $\mu_e = (0, 0, 0)$ and covariance matrix $\Sigma_e = 0.15^2 I_3$. We included in the model also a random discrepancy $b \sim \text{Uniform}(-0.2, 0.2)$.[2]

In our simulation study, the observed data $y_0 = (32.63, 96.73, 208.61)$ have been produced running the FEM assuming $\theta^{\text{true}} = 2423.8$ and $x^{\text{true}} = 6.18$ (values generated at random). We trained the ANN with 2 inputs (θ and x), three hidden layers with 50 neurons, and 3 outputs (f_1, f_2 and f_3). We used the Relu activation function for all the layers, the Mean Square Error (MSE) as loss function, and Adam (6) as the optimization algorithm. Our training set has size $S = 160\,000$. The performance of the trained network is good enough to consider negligible the discrepancy between the simulator and the emulator (MSE $= (1.09 \cdot 10^{-5}, 4.88 \cdot 10^{-6}, 9.48 \cdot 10^{-6})$ and $R^2 = (0.99, 0.99, 0.99)$ computed on a test set).

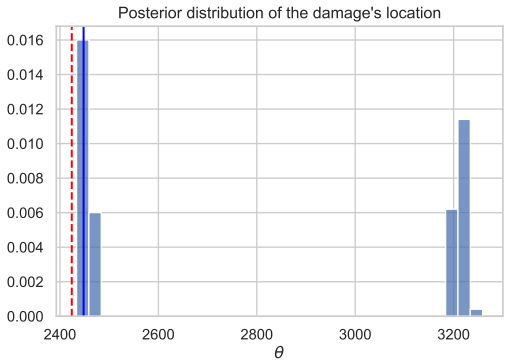

Figure 2: Posterior distribution of θ with θ^{true} (red line) and θ^{MAP} (blue line).

	Posterior predictive distributions		
	mean	s.d.	95% CI
f_1	38.60	2.22	32.88; 41.03
f_2	113.31	6.26	97.70; 120.85
f_3	243.56	14.41	210.60; 263.30

Table 1: Mean, standard deviation and 95% credible intervals of the posterior predictive distributions.

We ran Algorithm 1 for 20 minutes with $N = 500$ and using the Euclidean distance. In the given budget of time, the final number of iterations is $M = 22$, and all of them required more than 100 000 calls to the generative model to accept 500 parameter proposals. The final threshold is $\epsilon_M = 0.07$.

Looking at Figure 2 we can see that the Maximum a Posteriori estimate of the damage's location, $\theta^{\text{MAP}} = 2448$, is very close to θ^{true}. Note that the FEM discretises the beam using meshes of size 50 mm, meaning that the difference $\theta^{\text{MAP}} - \theta^{\text{true}} = 24.2$ mm can be ignored since it is too small to be detected by the model. The bimodality of the posterior distribution is due to the symmetry of the beam. However, in the reality this perfect symmetry does not occur, thus we speculate that posterior distributions based on real data will be unimodal. The uncertainty about the damage's location has been propagated to future frequencies by computing posterior predictive distributions described in Table 4. The variability of the distribution increases moving from the first to the third frequency. In a more realistic framework, the uncertainty would be even larger and ignoring posterior predictive distributions may lead to the observation of completely unexpected scenarios.

5. Discussion and future work

In this work, we investigate the use of a formal model for uncertainty quantification in the identification of damages in civil structures. A probabilistic approach is essential to be aware of the uncertainty

[2]Prior distributions have been set exploiting information coming from preliminary investigations as well as the experts' knowledge.

around estimates and predictions and to conduct a more conscious process of decision-making. However, including different sources of uncertainty often leads to complex probabilistic models with an intractable likelihood function. We propose a likelihood-free approach to provide fully Bayesian estimates. The presented ABC method overcomes problems related to the computational cost of the simulator resorting to an emulator. In particular, we exploit the deterministic nature of the function that links parameters and latent variables to the frequencies and propose an emulator based on ANNs.

Our exploratory analysis showed that the method is able to infer the damage's location and gave some insights into the uncertainty of future frequencies pointing out the importance of considering posterior predictive distributions. This aspect makes the proposed framework particularly relevant in the structural health monitoring field.

One of the main strengths of the proposed approach is its flexibility. In our example, we assumed simple Gaussian and Uniform distributions over the measurement errors and the bias of the model. However, the method allows one to straightforwardly replace them with more complex random variables – e.g. considering Gaussian processes (5). In fact, we need only the ability to produce simulations from the assumed distributions and no analytical evaluations are required. Furthermore, in this framework, the statistician can take full advantage of the expert knowledge in the specification of the prior distributions and the definition of a model that is as close as possible to reality.

The major drawback of the method is that it still requires a large number of calls to the FEM to build a training set for the ANN. However, in our example, the size of the training set turned out to be far lower than the number of simulations needed in the PMC-ABC procedure. Furthermore, the use of the trained emulator is not limited to the implementation of the PMC-ABC algorithm since it can be integrated into the health monitoring system which, otherwise, would call the FEM many times.

Future work should focus on the application of the method to real data and on the extension to more complex structures such as bridges, towers, etc. Moreover, we plan to define a more sophisticated model that allows inferring also the presence/absence and the entity of the damage.

Estimation of scientific productivity with a hierarchical Bayesian model

Maura Mezzetti[a] and Ilia Negri[b]

Abstract

A new measure for the scientific productivity of researchers is introduced. Through a Bayesian hierarchical model, the productivity of Italian researchers is reconstructed and used to understand whether within Italian academics gender difference can be assessed. The new measure takes into account not only the quantity and quality of the scientific production but also the time that elapses between two successive research products, obtaining a productivity curve for each male and female scientist. The results show a persistence of women in the lower levels of the university career even if their scientific productivity is greater than that of their male colleagues.

Keywords: Piecewise Bayesian linear model, Research evaluation, Gender gap

1. Introduction

In gender study there exists a major stream of literature that demonstrates the presence of a so-called *productivity gap* in favor of men (1). The lesser productivity of female researchers has been underlined for different disciplines and countries (6; 4). Moreover women academics tend to advance in career at a slower pace and are rewarded less than males (10). Differences in the high tail of the productivity distribution, the so call *top* or *star* scientists, have been studied by (3) and (2). From these studies emerges the idea that to asses about gender differences in productivity, not only the mean value of the productivity has to be considered but the entire distribution along the entire period of productivity has to be investigated. Moreover, not only the quantity, but also the quality of the research output needs to be taken into account. In the next section a measure of individual research productivity is introduced. A curve of productivity is defined that takes in account not only the quantity and quality for any publication but also the time elapse between two successive publications along all the academic career of any scholar. The obtained raw curve is smoothed through a Bayesian hierarchical model that estimates the productivity curve using a piecewise linear regression model as a function of time. The different slopes correspond to different levels of productivity of the researchers, while the instants of time where the slope changes correspond to the different phases that can be supposed the individuals face along the entire period of observation. The curves estimated in this way allow to observe what happens at the lowest levels of the university career. In fact, we are going to investigate what happens among permanent researchers, a figure of tenured assistant professor present only in Italy, where we observe a sort of stagnation of researchers who do not progress to the higher level of the academic hierarchy. To better understand the reasons of this stagnation the reconstruction of the productivity along

the entire career of all academicians at any level is done through the proposed hierarchical Bayesian model. The hierarchical Bayesian model permits to estimate the entire distribution of the productivity and furthermore to analyze the scientific productivity by gender and by position. The estimated model seems to confirm that gender differences are present in the lower tail of productivity distribution, giving rise to a sort of pocket of stagnation.

2. A researcher productivity's measure

Evaluation of research productivity and its impact on the scientific community is extremely difficult to achieve, because the multifaceted nature of evaluation, the lack of standard terminology, and the heterogeneity of research fields make hard to identify a preferred model of measurement. As a matter of fact, research productivity in academia is defined differently among academic fields but most of the measures involved to this purpose are related to publications in books and journals. A commonly used measure of research productivity is publication rate (9). Publication rate takes into account only quantity of publications and not quality. As a measure of scientific impact, or quality, a wide range of indicators and metrics are available and their choice depends on considerations of their strengths and limitations. The most widely used research output indicators are based on bibliometric indices and citation parameters (e.g. number of publications in peer-reviewed journals, impact factor and H-index). In this study the productivity for each scholar is measured not only through the number of publications but also considering the impact of the publication on the scientific community. In this direction, for sake of simplicity, let us measure the productivity considering only publications, but the same approach can be used for any product that define the scientific production of a scholar. Let $t_1, \ldots, t_n$, denote the time (in year) when the n papers of a scholar are published. To each publication is associated a weight p_i that represent its quality. The productivity curve is given by the cumulative score, defined for $0 \leq t < T$ as $c(t) = \sum_{i=1}^{n} p_i I_{[t_i \leq t \leq t_{i+1}]}$, where $t_1 = 0$ and $t_{n+1} = T$. Here T represents a hypothetical last moment by which all scientists still manage to publish a paper. A hierarchical Bayesian model is defined and estimated (5) as follows. The *productivity* observed can be characterized by different phases and can be reasonably described by a piecewise linear model with time as independent variable and cumulative score as dependent. In our approach a statistical framework based on a piecewise linear regression with random breakpoints is provided for each subject, in order to allow to describe the productivity along all the career life. The basic idea behind this approach is that each scientist experiments different phases during the career. The *production* is not constant in time due to many factors, as for example maternity leaves or periods committed to governance duties, that we do not have information on. Based on the cumulative curve of the production of any scholar, the Bayesian piecewise linear linear model is able to estimate different slope values that represent different rate of productivity for any scholar. Let Y_{it} be the cumulative score for subject i at year t, ($t = 0$ for the year of the first publication) we assume the following model: $Y_{it} \sim N(\mu_{it}, \sigma_i^2)$ where $\mu_{it} = \alpha_i + \beta_i^0 t + \sum_{h=1}^{H} \beta_i^h (t - t_i^h) I_{\left[t > t_i^h\right]}$. Here for each subject i, parameters β_i^h are the individual slopes, the parameters t_i^h are the individual breakpoints and H is the fixed number of different phases can be supposed the individuals face during all the period of observation. This is fixed and chosen by the researcher. According to the Bayesian paradigm the priors for the individual regression parameters are chosen appropriately. According to this model the eventual change in *scientific production* speed is estimated from the data and can be different for every subject. For any i, the estimated curve μ_{it} represents a proxy of the *scientific production* of researcher i, along the time of his/her entire career t. The estimated slopes of the piecewise linear regression represent the speed of the production. An average of the slopes weighted with time is considered the *average speed* of production. An advantage of a hierarchical Bayesian model is the possibility to fit a second level curve. The model is thus producing, on one hand, an individual curve and, on the other hand, an overall curve. The second level can be specified according to a partition of the subjects in G groups. The partition can be defined either a priori o through a cluster analysis. In the second level the same breakpoints for all the subjects as to be considered. So, in the estimated global curve, for each group, not only the number of breaks are the same for all the subject, but also their location. In the application they are chosen reasonably according to the development of a classic academic career.

3. Data

Data are extracted from three different data sources and combined. First, for any scholar working in an Italian university, the academic positions, gender, university and disciplines are available from the Ministry of Education, University and Research website, from 2000 to nowaday. Then from Scopus the publications of each researcher during the entire career were downloaded. Data analysed in the paper refer to March 2021, there were 466 individuals covering a position in Statistics. Finally each publication is linked to the database of the Italian National Agency for the evaluation of Universities and Research institutes (ANVUR) that provides a score of the journal where the paper is published according to four indicators. See (8) for the details. The cumulative score Y_{it} for each schoolar i in year t is computed as follows. If J articles were published in the year t by the researcher i, a score p_j is associated with each publication and y_{it} is given by the sum of the scores of all the publications published in that year.

4. Results

Following the approach of a piecewise linear regression illustrated in Section 2, a line with four linear trends, $(\beta_i^0, \beta_i^1, \beta_i^2, \beta_i^3)$, is estimated with different estimated break points (t_i^1, t_i^2, t_i^3) for each researcher i. The posterior estimates are the average values of the 5000 MCMC iterations after 50000 burn-in iterations. The choice of $H = 3$ is done according to the idea that the entire period of productivity can be split in four periods. Precisely: an initial part, in the first years of the career, where the scholar starts to produce, followed by a second period, where the scholar consolidate is productivity, then a third period characterized by the maturity of the scholar, and a final period till the end of the career. The posterior estimates result quite robust to the choice of hyperparameters. When a change in the linear trend is observed, it corresponds to a change in the production, either a deceleration or an acceleration of productivity. The punctual slope can be interpreted as the increase of the *productivity score* in one year.

4.1 Tenured Assistant Professors

We focus our analysis on tenured assistant professors of the research area Statistics, classified as SECS/S-01 in Italian university system. In Italy positions for tenured assistant professors were not opening anymore after 2011. At the end of 2021 in the area of Statistics there were 51 tenured assistant professors. The tenured assistant females are more than males but if this gap were small at the early 2000's than it increases till the 40% of 2021. Figure 1 (left) shows the *scientific production* along the entire career of 44 Tenured Assistant Professors, reconstructed with a piecewise linear curve according to model presented in Section 2. We have to exclude 7 of these subjects with null publication score because the model cannot be estimated for them. Observing the curves it is evident that red curves, corresponding to female researchers, tend to reach higher values: female tenured assistant professors obtain higher scores in publications respect to male tenured assistant professors. This is confirmed fitting a second level curve within each group. Indeed, we add a second level in the model, that considers an average model for two groups, men and women. As mentioned at the end of Section 2, we need to fix the change points of time. We assume three fixed change-points in $(5, 10, 20)$. This choice means we suppose that each scientist can experience a change in the speed of his/her production after 5, 10 and 20 years after the start of his/her career. These points are a reasonable choice considering the typical career of an academic scholar, (7). The chosen points represents an average of the time where scholars usual face with a change in production. The estimated second level curves are shown in Figure 1 (right). The two curves estimated for tenured assistant professors are separated, the curve for female is higher than the corresponding curve for male. The curves represent the growth in research performance for male (blue) and female (red). Difference between gender can easily be observed. Women show to better perform in terms of productivity along all the career. At the end of the observed time, female researchers reach an average value of *productivity* of 63 versus an average male values of 25. The top 20% of most productive tenured assistant professors are all women. The posterior density of parameters shows that the intercept is superior for women. The biggest difference is observed in the parameter representing the change of

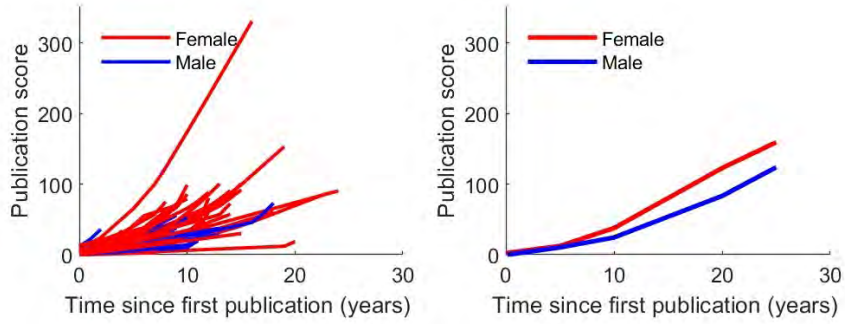

Figure 1: On the left curves of publication score for 44 Tenured Assistant Professors. On the right Second level curves of publication score for the two groups. Red for female, blue for male

slope after 5 years. The mean value of this parameter within men is equal to 0.63, while the mean value of the same parameter within women is 2.97. We analysed data regarding the qualification to associate professor, the necessary title to get promoted to an higher level in academia. The waiting time elapsed from getting the national qualification to be promoted associate professor is about the same between gender, more specifically waiting time from national qualification to associate professor is 1.63 years for men and 1.73 for women. In the residual group of 44 tenured assistant professor, twelve of them (27%) got the habilitation. Between them 10 (83%) are women. Between the 32 that did not take the habilitation 20 (63%) are women. The chi-square test cannot reject the hypothesis of independence between gender and getting the habilitation. A logistic model that relates ability to get the national qualification with the final score within tenured position by gender reveals a significant effect only for women, suggesting that the women should work harder to get rewarded.

5. Conclusions

All these facts seem to confirm that the lower tail of distribution of scientific performance is affected by gender difference as pointed out in (1). Women tenured assistant professors continue to work and their productivity is greater than that of men, but they receive promotion less than their male colleagues. So we can argue that it exists a pocket of stagnation for women that cannot leave this position. The analyses for the other levels of the academic career do not show the same differences by gender observed for the tenured assistant professors, both for the second level estimated curves and for the posterior distributions of the parameters. Further analysis could be done including information about application for a higher position.

Abstract

We investigate the trend of heat waves in four different locations in Europe. In particular, we employ a flexible semiparametric nonlinear model to detect possible accelerations in the phenomenon's growth. Heat waves are expected to increase in frequency and intensity globally, but the geographical heterogeneity is substantial, thus making local analysis relevant. Our results confirm the expectations in that we detect a significant nonlinear increase in the frequency of heat waves; on the other hand, the intensity appears constant.

Keywords: heat wave, knot locations, TLB, Bayesian inference

1. Introduction

The study of climate is the study of the average behaviour of weather. Analyzing the global mean temperature (or a global mean temperature) is a typical example and has been thoroughly discussed (4). The global mean temperature, however, does not exist: it is an artificial construct useful to summarize the climate's state but not something that anyone experiences. Alongside the studies focusing on general behaviour, it is also relevant to investigate more local phenomena that have a direct impact, such as heat waves. Heat waves (HW) can harm the health of the human population, crop yield, energy demand and production, and economic activity. It is also relevant to point out that while the fact that the world is experiencing an increase in the global temperature is clearly recognizable and acknowledged, this does not necessarily translate into an increase of HWs at every location and the same pace. The specificities of the local climate and the fact that the extreme behaviour does not necessarily follow the same trend as the mean may lead to different behaviours (4; 5). In this work, we aim to assess whether some locations in Europe experienced an increase in HW and whether there has been an acceleration in the most recent period. Several solutions exist to model a nonlinear relationship between two quantities. Spline functions, piecewise polynomials with a fixed degree whose joint points are called knots, are one of the most flexible and efficient. Within the various approaches to specifying and estimating a spline function, we employ the method proposed by (2) since it explicitly models the position of the knots, which would correspond to changes in the pace of the trend of the phenomenon. There are no universally agreed criteria to define an HW. We will not discuss the various possibilities and consider a relatively standard definition: a heat wave occurs when the daily maximum temperature is above a daily varying threshold (precisely, the 90th percentile of the daily maximum temperatures observed in a window of 15 days during a reference period, here 1961-1981) for at least three days.

2. Methods

The presence of a piecewise linear effect of the covariate on the response variable is evaluated through a linear spline function with free knots. Each knot location, treated as a parameter, detects a change in the slope of the linear spline and a discontinuity on the first–order derivative. In the generalized linear model (GLM) under the Bayesian framework, the probability distribution of the response and the link function is chosen accordingly to the selected response variable. In contrast, the linear predictor specification is common to all the presented models. Without loss of generality, we define the linear predictor for the i-th observation, as

$$\eta_i = \beta_0 + \beta_1 x_i + \sum_{k=1}^{K} \gamma_k (x_i - \xi_k)_+, \tag{1}$$

for $i = 1, \ldots, n$, where x_i is a continuous predictor, β_0, β_1, and γ_k, for $k = 1, \ldots, K$, are the spline coefficients, ξ_k represents the location of the k^{th} knot and K is the total number of knots. The function $(x - \xi_k)_+$ is the truncated linear function defined as $(x - \xi_k) I(x \geq \xi_k)$. By construction, the truncated linear basis (TLB) may be characterized by a high correlation among basis functions, sometimes leading to estimation problems. Therefore we suggest applying this methodology when a limited number of change points can be assumed. In this framework, the ease of interpretability of the knot locations and the spline coefficients is the main advantage of choosing the TLB representation.

Following the default prior definition as in (3), the prior distributions of the spline coefficients and the dispersion parameter are chosen as

$$\beta_0 \sim N(g(m_y), 10 s_y), \quad \beta_1 \sim N(0, 2.5 s_y / s_x), \tag{2}$$

$$\gamma_k \sim N(0, 2.5 s_y / s_{\xi_k}), \quad \sigma \sim \exp(1/s_y) \tag{3}$$

where $g(.)$ is the link function, m_y and s_y are equal to the mean and standard deviation of the response variable in the Gaussian case, and $s_y = 1$ otherwise. Also, s_x is the standard deviation of the predictor, and s_{ξ_k} is computed on the k-th truncated linear basis term. These prior distributions allow us to handle the different scales of the variables automatically. The autoscaling characteristic is appealing in the TLB situation; indeed, the closer a knot is to the upper bound of the predictor, the smaller the variance of the associated basis element. In Sect. 3, we consider two GLMs: a Poisson and a Gaussian with canonical link function. The prior distribution of each knot location ξ_k is set as Uniform on the range of the predictor. When more than one knot is assumed, knot locations are subject to order constraints to ensure identifiability.

Lastly, considering the number of knots as a parameter requires applying transdimensional techniques such as the Reversible-jump Markov chain Monte Carlo. However, due to the limited number of assumed knots and the simple model specification, we decided to fit several models with fixed but increasing numbers of knots. The final number of knots is selected through a model's diagnostic checks and comparing the approximate leave-one-out cross-validation (LOO) information criterion, a fully Bayesian equivalent to the AIC (7), and the weights associated with model averaging via stacking of predictive distributions (8).

3. Results

We compute yearly summaries for the period 1950-2021 of HW phenomena in four geographic locations; in particular, we considered the following grid cells (long $\times$ lat): A: $[26, 27] \times [68, 69]$, located in Finland; B: $[-2, -1] \times [53, 54]$, located in UK; C : $[9, 10] \times [45, 46]$, located in Italy; D: $[44, 45] \times [56, 57]$, located in Russia. For the purpose of this work, an HW is defined as a period of at least three days in which the maximum daily temperature exceeds the 90–th percentile of the distribution of the maximum temperature in a window of 15 days in a reference period. The temperature time series were

obtained from the Berkeley Earth Surface Temperature dataset (6). We consider summer HWs, that is, HW occurring between May and September of each year.

An HW is a multidimensional phenomenon characterized by duration and intensity; in order to keep into account this multidimensionality, multiple yearly summaries are considered, in particular: the count, i.e., the number of observed heat waves; the duration, i.e., the sum of the duration of all HWs in that year; the maximum duration, i.e., the duration of the longest HW for that year; the average intensity, i.e., the average temperature above the threshold during HWs in that year; the maximum intensity, i.e., the temperature above the threshold in the HW with the maximum observed excess. We model the first and the third using a Poisson regression model with a log link function, and the others assuming a Normal distribution.

We run four chains of 2000 iterations each using the NUTS sampler through Rstan interface (1). Inference is based on the simulation's second half, that is, 4000 final simulations. LOO results and stacking weights agree on the model selection; therefore, we select the model with the lowest expected log pointwise predictive density and highest stacking weight. No divergence transitions appear in the algorithm's sampling step, and the effective sample size parameter and the Rhat statistic do not highlight sampling difficulties for the selected models. As shown in Figure 1, one knot resulted in all the Italian location models, on the count model for UK and Russia, and the maximum duration model for Finland. Two knots are selected in the mean and maximum duration models in the UK and the count model for Finland. The linear predictor shows a slope change at each knot location, mostly of positive signs. The posterior mean and quartiles estimates of the knot locations are reported in Table 1. Figure 2 reports the results for the Poisson models on the count and maximum duration response variables scale.

4. Conclusion

One of the effects of climate change is an increase in heat waves frequency and intensity at a global level, with substantial variability in space and time. We study the interannual variability by employing a nonlinear semiparametric model whose estimates suggest that an acceleration in the frequency of the phenomenon occurred since approximately the 80s in all locations considered (see Table 1 and Figure 1). The intensity, on the other hand, does not show a significant increase. These results are broadly coherent with previous analyses of the BEST data. Although the fact that we consider four very specific locations makes the comparison with regional estimates not obvious, we notice that in (5), an increase in frequency was noted for the European area. At the same time, the average intensity had no significant trend. We plan to elaborate on this preliminary exploration by considering more locations to explore the geographical heterogeneity of the phenomenon in its various manifestations (exploring the different measures of frequency and intensity proposed in the literature) and its spatial structure. In particular, we plan to implement models allowing for spatial correlation and the pattern of variation across space.

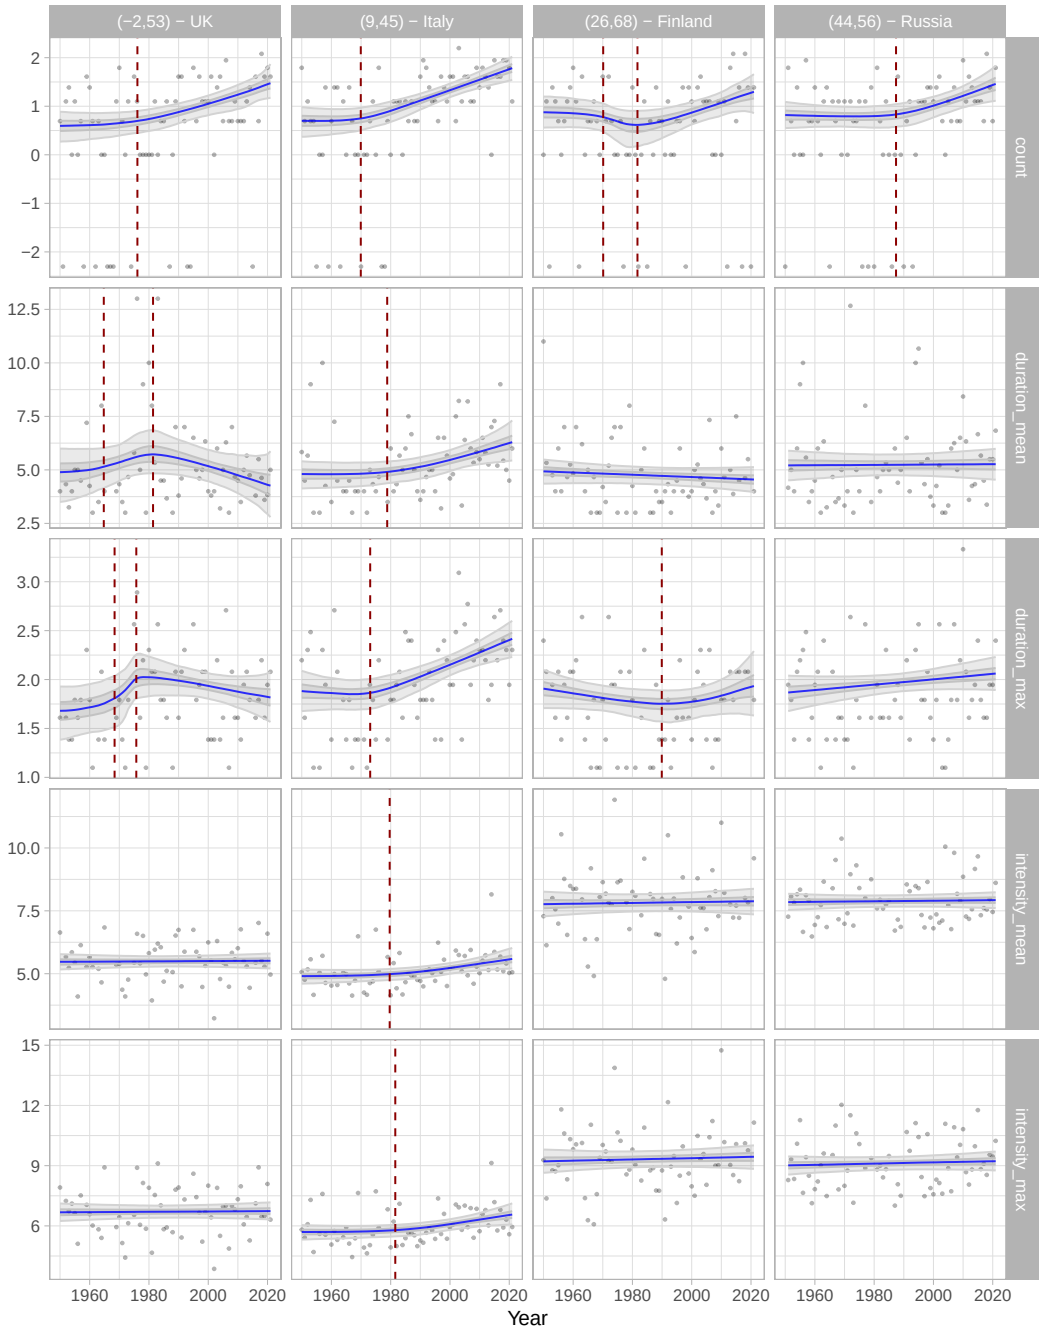

Figure 1: Results of the fitted model on the linear predictor scale. Locations are on the columns with longitude and latitude between brackets, while response variables are on the rows. Grey points represent the observed values. The solid blue line is the linear predictor computed using the posterior median estimates of the spline coefficients and the knot locations (vertical red dashed lines).

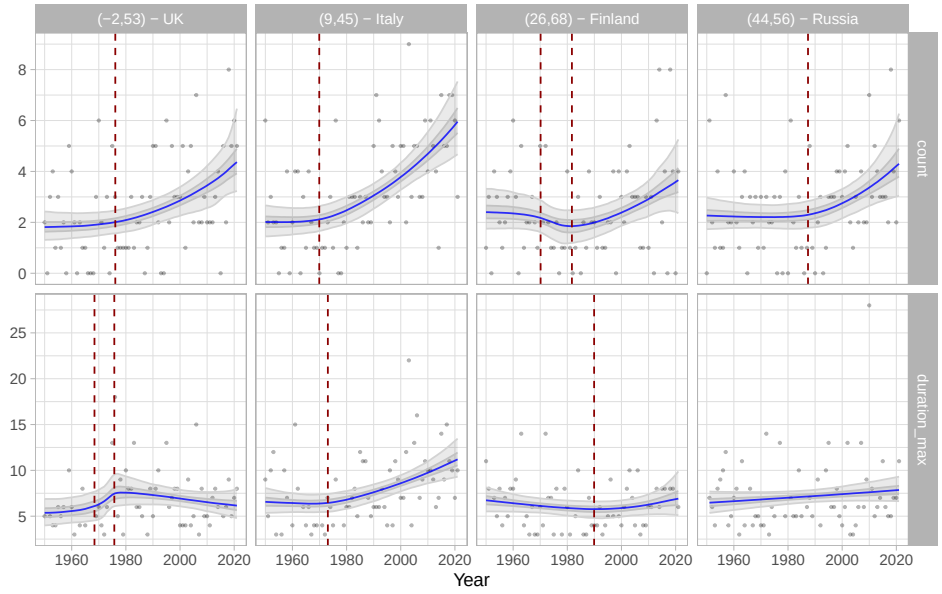

Figure 2: Results of the fitted Poisson models on the response scale. Locations are on the columns with longitude and latitude between brackets, while response variables are listed on the rows. Grey points represent the observed values. The solid blue line is the linear predictor on the exponential scale computed using the posterior median estimates of the spline coefficients and the knot locations (vertical red dashed lines).

The Hierarchical Beta-Bernoulli Process as Out-of-Scope Query Detector

Abstract

Task-oriented dialog systems are computer systems that interact with humans in natural language. The system receives a query, converts the sequence of words into a semantic representation to be used by the dialog manager, decides the best response for the user, and manages the task. Occasionally, the system may receive an *out-of-scope* query, namely, a query that falls outside the range of the system's capabilites. In this work, we focus on out-of-scope query prediction, and show how the hierarchical Beta-Bernoulli process outperforms state-of-the-art machine learning classifiers.

Keywords: Hierarchical Beta-Bernoulli processes, nonparametric Bayesian modelling, task-oriented dialog systems, out-of-scope query prediction

1 Introduction

The increasing sophistication of machine learning algorithms in the last years has led to a revolution in task-oriented dialog systems: nowadays people can ask Amazon's Alexa what is their bank account balance while they are cooking, and will get a satisfactory answer from her. Any dialog system is designed to support a fixed number of intents only. For example, a task-driven system designed to support personal finance queries cannot answer the question "What is the weather like tomorrow?". Queries falling outside the range of intents which the dialog system is designed to work upon are defined *out-of-scope* queries (hereafter, OOS). Correctly identifying that a query is OOS is of paramount importance for the system to avoid performing wrong actions. Thus far, however, little attention has been given to evaluating the performance of state-of-the-art, dialog system machine learning classifiers in OOS prediction. An exception is given by [1], who evaluate and compare the performance of a range of benchmark classifier models focusing on OOS prediction relying on a novel dataset. Whilst the tested models work well in predicting known intents, the authors show that all methods struggle with identifying OOS queries.

The hierarchical Beta-Bernoulli process is a well known Bayesian nonparametric process that has shown good performance in document classification tasks [2]. Informally speaking, documents are a collection of words, thus queries themselves can be seen as documents. However, unlike long-text documents, the fact that queries consist of only a few words is an obstacle towards distinguishing an OOS from an in-scope query, which indeed become indistinguishable if a couple of key words were removed from the OOS query; see Table 1. In face of these difficulties, we believe that the flexibility of a nonparametric model could be instrumental in detecting OOS queries. In this work, we fit a Beta-Bernoulli process to the classification data in [1], and show that it outperforms benchmark machine learning classifiers in OOS query prediction.

The remainder of this paper is organised as follows. In Section 2, we introduce the discrete form of the hierarchical Beta-Bernoulli process [2], which we leverage on in this work, and explain how this process can serve as nonparametric Bayesian prior in document classification tasks. Section 3 illustrates the inferential procedure leading to the classification of an unlabelled document. In Section 4, we analyse the dataset in [1] by means of the hierarchical Beta-Bernoulli process, and Section 5 presents conclusions and directions for future work.

2 Methods

The (discrete) Beta process, denoted $BP(c, B_0)$, is a Lévy process over a space Ω whose Lévy intensity is defined by:

$$\nu(d\omega, dp) = \sum \text{Beta}(cq_i, c(1-q_i))(dp)\delta_{\omega_i}(d\omega)$$

where the *base measure* $B_0 = \sum_i q_i \delta_{\omega_i}$ is discrete, the positive real constant c is the *concentration parameter*, and the total mass $\gamma = B_0(\Omega)$ of the base measure is called *mass parameter*; γ is required to be finite. Note that each q_i must lie in $(0, 1)$ in order for the Lévy intensity to be well defined.

The (discrete) Bernoulli process, denoted $BeP(B)$, is the Lévy process characterised by the Lévy intensity:

$$\mu(d\omega, dp) = \sum \text{Bernoulli}(p_i)(dp)\delta_{\omega_i}(d\omega)$$

where the base measure $B = \sum_i p_i \delta_{\omega_i}$ is discrete. Note that the masses p_i must lie in $(0, 1]$ in order for the Lévy intensity to be well defined. The probability of a particular realisation of a $BeP(B)$ with B discrete is:

$$\mathbb{P}\left(X = \{\omega_{j_1}, \omega_{j_2}, ..., \omega_{j_K}\}\right) = \prod_{k=1}^{K} \mathbb{P}\left(\omega_{j_k} \in X\right) = \prod_{k=1}^{K} \int_{[0,1]} \text{Ber}\left(p_{j_k}\right)(dp) = \prod_{k=1}^{K} p_{j_k}$$

Given a discrete base measure B_0 and a positive real constant c, we can combine the two processes above and obtain the Beta-Bernoulli process (BBp):

$$B \sim BP(c, B_0), \quad X|B \sim BeP(B)$$

and conjugacy holds, that is, given n conditionally *iid* samples $X_1, ..., X_n|B \sim BeP(B)$,

$$B|X_1, ..., X_n \sim BP\left(c + n, \frac{c}{c+n}B_0 + \frac{1}{c+n}\sum_{i=1}^{n} X_i\right).$$

Indeed, by independence over disjoint subsets of Ω and by the discreteness of B_0, inference can be carried out separately for each atom ω_i. The result follows from the well-known Beta-Binomial conjugacy.

We follow [2] and embed the BBp into a hierarchical model, leading to the hierarchical BBp (hBBp):

$$B \sim BP(c_0, B_0), \quad B_1, ..., B_J|B \sim BP(c_j, B), \quad X_{1,j}, ..., X_{n_j,j}|B_j \sim BeP(B_j) \quad j = 1, ..., J$$

An helpful analogy to better understand the model is the following. Consider a corpus X of n documents, each of which is associated with one of J subjects, such that there are n_j documents $X_{1,j}, ..., X_{n_j,j}$ belonging to topic j. Any given word in the English vocabulary is more or less likely to appear in a document depending on the subject: some technical terms will be exclusively used in certain domains, other terms are likely to appear in affine subjects, and some other will be ubiquitous. Let us model a document as a subset of words in some vocabulary, or, equivalently, as a binary vector whose components are indexed by the words in the vocabulary. At a given component, $0/1$ stands for the absence/presence of that word in the document, respectively.

Taking the underlying space $\Omega = \{\omega_1, \omega_2, \omega_3, ...\}$ as the vocabulary, which is potentially infinite (think of every possible misspelled word) but countable, let $B_0 = \sum_i b_0(\omega_i)\delta_{\omega_i}$ be a discrete measure

over Ω such that $b_0(\omega_i) \in (0,1)\ \forall i$, and let c_0 be a real constant. Then, B is also discrete, and $B(\omega_i) \sim \text{Beta}(c_0 b_0(\omega_i), c_0(1-b_0(\omega_i)))\ \forall i$. In this setting each B_j is discrete, supported by Ω and such that $B_j(\omega_i) \sim \text{Beta}(c_j B(\omega_i), c_j(1-B(\omega_i)))$. Then, $B_j(\omega_i)$ gives the probability that word ω_i appears in a document with topic j, while $B(\cdot)$ encodes the sharing of information between topics. Parameters c_0, c_j encode the semantic richness overall and within each topic, respectively. Specifically, if c_j is small then documents of subject j contain the same few words, whereas if c_j is large documents of topic j are dissimilar. Similarly, a small c_0 induces a lot of shared terms among the different topics, while a large c_0 means that each topic has its own set of specialised terms. Concentration parameters c_0, c_j's will play a key role for the performance of the hBBp.

3 Inference

We rely on the hBBp presented above to assign a topic to an unlabelled document X_{new}. Here we explain the inferential procedure.

Because Lévy processes have independent increments over disjoint sets, it is legitimate to carry out inference separately for the set of observed words (the bag-of-words obtained by the union of all the words in every document) and for its complement (the words in Ω which never appeared in any document of the corpus). Let $\Omega_{\text{obs}} \subset \Omega$ be the collection of unique words that appeared at least once in some document, and let Ω_0 be its complement. The procedures discussed in this Section are summarised in Algorithm 1 and Algorithm 2.

Inference over Ω_{obs} Fix a $\omega \in \Omega_{\text{obs}}$ and define $x_{i,j} = X_{i,j}(\omega)$, $x = \{X_{i,j}(\omega) | j \leq J; i \leq n_j\}$, $b_j = \{B_j(\omega) | j \leq J\}$, $b = B(\omega)$, and $m_j = \sum_{i=1}^{n_j} x_{i,j}$. It is possible to show that:

$$\mathbb{P}\left(x_{n_j+1,j} = 1 \middle| x\right) = \mathbb{E}\left[\mathbb{E}\left[b_j | b, x\right] | x\right] = \mathbb{E}\left[\frac{c_j b + m_j}{c_j b + m_j + c_j(1-b) + (n_j - m_j)} \middle| x\right] = \frac{c_j \mathbb{E}\left[b|x\right] + m_j}{c_j + n_j}.$$

The posterior expectation $\mathbb{E}\left[b|x\right]$ is not available in closed form analytically, thus we will rely on its Monte Carlo approximation. In particular, it is possible to show that the density of $b|x$ is bounded above by the unnormalised density of a Gamma(α, β), where

$$\alpha = c_0 b_0 + \sum_{j=1}^{J} 1(m_j > 0),\ \beta = \frac{c_0(1-b_0)-1}{1-b^*} - \sum_{j=1}^{J}\sum_{i=1}^{m_j-1} \frac{c_j}{c_j b^* + i} + \sum_{j=1}^{J}\sum_{i=0}^{n_j-m_j-1} \frac{c_j}{c_j(1-b^*)+i}$$

where b^* is the mode of the density of $b|x$, which can be easily obtained by any appropriate numerical optimisation method, being such a density concave in $(0,1)$. Relying on the Gamma(α, β) as proposal distribution, we generate T samples $b_1, b_2, \ldots, b_T$ via Metropolis-Hastings and then approximate $\mathbb{E}\left[b|x\right]$ via the empirical mean. After some testing, we realised that the Gamma approximation is very precise: $20 \leq T \leq 30$ samples yield a satisfactory approximation in the application discussed hereafter.

Inference over Ω_0 Fix some $\omega \in \Omega_0$. Adapt the notation used above to this new ω. As before, we would like to compute the probability $\mathbb{P}\left(x_{n_j+1,j} = 1 \middle| x = 0\right)$, but this turns out to be more challenging. Given W words $\{\omega_1, ..., \omega_W\} \subset \Omega_0$, and defining $\lambda_j := \sum_{k=1}^{K} \frac{c_0 B_0(\Omega_0)}{c_0 + k - 1} p_{k,j}$,

$$\mathbb{P}\left(\{\omega_1, ..., \omega_W\} \subset X_{n_j+1,j} \middle| x = 0\right) \approx \text{Pois}\left(\lambda_j\right)(W) \prod_{i=1}^{W} b_0(\omega_i)$$

where $p_{k,j} = \mathbb{P}_k(x_{n_j+1,j} = 1, x = 0)$ and $\mathbb{P}_k$ is the probability over the slice of the hBBp corresponding to ω, and is approximated via simulation. The larger K, the better the approximation, which is in fact exact for $K \to \infty$. See Algorithm 2 and [2] for further details.

Combining the above, given a new document $X_{\text{new}} = \{\omega_1, ..., \omega_W\}$ whose subject has to be inferred, we compute

$$\mathbb{P}(X_{n_j+1,j} = X_{\text{new}}|X) \approx \prod_{\omega \in X_{\text{new}} \cap \Omega_{\text{obs}}} \frac{c_j \mathbb{E}\left[B(\omega)|X\right] + m_j}{c_j + n_j} \times \text{Pois}\left(\lambda_j\right)(W) \prod_{\omega \in X_{\text{new}} \cap \Omega_0} b_0(\omega).$$

We compute this probability for all topics $j = 1, \ldots, J$, and then assign X_{new} to the topic j^* that maximises the probability above.

Algorithm 1: HBBp training

Data: corpus X of n documents, n_j documents for each topic $1 \leq j \leq J$; Ω ; $c_1, \ldots, c_J$; B_0
$\gamma \leftarrow$ mean number of unique words in a query ;
$B_0 \leftarrow \frac{B_0}{B_0(\Omega)}\gamma$;
$\Omega_{\text{obs}} \leftarrow$ unique words in the corpus ;
$F \leftarrow |\Omega_{\text{obs}}|$;
$c_0 \leftarrow$ solution of $c_0 = \frac{F-\gamma}{\gamma \log\left(\frac{c_0+n}{c_0+1}\right)}$;
for $\omega \in \Omega_{\text{obs}}$ **do**
  $M_{\omega,j} \leftarrow$ number of documents of topic j having ω, for $1 \leq j \leq J$
  $b^*_\omega \leftarrow$ mode of the posterior density of $B(\omega)|X(\omega)$
  $\alpha_\omega \leftarrow c_0 b_0(\omega) + \sum_{j=1}^{J} 1(M_{\omega,j} > 0)$, with $b_0(\omega) := 0$ if $\omega \notin \Omega$
  $\beta_\omega \leftarrow \frac{c_0(1-b_0(\omega))-1}{1-b^*_\omega} - \sum_{j=1}^{J} \sum_{i=1}^{M_{\omega,j}-1} \frac{c_j}{c_j b^*_\omega + i} + \sum_{j=1}^{J} \sum_{i=0}^{n_j - M_{\omega,j}-1} \frac{c_j}{c_j(1-b^*_\omega)+i}$
end

Algorithm 2: Document classification via hBBp

Input: New document $X_{\text{new}} = \{\omega_1, \ldots, \omega_W\}$; trained hBBp ; $T_1, T_2, K \in \mathbb{N}$
Output: Most likely topic j s.t. $X_{\text{new}} = X_{n_j+1,j}$
for unique $\omega \in X_{\text{new}} \cap \Omega_{\text{obs}}$ **do**
  $b_1, \ldots, b_{T_1} \leftarrow$ Metropolis-Hastings with Gamma(α_ω, β_ω) proposal and target $B(\omega)|X(\omega)$
  $\overline{b} \leftarrow \frac{1}{T_1} \sum_{i=1}^{T_1} b_i$
  $P_{1,j} \leftarrow P_{1,j} \frac{c_j \overline{b} + M_{\omega,j}}{c_j + n_j}, \ \forall\, 1 \leq j \leq J$
end
for $1 \leq k \leq K$ **do**
  $b_1, \ldots, b_{T_2} \leftarrow$ sample from Beta(1, $c_0 + k - 1$)
  for $1 \leq j \leq J$ **do**
    $r_{i,j} \leftarrow \frac{c_j b_i}{c_j + n_j} \prod_{j'=1}^{J} \frac{\Gamma(c_{j'})\Gamma(c_{j'}(1-b_i)+n_{j'})}{\Gamma(c_{j'}(1-b_i))\Gamma(c_{j'}+n_{j'})}, \forall\, 1 \leq i \leq T_2$
    $p_{k,j} \leftarrow \frac{1}{T_2} \sum_{i=1}^{T_2} r_{i,j}$
  end
end
$\lambda_j \leftarrow \sum_{k=1}^{K} \frac{c_0 B_0(\Omega_0)}{c_0+k-1} p_{k,j}, \ \forall\, 1 \leq j \leq J$;
$P_{2,j} \leftarrow \text{Pois}(\lambda_j)(W) \times \prod_{\text{unique } \omega \in X_{\text{new}} \cap \Omega_0} b_0(\omega), \ \forall\, 1 \leq j \leq J$;
return $j^* \leftarrow 1 \leq j \leq J$ maximising $P_{1,j} \times P_{2,j}$

4 Data Analysis and Results

We fit the hBBp to the CLINC150[1] data. The dataset contains a training set made of 15000 in-scope queries, 100 for each of 150 intents, 100 OOS training queries, and a test set made of 4500 in-scope queries and 1000 OOS queries. A snapshot of the CLINC150 data is provided in Table 1.

Table 1: A snapshot of in-scope and OOS queries from the CLINC150 dataset.

Query	Intent
what is the temperature in costa mesa	weather
does france have their own version of a visa	international_visa
where can i pick up my w2 to do my taxes	w2
pay my gas bill from my saving account	pay_bill
what do i have on my calendar for march 2	calendar
who are some notable alumni of ucsd	OOS
when was nintendo created	OOS
when was the theory of evolution first considered	OOS
why do males want to be alpha	OOS
what are van gogh's best pieces	OOS

We consider as our space Ω the set of the most common words in Wikipedia[2], which contains more that 280000 terms. Despite its size, such a vocabulary does not contain many frequent terms appearing in the dataset. Indeed CLINC150 queries are full of misspelled words, symbols, numbers and proper names. However this is not an issue for the hBBp in that its nonparametric nature allows Ω to grow as the data is observed. Here the underlying assumption is that if ω is observed in a training query but it is not in Ω, then we treat it as if ω belongs to Ω with $b_0(\omega) = 0$. The prior distribution over such ω is improper, but becomes proper after the Bayesian update. Therefore, misspelled words have been retained in the dataset. Further, we did not remove stop words, which indeed appear to be informative predictors especially when appearing in clusters (e.g., "how would I...in...?", often appears under the intent "translate"), and no stemming has been applied.

Note that a test query might include a word that has never been observed in the training set and is also not present in Ω. Indeed, this is quite common, especially if the test query is OOS. Assuming $b_0(\omega) = 0$ is not a good choice in such case since this would translate into a zero probability of observing such query under every intent, and the classification would not be possible. To overcome this issue, we add a special out-of-training (OOT) feature to the vocabulary of Wikipedia's most common terms. Specifically, if a test query contains a word that has never been observed in the training set and is not present in Wikipedia's vocabulary, then such a word is mapped to OOT and is interpreted as a feature of the query at hand.

To choose an appropriate B_0, we rely on a power-law determined by the ranking in the list of Wikipedia's most frequent terms. Having shifted down in the ranking each word by one position (the most frequent word becomes the second most, the second most frequent becomes the third most, and so on) and having put OOS on top of the ranking in the first position, the chosen power-law is $\text{rank}^{-0.1}$, the exponent close to zero to avoid the tail from becoming too thin. The total mass of B_0 has also to be coherent with the data. One can show that $\gamma = B_0(\Omega)$ is the mean number of unique words per document, which amounts to 8.31 in CLINC150.

Choosing the concentration parameters is challenging. Besides c_0, which is computed as the fixed point solution of a real valued function (see Algorithm 1 and [2]), the crucial point is the choice of the concentration parameters associated to the 151 topics. Unfortunately, an exhaustive grid search for the optimal combination for these hyperparameters is unfeasible given our computational resources. After some trial and error, a tuning "by hand" led to choices giving a good trade-off between in-scope accuracy and OOS recall, and is the chosen setting leading to the results presented hereafter.

[1] https://github.com/clinc/oos-eval
[2] https://en.lexipedia.org/

Table 2: In-scope and out-of-scope performance comparison between the hierarchical Beta-Bernoulli process and benchmark machine learning methods in [1]: FastText, CNN, MLP, BERT neural networks; SVM, a linear support-vector classifier; Google's DialogFlow and Rasa's NLU conversational AIs.

Classifier	In-Scope Accuracy	Out-of-Scope Recall
FastText	89.0	9.7
SVM	91.0	14.5
CNN	91.2	18.9
DialogFlow	91.7	14.0
Rasa	91.5	45.3
MLP	93.5	47.4
BERT	**96.9**	40.3
Hierarchical Beta-Bernoulli process	86.5	**79.5**

A comparison with benchmark machine learning methods is displayed in Table 2, where results referring to models from FastText to BERT are taken from [1] (see [1] for details on these models). These results are promising: although slightly underperforming in terms of in-scope accuracy, the hBBp outperforms in terms of OOS recall, which is the goal of our application. Further, these results should be treated as preliminary results for our work and we expect both in-scope and OOS perfomance to improve with more accurate tuning of the model hyperparameters, as done for the machine learning competitors instead.

5 Conclusions

In this paper, we proposed a hierarchical Beta-Bernoulli process for OOS query prediction. The methodology outperforms state-of-the-art machine learning techniques used by task-based dialog systems, and its in-scope performance is in line with that of existing techniques. Moreover, it can handle misspelled words in a straightforward and appealing manner.

Possible future work could be the estimation of the number of different topics within the OOS class via Kingman's *Coalescent*, which plays the role of a nonparametric prior over the dendrogram governing the clustering structure of OOS queries.

Abstract

Understanding comorbidity characteristics is essential for policymakers and healthcare providers to allocate resources accordingly. However, several definitions of comorbidity can be found in the literature. The main reason for these differences lies in the available information about the analyzed diseases (i.e., the target population analyzed), how to define the burden of diseases, and how to aggregate the occurrence of the detected health conditions. In this manuscript, we focus on the data from the Italian surveillance system PASSI proposing a definition of comorbidity based on the disability weights coming from the Global Burden of Disease project. Thanks to that, we can explore the level of comorbidity based on the presence of ten different non-communicable diseases across socioeconomic sub-populations in Italy.

Keywords: Health-statistics, comorbidity, disability weights, surveillance system PASSI, global burden of disease project

1. Introduction

The term comorbidity indicates the simultaneous presence of two or more diseases in the same person. These conditions can be related or unrelated and co-occur one after the other. Comorbidity is common, especially in older people and those with chronic conditions. It can complicate the diagnosis and treatment of individual conditions and impact the person's overall health, and well-being (12).

Understanding morbidity is vital for supporting decision-making health processes. It helps policymakers, healthcare providers, and other stakeholders identify the most pressing health issues facing a population and allocate resources accordingly. Morbidity data can help researchers and scientists identify trends and patterns in the occurrence of different diseases and conditions, which can inform the development of new treatments and prevention strategies (5; 10).

The concept of comorbidity is complex and multidimensional. For that, several definitions can be found in the literature (15). Three main reasons can be identified: (i) analyzing comorbidity depends on the type of available data (e.g., the type of detected diseases in the surveillance/study considered, study objective, target population), (ii) the burden of disease on a person's health depends on the severity or duration of the diseases or conditions, (iii) the presence of multiple morbidities must be aggregated in some way to define the concept of comorbidity. For example, Pastore et al.(11) defines the concept of comorbidity as a binary variable describing the presence of at least one disease over ten detected diseases. The authors of (11) used data from the Italian surveillance system PASSI (1), a monthly cross-sectional study where self-declared health status, diagnosed diseases, and socio-demographic variables are recorded.

Therefore, the definition proposed by Pastore et al.(11) is pretty simple. The burden of disability associated with each disease is not taken into account, as is the burden of having at least one disease versus having no disease. The authors themselves, in fact, suggest using some weights to take into account the level of possible disability coming from each detected disease. For that, in this work, we propose a new definition of comorbidity, focusing on the Italian framework. We then analyze the same surveillance system used by Pastore et al.(11) (i.e., PASSI), considering as disease weights the ones coming from the Global Burden of Diseases (GBD) project (9; 7). These weights, called disability weights, reflect the magnitude of health loss linked with specific health conditions (13). The disability weights are computed using data from surveys based on paired comparison questions. The respondents must consider two hypothetical individuals with different health state names (randomly selected), and they must indicate which one is considered healthier (13). Many factors can influence the computation of the disability weights, i.e., health state description, the panel of judges, valuations methods for health states, time presentation, and surveying techniques (4). However, this paper focuses on defining the comorbidity rather than the disability weights. We decided then to use the GBD disability weights, having been tested and validated several times over time.

The outline of the paper is as follows. Subsect. 2.1 shows the steps to create the comorbidity index based on the disability weights coming from the GBD and non-communicable diseases declared in the Italian surveillance system PASSI. An example of how using this novel comorbidity index (i.e., random forest (2)) is provided in Subsect. 2.2. This analysis permits understanding the level of comorbidity in Italian sub-populations characterized by different socio-economic statuses. Finally, Sect. 3. shows the results of the application of the random forest.

2. Methods

2.1 Comorbidity index

We use data from the Italian surveillance system PASSI which includes the following question: “Has a doctor ever diagnosed or confirmed you with one or more of the following diseases?”. The surveillance system then measures the following self-reported non-communicable diseases: diabetes, kidney failure, bronchitis/emphysema/respiratory failure, myocardial infarction/cardiac ischemia/coronary artery disease, tumor (including leukemias and lymphomas), chronic liver disease/cirrhosis, stroke/cerebral ischemia, heart diseases (e.g., valvulopathy decompensation), bronchial asthma, and arthrosis/arthritis (e.g., rheumatoid, arthritis, gout, lupus, fibromyalgia). In addition, socio-economic variables are collected and used in this analysis, such as sex, age, level of education (low and medium-high), and the economic difficulties (yes and no) of the respondent. For further details about these socio-economic variables, please refer to the work of Pastore et al.(11).

When the aim is to analyze the comorbidity of a population, one must take into account that the impact on a person’s life of a given disease depends on the severity of this disease. In addition, since the same individual can declare more than one disease, we must define a way to aggregate multiple severities in order to define the concept of comorbidity. In order to take these two aspects into account, we use the disability weights coming from the GBD (13). So, we must associate each non-communicable disease measured by the surveillance system PASSI with one disability weight coming from the GBD. These weights are measured on a scale from 0 to 1, where 0 equals a state of full health, and 1 equals a state of death. However, we must deal with several problems in this step. First, the GBD provides weights for 440 diseases, whereas PASSI only examines ten non-communicable diseases. Secondly, for each disease analyzed, the GBD provides different weights depending on the severity of the disease. In order to solve these two problems, we moved in two steps.

As a first step, we selected the diseases considered by the GBD that recall the non-communicable diseases detected by PASSI. For example, focusing on diabetes, we selected through a text mining process all those weights that refer to diseases containing the words ”diabet”, ”diabetes”, ”diabetic”, ”diabeetus”, ”diabetes mellitus”, ”hypertension”, ”obesity”, and ”insulin”. We deal with singular and plural, and the keywords include synonymous coming from the Cambridge English dictionary (6).

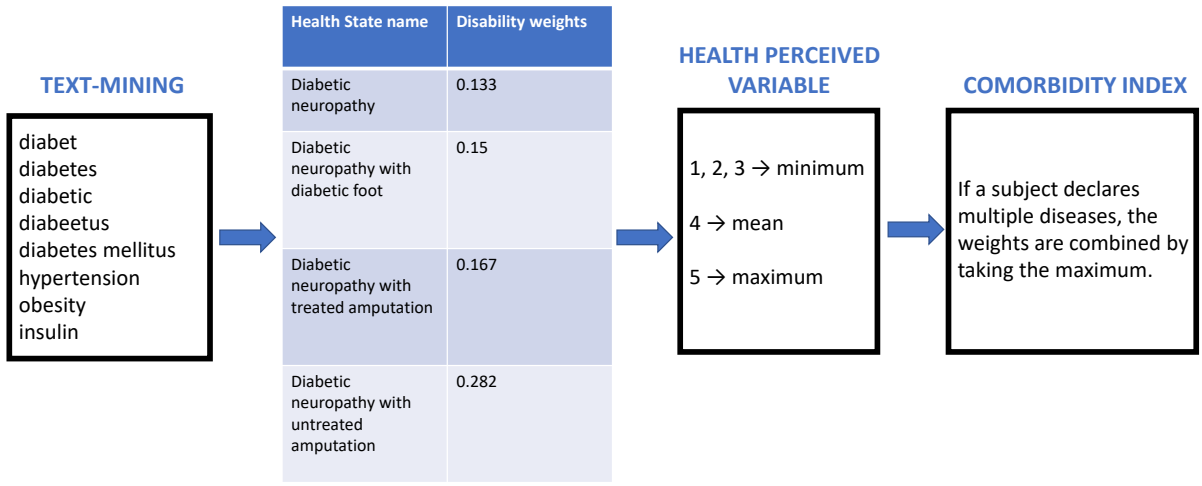

Figure 1: Steps to associate the weights coming from the GBD to the diseases declared in the Italian surveillance system PASSI.

From the first step, for example, still focusing on diabetes, we found 4 weights with a standard deviation equal to 0.06. In order to choose which of these 4 weights to associate with the individual who declared to have diabetes in PASSI, we use the perceived health variable detected in PASSI. The perceived health variable is an ordinal categorical variable that takes values between 1 and 5, where 1 means excellent self-reported health and 5 means very bad self-reported health. Thus, if perceived health is between 1 and 3, we use the minimum value of the weights. If it equals 4, we use the average of the disability weights selected, and if it equals 5, we use the maximum value of these weights. Figure 1 summarizes this process.

Finally, if an individual declares more than one disease, the maximum value between the disability weights selected is considered. In this way, we consider the most impactful disease within the life of the individual who declared more than one disease.

2.2 Model

This section proposes a naive utilization of the comorbidity index defined in Sect. 2.1. First of all, the response variable we want to analyze has a particular distribution. The comorbidity index described in Subsect. 2.1, in fact, is a "semi-continuous" multimodal skewed nonnegative variable with several zero values. We decided then to use nonparametric methods, such as machine learning methods, that can handle any functional form of the analyzed response variable. Here, we report the results coming from the random forest approach (2). However, other methods can be used and compared (e.g., Tweedie regression, support vector machine), but it is beyond the scope of this paper.

3. Results

Table 1 shows the importance of the covariates analyzed, i.e., age, sex, educational level, and economic problems. The importance is calculated as follows: the method permutes the feature values of each variable and computes the out-of-bag error (mean squared error in this case). The importance score, defined by Strobl et al.(14), is then calculated by averaging the difference in out-of-bag error before and after the permutation over all trees. If the prediction error does change consistently, the related variable is defined as important inside the random forest model. The permutation-based importance measures are then scaled to have a maximum equal to 100 and a minimum equal to 0. Finally, this importance score is conditional in the sense of coefficients in regression models considering both the main and interaction

effects of the variable (14).

	Importance
Age	100.000
Educational level	10.718
Sex	6.148
Economic problems	0

Table 1: Variable importance measure from random forest model.

We can note that age is the main variable that impacts the split of the random forest tree, having an importance score equal to 100. In contrast, the economic problems variable has a minimal effect on the results of the model, i.e., the importance score equals 0. This is probably due to the presence of a strong association between the economic and educational level variables.

Figure 2 shows the predicted values of the GBD disability weights across age, analyzing 4 sub-populations characterized by different economic (no economic problem, economic problem) and educational (low, medium-high) status levels divided by sex. As expected, We can note how the disability weights increase as age increases. We can note a great difference between males and females, particularly in the elderly ages, if the sub-population characterized by a high educational level (i.e., left and right top plots of Figure 2). More interestingly, in older ages, the comorbidity index is lower in the sub-population characterized by high educational level and no economic problems (i.e., left top plot of Figure 2) than in sub-population having economic problems and low educational level (i.e., right bottom plot of Figure 2). For example, focusing on the elderly population (i.e., age equals 69), the comorbidity index equals 0.109 for the females and 0.072 for the males if the sub-population with a high educational level and no economic problem is analyzed. In contrast, it equals 0.13 for the females and 0.113 for the males if the sub-population with a low educational level and no economic problem is considered. In addition, we can note how the difference in terms of comorbidity index is substantial also in adult ages, not only in elderly ages if the sub-population characterized by economic problems and low educational level is analyzed (e.g., the index equals 0.066 for females and 0.043 for males at age 49). According to the literature, these statements support the presence of a difference in terms of comorbidity in socioeconomic class (8; 3).

Finally, the predicted values reported in Figure 2 are in line with the analysis of the Years Lived with Disability (YLD) index coming from the GBD (http://ihmeuw.org/5z0s, http://ihmeuw.org/5z0t) if only the division by age and sex variables is considered which are the only one available from the GBD project. Therefore, thanks to the proposed new comorbidity index, we can also analyze the level of comorbidity of the Italian population characterized by different educational levels and economic status, which the GBD project does not detect.

4. Discussion

In this paper, we proposed an alternative definition of comorbidity by analyzing the Italian surveillance system PASSI data and the disability weights given by the GBD project. The diseases detected in PASSI were associated with the disability weights of the GBD by several steps: a text mining one to extract the related GBD weights and the utilization of the perceived health variable reported in PASSI to filter the extracted GBD weights.

We finally proposed a naive analysis of this comorbidity index considering sub-populations characterized by sex, age, and different levels of education and economic situation of the subjects. Therefore, the comorbidity definition proposed permits exploring two novel analyses: the level of comorbidity from the PASSI data and the socio-economic population structure of the GBD data.

However, we made some assumptions in order to create this comorbidity index. These assumptions must be explored in more detail in the future. For example, the process of selecting the weights was done automatically by text mining. It would be appropriate in future works to select these weights with experts.

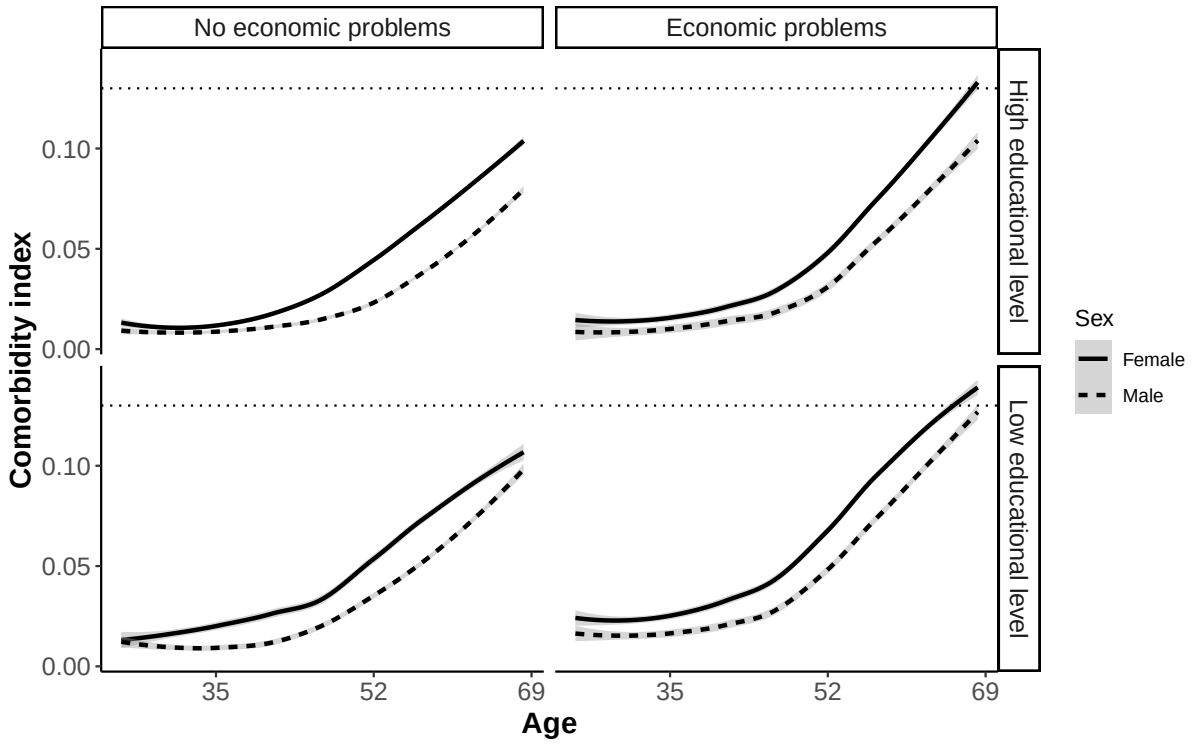

Figure 2: Predictions of the comorbidity index across age considering sub-populations characterized by different levels of education (low-high) and economic status (no economic problems-economic problems). The grey area represents the prediction interval at level 0.95.

In fact, some of the weights analyzed consider combinations of diseases that should be analyzed in more detail. In addition, we examined the maximum disability weights across declared non-communicable diseases while a different propriety could be chosen (i.e., the sum of disease weights, the mean, the minimum, or a novel combination). Finally, analyzing the comorbidity trend would be interesting by comparing different years of the PASSI survey as done in Pastore et al.'s work(11).

Abstract

In this paper, we propose an Age-Period-Cohort (A-P-C) model leveraging Skew-Normal distribution, aiming at modelling the gender gap in youth mortality.
We noticed that gender differences in youth mortality are largest around the age of 20, but these differences are not symmetrical with respect to the peak. Following this evidence, we perform the APC analysis using a mixed-effects model in which the response variable follows the Skew-Normal distribution. We adopt a sex ratio approach, using the ratio of age-specific mortality rates of men and women as the response variable. We test and compare different models in which we consider age as a fixed effect and different combinations of period and cohort as fixed or random effects.
Our research focuses on the population under age 45 in the United States between 1960 and 2020. In the results, we see a decrease in gender differences in youth mortality over the last 25 years, and it is evident that cohorts born between the mid-1940s and the 1960s had the highest excess in male mortality at younger ages.

Keywords: Mortality modelling, Skew-Normal, Age-Period-Cohort Model

1. Introduction

Gender differences in mortality are increasingly discussed and studied in the social and demographic fields. Modelling and analysing gender differences in mortality can tell us a lot about the social context of a population or a country [9]. Thus, a better understanding of sex differences in mortality can guide public health efforts to reduce overall mortality rates and promote greater equity in health outcomes.
Gender differences are not constant at all ages and are driven by different causes of death. Many studies focus on gender differences in mortality at adult ages, but there is less literature on differences at younger ages. At the same time, gender differences in mortality are greater at younger ages [7] and this is mainly due to the different behaviour of the two groups. Men in particular run a much higher risk of accidental death around the age of 20 [8]. In addition to age, mortality differences change over time because the behaviour that generates them changes over the years [2].
We aim to study how the gender gap in mortality at younger ages (under 45) varies concerning individual age groups and over time. We want to define and interpret the effects of different ages and social, cultural and behavioural changes in society [14]. To do this, we work in an Age-Period-Cohort (APC) framework

leveraging mixed model effects based on a Skew-Normal distribution. The Skew-Normal distribution is not widely used in the APC framework.
In particular, we are interested in studying in the United States (US), where more than the 30% of deaths at young ages are due to external causes (unintentional injuries) [3] and the issue of road accidents, and violent and risky behaviour among young people is often at the centre of public debate.

2. Data and Measure

We use a sex-ratio approach to study gender differences: we analyse the ratio of age-specific mortality rates between males ($m^M_{x,t}$) and females ($m^F_{x,t}$) over time.

$$SR_{x,t} = \frac{m^M_{x,t}}{m^F_{x,t}} \tag{1}$$

This measure 1 is useful for several reasons: it allows us to use a single variable to study the two sexes, it is less sensitive to the general level of mortality than the absolute difference in deaths [2], and finally, it has a well-defined and known shape [8] (Fig.1). We use age-specific mortality rates per sex and single year of age (0 - 100) from the Human Mortality Database [12] of the United States in the study period.

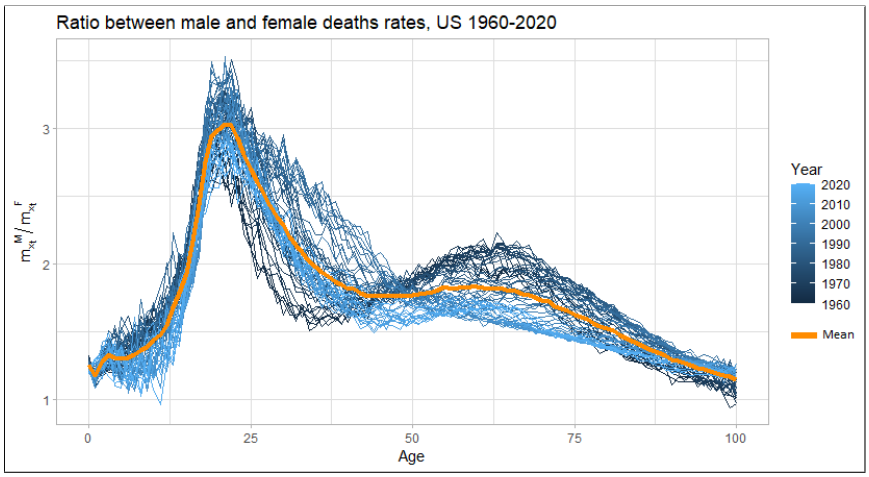

Figure 1: Sex-Ratio of the Age-Specific Mortality Rates in US between 1960 and 2020. Data source: HMD

Generally, this sex-ratio over the ages is characterized by a Peak and a Hump. The peak, which is the highest and most concentrated, coincides with youthful ages and is generally attributed to the highest male mortality due to riskier behaviours [8]. The hump (Fig.2) corresponds to the adult ages and it was primarily caused by excess male mortality from cancer [2]. According to [8] we set the threshold age (between the peak and the hump) at 45 ages and we will focus only on the peak, in order to study the gender gap in mortality at young ages.

The differences between the two sex in infant mortality are very low in all the considered periods, the differences start to increase in the years of adolescence. Male mortality at the peak comes to more than 3 times that of females in most years and there is no trend in the shift of the peak age over the years.
We have noticed that the sex-ratio at younger ages has a Gaussian shape around the peak, but in most of the years, it is not symmetrical around the peak.

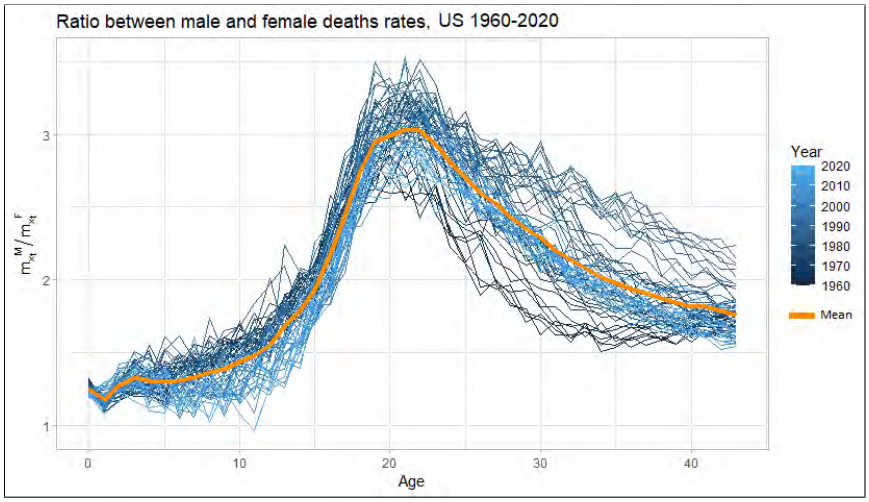

Figure 2: Sex-Ratio of the Age-Specific Mortality Rates in US between 1960 and 2020 for young (under 45) population. Data source: HMD

3. Model

In order to study the age, period and cohort effects we suggest leveraging a mixed model effects model based on a *Skew-Normal* distribution. Here is the density function of a Skew-Normal distribution as presented by Azzalini [1]:

$$f(y;\boldsymbol{\theta}) = f(y;\mu,\sigma^2,\delta) = \frac{2}{\sqrt{\sigma^2+\delta^2}}\phi\left(\frac{\sqrt{y-\mu}}{\sqrt{\sigma^2+\delta^2}}\right)\Phi\left(\frac{\delta}{\sigma}\frac{\sqrt{y-\mu}}{\sqrt{\sigma^2+\delta^2}}\right) \tag{2}$$

Following the framework proposed by Klein et al.[6], we can generally set up the relationship between distribution parameters and the elements of the linear predictor as:

$$g(\varphi) = \sum_{j=1}^{J} f_j(\boldsymbol{\nu}),$$

Where f may comprise various forms, defined on basis of the covariate structure, as follows: a linear function $f_j(\nu) = \mathbf{X}\beta_j$, that represents the fixed effects; and a random effects part γ_g, in which g is a cluster variable that groups the observations. This can be written in the generic matrix notation $\mathbf{Z}\gamma$, where $\mathbf{Z}$ is the random effects design matrix and γ is a correspondent coefficient.

Specifically, let's consider $y^{\mathrm{T}} = (y_1, y_2, \ldots, y_n)$ as the vector of the response variable and $f(y;\boldsymbol{\varphi})$, a density function with k parameters $\boldsymbol{\varphi}^{\mathrm{T}} = (\varphi_1, \varphi_2, \ldots, \varphi_n)$ modelled by using linear additive models. We assume that observations y_i are independent conditional on $\boldsymbol{\varphi}$, with density function $f(y_i;\varphi_i)$, where ${\varphi_i}^{\mathrm{T}}$ is a vector of k parameters related to explanatory variables and random effects. Let $g(\cdot)$ be a known monotonic link function relating φ_k to explanatory variables and random effects through an additive model given by:

$$g(\varphi) = \eta = \mathbf{X}\boldsymbol{\beta} + \mathbf{Z}\boldsymbol{\gamma}$$

where: $\beta^{\mathrm{T}} = (\beta_{1k}, \beta_{2k}, \ldots, \beta_{J'k})$ is a parameter vector of length J', $\mathbf{X}$ is the design matrix of fixed effects of order $n \times J'$, $\mathbf{Z}$ is a $n \times q_j$ random effects design matrix and γ_j is a correspondent q_j-dimensional coefficient. In our study, for the skewed normal family distribution: $\varphi = \mu$ and $g(.)$ is the identity function. So, we have the following model:

$$\mu = \mathbf{X}\boldsymbol{\beta} + \mathbf{Z}\boldsymbol{\gamma}$$

Thereby, the components of the model are: $\mathbf{y}$, is the response vector of length n; $\mathbf{X} = (\mathbf{X}_1, \mathbf{X}_2, \ldots, \mathbf{X}_p)$ are the design matrices for the fixed effects and $\boldsymbol{\beta}^{\mathrm{T}} = \left(\boldsymbol{\beta}_1^{\mathrm{T}}, \ldots, \boldsymbol{\beta}_p^{\mathrm{T}}\right)$ are the linear parameters. The

random effects part is given by the design matrices $\mathbf{Z} = (\mathbf{Z}_{11}, \mathbf{Z}_{21}, \ldots, \mathbf{Z}_{J_11})$ and the coefficients: $\gamma^{\mathrm{T}} = \left(\gamma_{11}^{\mathrm{T}}, \gamma_{21}^{\mathrm{T}}, \ldots, \gamma_{\mathcal{L}_11}^{\mathrm{T}}, \ldots, \gamma_{p}^{\mathrm{T}}, \gamma_{2p}^{\mathrm{T}}, \ldots, \gamma_{L_pp}^{\mathrm{T}}\right)$.

4. Model specification as an Age-Period-Cohort model

Here, we provide the model to an APC Skew-Normal mixed model to be applied to the study of the gender gap while including the Age-Period-Cohort (A-P-C) structure as predictor. We aim to provide the broadest possible overview of solutions, taking into account model specifications with classical constraints, and using random effects.

Let $\mathcal{A} = \{a_0, a_1, \ldots, a_\omega\}$, $\mathcal{P} = \{p_0, p_1, \ldots, p_n\}$ and $\mathcal{C} = \{c_0, c_1, \ldots, c_m\}$ be the set of age, year and cohort categories, respectively. The APC model describes the gender ration of death rates at age $a \in \mathcal{A}$, time $p \in \mathcal{P}$, and cohort $c \in \mathcal{C}$.

Constrained Model

We start by introducing the constrained model as the classic way and thus adapting the constraints to our framework in the following formulation:

$$\mu = \beta_{(a)} + \beta_{(p)} + \beta_{(c)} \tag{3}$$

where, βs are coefficients of fixed effects using categorical coding for Age, Period and Cohort respectively, imposing the following constraints:

$$\sum_{\omega=1}^{\Omega} \beta_{(a\omega)} = \sum_{n=1}^{N} \beta_{(p_n)} = \sum_{m=1}^{M} \beta_{(c_m)} = 0$$

Random Effects - Period, Cohort

We, then, introduce the mixed effects model. We treat Age as fixed effects according to Reither et al. [10], who justify the treatment of period and cohort random effects.

$$\mu = \beta_{(a)} + \gamma_p + \gamma_c \tag{4}$$

In this case, γ_p and γ_c are random effects for the period and cohort level, and β provide fixed effects using categorical coding for Age.

Random Effects - Cohort

An alternative is to consider only cohorts as random effects:

$$\mu = \beta_{(a)} + \beta_{(p)} + \gamma_c \tag{5}$$

Where, γ_c is the random effect for cohort level and βs fixed effects using categorical coding for Age and Period.

For all tree models, we specify a $\sigma^2 \sim \Gamma(0.01, 0.01)$ and a $\delta \sim \Gamma(0.01, 0.01)$. Furthermore, we use flat priors for random effects coefficients.

5. Results

In our analysis, we estimate the models described in the previous section (4) with a Bayesian approach. Samples from the posterior distributions of the parameters and effects were drawn by using Hamiltonian Monte Carlo sampling and specifically using the `stan` software package [5].

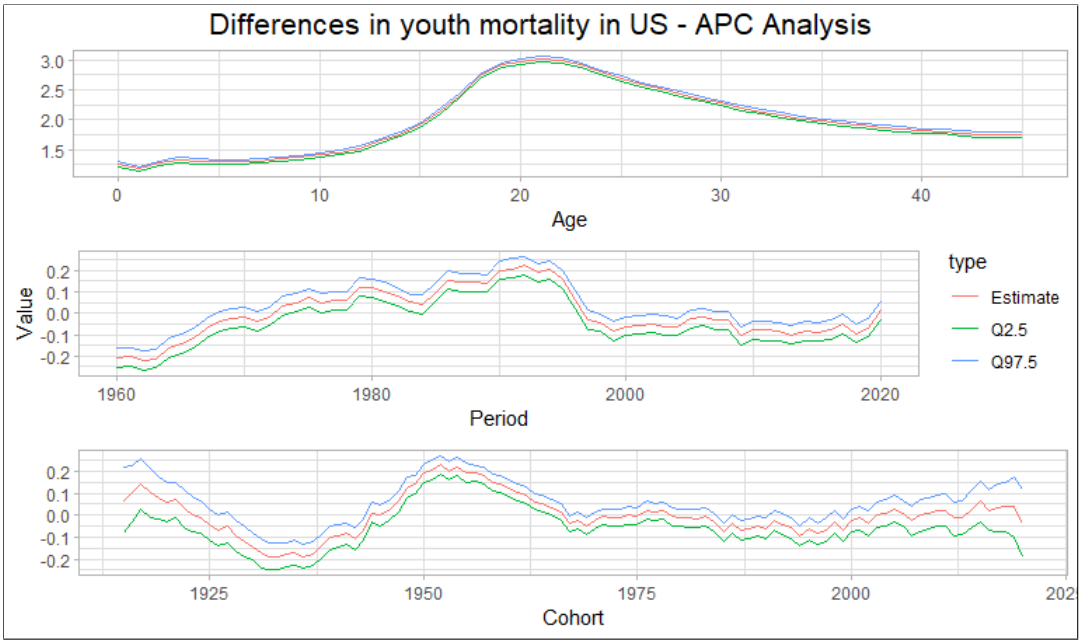

Figure 3: APC model: Age fixed effect, Period and Cohort random effects. Data Source: HMD

Here we report the results (Fig.3) for the model in which we coded age as a categorical variable and treat it as a fixed effect; period and cohort are random effects (Eq. 4).

The age parameters provide the structure of the gender gap in youth mortality, which can be found on average in all years of the period and for all cohorts. The value of the estimated parameters for age increases with adolescence. Researchers usually do not look at biological factors to explain the excess mortality among men at these ages, but rather at individual and social reasons [4] [11]. These reasons become even bigger and more important in the peak years of gender differences (21-22 years): car accidents, suicides and violence are by far the most important causes.

From the two graphs of period and cohort parameters, we can suppose to observe the impact that AIDS has had on US society. AIDS-related mortality is higher for men than for women [13]. Thus, as the pandemic in the US diminished during the 1990s, mortality differences decreased. Cohorts born between the 1940s and 1970s are those on which the AIDS pandemic had the greatest impact.

6. Discussion

We observed the gender gap in youth mortality in the US between 1960 and 2020. For this aim, we used a sex-ratio approach in the Age-Period-Cohort framework, leveraging a mixed-effects model based on a Skew-Normal distribution. We tested different models considering age as a fixed effect and various combinations of period and cohort as fixed or random effects.

The parameter estimates were performed adopting a Bayesian approach and using `stan` software.

The innovation of this work is to implement an Age-Period-Cohort analysis, assuming that the target variable has an asymmetric distribution: the Skew-Normal distribution is not widely used in the APC framework, which usually is based on the normal distribution in the demographic field.

Observing sex differences in mortality and how these vary across ages and over time is useful for understanding society and the behaviours that determine them. Moreover, the knowledge of the mortality dynamics and of the differences between the sexes can be an excellent tool in the hands of policymakers. Preliminary results show that over the past 25 years in the US, we have observed a decrease in sex differences in youth mortality. Younger cohorts are benefiting from societal changes and the attention that the topic of youth mortality is receiving in the public debate.

Kinlessness in adult and old age across Europe

Marta Pittavino[a], Bruno Arpino[a], and Elena Pirani[a]

[a]Department of Statistics, Computer Science, Applications "Giuseppe Parenti", University of Florence
marta.pittavino@unifi.it, bruno.arpino@unifi.it, elena.pirani@unifi.it

Abstract

In this work we estimate the prevalence of older adults aged 50 and more without close kin in several European countries. Using data from the Survey of Health, Ageing and Retirement in Europe (SHARE), we examine the prevalence of lacking different types and combinations of living kin, considering how kinlessness vary over time and at different ages. In 2019-2020, the prevalence of adults aged 50 and above who lacked a partner/spouse ranged between 22% and 47% across countries, while the prevalence of childless individuals between 4% and 14%. We detected a large variation of kinlessness across countries and age groups. This is of interest to policy makers because kinlessness is associated with poorer economic and health conditions, living alone, and unmeet care needs. Aging research should address the implications of kinlessness for public health, social isolation, and the demand for institutional care.

1. Introduction

Kinlesness is the lack of close kin. Different definitions have been used in previous studies that vary because of the (combination of) specific kinship ties considered. When studying older adults, it is particularly relevant to focus on the absence of a partner/spouse and children (5) because they are the main providers of care and emotional support, as well as the main agents of social control. Recently, there has been a growing interest on kinlessness. Several studies have focused on the estimation of the prevalence and demograhic characteristics of individuals who lack a specific type of kin (e.g., grandchildren) (3). Other studies, have estimating the prevalence of kinlessness, i.e. lack of more than one kin, especially among older adults (5; 6; 9; 10) and its consequences on health, loneliness, care needs, etc. For example, research has shown that kinless individuals tend to report worse wellbeing and health conditions (although this varies considerably across countries and type of health outcome (1; 4; 7) and show higher likelihood of engaging in unhealthy behaviors (2).

In this work we document the size of the population of older adults (aged 50 and more) without close kin in several European countries. Only (9) provided estimates of kinlessness for several European countries in 2015. We contribute to this literature by providing more recent estimates and by showing the variability in kinlessness across age groups and over time.

2. Data and Methods

For this analysis we rely on the data from the Survey of Health, Ageing and Retirement in Europe (SHARE), especially wave 8 carried out in 2019/2020. In each wave, SHARE data cover several key

areas of life - health, socio-economic status, social and family networks - of more than 60,000 individuals aged 50 or over, enabling us to detect kinship ties of individuals. We considered all the 25 countries included in the survey. Additional analyses will use wave 2, 4 and 6 of SHARE to examine changes over time. We will not use all waves because in wave 1 fewer countries than in the other waves participated, while the other waves collected only (wave 3) or mostly (wave 7) retrospective information.

In terms of methods, this study is purely descriptive. We present estimated prevalences (with 95% confidence intervals (CI)). We use cross-sectional calibrated weights that account for sampling design and attrition.

3. Results

Tables 1 and 2 report the (weighted) estimates (and 95% confidence intervals (CI)) of the prevalence of individuals aged 50 and over without a given type of kinship tie, by country. On average, about one third of 50+ individuals lack a living partner/spouse, ranging from the minimum of Spain and Finland (respectively 22 and 25%) to a maximum of 47% for Luxemburg (values around 40% are registered also for Poland and Latvia). The absence of children is depicted for one older individual out of ten on average. The lowest values appear for Eastern European countries (e.g., Hungary, Romania, Lithuania around 4-7%) and Northern ones (e.g., Denmark and Sweden with 7-8%), and the highest values of the prevalence (13-14%) are found for countries like Belgium, Croatia, Czech Republic and Spain. Overall, a large variability is found across this group of countries. Italy occupies an intermediate position: about 29% of individuals aged 50 and over is without a partner and just under 12% lacks children.

An even larger variation has been found with respect lacking grandchildren. About 33% of older Europeans declare to have no grandchildren, with the lowest values (15-17%) found for Greece and Hungary. In this case, Italy is - somewhat unsurprisingly - the European country with the largest share of older individuals without grandchildren, almost 53%, but values around 50% are found also for France, Finland and Croatia.

The absence of living parents is clearly higher due to the age group considered. 3 out of 4 respondents aged 50 and over no longer have parents (62-63% in Italy and Romania, 80% in Poland and Sweden). As expected, due to the higher male mortality, the prevalence of individuals without a living father is higher to that of individuals without a living mother (in some countries the difference reaches 15-20 percentage points).

Finally, also the horizontal kinships - existence of living siblings - proves a large variability across countries. Less than 10% of individuals aged 50 and over has no brothers nor sisters in Croatia, Romania and Spain, but the prevalence raises to 30 or even 40% in Luxembourg, Switzerland, Latvia and Slovenia. The average stands around 20%.

It is straightforward to imagine that this overall picture, already highly differentiated by country, varies greatly on the basis of the age considered and the kinship types. If the presence of ascendants is going to reduce as individuals get older, that of descendents (grandchildren) can somewhat compensate for it, especially in those countries where family formation is postponed. In addition, the absence of one type of kinship may be replaced by the presence of other relatives. To get more insights, we considered various combinations of lack of kinship types, differentiating by the level of absence of kinshp ties (k1: no partner AND no children; k2: no partner AND no children AND no sibling; k3: no partner AND no children AND no siblings AND no grandchildren; k4: no partner AND no children AND no siblings AND no grandchildren AND no parent).

Figure 1 displays the estimate of the four considered kinlessness types for 3 age groups, considering four countries which represent different models of mortality and fertility. First, it is worthwhile noting that the lack of various types of kinship (k2-k4) remains low in all the countries, especially for younger older individuals (50-64). Nevertheless, in France a large variation across age groups is depicted: the lack of kinships progressively increases by age, and reaches a prevalence of almost 10% for the oldest individuals. On the contrary, in Czech Republic the absence of various types of kinships is rather similar regardless the age class considered, from 0 to less than 5%. Somewhat surprisingly, the picture in Italy and Denmark - two countries differing from a demographic and socio-cultural point of view - appears

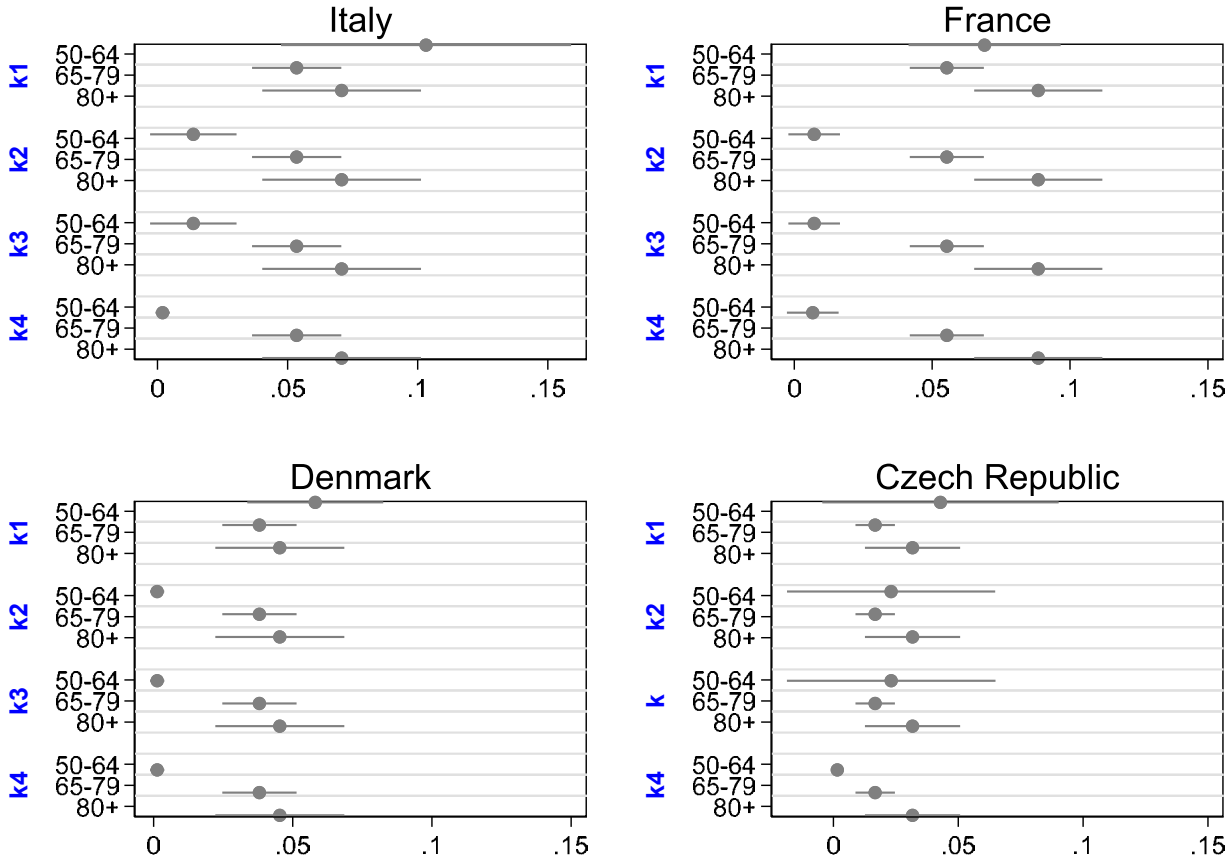

Figure 1: Estimate of kinlessness: $k1, k2, k3$ and $k4$, by 3 age groups (50-64, 65-79, 80+) considering countries which represent different models of mortality and fertility. $k1$ represents no partner AND no children; $k2$ indicates no partner AND no children AND no sibling; $k3$ means no partner AND no children AND no siblings AND no grandchildren; $k4$ represents no partner AND no children AND no siblings AND no grandchildren AND no parent

more similar than foreseen. For instance, the percentage of those who lack both living partner and children (k2) equals to 6-10% for younger respondents, but the lack of also other relatives is extremely reduced less then 2%. For 65-79 and 80+ individuals, the prevalence slightly increases (around 4-7%), but without showing a significant deterioration for the oldest group.

4. Discussion

Our analyses show that the prevalence of kinlessness vary considerably across European countries as the result of different socio-demographic dynamics in the past. Due to the recent and current (decreasing) trends in fertility and (increasing) trends in longevity across European countries, it is not difficult to envisage a progressive shrinking in kinship ties. A deeper investigation of the future progression in kinlessness trends is needed.

In the next steps of the analyses we will also provide estimates of kinlessness over a period of about 12 years (2006/7-2019/20). Preliminary estimates show a considerable increase in kinlessness among the majority of the investigated countries.

Parameter orthogonalization for the Siler mortality model

Claudia Di Caterina[a] and Lucia Zanotto[b]

[a]University of Verona; claudia.dicaterina@univr.it
[b]University of Bologna; lucia.zanotto@unive.it

Abstract

Correlation and, in general, close relationships between parameters can cause problems in the estimation of a model and the consequent fluctuation in the trend of its coefficients. We show the connections existing between parameters in the Siler model, one of the most widely used in demography to approximate mortality over the entire life span, and propose a method to reduce them. Parameter orthogonalization via the Gram-Schmidt-Fisher scoring algorithm seems a promising technique for limiting identification issues and numerical instabilities often encountered when maximizing the likelihood.

Keywords: Siler model, collinearity, orthogonal parameters.

1. Introduction

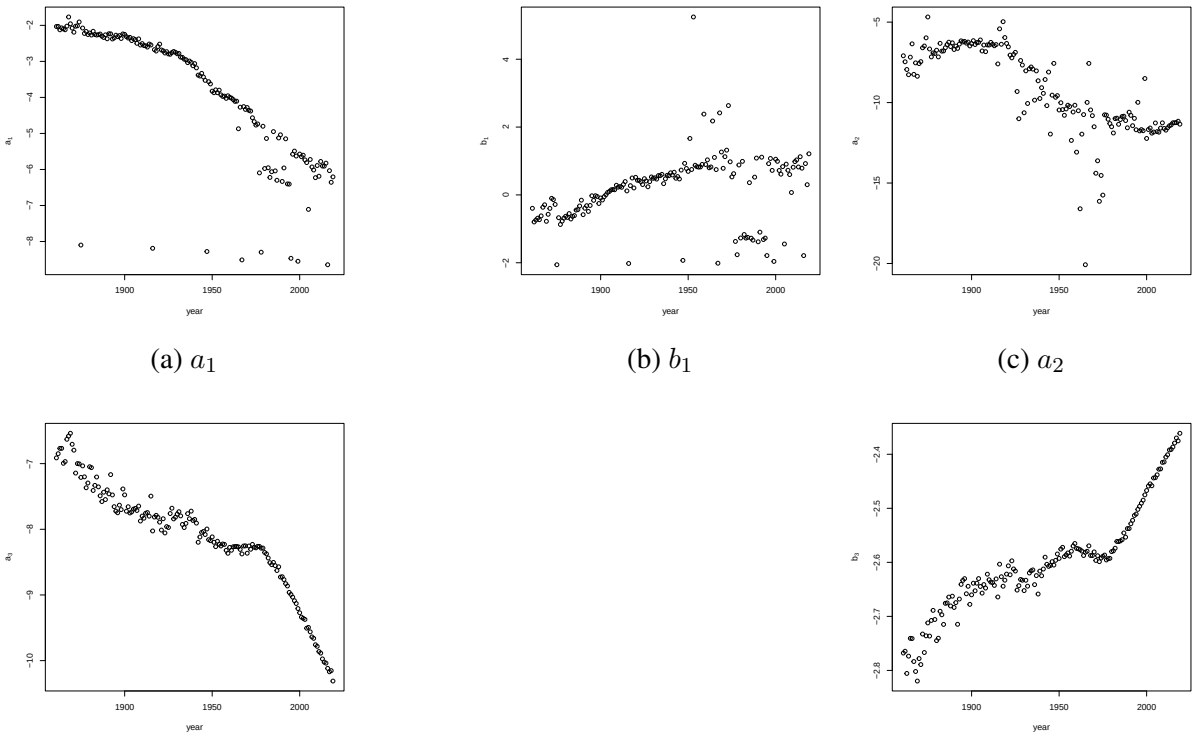
Historically, there are two models mainly used in demography to approximate mortality over the entire lifespan. The first was proposed by Siler (21; 22) to estimate the death rates and consists of three components (five parameters): a negative Gompertz function for infant mortality, a constant representing deaths occurring randomly with respect to age (15), and a Gompertz function (9) for the latter part of the curve. Subsequently, to estimate the probability of death, Heligman and Pollard (10) introduced an 8-parameter model that also captures accidental mortality (i.e., a hump often observed in the death function for males, corresponding to teenage or young adult ages). Rogers (19) and Gage and Mode (7) noted that estimation of the Heligman-Pollard model is difficult, due to model overparameterization and numerical issues. Such numerical difficulties create large fluctuations in parameter estimation over time and space, resulting because of inconsistencies in the dispersion matrix (6). These estimation problems led Dellaportas et al. (6) and Sharrow et al. (20) to use a Bayesian estimation approach.

Although the Siler model has fewer coefficients, both its least squares and maximum likelihood (ML) estimates are quite unstable. This is due to the strong dependence between some of the five parameters. Since the use of parametric models is often preferable (4), in attempt to solve or at least contain the identification problems, we suggest to apply an algorithm which simultaneously orthogonalizes and estimates the parameters of the Siler model (see Section 3) so as to facilitate inferences.

2. Siler Model and correlation between its parameters

The model proposed by Siler (21; 22) represents the death rate at age x using the formula:

$$\mu(x) = a_1 e^{b_1 x} + a_2 + a_3 e^{b_3 x}, \quad x \geq 0, \tag{1}$$



(a) a_1 (b) b_1 (c) a_2

(d) a_3 (e) b_3

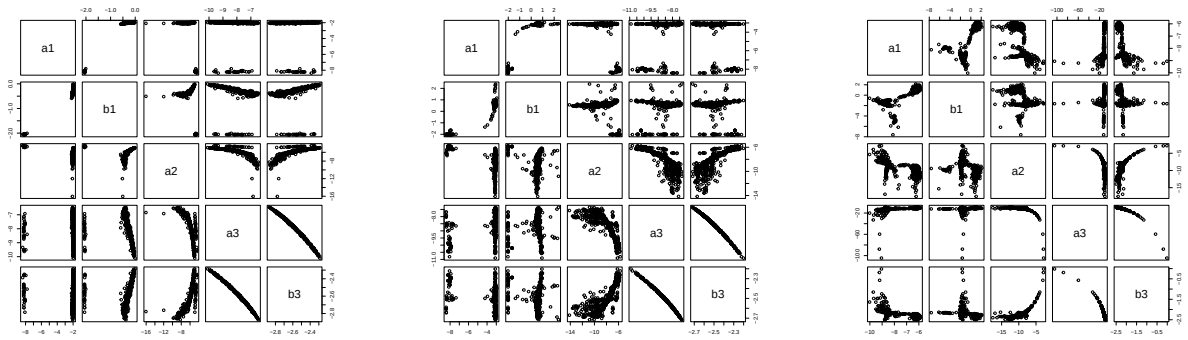
Figure 1: Estimation of the Siler model parameters for Sweden 1861–2019.

where $a_1 e^{b_1 x}$ is a negative exponential function used to approximate the first part of the curve, $a_2 > 0$ is the Makeham's constant and $a_3 e^{b_3 x}$ is the Gompertz model (9), fitting senescent death rates.

Two methods are usually adopted to estimate the five positive model parameters: least squares or ML. However, least squares are less convenient for this model because nonlinear least squares do not have the same desirable properties of ordinary ones (2). Instead, the ML approach has been tried since 1970 (8) with good results. In the latter case, we can assume that the number of deaths in a given age interval follows a Poisson distribution, where its rate equals the assumed hazard function (for details, see the Section 3 "Estimation methods" in 2). ML estimates are then obtained by numerically maximizing the resulting likelihood function (see Section 3.2), for example using the `optim` routine in R (18).

For illustrative purposes, we focus on Swedish male mortality rates from 1861 to 2019 downloaded from the Human Mortality Database (11). This country offers a long time series covering different mortality scenarios: from before the demographic transition (very high infant mortality, low life expectancy at birth) to the present day (very low infant mortality, compression and shifting of adult deaths resulting in the exceptional increase in life expectancy). As shown in Figure 1, parameter estimates for the Siler model have an irregular behavior over time. This is not due to the quality of the data, but to identification problems caused by their intercorrelation.

A simulation study was implemented in order to better understand cross-correlation among parameters. Three years were selected to represent the whole time series for Sweden: 1861, characterized by pre-demographic transition mortality, 1939, a period of changing from high to low mortality, and the pre-pandemic 2019, marked by high life expectancy. For every year, 1,000 samples of 100,000 observations were drawn from a multinomial distribution with parameters equal to the death probabilities in each age group. These probabilities were derived from the mortality table for the corresponding year. The Siler model was fit on each sample and the correlations between parameter estimates were computed. Figure 2 reports, for all three years, very strong relationships between the parameters a_1 and b_1, related to infant mortality (correlation greater than 0.88) and between a_3 and b_3, related to adult mortality (correlation lower than -0.86 and, for 1861 and 1939, lower than -0.96) (16). Also not negligible is the correlation



(a) Sweden 1861 (b) Sweden 1939 (c) Sweden 2019

Figure 2: Correlation plots between estimates of the Siler model for Swedish mortality data.

between a_2 and b_3, always higher than 0.77.

3. Parameter Orthogonalization

When the parameters of a statistical model are orthogonal, it is easier to quantify and distinguish the amount of information carried by the data on the different aspects of the phenomenon under investigation. The fact that resulting estimates are not strongly correlated allows optimization algorithms to converge faster and interpretation of results to be more reliable.

3.1 Likelihood setting

The problem of parameter orthogonality in ML estimation dates back to (13) and was later studied, among others, by (12), (1) and (5). Suppose the data $y = (y_1, \ldots, y_n)$ have distribution $f(y; \theta)$ depending on the unknown parameter $\theta \in \Theta \subseteq \mathbb{R}^p$. We denote by $l(\theta) = \log f(y; \theta)$ the log-likelihood and by $u(\theta) = \partial l(\theta)/\partial\theta$ the score, and assume that usual regularity conditions are met by the parametric model (17). Two parameter components, θ_1 of dimension p_1 and θ_2 of dimension p_2, with $p = p_1 + p_2$, are said to be (globally) orthogonal if the entries of the Fisher information $i(\theta)$ matrix satisfy

$$i_{st} = E_\theta\left(\frac{\partial l}{\partial\theta_s}\frac{\partial l}{\partial\theta_t}\right) = E_\theta\left(-\frac{\partial^2 l}{\partial\theta_s\partial\theta_t}\right) = 0\,, \quad \forall\theta \in \Theta, \quad s = 1, \ldots, p_1;\ t = p_1 + 1, \ldots, p.$$

The major consequence of such condition is that the ML estimators of θ_1 and θ_2 are asymptotically independent. This implies that the ML estimate of one parameter is not affected or changes slowly with that of the other, which is helpful to reduce numerical instabilities during the estimation process.

Cox and Reid (5) proposed a general strategy to achieve orthogonalization between a scalar parameter of interest and a set of q nuisance parameters. However, that procedure is based on the solution of q partial differential equations, which is often computationally infeasible or not unique. A more practical solution consists in applying the Gram-Schmidt orthogonalization process (3) via the iterative Fisher scoring algorithm presented in (14). More specifically, a reparameterization Θ^* is sought through a linear transformation of Θ with unity Jacobian such that the parameters in $\theta^* = (\theta_1^*, \ldots, \theta_p^*)^\top$ are mutually uncorrelated. As shown in (14, Sect. 4.1), solving a system of linear equations leads to $\theta^* = \theta^*(\theta) = B\theta$, where $B = B(\theta)$ is a lower triangular $p \times p$ matrix with ones on the main diagonal and (j, k)-th element

$$b_{jk} = \sum_{r=1}^{j-1} i^{rj} i_{r,j-k}, \qquad j = 2, \ldots, p;\ k = 1, \ldots, j-1, \tag{2}$$

where i^{rj} equals the (r, j)-th entry of the inverse Fisher information matrix $i(\theta)^{-1}$. Starting from the update $(m + 1)$ of the classical Fisher scoring algorithm, since the transformation matrix B is non-

singular by construction, it is possible to summarize the Gram-Schmidt-Fisher scoring algorithm (14, Sect. 4.3) by the iterative routine

$$\theta^*_{(m+1)} = \theta^*_{(m)} + i(\theta^*_{(m)})^{-1} u(\theta^*_{(m)}) \,, \tag{3}$$

where $\theta^*_{(m)} = B\theta_{(m)}$ is the orthogonal parameter vector at the m-th iteration, $i^{-1}(\theta^*_{(m)}) = Bi(\theta_{(m)})^{-1}B^\top$ is asymptotically diagonal and $u(\theta^*_{(m)}) = (B^\top)^{-1}u(\theta_{(m)})$ is the score function in the parameterization Θ^*.

3.2 Gram-Schmidt-Fisher scoring algorithm for the Siler model

As the Gram-Schmidt-Fisher scoring algorithm seems particularly convenient for non-linear ML estimation of models with a small parameter space dimension (14, Sect. 6), we propose to apply it as an approximate orthogonalization technique for the parameter $\theta = (\theta_1, \ldots, \theta_p)^\top = (a_1, b_1, a_2, b_2, b_3)^\top$ of the Siler model (see Section 2).

Consider the dataset of mortality rates m_x at age x ($x = x_0, \ldots, \omega$) and Siler's mortality hazard function $\mu(x) = \mu_x(\theta)$. Assuming the number of deaths are independent across age groups and follow a Poisson distribution, the log-likelihood of the model can be expressed by

$$l(\theta) = \sum_{x=x_0}^{\omega} \{m_x \log \mu_x(\theta) - \mu_x(\theta)\} \,,$$

and the 5-dimensional score function $u(\theta)$ has j-th entry

$$u_j = \frac{\partial l}{\partial \theta_j} = \sum_{x=x_0}^{\omega} \left\{ \frac{m_x}{\mu_x(\theta)} - 1 \right\} \frac{\partial \mu_x(\theta)}{\partial \theta_j} \,, \qquad j = 1, \ldots, 5 \,,$$

where $\partial\mu_x(\theta)/\partial\theta_1 = e^{-\theta_2 x}$, $\partial\mu_x(\theta)/\partial\theta_2 = -\theta_1 x e^{-\theta_2 x}$, $\partial\mu_x(\theta)/\partial\theta_3 = 1$, $\partial\mu_x(\theta)/\partial\theta_4 = e^{\theta_5 x}$ and $\partial\mu_x(\theta)/\partial\theta_5 = \theta_4 x e^{\theta_5 x}$. Then, as $E_\theta(m_x) = \mu_x(\theta)$, it is possible to show that the (j,k)-th element of the Fisher information matrix $i(\theta)$ equals

$$i_{jk} = \sum_{x=x_0}^{\omega} \frac{1}{\mu_x(\theta)} \frac{\partial \mu_x(\theta)}{\partial \theta_j} \frac{\partial \mu_x(\theta)}{\partial \theta_k} \,, \qquad j = 1, \ldots, 5 \,;\; k = 1, \ldots, 5.$$

Since the parameters of the Siler model must be positive, i.e. $\theta_j > 0$ ($j = 1, \ldots, 5$), it is safer to maximize numerically the log-likelihood in the unconstrained parameter space $\mathbb{R}^5$ under the reparameterization $\psi = \psi(\theta) = \log\theta$. The likelihood quantities we need to perform the Gram-Schmidt-Fisher scoring algorithm in the parameterization Ψ can be readily obtained by (17)

$$u^\Psi(\psi) = J_\theta(\psi)^\top u(\theta(\psi)) \quad \text{and} \quad i^\Psi(\psi) = J_\theta(\psi)^\top i(\theta(\psi)) J_\theta(\psi) \,,$$

where $J_\theta(\psi)$ is the diagonal Jacobian matrix of the inverse transformation $\theta(\psi) = e^\psi$, with j-th diagonal entry $\partial\theta_j/\partial\psi_j = e^{\psi_j}$.

Once we derive analytically $u^\Psi(\psi)$ and $i^\Psi(\psi)$, the implementation of the Gram-Schmidt-Fisher scoring algorithm exposed in (14, Sect. 4.3.1) can be adapted as follows:

1. Start with an initial estimate $\psi_{(0)}$ of $\psi = \log\theta$.
2. Set $m = 0$.
3. Estimate the 5×5 transformation matrix $B = B(\psi_{(m)})$ with entries given in (2).
4. Calculate the current orthogonal parameter estimate $\psi^*_{(m)} = B\psi_{(m)}$.
5. Update ψ^* by (3): $\psi^*_{(m+1)} = \psi^*_{(m)} + i^\Psi(\psi^*_{(m)})^{-1} u^\Psi(\psi^*_{(m)})$.
6. Update ψ: $\psi_{(m+1)} = B^{-1}\psi^*_{(m)}$.
7. Stop if $||\psi^*_{(m+1)} - \psi^*_{(m)}||_2 / ||\psi^*_{(m)}||_2 < \varepsilon$.
8. Set $m = m + 1$ and repeat from Step 3.

Table 1: Correlation matrix for estimates of the Siler model obtained in the original parameterization via `optim` (left) and in the orthogonal parameterization via the Gram-Schmidt-Fisher scoring algorithm (right) for Sweden 2019.

	Original parameterization θ						Orthogonal parameterization θ^*				
	a_1	b_1	a_2	a_3	b_3		a_1^*	b_1^*	a_2^*	a_3^*	b_3^*
a_1	1.000	0.890	-0.676	0.279	-0.508	a_1^*	1.000	-0.160	-0.150	0.024	-0.293
b_1	0.890	1.000	-0.530	0.189	-0.387	b_1^*	-0.160	1.000	0.362	-0.186	-0.177
a_2	-0.676	-0.530	1.000	-0.492	0.773	a_2^*	-0.150	0.362	1.000	-0.296	-0.283
a_3	0.279	0.189	-0.4924	1.000	-0.865	a_3^*	0.024	-0.186	-0.296	1.000	0.731
b_3	-0.508	-0.387	0.773	-0.865	1.000	b_3^*	-0.293	-0.177	-0.283	0.731	1.000

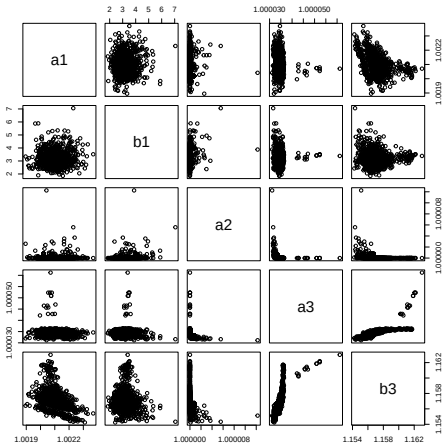


Figure 3: Correlation plots of the Siler model for Sweden 2019 with the orthogonal parametrization.

3.3 Preliminary results and future work

R is used to program the Gram-Schmidt-Fisher scoring algorithm described above. Partial results are shown in Figure 3, which refers to year 2019. In the original parameterization, as discussed in Section 2, estimates of a_1 and b_1 are highly positively correlated, while a_2 and b_3 are highly negatively related. When switching to the orthogonal parameterization, instead, the corresponding correlations are smaller. We note an overall drop in the intercorrelation between parameters under the orthogonal parameterization, except for that between a_3 and b_3 whose reduction is only partial (see Table 1.

It is worth pointing out that the Gram-Schmidt orthogonalization affects differently the single components of the parameter vector, so the estimates in the first positions are less prone to suffer from round-off errors (14, Sect. 4). This might explain the inflation observed in the correlation between the parameters a_3 and b_3, in positions $j = p - 1, p$ of θ. Another important remark concerns the interpretation of the orthogonal estimates with respect to the original parameterization: $\theta_j^* = \theta_j - \sum_{k=1}^{j-1} b_{j,j-k}\theta_{j-k}$ $(j = 1 \ldots, 5)$ where the b_{jk}s can be viewed as coefficients of the multiple linear regression of θ_j on the previous parameters $\theta_1, \ldots, \theta_{j-1}$ (14, Sect. 4).

Finally, the current implementation of the Gram-Schmidt-Fisher scoring algorithm for the Siler model is at a very early stage. We plan to study more in depth its numerical stability, sensitivity to starting values and convergence times. The ultimate goal is to reduce identification problems and obtain more stable ML estimates, smoothing out the trend of the parameters.

Pseudo-observations in survival analysis

Marta Cipriani[a], Alfonso Piciocchi[b], Valentina Arena[b], and Marco Alfo'[a]

Abstract

In recent years, pseudo-observations have gained much interest as they address one of the main issues with survival data, i.e. incomplete observations due to right-censoring, and they allow for the analysis of such data by standard statistical methods. In this work, a method based on pseudo-values will be illustrated for direct regression modelling of the survival function, the restricted mean survival time, and the cumulative incidence function in a competing risks situation. The method based on pseudo-observations will be compared to the traditional Cox proportional hazard and Fine-Gray models.

Keywords: survival data, pseudo-observations, right-censoring, GEE, informative missing

1. Introduction

The existence of missing data is a topic of crucial interest in survival analysis. Frequently, we do not have complete observations for some individuals in the study due to the inherent structure of survival data. In this context, a source of information loss is the occurrence of censoring, a technicality which must be dealt with when examining survival data. Thus, standard statistical models cannot be used to analyse this kind of data.

In the classical theory of survival analysis, the censoring is assumed to be independent of the survival time (8), i.e. censoring is non-informative on the *true* survival time. In this perspective, censoring is essentially due to delayed entry. Namely, units that enter late in the study remain under observation for a shorter time and, reasonably, are less likely to be associated with an event, given the individual features. This assumption implies that the velocity of occurrence of the event of interest can be estimated by considering only the survival experience of non-censored units.

In more complex situations, when units drop out prematurely, censoring cannot be directly assumed to be independent of the survival experience and, therefore, it may be informative. In this case, the issue is to account for the information that could not be observed. Therefore, under the *missing at random* (MAR) assumption (12), the censored observations can be imputed on the basis of the observed ones.

The so-called pseudo-observations estimate a set of pseudo-values of the (time-related) response variable for each individual in the study at a given set of time points. Hence, they allow to model the effect of covariates on the event times by methods usually restricted to longitudinal data with full information.

2. Methods

The pseudo-observation approach was first suggested by Andersen *et al.* (3) to perform a generalized linear regression analysis of survival data, albeit it is a more general method with many fields of application. The theory is based on the pseudo-observations drawn from the jackknife method (11). The following definition can be used to introduce the concept.

Definition 1. *Let ϕ be some function of the survival time T for which we are interested in the parameter $\theta(T) = E(\phi(T))$ and let $\widehat{\theta}(T)$ be an unbiased (or approximately unbiased) estimator of $\theta(T)$. The pseudo-observations for subject i is then defined as*

$$\widehat{\theta}_i(t) = n\widehat{\theta}(t) - (n-1)\widehat{\theta}^{-i}(t)$$

where $\widehat{\theta}^{-i}$ is the estimator derived from the sample of size $n-1$ obtained by ignoring subject i.

In general, one may then think of the pseudo-observation $\theta_i(t)$ as a replacement for the, possibly incompletely observed, random variable $\phi_i(t)$. Once the pseudo values are obtained they can be used in a standard generalized estimation equation (GEE) or generalized linear model (GLM) to obtain regression estimates:

$$g(E(\phi_i(t)|\mathbf{Z}_i)) = \alpha + \beta'\mathbf{Z}_i$$

with $g(.)$ a *link function* and $\mathbf{Z}_i$ the subject-specific covariates vector.
The GEE approach based on pseudo-values is frequently proposed in the literature to fit a model for functions of the event time. The justification for using pseudo-observations in such approach relies on some neat results by Graw *et al.* (7) concerning the estimated regression parameters.
The main advantage of this technique is that it enables modelling the survival data by a wider number of regression methods. Consequently, it allows to take into account very useful parameters estimates in the context of survival analysis (e.g. a regression model for the restricted mean survival time).
In addition, as discussed by Andersen *et al.* (4), the so-called classical survival methods require that several assumptions about the models used are tested, such as the propotional hazard hypothesis in the Cox model. By contrast, the hypotheses needed to use pseudo-observations are less restrictive. Simple uses of the method do, however, require that censoring is independent of covariates, although this assumption might be relaxed (5).

2.1 Pseudo-values for the survival function

If the target parameter $\theta(t)$ is the survival function, $\widehat{\theta}(t)$ can be obtained by the Kaplan-Meier estimator $\widehat{S}(t)$. The pseudo-observations for subject i is then

$$\widehat{S}_i(t) = n \cdot \widehat{S}(t) - (n-1) \cdot \widehat{S}^{-i}(t)$$

As usual in survival analysis in discrete time (2), we may use a *complementary log-log* link function and define the estimation model as follows

$$g(S(t|\mathbf{Z}_i)) = \log(-\log(S(t|\mathbf{Z}_i))) = \log H_0(t) + \beta'\mathbf{Z}_i$$

This model corresponds to the Cox model in discrete time, where

$$S(t|\mathbf{Z}_i) = S_0(t)^{\exp(\beta'\mathbf{Z}_i)} = \exp\Big(-H_0(t)\exp\big(\beta'\mathbf{Z}_i\big)\Big)$$

2.2 Pseudo-values for other quantities

Pseudo-observations allow us to define a model for other quantities associated to the survival function, as the **restricted mean survival** (RMS). The RMS is defined as $\mu(t) = \int_0^t S_t(u)$ and it can be estimated by the area under the Kaplan-Meier curve up to time t:

$$\widehat{\theta}(t) = \widehat{\mu}(t) = \int_0^t \widehat{S}_t(u)du$$

and pseudo-observations are

$$\widehat{\mu}_i(t) = n \cdot \widehat{\mu}(t) - (n-1) \cdot \widehat{\mu}^{-i}(t)$$

In a situation with two competitive risks, associated to hazard functions $h_1(t)$ and $h_2(t)$, respectively, the **cumulative incidence function** is defined by

$$C_k(t) = \int_0^t h_k(u) \exp\left[\int_0^u \big(h_1(v) + h_2(v)\big)dv\right]du \qquad k = 1, 2$$

and it may be estimated by the Aalen-Johansen estimator $\widehat{C}_k(t)$. The i'th pseudo-observation corresponding to $C_k(\cdot)$ at time t is then given by

$$\widehat{C}_{ki}(t) = n \cdot \widehat{C}_k(t) - (n-1) \cdot \widehat{C}_k^{-i}(t)$$

Using the *complementary log-log* link function leads to the definition of an estimation model corresponding to the proportional subdistribution hazards model proposed by Fine and Gray (6):

$$g(C_k(t|\mathbf{Z}_i)) = \log\Big(-\log\big(C_k(t|\mathbf{Z}_i)\big)\Big) = 1 - \exp\big[H_0 \cdot e^{\beta' \mathbf{Z}_i}\big]$$

3. Case study

The potential of methods based on pseudo-observations is shown through an application to data collected in a phase II experimental trial, the GIMEMA AML1310, and carried out by Fondazione GIMEMA Franco Mandelli Onlus (13). In order to make a comparison, standard methods of survival analysis and pseudo-observations approach have been compared on these data.

3.1 Available data

The sample includes 500 acute myeloid leukemia (AML) patients on which several prognostic factors have been collected:

- *demographic characteristics*: age, sex
- *hematological characteristics*: white blood cells, platelets, etc.
- *genetic profiles*: mutations of specific genes
- *risk categories*: identified according to NCCN 2009[1]
- *clinical parameters*: minimal residual disease (MRD), performance status, etc.

The GIMEMA Foundation has developed a risk-adapted, MRD-oriented, prospective clinical trial, the strategy of which consisted of the prognostic integration of pre-treatment cytogenetics and genetics with post-consolidation MRD. Based on this strategy, patients were to receive post-consolidation autologous or allogenic stem cell transplantation, respectively, depending on their risk profile.
The primary trial objective was to evaluate the treatment strategy in terms of Overall Survival (OS) at 24 months.

3.2 Results

The number and position of time points, for which the pseudo-observations are calculated, is a choice which must be made prior to the analysis. One time point is enough to obtain estimates of the regression parameter (9); however, more time points may needed to capture the trend in the time to event distribution. In this analysis five time points, equally spaced and concentrated within the most dense region of the time to event distribution, have been chosen.
The pseudo-observation-based models discussed in the following are based on the assumption that the censoring time is independent of the event time and of all covariates in the survival model.
As for the **survival function** estimates, the results obtained using the two methods (the Cox model and

[1]National Comprehensive Cancer Network (NCCN) 2009 recommendations

the model based on pseudo-observations) do not substantially differ in terms of point estimate or significance. However, the pseudo-observation approach helps avoid the assumption of hazard proportionality needed in the former.
Even though the impact of using pseudo-observations for inference on survival function was minor, the strength of this approach arises in situations where no standard models exist. Indeed, the pseudo-observations allow to build regression models for the **restricted mean survival** time.
The R package `survival` does not enable to compute the RMS conditional on more than one covariate. On the contrary, the two packages devoted to modelling pseudo-observations (`pseudo` and `eventglm`) provide the chance to assess the simultaneous effect of a set of covariates on the restricted mean lifetime. In this case the *link function* $g(.)$ used in the estimation model is an identity function, so that the estimated parameters represent the difference between the areas under the estimated survival curves.
As for the **cumulative incidence function** estimates, the relapse has been considered the primary event (death is the competing event) to build the competing risk model. The comparison between the Fine-Gray and the GEE models shows that the first produces a reduced set of significant effects than that obtained using the pseudo-observations.

3.2.1 Some clues on censoring distribution

Thanks to the tools available in the R packages to work with pseudo-observations (10), it is possible to evaluate the sensitivity of models to hypotheses on the censoring-data mechanism.
The identification of the assumption which reasonably best fits the analysed data has been carried out by comparing the results obtained according to the different hypotheses. The best fitting is found by looking at the length of the estimated confidence intervals.
The results of this work point out that the censoring times are reasonably described by an additive risk model (1). Thus, assuming that the censoring depends on covariates, the pseudo observations are calculated with the inverse probability of censoring weighted (IPCW) approach, where the censoring probabilities are estimated using Aalen's additive hazards model.

4. Conclusions

The characteristic of recovering censored information at an event time makes pseudo-observations particularly advantageous to derive more efficient estimators for quantities of interest in survival analysis. Especially when considering studies meant to assess causal links, methods based on pseudo-observations are going to be widely used to deal with the issue of partially observed information due to censoring.
The main advantage of this approach is that it enables modelling the survival data by a wider number of regression methods, e.g. a regression model for the restricted mean survival time.
The comparison between standard methodologies in survival analysis and techniques based on pseudo-observations may highlight the potentialities of the proposed method and the ease to consider a larger number of models generally precluded to censored data. Furthermore, it is possible to obtain more detailed information and evaluate the sensitivity with respect to the hypotheses about the censoring mechanism.
Over recent years, interest in pseudo-observations has been growing and researchers have focused on new methodologies for producing increasingly precise pseudo-observations. Among these, the use of a semi-parametric approach to computing pseudo-observations proved to be more efficient than a completely non-parametric one.
In the literature about pseudo-observations there are still few unanswered questions which may provide ideas for future research developments in this area. Indeed, the performance of the methods based on pseudo-observations may depend on the amount and type of missing information (missing at random or not) recorded up to the end of the study. For this reason an in-depth research on this issue is needed and may contribute to improving the method.

Abstract

We measured sex-specific total life expectancy, cancer-free life expectancy (CFLE), and years spent with cancer according to the (co-) occurrence of three behavioural risk factors, such as smoking, obesity and physical inactivity. We examined differences between women and men using data from the United States Health and Retirement Study 2008–2018 and we applied multistate lifetable approach for each combination of smoking, obesity, and physical inactivity, controlling for education. Risk factors were associated with shorter CFLE, the shortest observed in current smoker's men and women (-4.7 years at age 50). Reductions of CFLE in physically inactive people was higher in women (-3.3 years) than in men (-2.3 years) and obesity had a significant effect only in women (-3.1 years). Sex differences decreased at older age. The (co-) occurrence of behavioural risk factors reduces the CFLE disadvantage of men compared to women.

Key words: sex gap, cancer-free life expectancy, mortality risk factors

1. Introduction

Cancer is second leading cause of death globally. According to the United States Cancer Statistics (USCS), around 16.9 million men and women had a cancer history in the United States (US) in 2019 and there are projected more than 22.0 million cases in 2030 (USCS 2019). In 2019, the prevalence of cancer in women and in men was 4.0% and 3.8%, respectively. Prostate, breast, lung and bronchus, and colorectal cancer are the most frequently diagnosed cancers in the US (USCS 2019). Although improvements in cancer survival due to advances in screening technology and implementation and treatments in recent decades, cancer still contributes significantly to years lived with disability and to the risk of mortality.

Studies have shown that modifiable lifestyle factors such as smoking, physical activity, alcohol intake, body weight, and diet quality affect both life expectancy and incidence of chronic diseases, including cancer (Stenholm et al 2016; Leskinen et al 2018). Nevertheless, little research has looked at how multiple behavioral risk factors may affect life expectancy free from the major diseases, especially free from cancer (i.e. Cancer-Free Life Expectancy - CFLE).

Using data from Nurses' Health Study and the Health Professionals Follow-Up Study in 1980–2014, Li and colleagues (Li et al 2020) estimated CFLE according to five healthy behaviours in the US They showed that at age 50, compared to women with healthy behaviours, women with unhealthy behaviours can expect to live 8.3 year less without cancer, whereas this difference was 6.0 years in men. Conversely, a study of Zaninotto and colleagues in the US between 2002 and 2013, observed larger reduction in chronic disease free life expectancy (including cancer) in men than in women in case of risky behaviour (Zaninotto al 2020). Most of the existing studies have some limitations related to non-representative populations (reducing the generalizability of results), short duration of follow-up and study populations aged <75 years (Li et al 2020; Zaninotto al 2020; Leskinen et al; Leskinen et al 2018).

Accordingly, the aim of this study was to examine the extent of the reduction in CFLE due the (co-) occurrence of risk factors such as smoking, obesity and physical inactivity, in a nationally representative

longitudinal survey of older people (aged 50 and over) in the United States. Additionally, we study the sex gap in CFLE and in the association with multiple risk factors, with a follow-up of 10+ years. The number of years lived without cancer is estimated with health expectancy outcomes, a measure that combines incidence and mortality to estimate life expectancy lived with and without cancer. Taking into account both morbidity and mortality, estimates of life expectancy free of cancer provide useful metrics for health professionals and policy makers in order to better estimate future healthcare costs of cancer and to plan for healthcare needs.

2. Data and methods

Data were retrieved from the Health and Retirement Study (HRS) in the US, an ongoing nationally representative longitudinal study on health, behavioural risk factors and wealth, in which people have been interviewed approximately every two years, from 1992 to 2018. In the HRS database, mortality follow-up is ascertained through linkages to the National Death Index and reports from survivors. We used data from 2008 (baseline) to 2018 and we included people aged 50+ with valid data on cancer and behavioural risk factors. At each wave of the study respondents were asked 'has a doctor ever told you that you have cancer'. This information was used to assess the presence of cancer at each wave, which includes any cancer conditions reported before the age of 50 from available information on respondents. In this study, all individuals in the sample had information on the presence of cancer at baseline (2008). Participants who had missing lifestyle factors at baseline were excluded (423 individuals, 2.5%). The resulting analytical samples included 16,438 aged 50 years and older (out of the 16,861 HRS members aged 50 years and older in 2008).

Smoking status was dichotomized into "Never or former smoker" and "Current smoker". Obesity was measured according to self-reported Body Mass Index (BMI) and dichotomized as "obese" (BMI $\geq$ 35 Kg/m2) and "not obese" (BMI < 35 Kg/m2). Frequency of moderate physical activity was used to assess physical inactivity, which was dichotomized as "physically inactive" if taking part in moderate physical activity for less than one day a week and "physically active" otherwise. The co-occurrence of multiple behavioural risk factors was defined as reporting 2 or more risks.

We used multistate Markov survival models to estimate how participants moved between no cancer (state 1), cancer (state 2), and death (state 3) states. This model had three possible transitions: no cancer to cancer, no cancer to death, and cancer to death. Participants who developed cancer could only move from the disease state to the death state. Age-specific transition rates were modelled using multinomial logistic regression using as covariates age and behavioral risk factors (smoking, obesity and physical inactivity); years of education was included as controlling variable. Separate models were specified for women and men. Sex-specific transition rates are then applied to a synthetic cohort in order to summarize them into duration: Total Life Expectancy (TLE); Cancer-Free Life Expectancy (CFLE) - expected average number of remaining years of life with no cancer; and Cancer Life Expectancy (CLE) - expected average number of remaining years of life expected to live in cancer states.

Sex gap in Cancer-Free Life Expectancy was calculated as absolute difference: females minus males. Transition rates were estimated with the *msm* R package (Jackson 2011) and R package Estimating Life Expectancies in Continuous Time (*ELECT*) was used in order to estimate state-specific life expectancies conditional on reaching age 50 years (van den Hout, Chan & Matthews 2019). Confidence intervals were estimated using 1000 bootstrap samples.

3. Preliminary findings

The sample includes 9,606 women (54.6%) with a mean age of 67.8 years and 6,832 men (45.4%) with a mean age of 66.7 years (p=0.07). At age 50, the average number of years that people can expect to live without cancer was 30.6 years in women and 26.8 years for men. The overall sex gap in CFLE at age 50 was 3.9 years. At age 50, a woman with no cancer at baseline could expect to live on average 36.2 years of remaining life expectancy, whereas remaining life expectancy was shorter to 29.5 years for a woman with cancer. Men with no cancer at age 50 can expect to live 33.3 years, whereas men with cancer can expect to live only 27.7 years.

Figure 1 shows life expectancy free from cancer over age, according to the occurrence of behavioral risk factors, for women (panel a) and for men (panel b). At age 50, CFLE was 33.7 years in women and 28.6 years in men with no behavioral risk factors. Compared to this group, in presence of behavioral

risk factors, years of life expected to leave without cancer were lower in both women and men: respectively, 28.9 and 24.0 for smoking, 30.6, 30.3 and 23.6 for physical inactivity, and 26.1 and 22.8 years for 2 or more risk factors. Compared to people with no risk factors, being current smokers was associated with the shortest CFLE in both sexes: approx. 4.7 fewer years free of cancer at age 50. Obesity had a significant effect on cancer-free life expectancy only in women (3.1 fewer years). Similarly, reductions of CFLE in physically inactive people was higher in women (3.3 years) than in men (2.3 years).

Panel c in Figure 1 displays the sex gap in CFLE according to behavioral risk factors. Compared to no risk factors, the presence of risk factors was associated with a smaller sex gaps in CFLE. At age 50, the difference in CFLE between women and men with no risk factors was around 5.0 years. The CFLE sex gap was similar for smoking (4.9 years at age 50), whereas it was smaller to 4.0 years for physical inactivity, 3.4 years for multiple risk factors, and the lowest for obesity, 1.2 years. Differences between women and men were narrower at older ages.

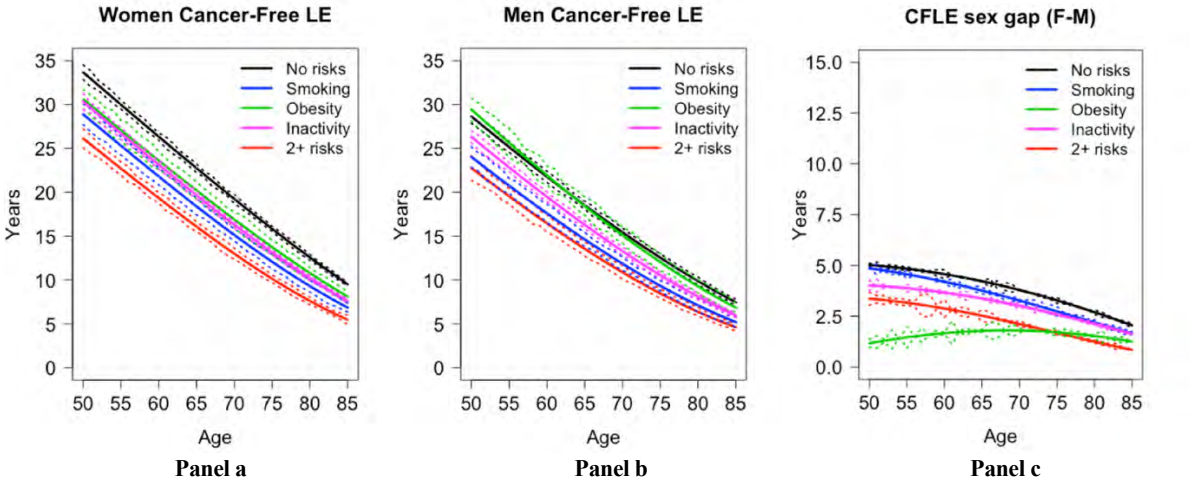

Figure 1: Women (panel a) and Men (panel b) Cancer-Free Life Expectancy (CFLE) and sex gap (Female (F) CFLE - Male (M) CFLE, panel c) in CFLE over age, according to behavioral risk factors.

4. Conclusion

Using a nationally representative study of ageing in the US, we showed that behavioural risk factors were associated with reduced remaining number of years spent without cancer. Reducing smoking and obesity, and increasing physical activity among older people could potentially lead not only to longer lives but also healthier lives (free of cancer). Compared to men, women live on average more years free of cancer (about 3.0 years on average between age 50–85). Additionally, the (co-) occurrence of risk factors reduces the cancer-free life expectancy disadvantage of men with respect to women, especially at younger ages. The results of this study provide useful metrics for health professional and policy makers in the quantification of future healthcare costs of cancer and in the plan for healthcare needs.

Women's Exposure to HIV in Africa: the Role of Intimate Partner Violence

Micaela Arcaio[a1], Anna Maria Parroco[a]

[a] University of Palermo; micaela.arcaio@unipa.it,annamaria.parroco@unipa.it

Abstract

Sub-Saharan Africa's female population is strongly affected both by HIV and intimate partner violence (IPV). The literature has paid great attention to the association between these two phenomena. This work aims at evaluating the relationship between IPV and HIV using survey data from countries in this region – specifically, data from the Demographic and Health Survey of currently partnered women who were tested for HIV during the survey and were administered the special module on domestic violence. We present the estimates of a logistic regression model with Firth's adjustment, to account for the rarity of being HIV-positive. Among the explanatory variables, a composite indicator of IPV is significantly associated with HIV. This result can be interpreted in the framework of the theory of polyvictimisation.

Keywords: HIV, Domestic Violence, Sub-Saharan Africa, Logistic Regression with Firth's adjustment

1. Introduction

Recent data about Sub-Saharan Africa (SSA) show that this region is extremely affected both by intimate partner violence[2] (IPV) and HIV. SSA is, indeed, the region most affected by it in the world, since over two-thirds of people living with HIV were residents in these countries in 2021 [2]. IPV is an equally important matter in these countries: 33% of women have been abused at least once in their life by their partner and 20% have been abused in the last year alone [23].

The association between gender dynamics within couples connected to practices of hegemonic masculinity and HIV has been paid great attention to in the literature, especially in countries with high HIV prevalence. Hegemonic masculinity refers to a societal pattern in which stereotypically male traits are idealized as the masculine cultural ideal, explaining how and why men maintain dominant social roles over women and other groups considered to be feminine [4]. Sexual decisions in couples, in particular, are uniformly attributed to men.

A systematic review of these matters shows that there are several ways in which violence makes women more vulnerable to this disease: on the one hand, marital rape by an HIV-positive partner is expected to expose them to the virus; wherever abuse is present, women lack agency in asking for safe sexual practices; revictimization processes put women in vicious cycles of risky sexual practices [15].

As far as we know, in the literature, IPV and HIV are mostly studied via qualitative studies or ad-hoc surveys – or in the clinical environment, which, however, goes beyond the scope of our work. This

[2] The United Nations define intimate partner violence or domestic violence as a behavioural pattern of power and control over an intimate partner [19].

study is the first step in the ongoing project to analyse the relationship between domestic violence and HIV using the DHS survey from African countries, which collects data on several topics such as socio-demographic characteristics, family planning, reproductive health, HIV, and domestic violence. The analysis will be carried out through the lens of ecological models, i.e., accounting for social and contextual factors, as well as personal characteristics that may be associated with HIV.

In this work, Section 2 highlights the current literature on HIV and intimate partner violence. In Section 3 we briefly discuss the data and methods used for this analysis. Sections 4 and 5 respectively contain the results of the analysis and a brief discussion of the results with conclusions.

2. Intimate Partner Violence and HIV: the contextualisation of disease

The contextualization of risk factors and the way the social context mediates the relationship between risk factors and disease have been widely discussed in their analysis [9]. When it comes to HIV, gender inequality plays a key role in the development of the infection, especially in Sub-Saharan Africa, where the phenomenon is so relevant. Indeed, in 2021, women accounted for 63% of new HIV infections in this region, with a slower decline in their incidence trend than in men's [22]. Moreover, while in the rest of the world 94% of new infections in 2021 were imputable to key populations[3], in Sub-Saharan Africa, almost half of the new infections are imputable to the general population [22].

Gender dynamics that favour men over women highlight the vulnerability of women and girls to the virus, with young women in Sub-Saharan Africa three times more likely to be HIV-positive than men their age [2]. A cross-sectional study conducted in South Africa in 2001 [6] shows that both physical and sexual partner violence are associated with increased odds of HIV infection, while a longitudinal study based, once again, in South Africa confirms that power inequity inside couples and intimate partner violence contribute to HIV infection in young women [12].

In this framework, ecological models have been proposed both for HIV and IPV to highlight the complex interplay between social and individual characteristics of both phenomena. These models move from societal and community-level factors to relationship and individual characteristics that are associated with the presence of HIV and IPV [3].

At the societal level, as women's empowerment grows, one might expect that women will also experience less abuse from intimate partners since gender equality is supposed to improve their conditions overall [11]. However, the opposite can be true as well: if men perceive female empowerment as a threat, they respond with increased levels of violence [16]. Gender inequality and violence against women and girls have also been shown to exacerbate the risk of HIV infection [6,12].

At the community level, violence seems to be associated with poverty and living in rural areas [13]. Moreover, the perpetration of violence itself is facilitated by the general acceptance of violence within couples [8]. On the contrary, rural areas have been shown to be characterised by a lower prevalence of HIV than urban areas [18]. Furthermore, while the highest HIV prevalence rates are found in low-income countries, more often than not, it is the richest population strata that are the most impacted by this virus [17]. This occurrence is, however, context-specific: the contrary is, indeed, found in rich countries, and it is due to several factors such as recurrence to sex workers [6].

Relationship and individual factors refer to gender dynamics within couples as well as their socio-economic characteristics. People with a higher education are less likely to either perpetrate or suffer IPV [1, 14] and to be affected by HIV [10].

The association between socioeconomic context and gender also plays a key role in the study of HIV. Most of the characteristics of the association between HIV and context here presented, indeed, are amplified in women. Specifically, sex work might become a necessity to women living in poverty, thus exposing them further to HIV infection, in particular for those living in substandard housing in urban environments, in case of unemployment, and when they have a history of intimate partner violence [6, 9].

[3] Key populations are considered to be particularly vulnerable to HIV infection. They include: sex workers; clients of sex workers and sex partners of key populations; people who inject drugs; gay men and other men who have sex with men; transgender women. These populations account for less than 5% of the global population, however, they are disproportionately affected by HIV – 70% of all new global infections were found among these groups in 2021 [21].

3. Data and methods

HIV and intimate partner violence are investigated using data from the Demographic and Health Survey (DHS) programme. The DHS is a nationally representative household survey, employed for the collection and analysis of harmonised demographic and health data [5]. Women of reproductive age (aged 15-49) are, indeed, the main subject of this survey.

The focus of this work is the "HIV dataset", which contains the result of ELISA (enzyme-linked immunosorbent assay) tests to determine respondents' serostatus, and the domestic violence module within the questionnaire administered to women. To collect data on these matters, in all households in which men are also included in the survey, blood samples are collected from those who volunteer for HIV testing; furthermore, the domestic violence module is administered to randomly selected ever-partnered women in heterosexual relationships already involved in the survey. Thus, the statistical units in this study are currently-married (or cohabiting) women, aged 15-49, whose serostatus and current experiences of abuse are known.

In this study, we included all the surveys that carried both the HIV dataset and the domestic violence module in the years between 2016 and 2019. Thus, four surveys from Sub-Saharan Africa were included: Burundi 2016-2017, Cameroon 2018, Sierra Leone 2019, and Zambia 2018. The sample, thus, consists of 10,532 currently partnered women, with an average age of 31 years (SD = 8.06).

Country-level estimates are weighted using DHS guidelines and specific cluster weights for HIV prevalence and the proportion of women who have been abused at least once by their current partners.

Table 1: Descriptive statistics

	Burundi	**Cameroon**	**Sierra Leone**	**Zambia**	**Total**
Number of respondents	2,058	1,059	2,464	4,951	10,532
HIV Prevalence (%)	0.65	3.03	1.89	13.96	7.38
Victims of domestic violence (%)	48.7	43.06	60.01	43.83	48.37

The aim of this analysis is to evaluate the relationship between HIV and IPV, controlling for other relevant socio-demographic characteristics. Because of the binary nature of the response variable – HIV status of respondents – the model here used is a logistic regression model. However, to account for the rarity of being HIV-positive in the sample, the Firth adjustment is here used [6]. Using this method, the log-likelihood is penalized with one-half of the logarithm of the determinant of the information matrix, thus reducing the bias seen in generalized linear models.

Domestic violence is assessed via a composite indicator, created using a confirmative factor analysis (CFA), using three binary variables. Indeed, the module on domestic violence primarily assesses IPV via three indicators:

- "Physical violence", referring to being pushed, shook, slapped, punched, or threatened at gunpoint by her partner;
- "Emotional Violence", involving humiliation, threats of physical harm or insults;
- "Sexual Violence", indicating marital rape by the respondent's partner.

The graphical representation of this (reflective) measurement model[4] – with the relative coefficients – can be found in Figure 1.

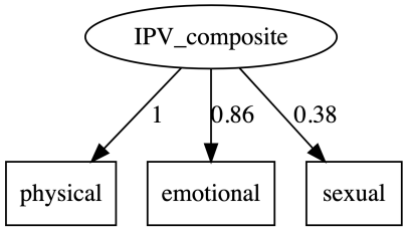

Figure 1: Path diagram of the CFA

[4] Cronbach's alpha = 0.61 $CI_{95\%}$: (0.597-0.624)

A minimum-maximum transformation of the post-estimation results of the CFA will be used within the selected model.

Other covariates in the model are divided into four domains, that reflect the structure of the ecological model:

- *Respondents' characteristics*: the number of justifications respondents give to men using physical violence on their wives; age at first sexual encounter;
- *Household characteristics:* age of respondent; whether the respondent has any children; employment status of respondent; wealth index (categorizing respondents in "poor", "middle", "rich"); the respondent and her husband's educational level ("no education", "primary", "secondary", "higher");
- *Community:* living in rural areas;
- *Context:* number of decisions the respondents take part in in their households; Country dummy variables - present also to account for the data being pooled over four different surveys from different countries.

4. Results

The result of the estimations of the selected model can be found in Table 2. A likelihood ratio test was also employed to check whether the composite indicator of violence is relevant in the fit of the model: given that LRT (1 d.f.) = 3.97 (p-value = 0.04), the model that also includes IPV fits significantly better than the model without it. The approximation of the LRT statistic with the Wald test – of the selected model vs. the null model – returns Wald (19 d.f.) = 654.45 (p-value ≈ 0), thus pointing to an overall good fit of the model.

Table 2: Model estimates

Domain	Covariate		Odds Ratio
Respondents' characteristics	IPV composite		1.002**
	No. justifications to wife beating		0.943**
	Age at first intercourse		0.897***
	Age		1.056***
Household characteristics	Respondent has children		0.684*
	Respondent is employed		0.978
	Wealth index (ref. poor)		
		Middle	1.347**
		Rich	1.955***
	Husband's education level (ref. No education)		
		Primary	0.950
		Secondary	1.512**
		Higher	1.274
	Respondent's education level (ref. No education)		
		Primary	1.187
		Secondary	1.263
		Higher	0.874
Community	Living in rural areas (vs. urban)		0.544***
Societal level	No. decisions she takes in her HH		1.077**
	Country (ref. Burundi)		
		Cameroon	2.128**
		Sierra	1.259
		Zambia	8.283***
	Constant		0.0141***

*** p < 0.01, ** p < 0.05, * p < 0.1

The IPV composite indicator resulted significantly and positively associated with the HIV status of respondents, even though the variation measured by the odds' size is small (OR = 1.002). However, when we consider the number of justifications respondents give to men using physical violence on their wives, each additional justification decreases the odds of being HIV positive by almost 6%. Age at first intercourse is also significantly associated with HIV: indeed, for each year of delay in age at first sex the odds of being HIV positive decrease by more than 10%.

Household characteristics also matter. Wealth, as stated in the literature, is positively associated with HIV: as the household of respondents gets richer, their odds to be HIV positive also increase. However, neither the respondent's nor her husband's education seem to be significantly associated with her HIV status. Furthermore, while being employed is not associated with respondents' serostatus, having children is negatively associated with their mothers being HIV positive, given the access to testing and anti-retroviral therapy once they enter antenatal care.

The community and the context in which respondents live are also associated with their HIV status. As it has been shown in the literature, living away from the city seems to expose respondents less to the HIV virus: people who live in rural areas are, indeed, 54% less likely to be HIV-positive. More power in making decisions within the household – here taken as a proxy of empowerment overall – is however significantly and positively associated with HIV. The coefficients for the Country dummy variables reflect the general condition of their resident populations with respect to HIV prevalence.

5. Conclusions

This work is the first step in our ongoing project to analyse the relationship between domestic violence and HIV using survey data from African countries. Our analysis has confirmed some of the results highlighted in the literature – being abused by the current partner makes women more likely to be HIV-positive. This result becomes especially relevant given that while the literature on HIV mostly focuses on physical and sexual violence separately, the literature on domestic violence is progressively moving towards the concept of polyvictimisation – abuse calls for other forms of abuse, thus reinforcing and facilitating the path from one form to another in victims [19].

However, some results from the model deserve further investigation: indeed, there seems to be a twisted association between decision-making power and the number of justifications given for physical violence, and HIV.

This work certainly does not lack limitations. Specifically, given the preliminary stage of this work, alternative models could be chosen for the analysis of the matter at hand – e.g. mixed-effects logistic regression models to account for the nature of the pooled data and Poisson regression models, that are often used in the literature to evaluate HIV. Further work can also be done on the choice of the covariates in the model and introducing interactions between relevant variables.

But this work also offers many possibilities for further development. Mainly, we want to evaluate the hypotheses according to which the context of residence may be relevant to women's likelihood to be HIV positive and of being victims of IPV; then, that IPV can be a relevant factor in the diffusion of HIV at a sub-national level. This will allow us to further check for the interplay between contextual and individual characteristics of respondents, always in the framework of the ecological model already employed in the analysis.

Abstract

Network data analysis has received increasing attention recently. Bipartite networks represent a specific type of network data describing the relationships between disjoint sets of nodes, called sending and receiving nodes. We extend the Mixture of Latent Trait Analyzers (MLTA) specifically tailored for the analysis of bipartite networks to achieve a twofold goal. First, the aim is to perform a joint clustering of sending and receiving nodes, thus partitioning the data matrix into homogeneous blocks, as in the biclustering approach. In addition, a latent trait is used to model the dependence between receiving nodes, as in the latent trait framework. The proposal also admits the inclusion of nodal attributes on the latent layer of the model to understand how they affect cluster formation. An EM algorithm with Gauss Hermite approximation is proposed to estimate the model parameters.

Keywords: Model-based clustering, Network data, Two-mode networks, Nodal attributes, EM algorithm

1. Introduction

Over the years, many social, technological, and biological processes have been represented as networks. These are collections of interconnected units (nodes) that can capture interactions within a system. In this context, bipartite networks are a special type of networks that represent the relationships between two disjoint sets of nodes, formally called sending and receiving nodes. A primary characteristic of this type of network is that connections exist only between nodes belonging to different sets, as illustrated in Figure 1.

A relevant aspect of network analysis concerns the simultaneous clustering of sending and receiving nodes aiming at partitioning the data matrix into homogeneous blocks, called biclusters. An example of a block structure is shown in Figure 2, where rows (sending nodes) and columns (receiving nodes) of the data matrix are reordered according to the corresponding class membership, thus returning blocks of sending nodes that connect similarly with subsets of receiving nodes.

A common example of application concerns the field of genetics, where the biclustering approach can be used to identify groups of genes which are co-expressed under subsets of experimental conditions.

Different biclustering approaches are available in the literature, such as the model-based ones (12; 17; 2; 14). In this specific context, several methods based on finite mixtures have been proposed (8; 9; 19; 11; 13; 18; 15).

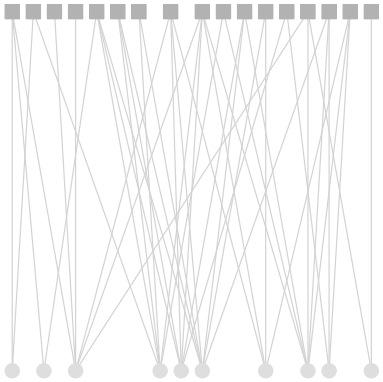

Figure 1: Example of bipartite networks

We start from the MLTA model, introduced by (6; 7). Here, the aim is of clustering sending nodes via a finite mixture specification, while accounting for the dependence between receiving nodes via a continuous latent variable, as in the latent trait framework. Our proposal is to modify the MLTA in two ways. First, allowing for a joint clustering of sending and receiving nodes, where sending nodes are partitioned into clusters called components and, in each of them, receiving nodes are partitioned into clusters called segments. Furthermore, we also allow for the inclusion of nodal attributes on the latent layer in order to understand how they influence component formation.

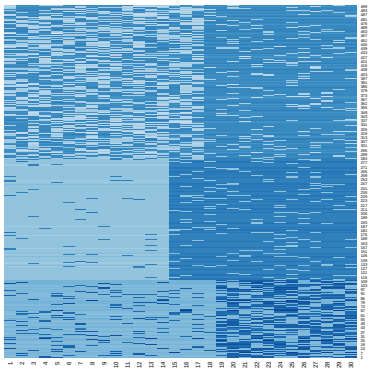

Figure 2: Example of block structure

The paper is organized as follows: in Section 2. we extend the MLTA model, also describing model assumptions, parameter estimation, and model selection. Section 3. shows the results of a simulation study conducted in order to verify the efficacy of the proposed approach. Section 4. contains concluding remarks and details further extensions of the approach.

2. Mixture of latent trait analyzers

Let $\mathcal{N} = \{n_1, n_2, \ldots, n_N\}$ denote the set of sending nodes and $\mathcal{R} = \{r_1, r_2, \ldots, r_R\}$ the set of receiving nodes. In this framework, bipartite networks can be formally described by a random incidence matrix $\boldsymbol{Y} = \{Y_{ik}\}$, with elements

$$Y_{ik} = \begin{cases} 1 \text{ if sending node } n_i \text{ is connected with receiving node } r_k, \\ 0 \text{ otherwise.} \end{cases} \tag{1}$$

To obtain a clearer picture of the data at hand, (7) propose to extend the Mixture of Latent Trait Analyzers (MLTA) (6) in the context of bipartite networks. The model combines latent class and latent trait analysis

by assuming that the set of N sending nodes can be divided into G distinct classes (or groups) and that the propensity of each sending node to be connected with the R receiving nodes depends also on a multidimensional continuous latent trait. Our contribution is to further extend the MLTA model by performing a joint clustering of sending and receiving nodes, also taking into account nodal attributes in the latent model structure.

2.1 The MLTA model

The MLTA model assumes that every sending node belongs to one of G unobserved groups identified by the latent random variable $\boldsymbol{z}_i = (z_{i1}, \ldots, z_{iG})' \sim \text{Multinomial}(1, (\eta_1, \ldots, \eta_G))$, whose generic element is

$$z_{ig} = \begin{cases} 1 \text{ if sending node } n_i \text{ belongs to group } g, \\ 0 \text{ otherwise.} \end{cases} \tag{2}$$

The parameter η_g denotes the probability that a randomly selected sending node belongs to group g, with $g = 1, \ldots, G$, under the constraints that $\sum_{g=1}^{G} \eta_g = 1$ and $\eta_g \geq 0$, $g = 1, \ldots, G$.
Furthermore, the model assumes the existence of a D-dimensional continuous latent trait $\boldsymbol{u}_i$ distributed according to a Gaussian density with null mean vector and identity covariance matrix, i.e. $\boldsymbol{u}_i \sim \mathcal{N}(\boldsymbol{0}, \boldsymbol{I})$, which captures the heterogeneity of the connections between sending and receiving nodes. Thus, response variables contained in the $\boldsymbol{y}_i$ vector are assumed to be independent Bernoulli random variables with parameters $\pi_{gk}(\boldsymbol{u}_i)$, $k = 1, \ldots, R$, modelled through the following logistic function:

$$\pi_{gk}(\boldsymbol{u}_i) = p(y_{ik} = 1 \mid \boldsymbol{u}_i, z_{ig} = 1) = \frac{1}{1 + \exp[-(b_{gk} + \boldsymbol{w}'_{gk}\boldsymbol{u}_i)]}. \tag{3}$$

Here, the parameter b_{gk} represents the attractiveness of the k-th receiving node for sending nodes belonging to group g, while $\boldsymbol{w}_{gk}$ represents the influence of the latent trait $\boldsymbol{u}_i$ on the probability of a connection between sending nodes belonging to the g-th group and receiving node r_k.

2.2 Extending the MLTA model

To perform a joint clustering of sending and receiving nodes, we follow an approach similar to that proposed by (15) and modify the logistic function in (3) as:

$$\pi_{gk}(\boldsymbol{u}_i) = p(y_{ik} = 1 \mid \boldsymbol{u}_i, z_{ig} = 1) = \frac{1}{1 + \exp[-(b_g + \boldsymbol{a}'_{gk}(\boldsymbol{\mu} + \boldsymbol{u}_i)]}. \tag{4}$$

Here, b_g is a component-specific latent effect, $\boldsymbol{\mu}$ is a D-dimensional vector of fixed effects, and $\boldsymbol{u}_i \sim N(\boldsymbol{0}, \boldsymbol{I})$ is a D-dimensional continuous latent trait capturing the residual heterogeneity of connections between sending nodes belonging to the g-th component and receiving nodes belonging to the d-th segment. Moreover, $\boldsymbol{a}_{gk}$ is a D-dimensional row stochastic vector ($D \leq R$) with

$$a_{gkd} = \begin{cases} 1 \text{ if receiving node } r_k \text{ belongs to segment } d, \\ 0 \text{ otherwise.} \end{cases} \tag{5}$$

This allows us to select the membership of the k-th receiving node to one of the D segments for those sending nodes belonging to component g.
Following the strategy adopted in (5), we account for the effect that nodal attributes may have on group membership by letting the parameter η_g vary across sending nodes. This is done by considering a latent class regression model based on the vector of nodal attributes $\boldsymbol{x}_i$, as follows:

$$\eta_{ig} = \frac{\exp\{\boldsymbol{x}'_i\boldsymbol{\beta}_g\}}{1 + \sum_{g'=2}^{G} \exp\{\boldsymbol{x}'_i\boldsymbol{\beta}_{g'}\}}, \quad g = 2, \ldots, G, \tag{6}$$

where $\boldsymbol{\beta}_g$ denotes the model coefficient vector for the g-th group.

2.3 Parameter estimation

Let $\boldsymbol{\theta} = (\boldsymbol{\beta}_2, \ldots, \boldsymbol{\beta}_G, b_1, \ldots, b_G, \boldsymbol{a}_{11}, \ldots, \boldsymbol{a}_{GR}, \mu_1, \ldots, \mu_D)$ represent the vector of all free model parameters. Given the assumptions described in the previous section, the log-likelihood function of the model can be written as:

$$\ell(\boldsymbol{\theta}) = \sum_{i=1}^{N} \log \Big(\sum_{g=1}^{G} \eta_{ig} \int \prod_{k=1}^{R} p(y_{ik} \mid \boldsymbol{u}_i, z_{ig} = 1) p(\boldsymbol{u}_i) d\boldsymbol{u}_i \Big), \tag{7}$$

where $p(y_{ik} \mid \boldsymbol{u}_i, z_{ig} = 1) = (\pi_{gk}(\boldsymbol{u}_i))^{y_{ik}} (1 - \pi_{gk}(\boldsymbol{u}_i))^{1-y_{ik}}$. The integral to be solved in equation (7) cannot be computed analytically, therefore an EM algorithm with a Gauss-Hermite approximation of the log-likelihood function is proposed. In detail, after the initialization of model parameters and the approximation of the intractable integral with Gauss-Hermite quadrature, the parameters b_g and μ_d are updated via a standard Newton-Raphson algorithm with augmented data, while the D-dimensional row stochastic vector $\boldsymbol{a}_{gk}$ is updated via a classification step, following a similar strategy to that proposed by (15). Finally, parameters $\boldsymbol{\beta}_g$ are estimated via a Newton-Raphson step and η_{ig} is updated accordingly.
At convergence, each sending node can be assigned to the g-th component via a Maximum a Posteriori (MAP) rule and each receiving node can be assigned to the d-th segment according to the vector $\boldsymbol{a}_{gk}$.

2.4 Standard errors and model selection

To evaluate the standard errors of the estimates obtained with the EM algorithm, several methods are available, such as the jackknife method (4; 6). Given an incidence matrix $\boldsymbol{Y}$ with N sending nodes and R receiving nodes, this method consists in extracting N samples of size $(N-1) \times R$, obtained by removing one sending node at a time from the original data matrix. However, we found that a more efficient strategy for deriving standard errors relies on the use of a non-parametric bootstrap (3), which consists in extracting with repetition N rows of the incidence matrix, so that each sending node can appear multiple times.
Since the number of components G and the number of segments D are considered as fixed quantities, it is possible to estimate the model for different values of G and D, then selecting the optimal model as the one corresponding to the smallest value of the chosen information criterion, such as the Bayesian Information Criterion (BIC) (16) or the Akaike's Information Criterion (AIC) (1).

3. Simulation study

The performance of the model in terms of parameters' recovery and clustering is evaluated through a simulation study with a different number of nodes, as described below.

3.1 Simulation setup

We simulated 100 samples in three different scenarios based on a varying number of sending nodes ($N = 500,\ N = 1000,\ N = 2000$), while the number of receiving nodes R is kept constant and equal to 30. Furthermore, we considered a fixed number of segments $D = 2$ and components $G = 3$. As regards the latent class variable, block membership is defined via a single nodal attribute x_i which is drawn from a Gaussian distribution with mean and variance equal to 1. In each scenario, a multi-start strategy based on 100 random starts is adopted.

3.2 Simulation study: clustering recovery

The ability of the proposal in correctly classifying sending and receiving nodes is evaluated through the Adjusted Rand Index (ARI) (10). The results are shown in Table 1. Looking at these results, we note that, for N greater than 500, the classification is good for both rows (sending nodes) and columns

(receiving nodes), and the Adjusted Rand Index remains stable. The variability in the estimates is due to the intrinsic variability of simulations.

Table 1: Distribution across samples of the Adjusted Rand Index for varying N

		Adjusted Rand Index		
		1st Qu.	Median	3rd Qu.
N=500	Row	0.9259	0.9802	0.9944
	Col.	0.1693	1.0000	1.0000
N=1000	Row	0.9369	0.9871	0.9966
	Col.	0.1788	1.0000	1.0000
N=2000	Row	0.9461	0.9823	0.9943
	Col.	0.3599	1.0000	1.0000

3.3 Simulation study: latent class parameters

Figure 3 shows the distributions of β_g parameters across samples, for different values of N. Looking at these figures, it is evident that variability reduces as the size of the network increases. Furthermore, as N increases, we are increasingly able to identify the true values of model parameters.

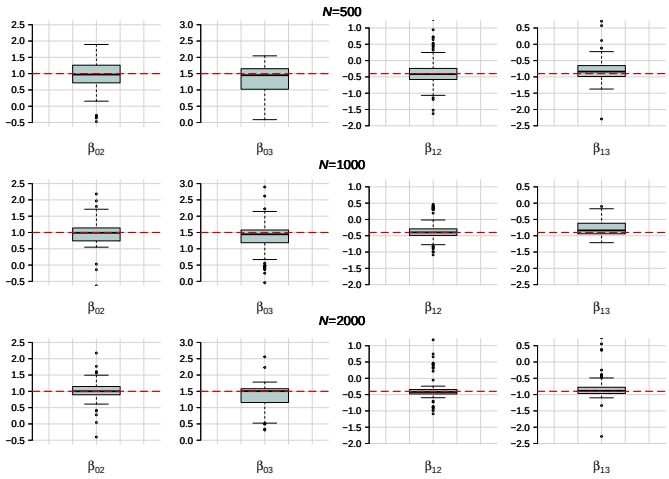

Figure 3: Distribution across samples of β_g parameters for varying N

4. Conclusions

The mixture of latent trait analyzers is modified to achieve a twofold objective for the analysis of bipartite networks: i) performing a joint clustering of sending and receiving nodes; ii) including nodal attributes to study how nodes' characteristics influence the component membership probability.
The simulation study shows that the model can be effectively employed for biclustering bipartite networks. In detail, when the number of sending nodes is large, the variability of estimates is reduced and the classification of nodes is good. However, the simulation study needs to be further extended by letting the number of partitions and receiving nodes vary, as well as reducing the number of sending nodes to investigate how classification performs in smaller networks.

A further development may involve the application of the proposal for the analysis of a large real-world data set, such as a gene-experimental condition network.

Abstract

In this work, constrained univariate mixtures of generalized normal distributions (CMGND) are introduced. Specifically, mixture parameters are constrained to be equal across mixture components. The expectation conditional maximization (ECM) algorithm is used to estimate the constrained parameters via the maximum likelihood estimation (MLE). In addition, the iterative Newton-Raphson method is applied to handle the non-linear iteration equations of the parameters during the estimation stage. Next, a simulation is performed to assess the parameter estimation performance for a two-component CMGND with the same scale and shape parameters, i.e. with the same variance and kurtosis. Simulation results show that the estimation accuracy of the constrained mixture is higher than the unconstrained mixture.

Keywords: Constrained mixtures of generalized normal distributions, ECM algorithm, Maximum likelihood estimation, Newton-Raphson method

1. Introduction

Over time, non-normal mixture distributions have gained increasing attention to analyse datasets characterized by non-normal features like skewness and heavy tails (10).

Among the statistical distributions available in the literature, the generalized normal distribution (GND) is able to model a large variety of statistical behaviours thanks to the additional shape parameter which controls the tail weights (14). Then, finite mixtures of generalized normal distributions (MGND) have the flexibility to fit non-normal data (16).

MGND have been successfully applied in signal processing, computer vision, pattern recognition and other recent statistical tasks that require mixture estimation (13).

Bazi et al. (2006) applied univariate MGND for image processing (5). The estimation of the parameters was performed via the maximum likelihood estimation (MLE), and the expectation maximization (EM) algorithm. Allili (2012) used the univariate MGND for wavelet representation (1). Parameters have been estimated with a Bayesian method which optimizes a minimum message length objective, and the EM algorithm. Nguyen et al. (2014) proposed a univariate bounded generalized Gaussian mixture model defining a bounded support region for each component (16). Recently, Wen et al. (2022) studied a univariate two-component MGND and proposed an expectation conditional maximization (ECM) algorithm for parameter estimation (18).

Mixture distributions with unconstrained parameters may have some problem in the estimation phase. Firstly, in normal mixtures it is well known that when parameters are not restricted the resulting likelihood from a sample is unbounded, *"no maximum likelihood estimator exists in the unconstrained problem"* (7). Thus, it is possible to observe this problem also in MGND, since the GND is a *"natural generalization of the normal distribution"* (14). Secondly, the number of parameters increases with the number of the mixture components and the estimation could result computationally problematic.

As a consequence, different methods have been proposed to overcome these critical issues[1]. These methods can be divided into two main approaches: linear constraints methods, and eigenvalue decomposition methods. The former impose linear restrictions on the mixture parameters. By contrast, the latter exploit the eigenvalue decomposition of the component covariance matrices to impose constraints. Mainly these methods have been applied to constrain mixtures of normals (4; 6; 8; 9; 15; 17) and Student-t (2; 3).

To the best of our knowledge none of the existing studies propose a constrained estimation of the univariate MGND. We aim to fill this gap by proposing constrained univariate mixtures of generalized normal distributions (CMGND) where the parameters are constrained to be equal across mixture components. The ECM algorithm is used to estimate constrained parameters via the MLE together with the Newton-Raphson method. Next, a simulation is performed to assess the parameter estimation performance for a two-component CMGND with the same scale and shape parameters.

The rest of the paper is organized as follows. Section 2. illustrates the methodology. Section 3. illustrates the simulation. Finally, Section 4. provides some conclusions.

2. Methodology

A univariate finite MGND is given by the marginal distribution of the random variable X

$$f(x|\theta) = \sum_{k=1}^{K} \pi_k p_k(x|\mu_k, \sigma_k, \nu_k), \tag{1}$$

where:

- $\theta = \{\pi_k, \mu_k, \sigma_k, \nu_k\}$, $k = 1, .., K$;
- K is the number of mixture components;
- π_k is the k-th mixture weight which satisfies $\sum_{k=1}^{K} \pi_k = 1$ and $\pi_k > 0$;
- $p_k(x|\mu_k, \sigma_k, \nu_k)$ is the k-th probability density function of the generalized normal distribution (GND), which is defined as follows

$$p_k(x) = \frac{\nu_k}{2\sigma_k \Gamma(1 \,/\, \nu_k)} \exp\left\{ - \left| \frac{x - \mu_k}{\sigma_k} \right|^{\nu_k} \right\} \qquad \text{with } \Gamma(1 \,/\, \nu_k) = \int_0^\infty t^{1/\nu_k - 1} \exp^{-t} dt, \tag{2}$$

  where μ_k is the k-th location parameter ($\mu_k \in$ R), σ_k is the k-th scale parameter ($\sigma_k > 0$), and ν_k is the k-th shape parameter ($\nu_k > 0$).

It is possible to capture a wide range of statistical distributions by varying the shape parameter ν_k who determines the tail weights (See Figure 1). The normal distribution is yielded with $\nu_k = 2$, whereas the Laplace distribution is yielded with $\nu_k = 1$. It is noticed that $1 < \nu_k < 2$ yields an "intermediate distribution" between the normal and the Laplace distribution. As limit cases, for $\nu_k \to +\infty$ the distribution tends to a uniform distribution, while for $\nu_k \to 0$ it will be impulsive (5; 13; 18).

[1] (11) and (7) give a more detailed account of what has been done so far.

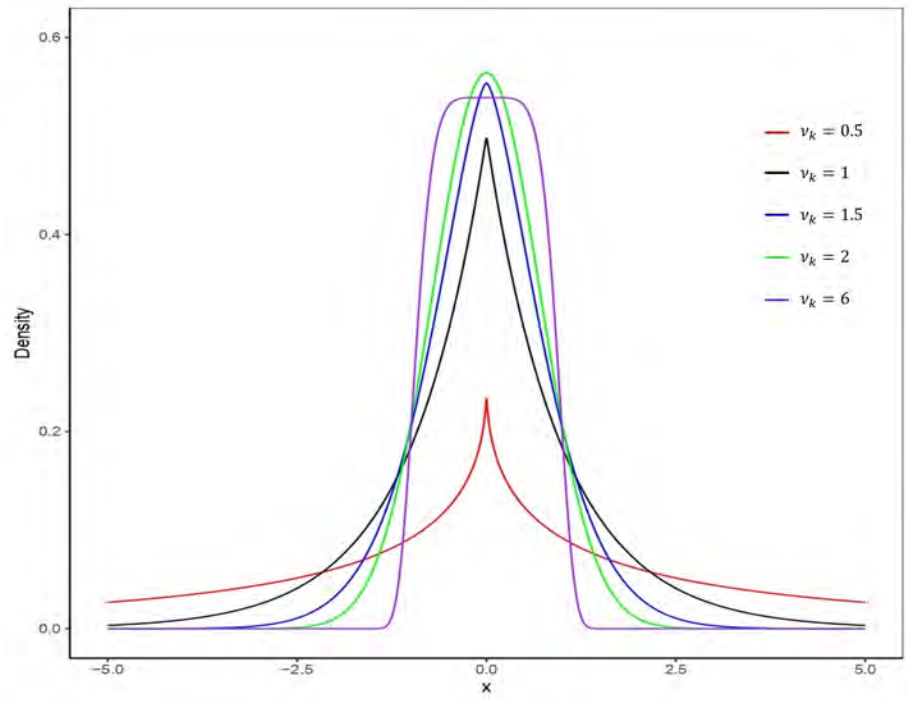

Figure 1: k-th probability density function for $\mu_k = 0$, $\sigma_k = 1$ and different shape values.

Constraints are imposed on μ_k, σ_k and ν_k to be equal across the mixture components: $\mu_k = \mu$, $\sigma_k = \sigma$, $\nu_k = \nu$, for $k = 1, ..., K$. Thus, taking all possible combinations of these constraints into consideration would result in a 8-model family[2]. For identifiability purposes, we need to impose that the mixture weights must be different to each other.

Following (18), the ECM algorithm (12) is applied to perform parameter estimation of the CMGND. From Eq. 1 the log-likelihood function is given by

$$\log L(\theta) = \sum_{n=1}^{N} \log \left\{ \sum_{k=1}^{K} \pi_k \frac{\nu_k}{2\sigma_k \Gamma(1 \,/\, \nu_k)} \exp\left\{ -\left| \frac{x_n - \mu_k}{\sigma_k} \right|^{\nu_k} \right\} \right\}. \tag{3}$$

The **E-step** involves computing the conditional expected value by using the following equation

$$Q(\theta, \theta^{(m-1)}) = \sum_{k=1}^{K} \left[\sum_{n=1}^{N} z_{nk}^{(m-1)} \log \left\{ \pi_k \frac{\nu_k}{2\sigma_k \Gamma(1 \,/\, \nu_k)} \exp\left\{ -\left| \frac{x_n - \mu_k}{\sigma_k} \right|^{\nu_k} \right\} \right\} \right], \tag{4}$$

where

$$z_{nk}^{(m-1)} = \frac{\pi_k p(x_n | \mu_k, \sigma_k, \nu_k)}{\sum_{k=1}^{K} \pi_k p(x_n | \mu_k, \sigma_k, \nu_k)}.$$

The **CM-Step** maximizes $Q(\theta, \theta^{(m-1)})$ with respect to θ to obtain the m-th parameter estimates and increases the expectation of the complete likelihood of the data. The derivatives of the log-likelihood function are set to zero with respect to π_k and each constrained parameter, i.e. μ, σ, and ν:

$$\frac{\partial Q(\theta, \theta^{(m-1)})}{\partial \pi_k} = 0, \quad \frac{\partial Q(\theta, \theta^{(m-1)})}{\partial \mu} = 0, \quad \frac{\partial Q(\theta, \theta^{(m-1)})}{\partial \sigma} = 0, \quad \frac{\partial Q(\theta, \theta^{(m-1)})}{\partial \nu} = 0. \tag{5}$$

It is possible to demonstrate that a non-linear equation is obtained from Eq. (5) for each constrained parameter. In order to compute the constrained parameters values at the ECM iteration m-th from the

[2]The iteration equations of the unconstrained parameters are provided by (18).

non-linear equations, the iterative Newton-Raphson method is applied (9; 5; 18) as follows

$$\mu^{(m)} = \mu^{(m-1)} - \frac{f\left(\mu^{(m-1)}\right)}{f'\left(\mu^{(m-1)}\right)}, \quad \sigma^{(m)} = \sigma^{(m-1)} - \frac{h\left(\sigma^{(m-1)}\right)}{h'\left(\sigma^{(m-1)}\right)}, \quad \nu^{(m)} = \nu^{(m-1)} - \frac{g\left(\nu^{(m-1)}\right)}{g'\left(\nu^{(m-1)}\right)}, \tag{6}$$

where

$$f\left(\mu^{(m-1)}\right) = \frac{\partial Q(\theta, \theta^{(m-1)})}{\partial \mu}, \quad h\left(\sigma^{(m-1)}\right) = \frac{\partial Q(\theta, \theta^{(m-1)})}{\partial \sigma}, \quad g\left(\nu^{(m-1)}\right) = \frac{\partial Q(\theta, \theta^{(m-1)})}{\partial \nu}. \tag{7}$$

3. Simulation

Using the **R** software, the simulation is performed for the CMGND with common scale and shape parameter, i.e. with the same variance and kurtosis. The common shape parameter is set to 1.5 in order to test the fitting of the "intermediate distribution" (See Section 2). Samples are generated with the **R**'s function *rgnorm*. Besides, the sampling procedure is repeated $R = 50$ times and sample sizes $N = 500, 2000, 5000$. To assess the estimation performance Bias, MSE and Std are computed as follows:

$$\begin{aligned} Bias\left(\hat{\theta}\right) &= \left| \frac{1}{R} \sum_{s=1}^{R} \hat{\theta}_r - \theta \right|, \\ MSE\left(\hat{\theta}\right) &= \frac{1}{R} \sum_{s=1}^{R} (\hat{\theta}_r - \theta)^2, \\ Std\left(\hat{\theta}\right) &= \sqrt{\frac{1}{R} \sum_{s=1}^{R} \left(\hat{\theta}_r - \frac{1}{R} \sum_{r=1}^{R} \hat{\theta}_r \right)^2}, \end{aligned} \tag{8}$$

where θ is the true parameter value and $\hat{\theta}_r$ is the estimate of θ for the r-th simulated data. To avoid the label switching issue, mixtures components are sorted according to the location parameter (μ_k) since $K = 2$ and $\mu_1 \neq \mu_2$.

Tables 1 and 2 show the simulation results. The bias, MSE, and Std of the CMGND are lower than those of the MGND. It can be seen that the estimation accuracy of the CMGND is high from that of the MGND. For $N = 5000$, the bias and MSE are quite similar for both mixtures models. To conclude, Table 3 shows the CPU time in seconds for sample sizes of 500, 2000, and 5000 of the MGND and CMGND. It is found that as the sample size increases the CMGND consumes les CPU time than the MGND.

4. Conclusions

In this work, a new constrained univariate mixture model has been introduced. Specifically, this study adds to the literature the CMGND where the parameters are constrained to be equal across mixture components. The ECM algorithm is used to estimate constrained parameters via the MLE. Besides, the iterative Newton-Raphson method is applied to handle the non-linear iteration equations of the parameters during the estimation stage. In brief, simulation results show that the estimation accuracy of the constrained mixture is higher than the unconstrained mixture. The proposed model can be improved in two directions: introducing the multivariate version, and applying a global optimization of the parameters since the solutions strongly depend on the initial starting point.

Abstract

Existing methods can perform likelihood-based clustering on a multivariate data matrix of ordinal responses, using finite mixtures to cluster the rows and columns of the matrix. Those models can incorporate the main effects of individual rows and columns and the cluster effects to model the matrix of responses. However, many real-world applications also include available covariates. In this study, we have extended mixture-based models to include covariates and test what effect this has on the resulting clustering structures. We focus on clustering the rows of the data matrix, using the proportional odds cumulative logit model for ordinal data. We fit the models using the Expectation-Maximization (EM) algorithm and assess their performance. Finally, we also illustrate an application of the models to the well-known arthritis clinical trial data set.

Keywords: cluster analysis, mixture models , EM algorithm, ordinal responses, proportional odds model

1. Introduction

A well-known definition of an ordinal variable says it is one characterized by a categorical data scale, which describes an order showing differing degrees of dissimilarity (1). Thus, although ordinal variables are affected by the distances among their ordinal categories, those distances are not known. Cluster analysis is the study of techniques to classify a set of related objects into the same cluster (6) and can be applied to identify groups, patterns, or clusters in a data set. Many different approaches to clustering have been developed. The earliest approaches use partition optimization; the most common method is the k-means clustering (11). Several authors have proposed extensions to this approach (see e.g., (24; 9; 21)). Moreover, the objects can be clustered in a hierarchical way, gradually agglomerating objects into larger and larger clusters (25). All approaches listed above are based on mathematical distance metrics and therefore statistical inferences, model selection procedures, and goodness-of-fit assessments cannot be easily applied due to the lack of an underlying probability model (6; 7). Cluster analysis based on finite mixture models (18) assumes that responses in the data matrix arise from mixtures of statistical distributions, with each cluster corresponding to one component of the mixture. The fitted parameters for those distributions are those that have the maximum likelihood based on the observed data. Likelihood-based

methods include those proposed by (18; 5; 15), among others. More recently, (10; 19) proposed an approach via finite mixtures for binary and count data using Bernoulli or Poisson building blocks. Other authors have introduced clustering algorithms specifically for ordinal data: see e.g. (4; 20; 14; 7; 8). (14) proposed a mixture-based two-dimensional clustering solution relying on the proportional odds assumption of the cumulative logit model. (7) developed an equivalent model-based clustering approach using the ordered stereotype model (3). Unlike distance-based methods, which only determine which objects should be clustered together, likelihood-based methods can additionally describe the properties of each cluster, based on the fitted parameters, and can also estimate the probability of each object being allocated to each cluster. Additionally, the mixture-based approaches for ordinal responses introduced above are focused on finding cluster structures based only on the matrix of ordinal responses, and assume that no associated covariates are available. Any available covariates can be analyzed alongside the clustering results, to assist with interpretation of the cluster structures, even though there has been no reference to the covariates during the clustering process, but actually incorporating covariates in the clustering process could lead to different fitted clustering structures, and a different estimate of the number of clusters. Generally speaking, if a model with covariates is fitted, subjects tend to be clustered according to their responses and covariate effects. Therefore, it is desirable to make available covariates endogenous to the clustering process to improve interpretation of the main characteristics of the clusters (17). Our approach to mixture-based clustering involves constructing an additive linear model of parameters, connected to the response data via a link function. Additional terms such as covariates may easily be added to the linear predictor. To the best of our knowledge, (8) introduced this formulation of model-based clustering for ordinal data with covariates, but the performance of these covariate methods and, more importantly, their influence on the resulting clustering structures, have not been documented so far. The main purpose of this article is to extend such models to include covariates and allow them to affect the detection of cluster structures. Moreover, we are also interested in comparing how the resulting clustering structures compare to those obtained without covariates, and how these changes may affect the interpretation of the results. We will focus on extending the one-dimensional clustering approach proposed in (14). This approach models ordinal response data using the proportional odds assumption of the cumulative logit model (from now on "proportional odds model"). We will include covariates directly in the linear predictor. Our approach to clustering follows the constructivist approach described by (12), but with an interest in realist clustering: we think there are many scenarios where patterns in the data can be simplified by identifying clusters of observations that follow similar patterns, but if there is a real structure in the data, then we wish to determine that structure. There are many real-world scenarios that we can model as a response variable being affected by predictor variables, and in some of those scenarios, certain groups of observations may have different patterns of response to the predictors than other groups of observations. If those groups have already been identified, then we might attempt mixed model analysis or multilevel modelling; but if the groups have not already been identified, then the method we propose here provides a pathway to detecting these groupings of response patterns. So our approach could be seen as a bridge between regression modelling and cluster analysis.

2. Model formulation

When the data are in matrix form, clustering of rows is called row clustering. We present the row clustering formulation for finite mixtures based on the proportional odds model. This closely follows the model formulations in (14; 8). Clustering can also be applied to the columns of the data matrix, but the formulation of those models is equivalent to the formulation of row clustering models applied to a transposed version of the data matrix, so we only present the row clustering formulation here. We decided to focus on row clustering because it is more common to have covariates linked to observations (rows) than to variables (columns). However, the variable version is very similar; in order to include column covariates instead of row covariates, we can simply change the indices in the formulae. We consider a set of n subjects and m ordinal response variables, each with q possible ordinal response categories. Thus, data can be represented by an $n \times m$ matrix $\mathbf{Y}$ with ordinal entries y_{ij}. The row cluster index r ($r = 1, \ldots, R$) represents the number of the row cluster and the symbol $i \in r$ indicates that row i is

allocated to row cluster r. We shall assume that all rows belonging to the same row cluster r have ordinal responses driven by the same row cluster effect, i.e. that there are no individual row effects. In the case of the proportional odds model where the effect of rows on the response is considered, the probability that y_{ij} takes category k, when row i is in row cluster r, is defined by

$$P[y_{ij} = k | i \in r] = \theta_{ijrk},$$

where $i = 1, \ldots, n,\ j = 1, \ldots, m$ and $k = 1, \ldots, q$ with $\sum_{k=1}^{q} \theta_{ijrk} = 1$ for a given i, j and r. This can be expressed using linear predictor terms as

$$\text{logit}\left(\sum_{h=1}^{k} \theta_{ijrh}\right) = \eta_{ijrk} = \mu_k - (\alpha_r + \beta_j + \gamma_{rj}), \tag{1}$$

where the parameters $\{\mu_k\}$ are the cutpoints. $\{\alpha_r\}$ and $\{\beta_j\}$ indicate the effects of row cluster r and column j, respectively, and $\{\gamma_{rj}\}$ represent the associations between different row clusters and individual columns. Corner-point or sum-to-zero constraints on $\{\alpha_r\}$, $\{\beta_j\}$ and $\{\gamma_{rj}\}$ must be included to avoid identifiability problems and the monotonically increasing constraint $\mu_1 < \mu_2 < \cdots < \mu_q (= \infty)$ is included to capture the ordinal nature of the responses. The (unknown) proportion of rows in each row group r is defined as $\{\pi_1, \ldots, \pi_R\}$, with $\sum_{r=1}^{R} \pi_r = 1$. In a simpler model with clustering of rows, the rows (observations/subjects) will tend to be clustered if they have similar patterns of responses, without taking into account the information present in the covariates. However, if we include in the clustering process the information from covariates such as type of cancer, treatment dose, initial tumour burden, size of the tumour, gender, and age then the resulting clusters may be different because patients with equal or similar values in the covariates should be *a priori* more likely to co-cluster than others. For instance, patients with larger tumour sizes will tend to be clustered together regardless of their responses to the questionnaire. This motivational example is based on the one given in (16).

We now define the model formulation of row clustering using the proportional odds model, with additional covariates $\mathbf{x}_i = (x_{i1}, \ldots, x_{ip})^T$, as follows,

$$\text{logit}\left(\sum_{h=1}^{k} \theta_{ijrh}\right) = \eta_{ijrk} = \mu_k - (\alpha_r + \beta_j + \gamma_{rj} + x_i^T \delta_r), \tag{2}$$

where $\mathbf{x}_i = (x_{i1}, \ldots, x_{ip})^T$ are a set of p covariates associated with row i of the data matrix; these covariates can be categorical or continuous. The parameters $\{\delta_r\}$ represent the effects of the covariates; we assume these effects are the same for all rows in the same row cluster r. When fitting this model, the subjects will be clustered according to both their response patterns and the values of their covariates, which may lead to different estimates of cluster assignment. Having in mind that R and C are the numbers of row clusters and column clusters, respectively, we will deal with the possible values of $C = m$ (when column effects are different and therefore they are included within the model, without clustering). $C = 1$ when the column effect is the same and it is not included into the model. Considering the simplest row clustering model, without column effects, the proportional odds model without covariates can be expressed as

$$\text{logit}\left(\sum_{h=1}^{k} \theta_{ijrh}\right) = \eta_{ijrk} = \mu_k - \alpha_r, \tag{3}$$

where the number of parameters, including the $R - 1$ independent values of π_r, is $q + 2R - 3$. Adding p covariates into model (3), we obtain

$$\text{logit}\left(\sum_{h=1}^{k} \theta_{ijrh}\right) = \eta_{ijrk} = \mu_k - (\alpha_r + x_i^T \delta_r), \tag{4}$$

where there are now $q + (p + 2)R - 3$ parameters in the model. Models (3) and (4) will be used in the simulation and application section to compare the clustering structure.

3. Application

We applied the models proposed in this article to the *arthritis clinical trial* data set (13), which compares the drug auranofin and placebo therapy for the treatment of rheumatoid arthritis. The data set is obtained from the **R** package $multgee$ (23). In this application, the covariate-dependent clustering could help to identify subsets of patients with similar covariate information patterns. This insight would be important because it would provide a flexible approach for identifying potential heterogeneous gender, age, and auranofin treatment effects on the arthritis scores. For instance, if the elderly experience more symptoms and, consequently, tend to be more pessimistic about their arthritis status, our proposed model would allow us to distinguish subsets of older people that tend to report higher/lower arthritis scores. However, we note that this is only an example and we do not advocate the clinical relevance of the covariate-dependent clustering model. In real settings, clinicians and the statisticians together should decide which model, i.e. no clustering, clustering with covariates, or clustering without covariates, is more relevant to answer their research questions. After fitting the models without covariates (3) and with covariates (4), with different number of row clusters, we compared them using the information criteria AIC and BIC (see results in Table 1). AIC indicates that the best model is the version of the row clustering model including age and treatment covariates ($\mu_k - (\alpha_r + x_{i1}\delta_{1r} + x_{i2}\delta_{2r})$) with $R = 4$ row clusters (AIC = 2136.78), which is better than its counterpart in the model without covariates (AIC=2154.40). However, BIC shows that the model without covariates ($\mu_k - \alpha_r$) and $R = 4$ is the best model (BIC=2202.05). A possible reason is that BIC penalizes higher numbers of parameters more strongly than AIC does, leading to a preference for more parsimonious models. This result might make sense as the model with covariates includes more information in the fitting process. On the other hand, AIC is a standard way in model selection to choose the best model but, as we mentioned above, ideally, clinicians and the statisticians should decide together which is the more relevant model. Additionally, Table 3 shows the results of the comparison of clustering structure agreement of the selected models with and without covariates by using the information theoretic criterion ARI, 1-NVI and 1-NID. The results assume each patient has been allocated to the cluster for which they have the highest posterior probability of membership. Comparing the clustering structure agreement (ARI, 1-NVI, and 1-NDI) of the best model (Model (4) with $R = 4$ including age and treatment covariates) and its counterpart without covariates (Model (3)), the values of the three measures are 0.66 (ARI), 0.47 (1-NVI), and 0.64 (1-NDI), which shows that models (3) and (4) result in different clustering structures.

Abstract

The standard mixture modelling framework has been widely used to study heterogeneous populations, by modelling them as being composed of a finite number of homogeneous sub-populations. However, the standard mixture model assumes that each data point belongs to one and only one mixture component, or cluster, but when data points have fractional membership in multiple clusters this assumption is unrealistic. It is in fact conceptually very different to represent an observation as partly belonging to multiple groups instead of belonging to one group with uncertainty. For this purpose, various soft clustering approaches, or individual-level mixture models, have been developed. In this context, (6) formulated the Bayesian partial membership model (BPM) as an alternative structure for individual-level mixtures, which also captures partial membership in the form of attribute-specific mixtures, but does not assume a factorization over attributes. Our work proposes using the BPM for soft clustering of count data. Learning and inference are carried out using Markov chain Monte Carlo methods. The method is applied on Capital Bike share data of Washington DC from 15 of June to 15 of July 2022.

Keywords: Partial membership models, Model based clustering, Mixture models

1. Introduction

Model-based clustering has been widely used among researchers to study heterogeneous populations, by modelling them as being composed of a finite number of homogeneous sub-populations (4; 7). Within this framework the observations in a dataset are modelled as they are drawn from one of several probability distributions. A clustering solution is sought whereby observations are partitioned into distinct groups, so that observations which have non-negligible posterior probability of belonging to more than one component are seen as having uncertain group membership, and are perhaps indicative of a poorly fit model. However, the standard mixture model assumes that each data point belongs to one and only one mixture component, or cluster, but, as explained in (11), when data points have fractional membership in multiple clusters this assumption is unrealistic; the idea of Mixed and Partial membership models accommodate partial membership. Following (6) example, let's consider an individual with a mixed ethnic background, say, partly Asian and partly European. It seems sensible to represent that individual as partly belonging to two different classes or sets. Being certain that a person is partly Asian and partly European, is very different than being uncertain about a person's ethnic background. The original idea for a mixed membership type of modeling goes back to at least the 1970s when the Grade of Membership (GoM) model was developed by mathematician Max Woodbury to allow for "fuzzy" classifications in medical

diagnosis problems (12). It was not until the early 2000s, with the widespread use of Bayesian methods and a better explanation of the duality between the discrete and continuous nature of latent structure in the GoM model, that a new Bayesian approach to the GoM model had been developed. Independently, within a short time of each other, three mixed membership models were developed to solve problems in three very different areas: (1) with Latent Dirichlet Allocation (LDA), (3) with Grade of Membership model (GoM) and (8) with Admixture model. Mixed membership models unifies the LDA, GoM, and Admixture models in a common framework and provides ways to construct other individual-level mixture models by varying assumptions on the population, sampling unit and latent variable levels, and the sampling scheme. In (6), Partial membership models are defined, which, albeit being part of the same framework, they overcome some of the drawbacks of mixed membership models.

2. Partial membership model

Consider a data set $\boldsymbol{X} = \{\boldsymbol{x}_{ij} : i = 1, 2, \ldots, N, j = 1, 2, \ldots, J\}$. In a finite mixture model, the density of a data point $\boldsymbol{x_i}$ given $\boldsymbol{\Theta}$, which contains the parameters for each of the K mixture components is

$$P(\boldsymbol{x_i}|\boldsymbol{\Theta}) = \sum_{\tau_i} P(\boldsymbol{\tau}_i) \prod_{k=1}^{K} P_k(\boldsymbol{x}_i|\boldsymbol{\theta}_k)^{\tau_{ik}}. \tag{1}$$

Where $\boldsymbol{\tau}_i$ are the weights (or partial membership) which represents how much each data point belongs to each component, so $\tau_{ik} \in \{0, 1\}$ and $\sum_k \tau_{ik} = 1$. We relax the constrain $\tau_{ik} \in \{0, 1\}$ to take any continuous value in the range $[0, 1]$. So we change τ_{ik} from being binary to being in the simplex. The complete data likelihood become

$$P(\boldsymbol{x}_i|\boldsymbol{\Theta}) = \frac{1}{c} \int_{\boldsymbol{\tau}_i} P(\boldsymbol{\tau}_i) \prod_{k=1}^{K} P_k(\boldsymbol{x}_i|\boldsymbol{\theta}_k)^{\tau_{ik}} d\boldsymbol{\tau}_i.$$

We integrate over all values of $\boldsymbol{\tau}_i$ instead of summing, and since the product over clusters K (in Equation 1) no longer normalizes, we put in a normalization constant c, which is a function of $\boldsymbol{\tau}_i$ and $\boldsymbol{\Theta}$. In this work we specify the case when the form of the distribution for each cluster $P_k(\boldsymbol{x}_i|\boldsymbol{\theta}_i)$ are Poisson

$$P_k(\boldsymbol{x}_i|\boldsymbol{\theta}_k) = \prod_{j=1}^{J} P_k(\boldsymbol{x}_{ij}|\lambda_{kj}) = \prod_{j} \frac{\lambda_{kj}^{\boldsymbol{x}_{ij}} e^{-\lambda_{kj}}}{\boldsymbol{x}_{ij}!}.$$

Consider a model with K clusters and let $\boldsymbol{\delta}$ be a K-dimensional vector of positive hyperparameters ($\boldsymbol{\delta} \sim unif(a, b)$). We start by drawing mixture weights from a Dirichlet distribution

$$\boldsymbol{\tau}_i \sim Dir(\boldsymbol{\delta}).$$

For each data point i, we draw a partial membership vector $\boldsymbol{\tau}_i$. We assumed that each cluster k is characterized by a Poisson distribution with natural parameters λ_{kj} and that

$$\lambda_{kj} \sim conj(\alpha, \beta).$$

A prior and likelihood are said to be *conjugate* when the resulting posterior distribution is the same type of distribution as the prior. Gamma distribution is a conjugate prior for the Poisson because they share the same functional form

$$P(\lambda_{kj}) \propto \lambda_{kj}^{\alpha-1} e^{-\beta\lambda_{kj}}.$$

Where α and β are hyperparameters of the prior. Given all these latent variables[1], each data point is drawn from

$$x_{ij} \sim Pois(\exp(\sum_{k=1}^{K} \tau_{ik} \log \lambda_{kj})).$$

[1]In the Bayesian framework the term latent variables could be used instead of parameters, to state that the model uses random variables that remain unobserved during inference.

Which is the shorthand for

$$P(\boldsymbol{x}_{ij}|\boldsymbol{\tau}_i, \lambda_{kj}) \sim Pois(\prod_{k=1}^{K} \lambda_{kj}^{\tau_{ik}}) = Pois(\exp(\sum_{k=1}^{K} \tau_{ik} \log \lambda_{kj})).$$

The generative process for $\boldsymbol{X}$ in the partial membership model, compared to those in mixed membership and mixture models is:

Mixture model	**Mixed membership model**	**Partial membership model**
for(i in $1:N$)	for(i in $1:N$)	for(i in $1:N$)
$\boldsymbol{\tau}_i = \boldsymbol{\delta}$	$\boldsymbol{\tau}_i \sim Dirichlet(\boldsymbol{\delta})$	$\boldsymbol{\tau}_i \sim Dirichlet(\boldsymbol{\delta})$
$\boldsymbol{Z}_i \sim Multinomial(\boldsymbol{\tau}_i)$	for(j in $1:J$)	for(j in $1:J$)
for(j in $1:J$)	$\boldsymbol{Z}_{ij} \sim Multinomial(\boldsymbol{\tau}_i)$	$\mu_{ij} = \exp(\sum_{k=1}^{K} \tau_{ik} \log \lambda_{kj})$
$\boldsymbol{X}_{ij} \sim Poisson(\lambda_{Z_i,j})$	$\boldsymbol{X}_{ij} \sim Poisson(\lambda_{Z_{ij},j})$	$\boldsymbol{X}_{ij} \sim Poisson(\mu_{ij})$

Partial membership model does not assume a factorization over attributes. More generally, mixed membership (MM) models, assume that each data attribute (for instance in a text analysis example the data attributes could be the words) of the data point (e.g. document) is drawn independently from a mixture distribution given the membership vector for the data point, $x_{nj} \sim \sum_k \tau_{nk} P(\boldsymbol{x}|\lambda_{kj})$. MM models only makes sense when the objects (e.g. documents) being modelled constitute bags of exchangeable sub-objects (e.g. words). Partial membership models make no such assumption.

The complete-data posterior takes the form

$$P(\boldsymbol{\tau}, \boldsymbol{\lambda}|\boldsymbol{x}, \alpha, \beta, a, b) \propto P(\boldsymbol{\lambda}|\alpha, \beta) P(\boldsymbol{\tau}|\boldsymbol{\delta}) \prod_{k=1}^{K} \prod_{j=1}^{J} P_k(\boldsymbol{x}_j|\lambda_{kj})^{\tau_k}.$$

Learning in the BPM consists of inferring all unknown variables given $\boldsymbol{X}$, for which we employ Monte Carlo Markov chain (MCMC). Another advantage of BPM over MM models, is that in the latter there is a discrete latent variable for every sub-object, corresponding to which mixture component that sub-object was drawn from. This large number of discrete latent variables makes MCMC sampling in MM potentially much more expensive than in BPM models.

2.1 Model selection

According to (10), a statistical model is said to be *regular* if the map taking parameters to probability distributions is one-to-one and if its Fisher information matrix is positive definite. If a model is not regular, then it is said to be *singular*. If a statistical model contains a hierarchical structure, hidden variables, or a grammatical rule, then the model is generally singular. In singular statistical models, the maximum likelihood estimator does not satisfy asymptotic normality. Consequently, AIC is not equal to the average generalization error (5), and the Bayes information criterion (BIC) is not equal to the Bayes marginal likelihood (9), even asymptotically. In singular models, the maximum likelihood estimator often diverges, or even if it does not diverge, makes the generalization error very large. Therefore, the maximum likelihood method is not appropriate for singular models. On the other hand, Bayes estimation was proven to make the generalization error smaller if the statistical model contains singularities. WAIC (10), (Widely Applicable Information Criterion) could be used for estimating the predictive loss of Bayesian models, using a sample from the full-data posterior, and it is applicable to non-regular models, including non-identifiable models and non-realizable models.

3. Application: Washington DC bikes data

We applied partial membership model on the data of the bike sharing company of Washington DC. The data are collected daily, from 15 of June to 15 of July 2022, and record each single ride: date and

time of start of trip, date and time of end of trip, name, ID, longitude and latitude of starting station, name, ID, longitude and latitude of ending station. We calculated how many times bikes are collected from each station and we modelled these counts using a partial membership model, with the intent that a more deep exploration of the interactions between the bikes stations usage, could allow to improve the allocation of the bikes. All the analysis has been carried out using NIMBLE, a system for programming statistical algorithms for general model structures within R (2). The model with the lowest WAIC is the one with 5 profiles (or components). For a better visualization, in Figure 3. are represented the natural log of the profiles means, while Figure 3. shows a pie chart on each bike stations, that represent the profiles memberships of each.

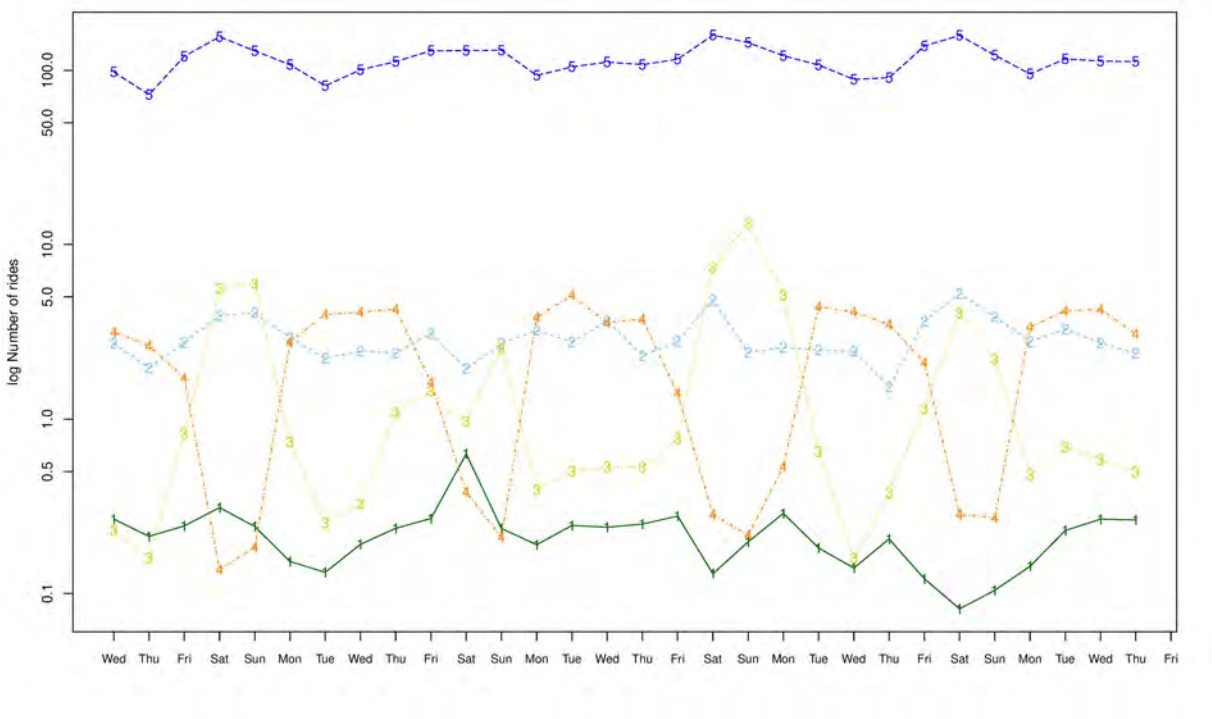

Figure 1: Log of the expected number of rides per day from 15 of June to 15 of July 2022, conditional on profile membership, with 5 profiles.

It could be seen that profile 5 groups the busiest stations, which are mainly located in the center of the city. Profile 1 the less used ones, which are mainly in the outlying areas, profile 2 is an average usage stations cluster and looking at the map, it seems to connect the centre to the peripheral areas, profile 3 groups the stations mostly used during the weekends, with an high peak of usage during the holiday of Monday 4 of July, which is bank holiday in the States. The stations with an high membership to this profile, are often located near the river or green ares, or also in the outlying areas. Profile 4 is the group of the stations mostly used on working days.

4. Conclusions and future developments

Partial membership models provide the analyst with tools of greater flexibility than current model based clustering or standard distance-based clustering methods. We specified the model for count data and applied to bike sharing data of Washington DC. We think this model can be of great use in many applications, such as social sciences, genetics, natural sciences and textual analysis, and can overcome some of the limitations of mixed membership models. As a future developments, it would be interesting to compare the results on applications of partial membership with mixed membership type of models,
