Figure 2: Bike stations' pie charts of profiles membership.

to be able to state which one suits better when dealing with count data. It would be also interesting to explore solutions to assess the over-dispersion issue.

Abstract

In many practical problems the assumption that the data are generated by a single process does not hold. Mixture models can deal with this issue and represent a useful resource also in the context of extreme values. A typical scenario with extreme events is that there are two processes underlying the data: one that occurs with a much higher frequency and another which takes place more rarely but can lead to stronger magnitudes. However, simulation studies and applications to real data show that the rare type may not always correspond to the most extreme events and that the tails of the type-specific data-generating processes are not always identified by this information. Therefore, we aim at creating a new regression model that exploits the type of event as a covariate, together with other variables of interest, such as spatial characteristics.

Keywords: extreme value theory, finite mixtures, environmental problems

1. Introduction

The typical assumption that the data are representative of a unique population of interest is often too restrictive in real world problems. This constitutes an issue that is interesting to tackle in the extreme value framework (1), where the focus is not as usual on the behaviour of the central part of the distribution of the process of interest, but on the tail behaviour, that corresponds to the rarely observed events. Extreme value theory aims indeed at quantifying the stochastic behaviour of a process at extremely large (or small) values on the basis of asymptotic results and provides approaches that are specifically designed for the analysis of this kind of data. In this context the observations, which consist in maximum values of the measured process in a block, are usually assumed to be i.i.d. draws from an appropriate long-tailed distribution, typically the Generalized Extreme Value (GEV) distribution, which is a limiting distribution supported by theoretical results, but other distributions have been proposed and exploited.

Examples of rare events where the data are actually generated by at least two distinct processes are rainfalls generated by typhoon and non-typhoon weather systems, floods originating from a mixture of rainfall and snowmelt or, in a non-environmental context, stock prices bursts linked to the impact of different economic cycles. In order to take into account the specific nature of the data and exploit appropriate methods to deal with variables whose distribution is determined by multiple components, it is possible to exploit finite mixture models (2; 3). These models are used to describe the data as being drawn from a density which is modelled as a convex combination of components, each with a specified parametric form. Hence, they typically involve more parameters than single population models, which results in a more complex estimation in favor of a gain in flexibility.

The research is driven by the application to hydrological area, where due to natural hazards the estimation of the frequency of the extreme events is crucial. In the literature there are numerous studies

on the application of mixture distributions for analysing hydrological extremes. The first contribution in this direction is the one of Rossi et al. (5), who defined the two-component extreme value (TCEV) distribution, which assumes the individual floods to arise from a mixture of two Exponential distributions and the number of events in a year to be generated from two Poisson distributions. Hence they specified a four-parameter distribution, that can be considered a generalization of the Gumbel distribution, which is a special case of the GEV distribution obtained by setting the shape parameter equal to 0. In particular, the TCEV distribution has CDF which is exactly the product of two Gumbel CDF's. Among others, Kjeldsen et al. (4) proposed instead a Gumbel mixture distribution for modelling extreme events from two different phenomena. Considering the independent random variables X_1 and X_2 that correspond to the annual maxima of two different processes, the CDF of the annual maximum X is expressed in terms of conditional distributions as

$$F_X(x) = G_1(x)(1-\omega) + G_2(x)\omega,$$

where ω is the probability that the annual maximum value is a result of the process of type 2 and G_1 and G_2 are conditional distributions of the events of type 1 and type 2, respectively, that are two-parameter Gumbel distributions. This model, unlike the TCEV one, allows to deal with scenarios in which events of type 2 do not occur every year. It also exploits more information than the TCEV one, by taking into account the label that identifies the type of event associated to the annual maximum, but there is, however, one additional parameter to estimate. Furthermore, knowing a priori the population originating each event is often difficult in practice. Even when the data are labelled with the type of event, it is not always the case that these labels actually identify the various subgroups in the tail population. Indeed, the events that happen infrequently are not always the most extreme. In this research we aim at using finite mixture models incorporating the labels as a covariate of the model rather than a deterministic identifier.

2. Models for multi-component extremes

We are interested in finite mixture models for the analysis of series of maximum events originated from multiple populations, focusing on a flexible description of the tail of the distribution. We begin from models which assume that the labels are a known deterministic identifier, and extend the idea to allow for noisy labels.

2.1 Finite mixture models for fixed categories

Without loss of generality, we consider data from two different processes. In the TCEV model (5) the CDF of the annual maximum is written as the product of two Gumbel CDF's: one with location parameter $\mu = \theta_1 \log \lambda_1$ and scale parameter $\sigma = \theta_1$, and the other with location parameter $\mu = \theta_2 \log \lambda_2$ and scale parameter $\sigma = \theta_2$. Table 1 shows the average proportion of type 2 events in the 10 most extreme values in 500 samples of 1000 simulations from a TCEV model with different choices of ratios of parameters, accounting for the fact that by definition of the model $\lambda_1 > \lambda_2$. It is not straightforward to understand how the combination of parameters controls the prevalence in the tail, and it is difficult also

	$\lambda_1/\lambda_2 = 1.5$	$\lambda_1/\lambda_2 = 2$	$\lambda_1/\lambda_2 = 5$
$\theta_2/\theta_1 = 0.5$	0.0018 (0.2213)	0.0012 (0.1565)	0.0000 (0.0357)
$\theta_2/\theta_1 = 1$	0.4042 (0.3969)	0.3244 (0.3321)	0.1732 (0.1664)
$\theta_2/\theta_1 = 1.5$	0.9090 (0.5135)	0.8794 (0.4591)	0.7624 (0.2999)
$\theta_2/\theta_1 = 2$	0.9924 (0.5902)	0.9892 (0.5450)	0.9722 (0.4055)

Table 1: Average proportion of events of type 2 in the 10 most extreme ones obtained from 500 series of 1000 simulations of the TCEV model with the corresponding ratios of location and scale parameters. Average proportion of type 2 events in the whole sample in parenthesis. For reference $\lambda_2 = 2$ always and $\theta_1 = 1$ everywhere except in the first row, where it is 2.

to acknowledge the role in the parameters in determining the total proportion of type 2 events (displayed in parenthesis in the table). Indeed, for some choices of ratios, type 2 events are not the rarest ones, but are still the strongest in terms of magnitude.

The Mixture Gumbel model (4) defines the CDF of the annual maximum as

$$F_X(x) = (1-\omega)\exp\left\{-\exp\left[-\frac{x-\mu_1}{\sigma_1}\right]\right\} + \omega\exp\left\{-\exp\left[-\frac{x-\mu_2}{\sigma_2}\right]\right\}, \tag{1}$$

with $\omega < 0.5$ since, as in (5), events of type 1 are expected to occur more frequently. The parameters $\mu_1, \sigma_1, \mu_2, \sigma_2$ are the location and scale parameters of the two Gumbel distributions of events from process 1 and 2, respectively. Figure 1 shows how the distribution of 1000 simulated data from this model (with $\omega = 0.2$) changes with different ratios between the location parameters and the scale parameters. The location parameter μ_1 is kept equal to 10, while the scale parameter σ_1 is put equal to 3, except in the case $\mu_2/\mu_1 = 1.5$ and $\sigma_2/\sigma_1 = 0.5$, when it is 4, and in the case $\mu_2/\mu_1 = 2$ and $\sigma_2/\sigma_1 = 0.5$, with $\sigma_1 = 5$. Every histogram displays the distribution of the simulated mixture model with corresponding choices of the parameters, and the proportion of density in each bin that comes from each process is identified by using two different colours, light for process 1 and dark for process 2.

It is possible to recognise that the conditional distribution dominating the tail of the mixture can change depending on the parameter combinations: with some choices of the parameters the rare events (type 2) do not prevail in the right tail and frequent events (type 1) also can correspond to the most extreme values. This is also noticeable in Table 2, which displays the proportion of type 2 events in the 10 most extreme values among 1000 simulations (top 1%) from the Mixture Gumbel model with the same ratios of scale and location parameters as Figure 1. As expected type 2 events are the majority when both μ_2/μ_1 and σ_2/σ_1 are large. These results indicate that the model is flexible and can represent multiple scenarios, which is appealing since real life data may also behave in this way. Therefore, it is preferred over the TCEV one as a starting point of our model.

	$\mu_2/\mu_1 = 1$	$\mu_2/\mu_1 = 1.5$	$\mu_2/\mu_1 = 2$
$\sigma_2/\sigma_1 = 0.5$	0.0062	0.0350	0.1030
$\sigma_2/\sigma_1 = 1$	0.2800	0.5408	0.8482
$\sigma_2/\sigma_1 = 1.5$	0.7254	0.9276	0.9632
$\sigma_2/\sigma_1 = 2$	0.9296	0.9742	0.9902

Table 2: Average proportion of events of type 2 in the 10 most extreme ones obtained from 500 series of 1000 simulations of the Mixture Gumbel model with the corresponding ratios of location and scale parameters. The mixing parameter ω is equal to 0.2.

2.2 Finite mixture models for uncertain categories

Although the division of the data point made using the labels may make sense from a physical point of view, it is not necessarily appropriate for describing the tails of the distribution, hence we want to use them to inform the inference but not completely condition it, using also other variables to enhance the model. Therefore, rather than having pre-fixed groups using the labels, we want to allow the data to be informative and to let the allocation be driven by them. Without loss of generality, we assume that the data come from two populations.

Considering the data $x = (x_1, \ldots, x_n)$ and the latent allocation variables $z = (z_1, \ldots, z_n)$, with z_i that identifies the mixture component x_i belongs to, and the denoting by $\ell = (\ell_1, \ldots, \ell_n)$ an observed vector of binary labels such that ℓ_i indicates the type of event generating the data point x_i, for $i = 1 \ldots, n$, we define the model

$$\begin{aligned} x_i \mid z_i = j &\overset{ind}{\sim} \text{Gumbel}\,(x_i \mid \theta_j)\,; \quad \theta_j = (\mu_j, \sigma_j) \\ z_i \mid \ell_i &\overset{ind}{\sim} \text{Bernoulli}\,(z_i \mid \omega_i)\,, \\ \omega_i &= \frac{\exp(\beta_0 + \beta_1 \ell_i)}{1 + \exp(\beta_0 + \beta_1 \ell_i)}, \quad i = 1, \ldots, n. \end{aligned} \tag{2}$$

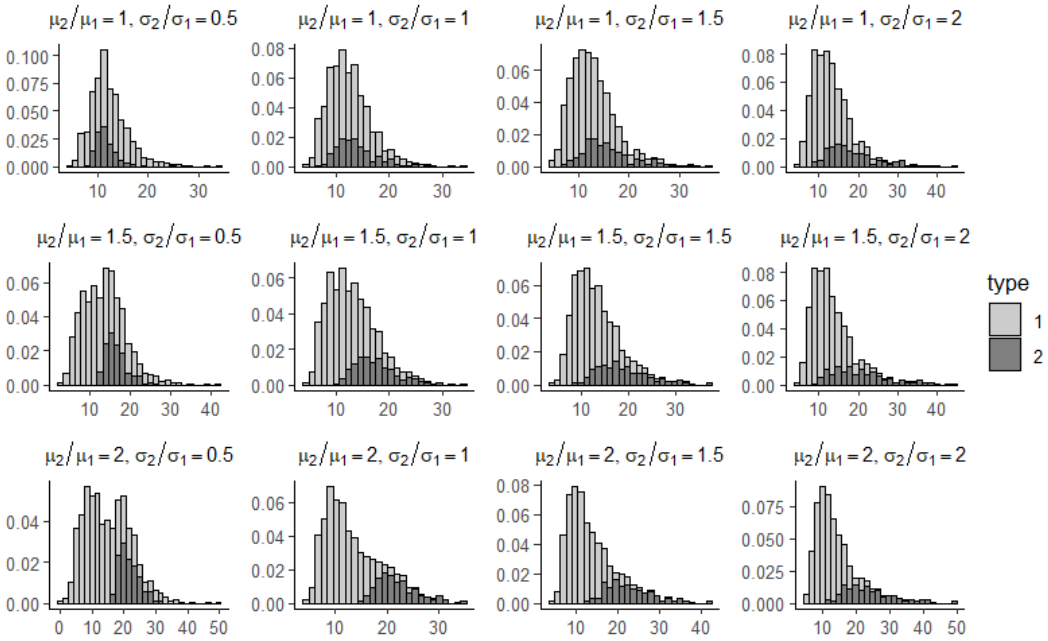

Figure 1: Histograms of the distribution of 1000 simulated data from the Mixture Gumbel model with different ratios of the location parameters and the scale parameters. The mixing parameter ω is always equal to 0.2. For each bin the area is coloured according to the proportion that is due to process 1 (light) and process 2 (dark).

Thus ω_i is derived from a logistic regression as a function of the labels, but this could be generalised to include additional covariates informing the data allocation in the tails. This hierarchical structure allows a more flexible modelling of extreme events that do not originate from a single population and, since the labelling is data-driven, it does not require the labels to be known.

3. Preliminary results

We carry out a simulation study to assess what happens when the labels are not a good representation of the mixture allocation for the tails, using both Model 1 and Model 2. Indeed, we explore how the results change and how robust they are by considering also a scenario where the labels are not the actual identifiers of the type of process, but a small percentage of them is swapped and therefore wrong. We produce 500 series of $n = 1000$ annual maximum events generated from a Mixture Gumbel model with parameters $\mu_1 = 10, \mu_2 = 20, \sigma_1 = 3, \sigma_2 = 5$ and $\omega = 0.2$, and we estimate the parameters by numerical maximum likelihood. For Model 2 we allocate to type 2 the data points with the estimated ω_i greater or equal to 0.5, and the other ones to type 1. For comparison with the Mixture Gumbel model, an estimate of a single ω is then computed as the number of units assigned to type 2 over the total. In Model 1 the parameter ω is simply estimated as the ratio between the number of observed type 2 events and the total number of events.

Tables 3 and 4 show the maximum likelihood estimates related to the two different likelihoods when the labels are the actual ones and when 10% of them are wrong, respectively. It is possible to notice that if the true labels are provided (so they actually identify the type of process) both models can accurately estimate the parameters, whereas when the information on the type of process is wrong, even by a small percentage, we get a more robust model by using the binary regression idea (Model 2). Similarly, the return level plots in 2 show that when the labels are not a good representation of the mixture allocation the model that solely relies on them for estimation (Model 1) is not able to correctly capture high quantiles while Model 2 does.

4. Discussion

When dealing with real world problems, it is reasonable to assume that extremes events originate from a number of different types of data-generating processes. However it is not easy to find data on extreme events that have information about the type of phenomenon which generated them. A further issue that is not very evident in the literature concerns the fact that even when this information is made available by domain experts, is not necessarily one that allows to discriminate between the multiple groups in the tail of the population. We define a model in which the allocation of the data points is not solely based on the knowledge on the type of process, i.e. the labels, but it exploits them to inform the

inference, leading to results that are more robust to noise in the labels.

We are interested in enhancing the model by using Bayesian methods to exploit the ability of setting priors which encode the understanding we have of the problem, and to borrow information between the groups to estimate the model parameters. The Bayesian setting also allows to integrate in the estimation the uncertainty in the labels. Furthermore, we aim at exploring the results of the simulation study with real data applications, which are usually not characterised by such a high number of observations, with a focus on the problem of unknown categories.

Abstract

Finite mixtures of regressions are a model-based clustering approach commonly adopted in many regression-type analyses. Unfortunately, real data often present atypical points that make unreliable the classical normality assumption of the mixture components. Thus, to robustify this approach, we introduce finite mixtures of matrix-variate contaminated normal regressions (FM-MVCNR). Furthermore, once the model is estimated and the observations are assigned to the groups, a finer intra-group classification in typical and atypical points can be directly obtained. From the analyses conducted on simulated data, we show the negative consequences of the wrong normality assumption in the presence of heavy-tailed clusters or noisy matrices, and how they are properly addressed by our FM-MVCNR.

Keywords: matrix-variate, robustness, mixture-models, regression

1. Introduction

The analysis of matrix-variate data is attracting a growing interest in the statistical literature, particularly within the model-based clustering framework (for recent contributions, see e.g. (1; 6; 10; 13; 15)). A matrix-variate dataset is characterized by three modes, namely p rows, r columns, and n layers. Depending on the entities indexed in the three modes, different examples are obtained (for a survey, see (17)).

When the data at hand are composed of a $p \times r$ response matrix $\mathcal{Y}$ and a $q \times r$ covariate matrix $\mathcal{X}$, and when there is a latent source of heterogeneity, finite mixtures of matrix-variate regression (FM-MVR) models constitute a reference framework of analysis (7; 14; 2; 9). For a continuous response matrix $\mathcal{Y}$, attention is generally focused on finite mixtures of matrix-variate normal regressions (FM-MVNR) because of their computational and theoretical convenience. Unfortunately, real data are often contaminated by atypical points that affect the estimation of the model parameters and data classification (5). Thus, their detection, and the development of robust methods insensitive to their presence, is a crucial task.

Based on the above considerations, in this work, we introduce finite mixtures of matrix-variate contaminated normal regressions (FM-MVCNR). The matrix-variate contaminated normal (MVCN), used for modeling the conditional distribution of the responses, is a heavy-tailed generalization of the matrix-variate normal (MVN) distribution. More in detail, it is a two-component matrix-variate normal mixture in which one of the components, with a large prior probability, represents the typical observations, and the other, with a small prior probability, the same mean, and an inflated covariance matrix, represents the atypical observations. Because of its heavier-than-normal tails, it provides greater flexibility in modeling data with heavy-tailed groups. This distribution has been successfully considered for the definition of unconditional matrix-variate mixture models in (16).

As it will be better explained in Sect. 2, once the FM-MVCNR is fitted to the data, each observation can be first assigned to one of the groups and then classified as either typical or atypical using maximum *a posteriori* probabilities. Thus, we have a model for simultaneous clustering and detection of atypical points in a matrix-variate regression context. This aspect is of particular importance for matrix-variate data given that visualization techniques - and, therefore, the visual detection of atypical points - are a problematic exercise.

The paper is organized as follows. In Sect. 2, we introduce the FM-MVCNR by providing information about its characteristics, parameter estimation, and atypical points detection. In Sect. 3, we conduct a simulated analysis where we show the negative consequences of the wrong normality assumption in the presence of heavy-tailed clusters or noisy matrices, and how they are properly addressed by our FM-MVCNR. Finally, in Sect. 4. we summarize our manuscript.

2. Methodology

Let $\mathcal{Y}$ be a continuous random matrix of dimension $p \times r$ containing p responses measured over r occasions. Let us also consider a random matrix $\mathcal{X}$ of dimension $q \times r$ containing q covariates evaluated over r occasions. Assume there exist K subgroups in the data. Then, the probability density function (pdf) of a matrix-variate FM-MVR is

$$h(\mathbf{Y}|\mathbf{X};\boldsymbol{\Theta}) = \sum_{k=1}^{K} \pi_k f(\mathbf{Y}|\mathbf{X};\boldsymbol{\Theta}_{\mathbf{Y}|k}), \tag{1}$$

where $\pi_k > 0$ is the mixing proportion, with $\sum_{k=1}^{K} \pi_k = 1$, $f(\mathbf{Y}|\mathbf{X};\boldsymbol{\Theta}_{\mathbf{Y}|k})$ is the conditional distribution of the responses, and $\boldsymbol{\Theta} = \{\pi_k, \boldsymbol{\Theta}_{\mathbf{Y}|k}\}_{k=1}^{K}$. Additionally, for each k, the location parameter in $\boldsymbol{\Theta}_{\mathbf{Y}|k}$ is a linear function of $\mathbf{X}$ depending on some other parameters.

In this manuscript, $f(\mathbf{Y}|\mathbf{X};\boldsymbol{\Theta}_{\mathbf{Y}|k})$ in (1) has the functional form of the matrix-variate contaminated normal distribution, whose pdf for a generic $p \times r$ random matrix $\mathcal{H}$ is

$$\alpha\phi(\mathbf{H};\mathbf{M},\boldsymbol{\Sigma},\boldsymbol{\Psi}) + (1-\alpha)\phi(\mathbf{H};\mathbf{M},\eta\boldsymbol{\Sigma},\boldsymbol{\Psi}), \tag{2}$$

where $\phi(\mathbf{H};\mathbf{M},\boldsymbol{\Sigma},\boldsymbol{\Psi})$ is the density of the MVN distribution having pdf

$$\frac{1}{(2\pi)^{\frac{pr}{2}}|\boldsymbol{\Sigma}|^{-\frac{r}{2}}|\boldsymbol{\Psi}|^{-\frac{p}{2}}} \exp\left[-\frac{\delta(\mathbf{H};\mathbf{M},\boldsymbol{\Sigma},\boldsymbol{\Psi})}{2}\right], \tag{3}$$

with $p \times r$ mean matrix $\mathbf{M}$, $p \times p$ and $r \times r$ covariance matrices $\boldsymbol{\Sigma}$ and $\boldsymbol{\Psi}$, respectively, and squared Mahalanobis distance $\delta(\mathbf{H};\mathbf{M},\boldsymbol{\Sigma},\boldsymbol{\Psi}) = \text{tr}\left[\boldsymbol{\Sigma}^{-1}(\mathbf{H}-\mathbf{M})\boldsymbol{\Psi}^{-1}(\mathbf{H}-\mathbf{M})'\right]$. In (2), α is the proportion of typical points in the group k, and η is an inflation parameter accounting for the degree of contamination in the group k. We assume a linear relationship $\mathbf{M}(\mathbf{X}^*;\mathbf{B}_k) = \mathbf{B}_k\mathbf{X}^*$, where $\mathbf{B}_k$ is a $p \times (1+q)$ matrix of regression coefficients and $\mathbf{X}^*$ is a $(1+q) \times r$ matrix containing a first row of ones (to incorporate the intercept in the model) and the covariates $\mathbf{X}$. Note that (2) approaches (3) as $\alpha \to 1^-$ and $\eta \to 1^+$.

We recall that an MVCN distribution can be represented as a scale mixture of MVN distributions with mixing random variable W being Bernoulli distributed (16). This characteristic is particularly useful for maximum likelihood parameter estimation, as briefly discussed in Section 2.1.

2.1 Parameter estimation

To estimate the parameters of our model, we implement the expectation conditional-maximization (ECM) algorithm (8). In detail, let $\mathbf{S} = \{(\mathbf{Y}_i, \mathbf{X}_i)\}_{i=1}^{N}$ be a sample of N independent observations. Within an ECM framework, $\mathbf{S}$ is viewed as incomplete: we have a first source of incompleteness that arises from the fact that we do not know the component membership of each observation, and a second source of incompleteness that arises from the aforementioned representation of the MVCN distribution in terms of a scale

mixture of MVN distributions. To address the first source, we use an indicator vector $\mathbf{z}_i = (z_{ik}, \ldots, z_{iK})$, where $z_{ik} = 1$ if observation i is in the group k, and $z_{ik} = 0$ otherwise. To consider the second source, for each observation $(\mathbf{Y}_i, \mathbf{X}_i)$ in the group k, we have $W_{ik\mathbf{Y}} \sim$ Bernoulli $(\alpha_{\mathbf{Y}|k})$. Based on these sources of incompleteness, we can write the complete-data log-likelihood as

$$
\begin{aligned}
l_c(\boldsymbol{\Theta}) = & \sum_{i=1}^{N}\sum_{k=1}^{K} z_{ik} \ln(\pi_k) + \sum_{i=1}^{N}\sum_{k=1}^{K} z_{ik}\left[w_{ik\mathbf{Y}} \ln(\alpha_{\mathbf{Y}|k}) + (1 - w_{ik\mathbf{Y}}) \ln(1 - \alpha_{\mathbf{Y}|k})\right] \\
& + \sum_{i=1}^{N}\sum_{k=1}^{K} z_{ik}\left[-\frac{r}{2}\ln|\boldsymbol{\Sigma}_{\mathbf{Y}|k}| - \frac{p}{2}\ln|\boldsymbol{\Psi}_{\mathbf{Y}|k}| - \frac{pr}{2}(1 - w_{ik\mathbf{Y}})\ln(\eta_{\mathbf{Y}|k})\right. \\
& \left. -\frac{1}{2}(w_{ik\mathbf{Y}} + \frac{1 - w_{ik\mathbf{Y}}}{\eta_{\mathbf{Y}|k}})\delta_k\left(\mathbf{Y}_i; \mathbf{B}_k\mathbf{X}_i^*, \boldsymbol{\Sigma}_{\mathbf{Y}|k}, \boldsymbol{\Psi}_{\mathbf{Y}|k}\right)\right].
\end{aligned} \tag{4}
$$

The ECM algorithm of our model consists of an E-Step and two CM-Steps. At the E-step, we calculate the conditional expectation of (4), given the observed data and the current estimate of the parameters. Then, we maximize the conditional expectation of (4) with respect to two separate sets of parameters, one for each CM-step. Here, we limit to report that closed-form expressions are available for all the parameters of the model, in the fashion of (16).

2.2 Atypical points detection

An interesting feature of the FM-MVCNR is the capability of detecting atypical observations. To label data points, we consider an *a posteriori* procedure. First of all, each observation $(\mathbf{Y}_i, \mathbf{X}_i)$ is assigned to one of the K groups through the maximum *a posteriori* probabilities (MAP) operator

$$
\text{MAP}(\widehat{z}_{ik}) = \begin{cases} 1 & \text{if } \max_h\{\widehat{z}_{ih}\} \text{ occurs in group } h = k, \\ 0 & \text{if otherwise,} \end{cases}
$$

where $\widehat{z}_{ik}$ is the estimated posterior probability that a point $(\mathbf{Y}_i, \mathbf{X}_i)$ belongs to the kth component of the model. Then, let $\widehat{w}_{ik}$ be the estimated value of W_{ik} at the convergence of the ECM algorithm. The commonly adopted decision rule when contaminated distributions are used (see, e.g. 4; 12; 16), consists of considering a point typical if $\widehat{w}_{ik} > 0.5$. Thus, once the observation has been classified in one of the K groups, this approach reveals richer information about the role of that observation in that group.

3. Synthetic data analyses

Here, we simulate different scenarios that may arise when analyzing real datasets. Specifically, we generate data from the following three data generation processes (DGPs): (a) FM-MVNR, (b) FM-MVCNR, and (c) FM-MVNR where 5% of points have been modified to incorporate noisy values. Regarding scenario (c), for each selected point, the values of $\mathbf{Y}$ are substituted by random numbers generated from a uniform distribution over the interval $[a_{\mathbf{Y}}, b_{\mathbf{Y}}]$, being $a_{\mathbf{Y}}$ and $b_{\mathbf{Y}}$ the minimum and the maximum value of $\mathbf{Y}$ in the sample.

We set $p = 2$, $q = 3$, $r = 5$, $K = 2$, and the following values for the parameters

$$
\pi_1 = \pi_2 = 0.50, \quad \alpha_{\mathbf{Y}} = (0.90, 0.80), \quad \eta_{\mathbf{Y}} = (15.00, 20.00),
$$

$$
\mathbf{B}_1 = \begin{bmatrix} 2.00 & 1.00 & 1.00 & -1.00 \\ 3.00 & 1.00 & -1.00 & 1.00 \end{bmatrix}, \quad \mathbf{B}_2 = \begin{bmatrix} -10.00 & 1.00 & 1.00 & -1.00 \\ -8.00 & 1.00 & -1.00 & 1.00 \end{bmatrix},
$$

$$
\boldsymbol{\Sigma}_1 = \boldsymbol{\Sigma}_2 = \begin{bmatrix} 1.00 & 0.50 \\ 0.50 & 1.00 \end{bmatrix}, \quad \boldsymbol{\Psi}_1 = \boldsymbol{\Psi}_2 = \begin{bmatrix} 1.00 & 0.70 & 0.49 & 0.34 & 0.24 \\ 0.70 & 1.00 & 0.70 & 0.49 & 0.34 \\ 0.49 & 0.70 & 1.00 & 0.70 & 0.49 \\ 0.34 & 0.49 & 0.70 & 1.00 & 0.70 \\ 0.24 & 0.34 & 0.49 & 0.70 & 1.00 \end{bmatrix}.
$$

For each DGP, we simulate 100 samples of size N, where $N \in (100, 500)$, yielding a total of 600 generated datasets. According to the above simulation scheme, we have scenarios characterized by no atypical points (a), heavy-tailed clusters (b), and noisy points (c). On each generated dataset we fit the FM-MVNR and FM-MVCNR with $K = 2$, and their performances are discussed in Sect. 3.1 in terms of parameter recovery, classification, and fitting performance.

3.1 Results

First of all, we examine the parameter recovery of the considered models. To this purpose, we compute the average mean squared error (MSE) of the estimated regression coefficients over the 100 datasets simulated by each DGP. Results are reported in Table 1.

Table 1: Average MSEs of the estimated regression coefficients under the three scenarios.

Model		$N = 100$	$N = 500$
Scenario (a)			
FM-MVNR	$\mathbf{B}_1$	$\begin{bmatrix} 0.008 & 0.004 & 0.005 & 0.005 \\ 0.012 & 0.005 & 0.004 & 0.006 \end{bmatrix}$	$\begin{bmatrix} 0.002 & 0.001 & 0.001 & 0.001 \\ 0.002 & 0.001 & 0.001 & 0.001 \end{bmatrix}$
	$\mathbf{B}_2$	$\begin{bmatrix} 0.012 & 0.005 & 0.006 & 0.006 \\ 0.011 & 0.005 & 0.004 & 0.006 \end{bmatrix}$	$\begin{bmatrix} 0.003 & 0.001 & 0.001 & 0.001 \\ 0.003 & 0.001 & 0.001 & 0.001 \end{bmatrix}$
FM-MVCNR	$\mathbf{B}_1$	$\begin{bmatrix} 0.008 & 0.004 & 0.005 & 0.005 \\ 0.012 & 0.005 & 0.004 & 0.006 \end{bmatrix}$	$\begin{bmatrix} 0.002 & 0.001 & 0.001 & 0.001 \\ 0.002 & 0.001 & 0.001 & 0.001 \end{bmatrix}$
	$\mathbf{B}_2$	$\begin{bmatrix} 0.012 & 0.005 & 0.006 & 0.006 \\ 0.011 & 0.005 & 0.004 & 0.006 \end{bmatrix}$	$\begin{bmatrix} 0.003 & 0.001 & 0.001 & 0.001 \\ 0.003 & 0.001 & 0.001 & 0.001 \end{bmatrix}$
Scenario (b)			
FM-MVNR	$\mathbf{B}_1$	$\begin{bmatrix} 0.406 & 0.003 & 0.003 & 0.002 \\ 0.324 & 0.002 & 0.002 & 0.002 \end{bmatrix}$	$\begin{bmatrix} 0.175 & 0.000 & 0.000 & 0.001 \\ 0.163 & 0.000 & 0.001 & 0.001 \end{bmatrix}$
	$\mathbf{B}_2$	$\begin{bmatrix} 0.402 & 0.002 & 0.003 & 0.003 \\ 0.303 & 0.002 & 0.003 & 0.002 \end{bmatrix}$	$\begin{bmatrix} 0.140 & 0.000 & 0.001 & 0.000 \\ 0.129 & 0.000 & 0.000 & 0.000 \end{bmatrix}$
FM-MVCNR	$\mathbf{B}_1$	$\begin{bmatrix} 0.014 & 0.001 & 0.001 & 0.001 \\ 0.016 & 0.001 & 0.001 & 0.001 \end{bmatrix}$	$\begin{bmatrix} 0.003 & 0.000 & 0.000 & 0.000 \\ 0.004 & 0.000 & 0.000 & 0.000 \end{bmatrix}$
	$\mathbf{B}_2$	$\begin{bmatrix} 0.020 & 0.001 & 0.001 & 0.001 \\ 0.019 & 0.001 & 0.001 & 0.001 \end{bmatrix}$	$\begin{bmatrix} 0.004 & 0.000 & 0.000 & 0.000 \\ 0.004 & 0.000 & 0.000 & 0.000 \end{bmatrix}$
Scenario (c)			
FM-MVNR	$\mathbf{B}_1$	$\begin{bmatrix} 0.347 & 0.068 & 0.066 & 0.052 \\ 0.523 & 0.047 & 0.043 & 0.069 \end{bmatrix}$	$\begin{bmatrix} 0.330 & 0.021 & 0.024 & 0.018 \\ 0.489 & 0.023 & 0.020 & 0.021 \end{bmatrix}$
	$\mathbf{B}_2$	$\begin{bmatrix} 0.687 & 0.071 & 0.062 & 0.072 \\ 0.372 & 0.045 & 0.073 & 0.061 \end{bmatrix}$	$\begin{bmatrix} 0.736 & 0.023 & 0.025 & 0.038 \\ 0.372 & 0.031 & 0.030 & 0.031 \end{bmatrix}$
FM-MVCNR	$\mathbf{B}_1$	$\begin{bmatrix} 0.016 & 0.007 & 0.006 & 0.005 \\ 0.014 & 0.006 & 0.004 & 0.005 \end{bmatrix}$	$\begin{bmatrix} 0.003 & 0.001 & 0.001 & 0.001 \\ 0.003 & 0.001 & 0.001 & 0.001 \end{bmatrix}$
	$\mathbf{B}_2$	$\begin{bmatrix} 0.016 & 0.006 & 0.005 & 0.007 \\ 0.015 & 0.005 & 0.006 & 0.006 \end{bmatrix}$	$\begin{bmatrix} 0.002 & 0.001 & 0.001 & 0.001 \\ 0.002 & 0.001 & 0.001 & 0.001 \end{bmatrix}$

By starting with scenario (a), i.e. when there are no atypical points, we see that both models provide the same results. This is because, in this situation, the FM-MVCNR tends to the FM-MVNR (refer to Sect. 2). Regardless of the considered model, the MSEs are negligible and improve with the increase of

N. Oppositely, when scenario (b) is considered, the FM-MVCNR performs better than the traditional FM-MVNR. Indeed, the latter model is not robust, with consequences on the parameter estimates, as we can see by the MSEs that are regularly higher than those of the FM-MVCNR. As in scenario (a), the MSEs improve with the increase of N. Lastly, under scenario (c), i.e. when there are noisy matrices, we immediately observe that the estimates of the FM-MVNR are even worse than those of scenario (b). On the contrary, because of its robustness, the FM-MVCNR performs comparably well, as shown by the negligible MSEs that become better as N increases.

Regarding the classification and fitting performance, we compute the average adjusted Rand index (ARI; 3) and average Bayesian information criterion (BIC; 11) of the models over the 100 datasets simulated by each DGP. Results are illustrated in Table 2. As we can see, under scenario (a), both models always provide a perfect data classification. However, in scenarios (b) and (c), the FM-MVCNR, because of its robustness, shows better results than the FM-MVNR. Similarly, from the fitting point of view, we notice that the FM-MVNR produces better BICs under scenario (a). However, in scenarios (b) and (c), the FM-MVCNR displays far better BICs, highlighting its greater flexibility in modeling data having atypical points.

Table 2: Average ARI and BIC for the considered models over the simulated datasets.

Model	ARI		BIC	
	$N = 100$	$N = 500$	$N = 100$	$N = 500$
Scenario (a)				
FM-MVNR	1.000	1.000	2476.279	11741.900
FM-MVCNR	1.000	1.000	2494.699	11766.760
Scenario (b)				
FM-MVNR	0.894	0.943	3888.669	19301.020
FM-MVCNR	0.967	0.980	3198.380	15227.990
Scenario (c)				
FM-MVNR	0.805	0.810	3958.796	19873.750
FM-MVCNR	0.811	0.815	3027.217	14507.830

For evaluating the performances of the FM-MVCNR in detecting atypical points in scenario (c), we consider the true positive rate (TPR), measuring the proportion of atypical points that are correctly identified as atypical, and the false positive rate (FPR), corresponding to the proportion of typical points incorrectly classified as atypical. Their average values over the 100 datasets simulated for each N are reported in Table 3. From the obtained results, we note that our model always recognizes the noisy matrices as atypical, and very rarely labels a typical observation as atypical.

Table 3: Average TPRs and FPRs under Scenario (c) over the simulated datasets.

	TPR		FPR	
Model	$N = 100$	$N = 500$	$N = 100$	$N = 500$
FM-MVCNR	1.000	1.000	0.008	0.006

4. Conclusions

In this manuscript, robust finite mixtures of matrix-variate regressions have been introduced. Specifically, we considered the matrix-variate contaminated normal (MVCN) for modeling the conditional distribution of the responses in the mixture components. The results of our simulated analyses showed

that in the presence of heavy-tailed clusters or noisy matrices, the mean squared errors of the regression coefficients are regularly higher when the normal distribution is used for the mixture components. Conversely, the use of the MVCN distribution, because of its heavier tails, results in more robust parameter estimation, classification, and fitting compared to the traditional case based on the matrix-variate normal distribution. Lastly, our model performs very well in detecting atypical points in the data.

On the use of auxiliary information to define the sampling design for large-scale geospatial data

Abstract

In many fields of application it's common to be interested in spatially-related phenomena and in particular to deal with attributes that, being defined on continuous spatial domains, are observed on a fine grid. It is well known that in order to investigate these phenomena through a sample survey it is more accurate to spread the sample over space and to exploit the rich auxiliary information available from various types of large-scale observations. Such information is often used in the estimation stage of a survey but it may be interesting to use it in the design stage as well. Therefore, we propose a two-step sampling design which investigates the relation between the auxiliary and study variables in order to identify when and how it is useful to exploit this information, in addition to the units' spatial location, in the the second-step of the sampling selection process.

Keywords: Balanced sampling, Cross-correlation, Local pivotal method, Spread sampling, Unequal probability sampling

1. Introduction

In many fields of application including forestry, geology, ecology, and similar, data contains geographical coordinates and such information can be used in the sampling design development process. Since nearby units interact with one another and tend to be influenced by the same set of natural and anthropogenic factors, geographical data generally show a spatial pattern and an uneven spatial distribution over the population. In such situations, it is well known that selecting the units spatially well spread over the study area allows to collect more information and consequently provides a better estimation of the population parameters. Moreover, technological advances have led to a growing availability of low-cost spatial data ready-to-use, frequently derived from large-scale observations (including GPS sensors data, remote sensing data, and similar), and this auxiliary information can be used in the sampling design development process in addition to the units' spatial location.

Many sampling methods have been suggested in literature to select a well-spread sample, for a comprehensive review we refer to (7), (8), (1) and (9). Some of these methods implement simultaneously the selection of well-spread samples and the use of auxiliary variables in the selection process. Among these are the Spatially Balanced Sampling through the Local Pivotal Method (LPM) (4) and the Double Balanced Sampling (5). The first method allows the use of auxiliary variables in two different ways: (i) through the drawing of samples spread in a multidimensional space defined by the auxiliary variables along with the spatial coordinates, therefore producing samples that are balanced on the auxiliary variables as well as on the space; or (ii) through the selection of unequal probability spatially balanced samples, using an auxiliary variable or a function of more auxiliary variables for the calculus of the inclusion probabilities. The second method selects samples that are simultaneously well spread and balanced on the auxiliary variables by combining the use of the cube method (2) and the local pivotal method.

In the design-based approach, the use of auxiliary variables in the design phase and/or in the estimation phase is based on some assumptions (usually not explicit) on the relationship between the response and the auxiliary variables and the resulting gain in the estimation efficiency depends on the validity of these assumptions. For spatially related data, specific considerations on this relation are opportune: nearby units tend to be similar with respect to each variable and in some situations the relationship between the study and auxiliary variables may be wholly or partially due to a spatial cross-covariability. In such cases, the use of the auxiliary variable in addition to the units' geographical location does not always produce gains in efficiency. The relationship between the target and auxiliary variables is obviously never known exactly. Moreover, for large-scale phenomena, it is often not even plausible to assume a unique relationship that holds everywhere. In order to identify a sampling design that could be globally applied by accounting for different areas characteristics in both the study and auxiliary variables, as well as for the differences in their relation, we propose a two-step informative design based on the sequential use of the LPM: (i) in the first step, a well-spread sample is selected and the information collected is used to investigate the relation between the auxiliary and study variable; (ii) then, on the basis of this analysis, a decision is made on whether or not to consider the auxiliary variables in drawing the second-step well-spread sample. The final sample is given by the union of the two samples.

2. Notation and sampling strategy

Usually, in a spatial setting, the population units are plots or cells of a grid overlapping an area of interest. A value, y_i, of a variable of interest is associated with each unit i $(i = 1, ..., N)$ of the population. Moreover for each unit the spatial location $\mathbf{s}_i$, $\mathbf{s} \in \mathbf{R^2}$ is known. Here, in addition we assume to know the value x_i of an auxiliary variable for each unit of the population.

To draw a spatial sample from such a population we consider as starting point the spatially balanced sampling through LPM (4). The basic idea of LPM is to avoid that units close in distance appear together in the sample. First an inclusion probability $0 < \pi_i \leq 1$ is assigned to each unit so that their sum over the population is equal to the fixed sample size n. These probabilities may be constant or variable. When we have access to an auxiliary variable (commonly defined as a size measure) whose values are thought to be approximately proportional to the unknown response values we can set π_i proportional to the known x_i. That is, for $i = 1, ..., N$

$$\pi_i = n \frac{x_i}{\sum_U x_j} \tag{1}$$

The sample is then obtained in at most N steps. At each step one unit i is selected randomly from the available population and another unit j is chosen among the remaining units in the population by minimizing a distance function among them. This can be a univariate or a multivariate function that measures the distance with respect to one or more auxiliary variables, among which we can include the spatial coordinates. When all the variables are continuous the Euclidean distance is commonly used. Moreover, when multiple auxiliary variables are used, they should be standardized or scaled in order to balance the contribution of each variable. After the selection of the unit i and j their inclusion probabilities are updated by using the following rule:

$$\begin{aligned}
&\text{if } \pi_i + \pi_j < 1 \text{ then } (\pi_i', \pi_j') = \begin{cases} (0, \pi_i + \pi_j) \text{ with probability } \frac{\pi_i}{\pi_i + \pi_j} \\ (\pi_i + \pi_j, 0) \text{ with probability } \frac{\pi_j}{\pi_i + \pi_j} \end{cases} \\
&\text{if } \pi_i + \pi_j \geq 1 \text{ then } (\pi_i', \pi_j') = \begin{cases} (1, \pi_i + \pi_j - 1) \text{ with probability } \frac{1 - \pi_j}{2 - \pi_i - \pi_j} \\ (\pi_i + \pi_j - 1, 1) \text{ with probability } \frac{1 - \pi_i}{2 - \pi_i - \pi_j} \end{cases}
\end{aligned} \tag{2}$$

As a result, in each step at least one unit is removed from the frame, either because its probability becomes zero, and consequently it is definitely excluded from the sample, or because its probability becomes one and therefore is included in the sample. The procedure continues, updating at each step the probabilities of inclusion obtained in the previous step, until all units in the population are processed.

We propose the following two-step sampling design. First, an initial sample S_0 of size $n_0 \leq n$ is selected by applying two times the spatially balanced sampling through LPM with constant inclusion probabilities π_is: at the first time for drawing a sample S of n units from the population and at the second time for drawing n_0 units from S. Then the information collected from S_0 is used to investigate the relationship between the auxiliary and the study variable. On the basis of the results of this exploratory analysis, the second-step sample S_1 of size $n_1 = n - n_0$ is either assumed equal to $(S - S_0) = (S \bigcap S_0^c)$ or is drawn from $(U - S_0) = (U \bigcap S_0^c)$ using a spatially balanced sampling design that exploits also the auxiliary variable. The final sample is $S_f = (S_0 \cup S_1)$ and to estimate the population mean we use the Horvitz-Thompson type estimator with the following inclusion probabilities:

$$\pi_i' = Pr(i \in S_0) + (1 - Pr(i \in S_0) Pr(i \in S_1) =$$

$$= \begin{cases} \frac{n}{N} & \text{if } S_1 \text{ is drawn with constant probabilities} \\ \frac{n_0}{N} + \left(1 - \frac{n_0}{N}\right) \frac{(n-n_0)x_i}{\sum_U X_j - \sum_{S_0} X_j} & \text{otherwise} \end{cases} \tag{3}$$

We consider two ways for exploiting the auxiliary variable to draw the second-step sample:

1. **SeqUneqLPM**: apply a spatially balanced sampling through LMP with unequal inclusion probabilities π_is proportional to the auxiliary variable;
2. **SeqBivLPM**: apply a sampling, with equal inclusion probabilities, balanced through LMP in the space spanned by both the geographical coordinates and the auxiliary variable.

3. Simulation study

In this section we compare our two proposals with several one-step designs all based on the use of the units' spatial location and/or of the auxiliary variable in the design phase:

3. **SpatLPM**: The original formulation of spatially balanced sampling through LPM which produces samples that are well spread in the geographic space and is based on equal inclusion probabilities;
4. **AuxLPM**: Sampling, with equal inclusion probabilities, balanced through LMP in the space spanned by the auxiliary variable;
5. **BivLPM**: Sampling, with equal inclusion probabilities, balanced through LMP in the space spanned by both the geographical coordinates and the auxiliary variable;
6. **UneqLPM**: Spatially balanced sampling through LMP with unequal inclusion probabilities π_is proportional to the auxiliary variable;
7. **UneqSampford** Sampford sampling, with unequal inclusion probabilities proportional to the auxiliary variable

An additional design that we could consider for comparison is the double balanced sampling of (5), however this design is highly computationally demanding when applied to a big dataset, and would be unfeasible in our experiments. Conversely, the LPM design has been optimized for large datasets using k-d trees (6), allowing to run our Monte Carlo experiments in a reasonable amount of time.

We investigate the performance of the different sampling designs through Monte Carlo experiments based on several synthetic datasets. In each of them the auxiliary (X) and response (Y) variables are drawn from a stationary bivariate spatial process $[X(\mathbf{s}), Y(\mathbf{s})]$ with $\mathbf{s} \in [0, 10]^2$ (1000×1000 grid). Following Diggle and Ribeiro (3, Chapter 3), each bivariate spatial process in turn is obtained as:

$$X(\mathbf{s}) = a * Z_1(\mathbf{s}) + c * Z_2(\mathbf{s}) + k_1 \qquad Y(\mathbf{s}) = b * Z_1(\mathbf{s}) + d * Z_3(\mathbf{s}) + k_2 \tag{4}$$

- $Z_1(\mathbf{s})$, $Z_2(\mathbf{s})$ and $Z_3(\mathbf{s})$ are independent univariate stationary Gaussian processes with an Exponential variogram with scale 1 and sill $C + C_0 = 50$, where C is the partial sill and C_0 is the nugget. For $Z_2(\mathbf{s})$ and $Z_3(\mathbf{s})$ we assume $C = 50$ and $C_0 = 0$ in all scenarios, while for $Z_1(\mathbf{s})$ their values vary ($C = 50, 30, 0$) to change the proportion of the co-variability that has spatial structure;

- a, b, c and d are constants which vary in order to obtain different correlation level and structure;
- k_1 and k_2 are adding constants to guarantee $X(\mathbf{s}) > 0$ and $Y(\mathbf{s}) > 0$.

Overall, we present our results for 21 synthetic datasets which differ in the spatial distribution of both the study and auxiliary variables, as well as in their relation. The complete list of settings used to generate the synthetic datasets is presented in Table 1. To give a better idea of the different relations between X, Y and $\mathbf{s}$ that can be simulated in our data, Figure 1 shows variables $X(\mathbf{s})$ and $Y(\mathbf{s})$ generated under settings A1, A6 and B6: in scenario A1 we observe a weak correlation between X and Y (equal to 0.298), with both variables strongly related with space; in both scenarios A6 and B6 the correlation between X and Y is stronger (more than 0.7), but in B6 part of the co-variability (about 40%) is not spatially related.

Table 1: Observed correlation for the simulated populations, by scenarios.

					$Corr(X,Y)$		
Scenario	a	b	c	d	Settings A	Settings B	Settings C
1	0.6	0.6	1	1	0.298	0.310	0.298
2	1	0.385	0.385	1	0.361	0.400	0.345
3	0.82	0.82	1	1	0.424	0.437	0.429
4	1	1	1	1	0.515	0.526	0.522
5	1	1	0.82	0.82	0.607	0.617	0.615
6	1	1	0.6	0.6	0.738	0.744	0.747

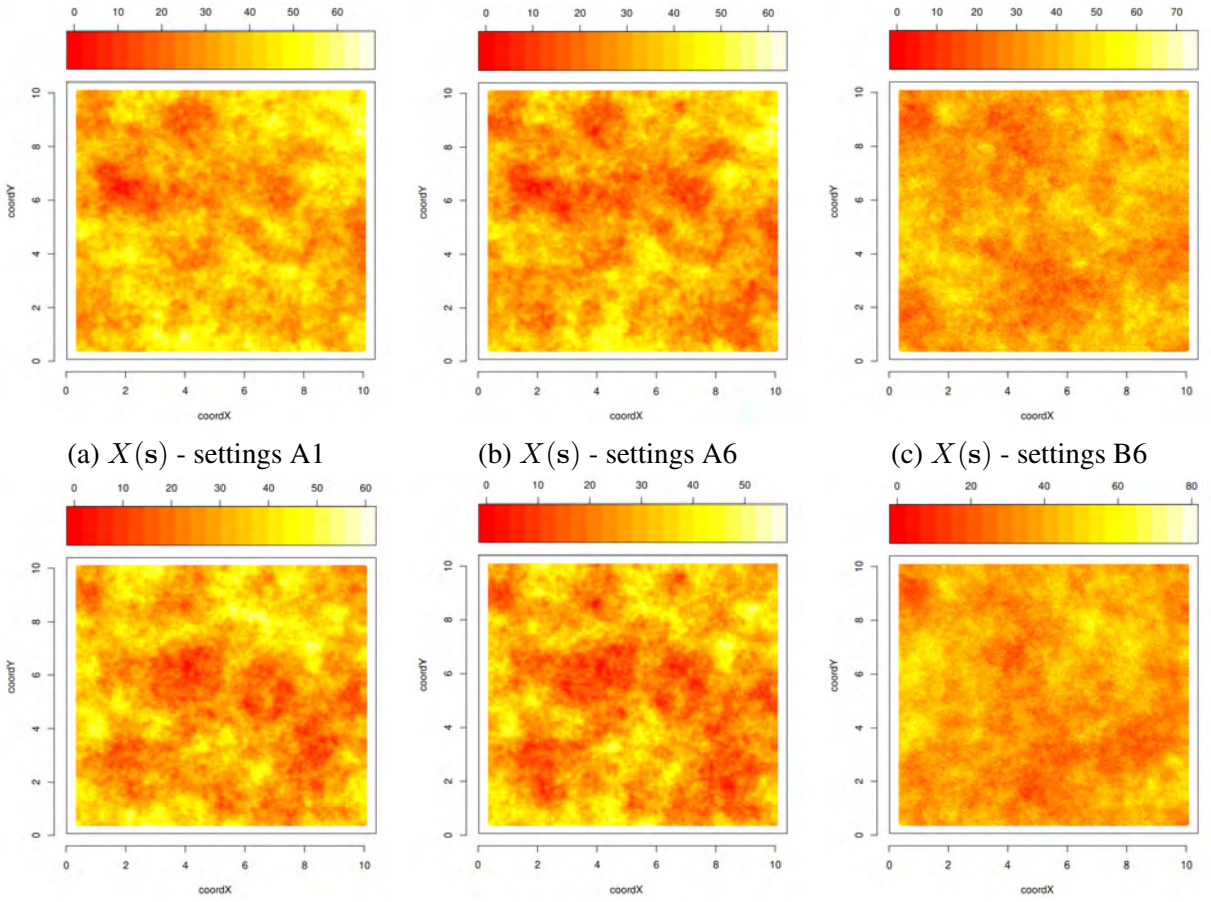
Settings A: Z_1, Z_2, Z_3 with $C = 50$, $C_0 = 0$
Settings B: Z_1 with $C = 30$, $C_0 = 20$ and Z_2, Z_3 with $C = 50$, $C_0 = 0$
Settings C: Z_1 with $C = 0$, $C_0 = 50$ and Z_2, Z_3 with $C = 50$, $C_0 = 0$

We choose to simulate scenarios with the different settings discussed above because when the analysis concerns a phenomenon measured at global scale it is common to observe different pattern between different areas of the globe and our aim is to find a strategy which could be globally applied by accounting for the various areas characteristics.

For each synthetic dataset we select 1000 replicate samples with $n = 1000$ and $n_0 = 200$. Figure 2 presents the empirical design effect (deff) of the mean estimator for each of the sampling designs, calculated in comparison with the simple random sampling (SRS). Results confirm that, as expected, when we analyse spatial-related phenomena spreading the sample over the area of interest is always convenient: the SpatLPM strategy is always better than the SRS, the UneqSampford and the AuxLPM. Nonetheless, the additional use of the auxiliary information can improve the efficiency of the estimates, in particular if it is used to calculate the inclusion probabilities in the unequal probability designs.

It is important to note that, in order to evaluate when it is more or less convenient to use also the auxiliary variable, it is not enough to consider the correlation between X and Y: given the same level of correlation, estimates' efficiency depends on the proportion of co-variability that is related to space. If the co-variability is all defined by a spatial structure (that is, when Z_1 has $C = 50$), the SpatLPM design (with equal selection probabilities) is enough; on the other hand when part (or all) of the co-variability in not spatially related (that is, when Z_1 has $C = 30$ or $C = 0$), the additional auxiliary variable improves the estimates' efficiency, especially if used to define the unequal inclusion probabilities (UneqLPM).

Unfortunately, in many real situations we don't know in advance the nature and the strength of the relationship between the study and the auxiliary variable. The suggested two-step design aims at addressing this lack of information by using the first-step sample to evaluate it from the data. In particular, we estimate the parameters (nugget, sill and range) of the cross-semivariogram function of X and Y, and consequently the nugget-to-sill ratio (NSR), to measure the proportion of co-variability that is not related to space. If this proportion is close to zero the auxiliary variable is useful only for high levels of correlation (as in Scenario A), on the contrary when the NSR increases (as in Scenarios B and C) we observe a gain in efficiency with any correlation above 0.4. Obviously, when the auxiliary variable is relevant, the two-step approach has a cost in term of efficiency in comparison to its correspondent one-step designs (that is the UneqLPM and the BivLPM). But this cost is unavoidable if the relation between



(a) $X(\mathbf{s})$ - settings A1 (b) $X(\mathbf{s})$ - settings A6 (c) $X(\mathbf{s})$ - settings B6

(d) $Y(\mathbf{s})$ - settings A1 (e) $Y(\mathbf{s})$ - settings A6 (f) $Y(\mathbf{s})$ - settings B6

Figure 1: Variables $X(\mathbf{s})$ and $Y(\mathbf{s})$ simulated under settings A1, A6 and B6.

the study and the auxiliary variable is unknown a priori and, more important, is lower that the efficiency loss that we would get if using the "wrong" design. Finally, it's worth noting that the SeqUneqLPM always outperform the SeqBivLPM, confirming that also in the two-step design is preferable to use the auxiliary variable to define the unequal inclusion probabilities.

Robustness and Balance of Sampling or Experimental Designs and Mixture of Designs

Yves Tillé[a] and Ejub Talovic[a]

[a]University of Neuchatel, Bellevaux 51, 2000 Neuchâtel, Switzerland; yves.tille@unine.ch, ejub.talovic@unine.ch

Abstract

We present simulations of different major sampling designs to compare their balance and robustness. We also present an existing algorithm to generate mixture of sampling designs in the context of design of experiments and we also present our own algorithm which is simpler and has desirable properties for interpretability and theoretical results.

Keywords: balanced sampling, variance operator, design of experiments, Algorithm

1. Introduction

The notion of robustness for a design of experiments has been introduced by (16) and (12). This notion is also valid for the sampling design. When we use balanced designs to decrease the variance due to an auxiliary variable, the variance may increase due to an effect which we call lack of robustness. This robustness can be written as the largest eigenvalue of the variance operator of a sampling or experimental design. If this eigenvalue is large, then it might induce a large variance in the Horvitz-Thompson estimator of the total. A consideration of a trade-off between the efficiency and the robustness of a design has been proposed by (12). They also propose an algorithm called "Gram-Schmidt Walk design" (GS) in which there is a tuning parameter that allows to oscillate between a design that would be totally robust and a balanced design that would integrate the auxiliary information as well as possible. Depending on the risk aversion, one can choose the appropriate value of the tuning parameter.

In this article, we review different sampling and experimental designs. We evaluate the robustness and balance of each of these designs using simulations. We propose a very simple procedure that allows to mix two designs that also uses a tuning parameter. This method offers a much more flexible alternative to the GS design of (12). In addition, this method allows any design to be mixed with any other, which opens the way to multiple combinations of designs. It can be used to handle the balance and robustness trade-off. We can also consider using this method for experimental or sampling design with more than one variable of interest. We next present a set of simulations that show that our mixing method gives similar results to the GS design while being simpler and much easier to interpret.

2. Notations and Main designs

Consider a finite population $U = \{1, \ldots, k, \ldots, N\}$ of size N. A sample without replacement is a subset, $s \in U$, of the population. A sampling design $p(s)$ assigns to each sample a probability such that $p(s) \geq 0$ and

$$\sum_{s \subset U} p(s) = 1.$$

A random sample S takes as value s with probability $Pr(S = s) = p(s)$.

Let a_k denote the indicator random variable which takes as value 1 if unit k is in S and 0 otherwise. If the sampling is with replacement a_k is the number of times unit k is selected in the sample. The random sample can also be defined by the column vector of the indicator variables $\mathbf{a}^\top = (a_1, \ldots, a_N)$. The inclusion probability is the probability that a unit is selected in the sample, i.e. $\pi_k = \Pr(k \in S) = \mathrm{E}_a(a_k), k \in U$, where $\mathrm{E}_a(.)$ is the expectation under the sampling design. We also define the vector $\boldsymbol{\pi}^\top = \mathrm{E}_a(\mathbf{a})^\top = (\pi_1, \ldots, \pi_N)$. It is assumed that the sum of the inclusion probabilities is an integer number denoted by n.

The joint inclusion probabilities are the probabilities that two units are jointly selected in the sample $\pi_{k\ell} = \mathrm{E}_a(a_k a_\ell)$, with $\pi_{kk} = \pi_k$, for all $k, \ell \in U$. The matrix of joint inclusion probabilities is thus $\boldsymbol{\Pi} = \mathrm{E}_a(\mathbf{a}\ \mathbf{a}^\top)$. The covariances between the indicator variables is defined by $\Delta_{k\ell} = \mathrm{cov}_a(a_k a_\ell) = \mathrm{E}_a(a_k a_\ell) - \mathrm{E}_a(a_k)\mathrm{E}_a(a_\ell) = \pi_{k\ell} - \pi_k \pi_\ell$, with $\Delta_{kk} = \pi_k(1 - \pi_k)$, for all $k, \ell \in U$. The variance-covariance matrix is thus $\boldsymbol{\Delta} = \mathrm{var}_a(\mathbf{a}) = \boldsymbol{\Pi} - \boldsymbol{\pi}\boldsymbol{\pi}^\top$, where $\mathrm{var}_a(.)$ is the expectation under the sampling design.

Simple Random Sampling Without Replacement (SRSWOR) is the design with a fixed sample size n for which all samples of size n have the same probability $n!(N - n)!/N!$ of being selected. For this design,

$$\pi_k = \frac{n}{N}, \Delta_{kk} = \frac{n(N-n)}{N^2}, \pi_{k\ell} = \frac{n(n-1)}{N(N-1)},$$

and

$$\Delta_{k\ell} = -\frac{n(N-n)}{(N-1)N^2}, k \neq \ell \in U.$$

Stratification consists of partitioning the population in H strata $U_1, \ldots, U_H$ of sizes $N_1, \ldots, N_H$. Next, in each stratum h, a sample of size n_h is selected independently from the other strata with SRSWOR. For this design $\pi_k = n_h/N_h, k \in U_h$, and

$$\Delta_{k\ell} = \begin{cases} \dfrac{n_h(N_h - nh)}{N_h^2} & \text{if } k = \ell \in U_h \\ -\dfrac{n_h(N_h - n_h)}{(N_h - 1)N_h^2} & \text{if } k \neq \ell \in U_h \\ 0 & \text{if } k \in U_h, \ell \in U_i, h \neq i. \end{cases}$$

Maximum entropy design also called *Conditional Poisson Sampling* (CPS) is the design with fixed sample size n that maximizes the entropy

$$-\sum_{s \subset U | \# s = n} p(s) \log p(s),$$

subject fixed inclusion probabilities π_k. The implementation of this design is quite complex and has only recently been resolved (4; 5; 6; 23). It is possible to compute the matrix of inclusion probabilities that satisfy the Yates-Grundy condition, for instance by using the R sampling package (23; 25). The Yates-Grundy condition allow us to guarantee a relatively low bound on the largest eigenvalue of the variance matrix of the sampling design. Therefore, sampling designs with this property are robust. If the inclusion probabilities are equal, the maximum entropy design reduces to SRSWOR.

The *Sampford design* (21) is described in the book of (1) as follows "Select the first unit with probability proportional to measure of size π_k/n. At each subsequent draw, select with probability of selection proportional to $\pi_k(1 - \pi_k)$ with replacement. If any unit is selected twice, reject the whole sample selected and start again." This design satisfy the Yates-Grundy condition. If the inclusion probabilities are equal, it also reduces to SRSWOR. At each subsequent draw, select with probability of selection proportional to $\pi_k(1 - \pi_k)$ with replacement. If any unit is selected twice, reject the whole sample selected and start again." This design satisfies the Yates-Grundy condition. If the inclusion probabilities are equal, it also reduces to SRSWOR.

Unequal probabilities systematic sampling (18; 19) that is defined as follows. First, compute the cumulated inclusion probabilities $V_k = \sum_{\ell=1}^{k} \pi_k$ with $V_0 = 0$ and $V_N = n$. Next generate a uniform

continuous random variable u and select in the sample the units k such that $V_{k-1} \leq u + j < V_k$ for $j = 0, \ldots, n-1$. This sample has a fixed sample size n. Systematic sampling has no more than N samples with non-zero probability (20). This design has thus a very small entropy. The joint inclusion probabilities can be computed for instance by using the R sampling package (25). *Equal probability systematic sampling* is the special case where the inclusion probabilities are equal. Moreover, if N/n is an integer, then only N/n samples have a non-null probability of being selected.

The pivotal method is one of the special cases of the splitting method proposed by (8). The method was republished by (22). At each step of the method, two units whose inclusion probabilities are not integer are modified randomly:

$$(\widetilde{\pi}_i, \widetilde{\pi}_j) = \begin{cases} (\min(1, \pi_i + \pi_j), \max(\pi_i + \pi_j - 1, 0)) & \text{with probability } q \\ (\max(\pi_i + \pi_j - 1, 0), \min(1, \pi_i + \pi_j)) & \text{with probability } 1 - q, \end{cases}$$

with

$$q = \frac{\min(1, \pi_i + \pi_j) - \pi_j}{2\min(1, \pi_i + \pi_j) - \pi_i - \pi_j}.$$

By choosing at each step a couple of close units in a space, (11) have built a method to obtain well spread samples. The method satisfies the Yates-Grundy condition (17; 3). If the initial probabilities are all equal to 1/2, the design reduces to a *matched pairs design*(Matched). The Matched design is also a stratified design where $N_h = 2$ and $n_h = 1$, for $h = 1, \ldots, H$. In a Matched design, there are $H = N/2$ pairs on units and

$$\Delta_{k\ell} = \begin{cases} \frac{1}{4} & \text{if } k = \ell \in U_h \\ -\frac{1}{4} & \text{if } k \neq \ell \in U_h \\ 0 & \text{if } k \in U_h, \ell \in U_i, h \neq i. \end{cases} \tag{1}$$

Let matrix $\mathbf{X} = (\mathbf{x}_1, \ldots, \mathbf{x}_n)^\top$ denote the $N \times p$ matrix of p covariates. *Balanced sampling* are methods for selecting random samples $\mathbf{a}$ that approximatively satisfies the balancing equations:

$$\sum_{k \in U} \frac{a_k \mathbf{x}_k}{\pi_k} \approx \sum_{k \in U} \mathbf{x}_k. \tag{2}$$

Fixed sample size is a special case of balanced sampled when matrix $\mathbf{X}$ contains a variable that is equal or proportional to the inclusion probabilities. *The cube method* (Cube) (9) outputs samples that are approximately balanced and also respect the inclusion probabilities of each unit of the population. When all inclusion probabilities are equal to $\pi = n/N$, then the sample mean is approximately equal to the population mean

$$\frac{1}{n} \sum_{k \in U} a_k \mathbf{x}_k \approx \frac{1}{N} \sum_{k \in U} \mathbf{x}_k.$$

Cube matched pairs design (Cube-Matched) (24) combines the matched pairs design with balanced sampling by the Cube method. Pairs of similar units are constructed and only one unit is selected in each pair. Moreover, the design is balanced on covariates. This method is a simple application of the stratified-balanced sampling where each stratum contains only two units whose one is selected in the sample (2; 13; 15).

Simple random sampling with replacement consists of selecting n times from the population a unit with equal probabilities $1/N$ and with replacement. The variable a_k contains the number of times the unit k is selected in the sample and has a binomial distribution with parameter $1/N$ and exponent n. Thus, $\mathrm{E}_a(a_k) = n/N$ and $\Sigma_{kk} = \mathrm{var}_a(a_k) = n(N-1)/N^2 = n/N - n/N^2$. Vector $\mathbf{a}$ has a multinomial distribution and $\Sigma_{k\ell} = \mathrm{cov}_a(a_k, a_\ell) = -n/N^2, k \neq \ell$.

Multinomial sampling consists of selecting n times from the population a unit with equal probabilities $p_k = \pi_k/n$ and with replacement. The variable a_k contains the number of times the unit k is selected in the sample and has a binomial distribution with parameter $p_k = \pi_k/n$ and exponent n. Thus,

$\mathrm{E}_a(a_k) = np_k = \pi_k$ and $\Sigma_{kk} = \mathrm{var}_a(a_k) = np_k(1-p_k) = \pi_k - \pi_k^2/n$. Vector $\mathbf{a}$ has a multinomial distribution and $\mathrm{var}_a(\mathbf{a}) = \mathbf{\Sigma}$, where $\Sigma_{k\ell} = \mathrm{cov}_a(a_k, a_\ell) = -np_kp_\ell = -\pi_k\pi_\ell/n, k \neq \ell$. When $p_k = 1/N$, the multinomial sampling reduces to the SRSWR. The properties of the main sampling designs are described in Table 1. The proofs of these properties can be found in (23).

3. Mixing designs

The GS design (12) handles the trade-off between balance and robustness. The basic step of the GS design is very similar to the Cube method of (9). In the Cube method, at each step, the vector of inclusion probabilities is randomly changed in a direction that respects the balancing equations. However, (12) uses the GS algorithm to balance an augmented covariate vector, which is a scaled concatenation of the covariates of the units and a unit-unique indicator variable. A tuning parameter ϕ allows to give more importance either to the robustness or to the balancing. It allows one to make a mixture of designs: a robust design like the Bernoulli design and a balanced design. When $\phi \in \{0, 1\}$, the GS algorithm will correspond either to a Bernoulli design or balanced design like the cube method.

We propose another method which allows to mix two designs that is presented in Algorithm 1. This method is much simpler than the GS design. It requires only three lines of code to be implemented. Moreover, it allows to mix any design with any other design. The inclusion probabilities of both sampling are supposed to be the same.

Algorithm 1 Simple method for mixing designs

- Select a sample $\mathbf{a}_A$ with a design $p_A(.)$, inclusion probabilities $\boldsymbol{\pi}$ and a variance-covariance matrix $\mathbf{\Delta}_A$.
- Next, we compute $\boldsymbol{\pi}_B = \sqrt{\phi}\,\mathbf{a}_A + (1-\sqrt{\phi})\boldsymbol{\pi}$.
- We then select a sample $\mathbf{a}$ with a design $p_B(.)$, inclusion probabilities $\boldsymbol{\pi}_B$ and a variance-covariance matrix $\mathbf{\Delta}_B(\boldsymbol{\pi}_B)$.

Result 1. *With Algorithm 1:*

(i) $\mathrm{E}_a(\mathbf{a}) = \boldsymbol{\pi}$,
(ii) $\mathbf{\Delta} = \mathrm{var}_a(\mathbf{a}) = \mathrm{E}_a\{\mathbf{\Delta}_B(\boldsymbol{\pi}_B)\} + \phi\mathbf{\Delta}_A$,
(iii) $\frac{1}{1-\phi}\mathrm{diag}\{\mathrm{E}_a(\mathbf{\Delta}_B)\} = \mathrm{diag}(\mathbf{\Delta}) = \mathrm{diag}(\mathbf{\Delta}_A)$.

Proof.

(i) The final inclusion probabilities are

$$\mathrm{E}_a(\mathbf{a}) = \mathrm{E}_a\ \mathrm{E}_a(\mathbf{a}|\mathbf{a}_A) = \mathrm{E}_a\{\sqrt{\phi}\ \mathbf{a}_A + (1-\sqrt{\phi})\boldsymbol{\pi}\} = \boldsymbol{\pi}.$$

(ii) The final variance matrix is:

$$\begin{aligned}\boldsymbol{\Delta} &= \mathrm{var}_a(\mathbf{a}) = \mathrm{E}_a\ \mathrm{var}_a(\mathbf{a}|\mathbf{a}_A) + \mathrm{var}_a\ \mathrm{E}_a(\mathbf{a}|\mathbf{a}_A)\\ &= \mathrm{E}_a\{\boldsymbol{\Delta}_B(\boldsymbol{\pi}_B)\} + \mathrm{var}_a\{\sqrt{\phi}\ \mathbf{a}_A + (1-\sqrt{\phi})\boldsymbol{\pi}\}\\ &= \mathrm{E}_a\{\boldsymbol{\Delta}_B(\boldsymbol{\pi}_B)\} + \phi\boldsymbol{\Delta}_A. \qquad (3)\end{aligned}$$

(iii) Vectors $\mathbf{a}$ and $\mathbf{a}_A$ have the same expectation. Thus $\mathrm{diag}(\boldsymbol{\Delta}) = \mathrm{diag}(\boldsymbol{\Delta}_A)$. From Equality (3), we have

$$\mathrm{diag}(\boldsymbol{\Delta}) = \mathrm{diag}\{\mathrm{E}_a(\boldsymbol{\Delta}_B)\} + \phi\ \mathrm{diag}(\boldsymbol{\Delta}_A),$$

and thus

$$\frac{1}{1-\phi}\mathrm{diag}\{\mathrm{E}_a(\boldsymbol{\Delta}_B)\} = \mathrm{diag}(\boldsymbol{\Delta}).$$

□

Ideally, we would have that $\mathrm{E}_a\{\boldsymbol{\Delta}_B(\boldsymbol{\pi}_B)\} \approx (1-\phi)\boldsymbol{\Delta}_B(\boldsymbol{\pi})$ for better interpretability of $\boldsymbol{\Delta}$ and theoretical results. It would mean that $\boldsymbol{\Delta} \approx \phi\boldsymbol{\Delta}_A + (1-\phi)\boldsymbol{\Delta}_B$. However, it is very difficult to calculate analytically the term $\mathrm{E}_a\{\boldsymbol{\Delta}_B(\boldsymbol{\pi}_B)\}$ and probably impossible with a mixture that uses a balanced sampling design. We carried out simulations of a mixture of design where $\boldsymbol{\Delta}_A$ and $\boldsymbol{\Delta}_B$ correspond respectively to a SRSWOR and balanced sampling design-based on the cube method. For $\boldsymbol{\Delta}_B(\boldsymbol{\pi}_B)$, the cube method has been parametrized in a way to ensure that the inclusion probabilities are $\boldsymbol{\pi}_B$ while also having the propriety that $\mathbf{X}^\top\mathbf{D}^{-1}\mathbf{a} \approx \mathbf{X}^\top\mathbf{D}^{-1}\boldsymbol{\pi}_B$. The auxiliary variables are generated from a normal distribution, $\pi = 1/2$ and $N = 250$. The simulations show that $\mathrm{E}_a\{\boldsymbol{\Delta}_B(\boldsymbol{\pi}_B)\}$ is very close to $(1-\phi)\boldsymbol{\Delta}_B(\boldsymbol{\pi})$.

Moreover if $\lambda_1, \lambda_{A1}, \lambda_{B1}$ are respectively the largest eigenvalues of $\boldsymbol{\Delta}$, $\boldsymbol{\Delta}_A$ and $\mathrm{E}_a(\boldsymbol{\Delta}_B)/(1-\phi)$, then

$$\lambda_1 \leq \phi\lambda_{A1} + (1-\phi)\lambda_{B1}.$$

4. Simulations

In this section, we compare the different sampling or experimental designs. In order to evaluate the robustness of the designs and the quality of the approximations, we performed simulations of the different designs on a clinical trial data set. It contains information about 40 patients split into two groups before and after their corneal astigmatism surgery (14). We are only interested in the variables measured before the operations. We retain five covariates: sex, eye, age, axis and topographic astigmatism. Two of those covariates are categorical. The number of patients is $N = 40$ and the inclusion probabilities are all equal to $\pi = 1/2$ and therefore $n = 20$. For the Matched and Cube-Matched designs, the pairs have been constructed by discrete linear programming by minimizing the sum on the pairs of the squares of the Mahalanobis distances between the paired units. The estimation of the largest eigenvalue by simulation is unstable, especially when the largest eigenvalues in a design are the same or similar. There are slight differences between the maximal eigenvalue estimated through simulation and the exact theoretical results can be noticed. Therefore, we performed a very large number of simulations (SIM=10,000,000).

We also ran the GS design of (12) using the Julia implementation (7). We used a version of the algorithm that outputs experimental designs with fixed size for each group. Unfortunately, we found that this algorithm does not provide comparable results depending on whether the variables have the same means or variances. This is due to the way the covariates are normalized in the GS algorithm. Therefore,

we centred and reduced all variables and made them orthogonal using a singular value decomposition. Without this change of variables, the results obtained by the GS method are inconsistent. This algorithm also creates a mixture of design which depends on a tuning parameter.

Figure 1 contains the scatterplot of the squares of the Mahalanobis distances by the largest eigenvalues estimated through simulations of the different designs. On the left side, one sees that the most robust designs are Bernoulli and SRSWOR but they are not balanced. The Cube-Matched method is on the right the least robust but most balanced method. Bernoulli design is not shown on figure because it is not balanced enough. Systematic sampling design is not shown on the figure because it is neither robust nor balanced. Some sampling designs, that we introduced, are not shown in the figure as some of them are reduced to SRSROW or the Matched design when the inclusion probabilities equal are all equal to 0.5.

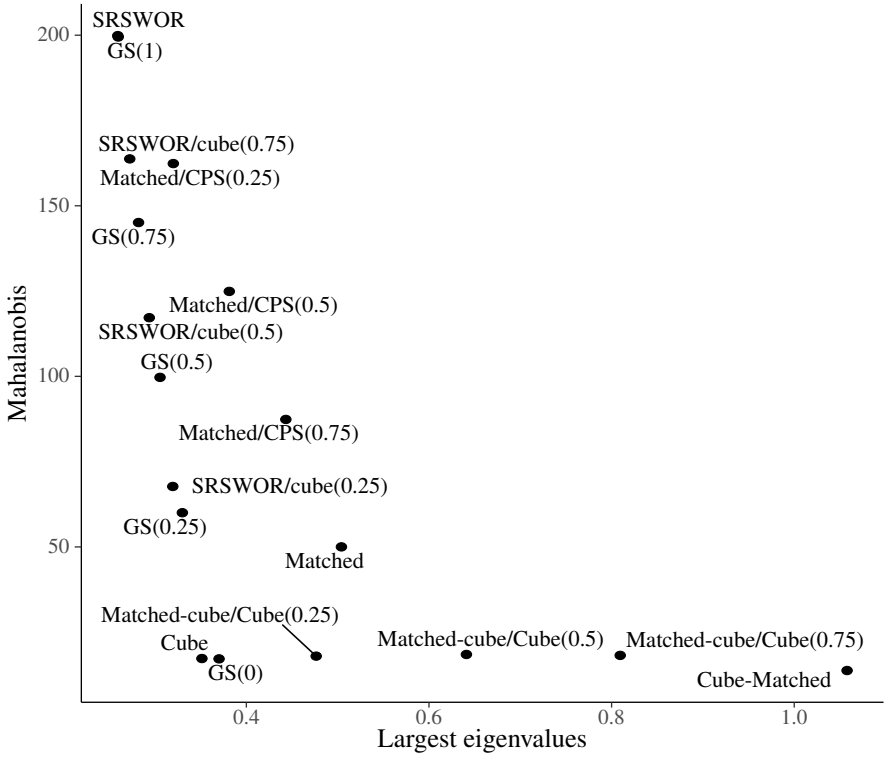

Figure 1: Scatterplot of the squares of the Mahalanobis distances by the largest eigenvalues.

The Cube method is a very good compromise between the two extremes as it is well balanced and relatively robust. The Matched method is not to be recommended as it is less balanced and less robust than the Cube method. The Matched method can also have difficulties finding pairs which are similar enough. However, one advantage of matching is that the samples or group generated from this method are relatively well-spread while samples generated from a balanced design like the Cube method could output samples which are not well-spread. Generating a mixture of design between the Cube method and the Matched method could give a good compromise in certain cases. See (10) for the advantages of well-spread samples. We also notice that the designs resulting from mixtures with our method lie between the two designs from which they originate in the graph in function of their weights ϕ. There are interesting designs by mixing SRSWOR and Cube or by mixing Cube and Cube-Matched. The GS design with $\phi = 1$ corresponds to SRSWOR, with $\phi = 0$ it corresponds to the cube method. When $\phi = 0, 25, 0.5$ and 0.75, they are close to the mixtures between SRSWOR and the Cube method we proposed.

Robustness Bounds for Sampling and Experimental Designs

Ejub Talovic[a] and Yves Tillé [a]

[a]University of Neuchatel, Bellevaux 51, 2000 Neuchâtel, Switzerland; ejub.talovic@unine.ch, yves.tille@unine.ch

Abstract

For both experimental and sampling designs, the efficiency of designs has been extensively studied. There are many ways to incorporate auxiliary information into designs. However, when we want to decrease the variance due to an auxiliary variable by the use of balanced designs, we risk seeing it increase due to another variable. For the most common designs, we study the robustness in the sense of the largest increase in variance compared to simple random sampling or a Bernoulli design. This robustness can be written as the largest eigenvalue of the variance operator. We determine lower and upper bounds and approximations of this eigenvalue for different designs.

Keywords: balanced sampling, design of experiments, variance operator

1. Introduction

Both sampling designs and experimental designs have a common feature: in both cases, random variables are generated in order to select units either to constitute a sample or to create a test group and a control group. For survey sampling, the recommendations relate primarily to issues of design efficiency under certain hypotheses relative to the variables of interest to be estimated. We can thus resort to designs of fixed size, stratified, balanced with equal or unequal probabilities (see amongst other 3; 14; 15). For experimental designs, randomization between the test group and the control group is also recommended. There are also stratification techniques, blocking, matching, rerandomization, balanced sampling to make the two groups as equivalent as possible (see amongst other 13; 11; 12; 17; 10; 8; 16). Unfortunately, everything has a price. It can be shown that if a design is more efficient for one variable, it is necessarily less efficient for another variable. Thus, one cannot rely solely on a single efficiency criterion to determine the appropriate design.

The notion of robustness for a design of experiments has been introduced by (9) and (6). This notion is also valid for the sampling design. When we use balanced or efficient designs to decrease the variance due to an auxiliary variable, the variance may increase due to an effect which we call lack of robustness. This robustness can be written as the largest eigenvalue of the variance operator of a sampling or experimental design. If this eigenvalue is large, then it might induce a large variance in the Horvitz-Thompson estimator of the total. We can thus evaluate the maximum price to pay for the application of a design that integrates auxiliary information.

We review the different sampling and experimental designs. We evaluate the robustness of each of these designs. To do so, we calculate upper and lower bounds for the largest eigenvalues of the variance matrices. We also give approximations for these eigenvalues. These calculations show the determining role of the Yates-Grundy conditions which allow us to calculate a relatively low upper bound. We also study the potential effect of the choice of the design on the variance of the Horvitz-Thompson estimator.

2. Sampling designs and designs of experiments

Consider a finite population $U = \{1, \ldots, k, \ldots, N\}$ of size N. A sample without replacement is a subset, $s \in U$, of the population. A sampling design $p(s)$ assigns to each sample a probability such that $p(s) \geq 0$ and

$$\sum_{s \subset U} p(s) = 1.$$

A random sample S takes as value s with probability $Pr(S = s) = p(s)$.

Let a_k denote the indicator random variable which takes as value 1 if unit k is in S and 0 otherwise. If the sampling is with replacement a_k is the number of times unit k is selected in the sample. The random sample can also be defined by the column vector of the indicator variables $\mathbf{a}^\top = (a_1, \ldots, a_N)$. The first-order inclusion probability is the probability that a unit is selected in the sample, i.e. $\pi_k = \Pr(k \in S) = \mathrm{E}_a(a_k), k \in U$, where $\mathrm{E}_a(.)$ is the expectation under the sampling design. In this article, when the order is not defined, it means we refer to the first-order inclusion probabilities. We also define the vector $\boldsymbol{\pi}^\top = \mathrm{E}_a(\mathbf{a})^\top = (\pi_1, \ldots, \pi_N)$. It is assumed that the sum of the inclusion probabilities is an integer number denoted by n.

The joint inclusion probabilities are the probabilities that two units are jointly selected in the sample $\pi_{k\ell} = \mathrm{E}_a(a_k a_\ell)$, with $\pi_{kk} = \pi_k$, for all $k, \ell \in U$. The matrix of joint inclusion probabilities is thus $\boldsymbol{\Pi} = \mathrm{E}_a(\mathbf{a}\ \mathbf{a}^\top)$. The covariances between the indicator variables is defined by $\Delta_{k\ell} = \mathrm{cov}_a(a_k a_\ell) = \mathrm{E}_a(a_k a_\ell) - \mathrm{E}_a(a_k)\mathrm{E}_a(a_\ell) = \pi_{k\ell} - \pi_k \pi_\ell$, with $\Delta_{kk} = \pi_k(1 - \pi_k)$, for all $k, \ell \in U$. The variance-covariance matrix is thus $\boldsymbol{\Delta} = \mathrm{var}_a(\mathbf{a}) = \boldsymbol{\Pi} - \boldsymbol{\pi}\boldsymbol{\pi}^\top$, where $\mathrm{var}_a(.)$ is the expectation under the sampling design.

The aim is to estimate the total of a variable of interest y_k given by

$$t_y = \sum_{k \in U} y_k.$$

If $\pi_k > 0, k \in U$, then the Horvitz-Thompson estimator (7) given by

$$\hat{t}_y = \sum_{k \in S} \frac{y_k}{\pi_k}$$

is an unbiased estimator of t_y. The variance of this estimator is

$$\mathrm{var}_a(\hat{t}_y) = \sum_{k \in U} \sum_{\ell \in U} \frac{y_k y_\ell}{\pi_k \pi_\ell} \Delta_{k\ell} = \mathbf{y}^\top \mathbf{D}^{-1} \boldsymbol{\Delta} \mathbf{D}^{-1} \mathbf{y},$$

where $\mathbf{D} = \mathrm{diag}(\boldsymbol{\pi})$. If the sampling design has a fixed sample size, (18) showed that the variance can also be written:

$$\mathrm{var}_a(\hat{t}_y) = -\frac{1}{2} \sum_{k \in U} \sum_{\ell \in U} \left(\frac{y_k}{\pi_k} - \frac{y_\ell}{\pi_\ell} \right)^2 \Delta_{k\ell}.$$

If $\pi_{k\ell} > 0$, for $k, \ell \in U$, two estimators of variance can be constructed. The Horvitz-Thompson estimator of the variance is given by

$$\widehat{\mathrm{var}}_a(\hat{t}_y) = \sum_{k \in S} \sum_{\ell \in S} \frac{y_k y_\ell}{\pi_k \pi_\ell} \frac{\Delta_{k\ell}}{\pi_{k\ell}}.$$

The Yates-Grundy estimator is only available for sampling designs with fixed sample size and is given by

$$\widehat{\mathrm{var}}_a(\hat{t}_y) = -\frac{1}{2} \sum_{k \in S} \sum_{\ell \in S} \left(\frac{y_k}{\pi_k} - \frac{y_\ell}{\pi_\ell} \right)^2 \frac{\Delta_{k\ell}}{\pi_{k\ell}}. \tag{1}$$

Definition 1. *A design satisfies the Yates-Grundy condition if* $\Delta_{k\ell} \leq 0$ *for all* $k \neq \ell \in U$.

Somes authors suggest using designs that satisfy this condition, since the Yates-Grundy estimator of the variance cannot then be negative (18). This condition is also called negative correlation. The Yates-Grundy condition is an important hypothesis to construct central limit theorems in finite population (2; 1; 5). In this paper, we will show that the Yates-Grundy condition also contribute to robustify a sampling or experimental design.

In randomized experiments, the problem is somewhat different. Suppose we have a population U of size N and that we want to test a treatment T on the units $k \in U$. If unit k receives the treatment, its response variable becomes y_k^T. If unit k does not receive the treatment, it belongs to the control group and is response is denoted by y_k^C. This is a randomized experiment with two groups. The goal is to estimate

$$\tau = \frac{1}{N}\sum_{k\in U} y_k^T - \frac{1}{N}\sum_{k\in U} y_k^C.$$

Here we adopt a purely design-based approach as in (6). The values of y_k^T and y_k^C cannot be observed at the same time for unit k, because no unit can belong to both the control and treatment groups. We select a sample with inclusion probabilities $\boldsymbol{\pi} = (\pi_1, \ldots, \pi_N)$ and apply the treatment to the chosen units.

Then, τ can be estimated using the difference of the two the Horvitz-Thompson estimators:

$$\begin{aligned}\widehat{\tau} &= \frac{1}{N}\sum_{k\in U}\frac{y_k^T a_k}{\pi_k} - \frac{1}{N}\sum_{k\in U}\frac{y_k^C(1-a_k)}{1-\pi_k} \\ &= \frac{1}{N}\sum_{k\in U}\frac{y_k^T(1-\pi_k)+y_k^C\pi_k}{(1-\pi_k)\pi_k}a_k - \frac{1}{N}\sum_{k\in U}\frac{y_k^C}{(1-\pi_k)}.\end{aligned}$$

If we define $\mathbf{z} = (z_1, \ldots, z_N)^\top$, where

$$z_k = \frac{y_k^T(1-\pi_k)+y_k^C\pi_k}{(1-\pi_k)\pi_k},$$

the variance becomes

$$\mathrm{var}_a(\widehat{\tau}) = \frac{\mathbf{z}^\top \mathrm{var}_a(\mathbf{a})\mathbf{z}}{N^2} = \frac{\mathbf{z}^\top \boldsymbol{\Delta}\mathbf{z}}{N^2}. \tag{2}$$

In both experimental and survey designs, the variance operator $\boldsymbol{\Delta}$ plays a fundamental role in the precision of the estimates.

The calculation of the variance given in (2) may seem similar to the calculation of the variance in a sample design. However, an important difference is that z_k is not known at the sample level. Estimating the variance is therefore a more difficult problem than for a sample design. In sampling designs, as in experimental designs, the $\boldsymbol{\Delta}$ matrix plays a determining role. If the largest eigenvalue of $\boldsymbol{\Delta}$ is large, then there is a risk that the variance of the Horvitz-Thompson estimator becomes large.

3. Upper bounds of the variance

The $\boldsymbol{\Delta}$ matrix is the heart of the precision problem for both the sampling and experimental designs. The analysis of this matrix is therefore the crucial question for the determination of the design that best fits the objectives of this randomization. The natural way to analyse the $\boldsymbol{\Delta}$ operator is to perform a diagonalization. We can look for the vector $\mathbf{u}$ which maximizes

$$\frac{\mathbf{u}^\top \boldsymbol{\Delta}\mathbf{u}}{\mathbf{u}^\top\mathbf{u}}.$$

The solution is that $\mathbf{u}$ is the eigenvector of $\boldsymbol{\Delta}$ associated to the largest eigenvalue λ_1. This eigenvalue is somehow associated with the greatest risk of the design, as it is a factor of the variance for the variable that will be most poorly estimated.

A first result shows that there is no design that is uniformly better than the others for given inclusion probabilities. Consider two designs $p_1(s)$ and $p_2(s)$ with the same inclusion probabilities π_k and whose variance operators are respectively $\mathbf{\Delta}_1$ and $\mathbf{\Delta}_2$. A design $p_1(s)$ would be uniformly better than a design $p_2(s)$ if $\mathbf{u}^\top \mathbf{\Delta}_1 \mathbf{u} \leq \mathbf{u}^\top \mathbf{\Delta}_2 \mathbf{u}$ for all $\mathbf{u} \in \mathbb{R}^N$ and that there is at least one vector $\mathbf{y}$ such that $\mathbf{y}^\top \mathbf{\Delta}_1 \mathbf{y} < \mathbf{y}^\top \mathbf{\Delta}_2 \mathbf{y}$. We refer to the following result:

Result 1. *For any design $p_1(s)$, there is no uniformly better design than $p_2(s)$ with the same first-order inclusion probability.*

Proof. (by contradiction) Suppose there is a design $p_1(s)$ uniformly better than a design $p_2(s)$ with the same first-order inclusion probabilities. In this case, $\mathbf{u}^\top(\mathbf{\Delta}_2 - \mathbf{\Delta}_1)\mathbf{u} \geq 0$, for all $\mathbf{u} \in \mathbb{R}^N$, which implies that the array $(\mathbf{\Delta}_2 - \mathbf{\Delta}_1)$ is semi-definite positive. Since the trace of $(\mathbf{\Delta}_2 - \mathbf{\Delta}_1)$ is zero, all eigenvalues of $(\mathbf{\Delta}_2 - \mathbf{\Delta}_1)$ are zero, which is in contradiction with the fact that there is at least one vector $\mathbf{y}$ such as $\mathbf{y}^\top \mathbf{\Delta}_1 \mathbf{y} < \mathbf{y}^\top \mathbf{\Delta}_2 \mathbf{y}$. □

We can see the problem like this. Since the inclusion probabilities determine the diagonal of $\mathbf{\Delta}$, two designs that have the same inclusion probabilities have the same trace for $\mathbf{\Delta}$ and therefore the same sum of eigenvalues. Each eigenvalue gives a variance factor in the direction of an eigenvector. So, if the variance is decreased in one direction, it is necessarily increased in another direction.

This result shows that there is no design which is better than all the others. Therefore, we cannot use a precision criterion linked to the variance to find the optimal design. If additional auxiliary information is not available, it is reasonable to try to equalize the eigenvalues and thus to take the most random design possible, that is to say, the design that maximizes the entropy. Additionally, we often measure several variables of interest so it is preferable that the dispersion is more or less the same in all directions.

Let us show a few basic results. Let us start with sampling designs with fixed sample size and with equal inclusion probabilities.

Result 2. *Let $p(s)$ be a sampling design of fixed sample size n from a population U of size N and with equal inclusion probabilities $\pi_k = \pi, k \in U$, then $\mathbf{\Pi}$ and $\mathbf{\Delta}$ have the same eigenvectors.*

Proof. Since $\mathbf{1}$ is the eigenvector of $\mathbf{\Delta}$ associated with the null eigenvalues, all the other eigenvectors are orthogonal to $\mathbf{1}$ and are thus centred. On one hand, we have $\mathbf{\Delta}\mathbf{1} = \mathbf{\Pi}\mathbf{1} - \boldsymbol{\pi}\boldsymbol{\pi}^\top \mathbf{1} = \mathbf{\Pi}\mathbf{1} - \boldsymbol{\pi} n = \mathbf{0}$. Thus, $\mathbf{\Pi}\mathbf{1} = \boldsymbol{\pi} n$ and $\mathbf{1}$ is an eigenvector of $\mathbf{\Pi}$ associated with the eigenvalue $n\pi$. On the other hand, if $\mathbf{u}$ is a centred eigenvector of $\mathbf{\Delta}$, $\mathbf{\Delta}\mathbf{u} = \lambda\mathbf{u}$, thus $\mathbf{\Pi} - \boldsymbol{\pi}\boldsymbol{\pi}^\top \mathbf{u} = \lambda\mathbf{u}$. Since $\boldsymbol{\pi}^\top \mathbf{u} = 0$, vector $\mathbf{u}$ is also an eigenvector of $\mathbf{\Pi}$ with the same eigenvalue as for $\mathbf{\Delta}$. □

The maximal eigenvalue of fixed sample size and with equal probabilities sampling designs is

$$\lambda_1 \leq \min\left(\frac{n^2}{N}, \frac{(N-n)^2}{N}\right).$$

This bound can be reached with systematic sampling. When the inclusion probabilities are unequal, the problem becomes a little more difficult.

Result 3. *For any sampling design on a finite population U of size N, the largest eigenvalue of $\mathbf{\Delta}$ is smaller than or equal to $\max_{k\in U}(\sum_{\ell\in U} \pi_{k\ell})$. If the sampling design has a fixed sample size n, then the bound can be express as $n \max_{k\in U}(\pi_k)$.*

Proof. Let us denote the eigenvalues of $\mathbf{\Pi}$ by $\lambda_1, \ldots, \lambda_n$. Using the Perron-Frobenius inequality, we know that

$$\lambda_1 \leq \max_{k\in U}\left(\sum_{\ell\in U} \pi_{k\ell}\right).$$

The matrix $\boldsymbol{\pi}\boldsymbol{\pi}^\top$ is a symmetric matrix of rank 1, whose only non-zero eigenvalue λ_1' is equal to $\sum_{k\in U} \pi_k^2$ with the eigenvector $\boldsymbol{\pi}$. The largest eigenvalue of $-\boldsymbol{\pi}\boldsymbol{\pi}^\top$ is thus 0. Each eigenvalue of $\mathbf{\Delta}$

is non-negative, because it is a covariance matrix. Both $\boldsymbol{\Pi}$ and $\boldsymbol{\pi}\boldsymbol{\pi}^\top$ are Hermitian matrices. Therefore, from Weyl's inequality, we deduce that the largest eigenvalue of $\boldsymbol{\Delta}$ is smaller than or equal to $\max_{k\in U}(\sum_{\ell\in U}\pi_{k\ell})$, i.e.,

$$\lambda_1 \leq \max_{k\in U}\left(\sum_{\ell\in U}\pi_{k\ell}\right).$$

If the sampling design has a fixed sample size n, then

$$\max_{k\in U}\left(\sum_{\ell\in U}\pi_{k\ell}\right) = \max_{k\in U}\left\{\mathrm{E}_a\left(a_k\sum_{\ell\in U}a_\ell\right)\right\} = n\max_{k\in U}(\pi_k).$$

□

Result 4. *For any sampling design on a finite population U of size N, the largest eigenvalue of $\boldsymbol{\Delta}$ is smaller than or equal to* $\max_{k\in U}\left(\sum_{\ell\in U}|\Delta_{k\ell}|\right) = \max_{k\in U}\left(\sum_{\ell\in U}|\pi_{k\ell}-\pi_k\pi_\ell|\right)$.

Proof. The proof is a simple corollary of the Gershgorin circle theorem. However, the result can also be derived from Theorem 4.1 of (4). □

The bound of Result 4 will often be smaller than the one from Result 3 but it is not always the case. The sampling design that selects one unit out of a population of 3 units with equal probability is a simple example where $n\max_{k\in U}(\pi_k) = 1/3 < \max_{k\in U}\left(\sum_{\ell\in U}|\Delta_{k\ell}|\right) = 4/9$.

If the Yates-Grundy conditions are satisfied, a simpler bound than the previous ones can be deduced.

Corollary 1. *For any sampling design that satisfies the Yates-Grundy conditions and a fixed sample size n, the largest eigenvalue of $\boldsymbol{\Delta}$ is smaller than or equal to* $2\max_{k\in U}\{\pi_k(1-\pi_k)\}$.

We know that $\Delta_{kk} = \pi_k(1-\pi_k)$ for all $i \in 1,\ldots,N$. Every off-diagonal entry of the matrix $\boldsymbol{\Delta}$ is negative because the selections of the units are all negatively correlated between each other due to the Yates-Grundy condition. Another property of $\boldsymbol{\Delta}$ is that the sum of every row is equal to 0 due to fixed sample size. We obtain that $\pi_k(1-\pi_k) = \sum_{\ell\in U|\ell\neq k}\Delta_{k\ell}$ for all $k \in U$. Thus,

$$\max_{k\in U}\left(\sum_{\ell\in U}|\Delta_{k\ell}|\right) = 2\max_{k\in U}\left\{\pi_k(1-\pi_k) + \sum_{\ell\in U|\ell\neq k}\Delta_{k\ell}\right\} = 2\max_{k\in U}\{\pi_k(1-\pi_k)\}.$$

The result follows from Result 4.

Corollary 2. *For any sampling design with a fixed sample size n on a finite population U of size N, the largest eigenvalue of $\boldsymbol{\Delta}$ is smaller than or equal to* $2\max_{k\in U}\left(\sum_{\ell\in U|\Delta_{k\ell}>0}\Delta_{k\ell}\right)$.

Corollary 2 shows that Yates-Grundy conditions are desirable for fixed samples size designs as they give a lower theoretical maximal eigenvalue of $\boldsymbol{\Delta}$. It also indicates that sampling designs with fixed sample size that have a lot of units a_i that are strongly positively correlated can be very weakly robust. Systematic sampling, which gives very high or maximal possible eigenvalues, corresponds to such sampling design. We have also calculated results for the minimal maximal eigenvalue of $\boldsymbol{\Delta}$.

4. Balance and robustness trade-off

Let matrix $\mathbf{X} = (\mathbf{x}_1,\ldots,\mathbf{x}_n)^\top$ denote the $N \times p$ matrix of p covariates. *Balanced sampling* are methods for selecting random samples $\mathbf{a}$ that approximatively satisfies the balancing equations:

$$\sum_{k\in U}\frac{a_k\mathbf{x}_k}{\pi_k} \approx \sum_{k\in U}\mathbf{x}_k. \tag{3}$$

Fixed sample size is a special case of balanced sampled when matrix $\mathbf{X}$ contains a variable that is equal or proportional to the inclusion probabilities. Define $\mathbf{D} = \text{diag}(\boldsymbol{\pi})$. For sampling designs that select balanced samples, we deduce from Equation (3) that $\text{var}_a(\mathbf{X}^\top \mathbf{D}^{-1}\mathbf{a}) = \mathbf{X}^\top \mathbf{D}^{-1}\boldsymbol{\Delta}\mathbf{D}^{-1}\mathbf{X} \approx 0$. In other words, balanced sampling designs will have a covariance matrix $\boldsymbol{\Delta}$ with p eigenvalues that are equal or close to 0. If the inclusion probabilities are all equal, the kernel of $\boldsymbol{\Delta}$ can be generated by the p covariates from $\mathbf{X}$. If we consider that the inclusion probabilities are fixed, then the trace $\boldsymbol{\Delta}$ is fixed. The trace is equal to the sum of the eigenvalues. Therefore, the use of a balanced sampling design induces that some eigenvalues are equal or close to 0, which will be pushed on the other non-zero eigenvalues of $\boldsymbol{\Delta}$.

In balanced designs, it seems difficult to bound the eigenvalues more tightly than in Result 4. Indeed, balanced designs can respect the fixed sample size, but do not respect the Yates-Grundy conditions. Ideally, one would like balancing to cause an approximately identical increase in all directions for variables that are orthogonal to the balancing variables. On the basis of simulations, this seems to be the case. The Yates-Grundy conditions are not satisfied and it is therefore difficult to bound the largest eigenvalue. For algorithms that output balanced samples, the matrix $\boldsymbol{\Delta}$ can usually only be estimated using simulations, which adds another layer of difficulty to bound the largest eigenvalue.

Expression (2) shows that if the objective is to minimize the worst-case design-based variance, then the largest eigenvalue of $\boldsymbol{\Delta}$ should be as small as possible. If we assume that the covariates $\mathbf{X} = (\mathbf{x}_1, \ldots, \mathbf{x}_n)^\top$ have an effect on the response, then the advantages of balanced sampling appear. Suppose that $y_k^C = \mathbf{x}_k\boldsymbol{\beta} + \varepsilon_k, y_k^T = \mathbf{x}_k\boldsymbol{\beta} + \tau + \varepsilon_k$ and that all inclusion probabilities are equal to π for any $k \in \{1, \ldots, N\}$. We assume that the sample size is fixed in order to make the term related to τ in the following expression disappear. Using Expression (2), the design-based variance becomes

$$\text{var}_a(\widehat{\tau}) = \left\{\frac{1}{N\pi(1-\pi)}\right\}^2 \left\{\boldsymbol{\beta}^\top \text{var}_a(\mathbf{X}^\top\mathbf{a})\boldsymbol{\beta} + \boldsymbol{\varepsilon}^\top\boldsymbol{\Delta}\boldsymbol{\varepsilon} + 2\boldsymbol{\beta}^\top\mathbf{X}^\top\boldsymbol{\Delta}\boldsymbol{\varepsilon}\right\}, \tag{4}$$

where $\boldsymbol{\varepsilon}^\top = (\varepsilon_1, \ldots, \varepsilon_N)$.

In order to minimise the variance under the design of $\widehat{\tau}$ in the worst-case scenario, both the maximal eigenvalue of $\boldsymbol{\Delta}$ and $\text{var}_a(\mathbf{X}^\top\mathbf{a})$ should be considered. Minimizing both terms is not possible so a trade-off has to be considered.

Abstract

This empirical study compares hotdeck and propensity score statistical matching (SM) procedures with the aim of providing useful guidance to researchers interested in the implementation of SM methods. Both methods are statistically robust, but the implementation of the propensity score method needs much more fine tuning.

Key words: Data fusion, matching methods, nearest neighbor

1. Introduction

In developed countries, socio-economic surveys with a national coverage normally focus on specific topics such as income, consumption, time use and quality of life to reach a high level of data detail and accuracy. When the research or policy objective is to obtain a reliable representation of living standards, costs of living, labor choices it is necessary to combine different surveys implementing a statistical matching procedure.

Statistical matching (SM) refers to a wide set of methods that can be divided into three classes: nonparametric, parametric, and mixed. The hotdeck SM methods, and in particular the nearest neighbor distance hotdeck SM method (D'Orazio et al. 2006), are very popular approaches within the non-parametric class. Parametric SM approaches assume a specific statistical model whose parameters are estimated exploiting all the available data. On the other hand, mixed SM approaches combine elements of both parametric and nonparametric approaches. Under the umbrella of the mixed SM approaches we can include also the methods related to the propensity score matching approach, traditionally applied also to estimate causal effects using observational data (Dalla Chiara et al. 2019, Kum and Masterson 2010, Rosenbaum and Rubin 1983 and 1985).

To the best of our knowledge, the statistical matching literature offers statistical comparisons of different methods within the same framework (Caliendo and Kopeinig 2008, Dehejia and Wahba 2002, Gu and Rosenbaum 1993, Rosenbaum and Rubin 1985), but comparisons of the statistical performance of competing nonparametric and semi-parametric methods are seldom done. This empirical study goes in this latter direction and compares hotdeck and propensity score SM procedures within the same experimental setting aimed at the integration of the US Annual Social and Economic Supplement, providing accurate information about income, with the US Consumer Expenditure Survey, containing information about both expenditures and incomes. The final objective consists in the creation of a robust integrated data set.

2. Methodology

Statistical matching (also known as *data fusion*) indicates a large set of statistical methods to integrate two data sources, identified as A and B, referred to the same target population (typically data from independent probabilistic sample survey) with the objective of investigating the relationship between variables, Y and Z, not jointly observed in a single data source, i.e. the Y variable is observed only in A while Z is available solely in B (D'Orazio et al. 2006). SM exploits information shared by both the sources, commonly identified as *common variables* $(X_1, X_2, \dots, X_p)$ assumed to have the same definition. Most SM methods integrate data at the micro-level to create a "synthetic" dataset including all the variables needed for planned subsequent analyses. The dataset, often denoted as *matched* or *fused*, is 'synthetic' because it is not the result of a direct observation.

In SM applications, only a subset of the common variables, said *matching variables*, is considered; parsimony is the guiding principle in selecting them (D'Orazio et al. 2017). Unfortunately, this way of working implicitly introduces an underlying "model" for the relationship between Y and Z; in other words, it is assumed that Y and Z are independent conditional on the matching variables (cf. D'Orazio et al. 2006). This assumption is seldom valid in SM applications; generally, it approximately holds when the set of matching variables includes at least a proxy variable of one of the target variables; i.e. a variable having a very strong correlation/association with Y or Z (see e.g. Donatiello et al. 2016).

2.1 Hotdeck

SM *hotdeck* methods consist in imputing the missing target variable in the A data source considered as reference (*recipient*) with values of Z observed on selected donors from B (donor dataset). The *nearest neighbor distance* (NND) is the most popular and consists in imputing for each observation in A the value of Z observed on the closest donor in B, whereas closeness is measured in terms of a distance (e.g. Manhattan, Euclidean, Gower, etc.) calculated on the chosen matching variables. It is common to divide units in both A and B in suitable donation classes selected from matching variables such that donation is allowed only between units belonging to the same class.

The *rank distance* hotdeck is a special case of the NND. It calculates the distance on a single continuous matching variable, but it replaces the observed values with the corresponding percentage points of the estimated empirical cumulative distribution. This device permits to overcome measurement errors that introduce bias in the observation of the chosen variable in one of the surveys that would make impossible a direct comparison of the observed values. This method is particularly suited to handle cases of a single matching variable that is a strong proxy of one of the target ones. For instance, in SM of socio-economic surveys aimed at studying the relationship between income and consumption, it may happen that the income variable is observed in both surveys but in one case it is heavily affected by negative bias because observed values are systematically below the true income. Introduction of donation classes often requires estimating the empirical cumulative distribution for each donation class, but the results are reliable if donation classes are not too small.

Finally, *random* hotdeck is designed to handle a set of matching variables that are all categorical. Essentially, for each recipient unit having given characteristics, the donor is chosen at random among the units showing the same characteristics in the donor dataset. This method corresponds to estimating the distribution of Z conditional on the matching variables in the donor dataset and then drawing an observation from it (D'Orazio 2015).

2.2 Propensity Score

The propensity score (PS) when applied in SM applications can be seen as a mixed approach that (1) fits an explicit statistical model (logistic model) and then (2) imputes Z in the recipient dataset applying matching algorithm that resemble hotdeck to the predictions (*scores*) of the model fitted in the first step. PS and hotdeck SM approaches differ in terms of: (i) the procedure adopted for the selection of the used common variables, that in the PS method (first step) is not necessarily parsimonious but requires the balancing of the logistic model that predicts the scores, and (ii) in the second step for the techniques used in associating the donor's observations to the nearest neighbor in the recipient survey.

The *balancing score* $b(X)$ is a function of a subset of the observed covariates X such that the conditional distribution of X given $b(X)$ is independent of assignment in the treatment. Therefore, the propensity score, one of the possible balancing scores, is the probability of treatment assignment conditional

on a set of measured covariates (Rosenbaum and Rubin, 1983). This means that for each value of $b(X)$, the distribution of the observed covariates is the same in the treated and untreated group. The propensity score is based on two assumptions that imply the strong ignorability in treatment assignment (Rosenbaum and Rubin 1983): the conditional independence and the common support. In the context of statistical matching the terms treated, and control refer to the recipient data set and the donor data set respectively.

The PS is estimated using a logistic model on selected set of covariates common to both surveys and its estimated score can be considered a synthetic indicator of the shared variables used in this function. The accuracy of the model specification is evaluated inspecting the distribution of both the propensity score, that also allows to investigate the region of common support, and the common covariates. Balance consists in exploring if the distribution of common covariates is similar in the recipient and donor database. After conditioning on propensity score, there should be no systematic differences in observed covariates between the two data sets (Austin 2011). The standardized difference (SD) is the most common balance diagnostic measure; it is computed as the ratio of the mean difference between recipient and donor sample and the root square of the pooled variance. A SD less than 0.1 denotes a negligible difference (Normand et al. 2001). Austin (2009) and Imai et al. (2008) also proposed to investigate higher moments of the distribution in particular the variance ratio between the two groups. A ratio close to 1 means group balance.

Practically, in the second step of the SM procedure the estimated PS is used to associate donor's observations to the closest observation in the recipient sample implementing a matching method. There is not an algorithm valid for all circumstances, but the choice should be evaluated case-by-case on the data structure and every choice entails a trade-off between bias and variance (Caliendo and Kopeinig 2008, Dehejia and Wahba 2002).

In our work we adopt the nearest neighbor (NN) method to facilitate comparability with the hotdeck procedure, that also uses a NN algorithm, implementing a NN with replacement using four donor observations to match one unit in the recipient data set. In HD applications the term "NN distance" refers to the same NN algorithm as in the PS, but the distance in the HD context is a choice among options like Euclidean or Manhattan. On the other hand, the implementation of the PS method does not require a choice among distances because the implied distance is the propensity score.

3. Data description

In the SM application, we use the 2019 wave of the Annual Social and Economic Supplement (ASEC) and the Consumer Expenditure Survey (CE), both administrated by the US Census Bureau. The surveys are nationally representative and share the same sampling design, a multistage stratified sample. The primary sample units (PSUs) are small clusters of counties grouped together into geographic entities called "core-based statistical areas" (CBSAs).

The common variables were aligned in terms of definition and classification, and we also compared their distribution to understand whether differences in the estimated distributions may point to problems that hinder comparability.

The CE collects data on expenditure, income, and demographics. The CE consists of two separate surveys: the Interview Survey and the Diary Survey. In this study we use the Interview Survey that includes 9,453 households (HHs).

The ASEC is an annual cross-sectional survey that provides the basic monthly demographic and labor force data collected with the Current Population Survey (CPS), plus additional data on work experience, income, noncash benefits, health insurance coverage, and migration. The ASEC survey is larger than the CE survey (47,475 HHs after some cleaning) but since we decided to use it as recipient database (recipient should be smaller than the donor in the application of hotdeck SM techniques) then we selected a subsample of 9,000 units with probability proportional to the sample weight. This approach ensures having approximatively a representative subsample.

4. Results

In this section we present some results of the SM approaches, where the ASEC subsample plays the role of recipient (treated), while the CE assumes the role of donor (control). The objective is to impute in ASEC the consumption variables observed in CE.

4.1 Hotdeck

Following the parsimony principle, the selected set of matching variables consists of relatively few strong predictors of the target variables: the HH size, the number of HH members with an employment and the HH annual income. This latter variable is also available in CE survey and shows an estimated distribution close to that observed in ASEC, which however remains the most reliable survey for investigating HH income. Including HH income in the set of matching variables is fundamental in SM as it makes holding the conditional independence assumption, i.e. the independence between income and consumption conditional on the matching variables.

In the application of the NND hotdeck the units in both data sources are divided in groups obtained crossing HH size with the number of employed HH members, then for each recipient unit in a given donation class it is imputed the consumption observed on the donor unit in CE having the closest distance in terms of HH income. This way of working considers the income observed in the two data sources as perfectly comparable and therefore exploitable for calculating the distances.

If it is assumed that HH income observed in CE cannot be directly compared with the corresponding variable available in ASEC, it is still possible to indirectly include HH income in the matching step by replacing its values with corresponding percentage points of the estimated empirical cumulative distribution. This approach corresponds to the rank distance hotdeck. The empirical cumulative distribution of the HH income is estimated separately for each category of the HH size. Consequently, a recipient HH with a given size "receives" the expenditure variables observed in the closest HH being the closest in terms of estimated empirical cumulative distribution of the income conditional to the HH same size.

A slight modification of rank distance hotdeck consists in picking the donor at random, that is a donor among those being at a distance less or equal to a given threshold in terms of distance calculated on the estimated empirical cumulative distribution of the HH income conditional to the HH size. In our application the chosen threshold is 0.05.

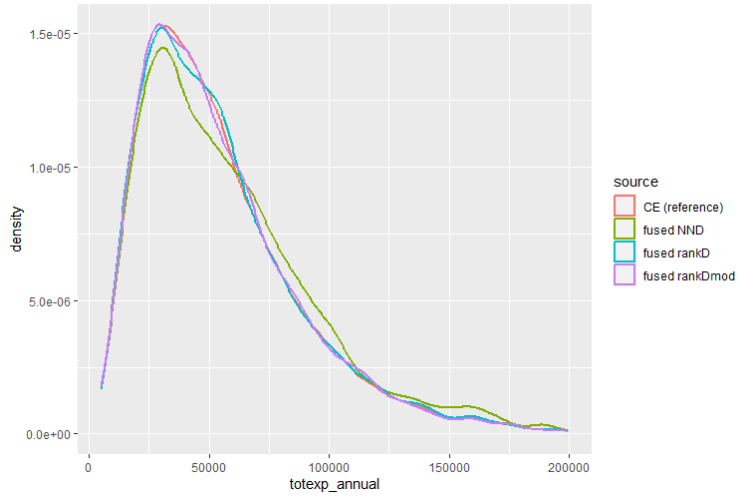

Figure 1 Estimated distribution of HH annual consumption expenditures in the fused dataset obtained after the applied hotdeck SM procedures and in the CE survey (reference).

The common way of assessing the results of the SM applications consists in comparing the estimated distribution of the imputed variable Z (HH consumption expenditures in our case, "totexp_annual") in the recipient dataset after the SM procedure with the reference distribution estimated on the donor. Figure 1 shows that the NND distance using directly the income ("fused NND" in the plot) performs poorly if compared to the other methods that contrarily use the percentage points of the conditional percentage points of the estimated empirical cumulative distribution of the income. In general, the slight modification of rank distance hotdeck ("fused rankDmod" in the plot) produces a curve quite close to the reference one estimated on CE ("CE (reference)" in the plot). This result is confirmed when looking at the estimated average values of HH consumption expenditures in different subsets of HHs formed considering the HH size, the number of perceivers in the HH, etc. (details not reported for sake of summary).

4.2 Propensity Score

The outcomes of PS matching are affected by the choice of the most appropriate propensity score model specification and by the matching algorithm, including the choice of the matching ratio and the replacement or not of the donor units. These issues affect the marginal distribution of the imputed variable.

We implemented two PS models. The first includes the same predictor variables used in the hotdeck methodology. We term this parsimonious specification as "short" model (Goldberger 1991) noting that in the hotdeck nonparametric method only short specifications are preferable due to the characteristics of these methods and more in general to the "curse of dimensionality" problem. This specification is used with the purpose to compare the result of the two methodologies to control for the confounding effect stemming from a different model specification. Donors with the same propensity score are more likely to have a different pattern of covariates when the propensity score model is less accurate than with a more detailed model. The propensity score balances only with respect to the common covariates, not preventing residual confounding by unmeasured factors. In a statistical imputation framework, this aspect has a strong implication on the precision of variables imputation.

For this reason our main selected model specification includes: HH size, number of employed members in the HH, HH income quintile, region of residence, education of the HH head, mortgage, age of the HH head and family type.

The quality assessment of the matching procedure first investigates the distribution of the PS in the original and matched data. The estimated PS has a suitable overlap in terms of support of distribution with a good control match for each observation in the recipient group, including the observations on the tail of the distribution, in both models, but in the main model "unmatched control units" covers almost all the same range of "matched units" in treated and control group. We can conclude that a parsimonious specification in the PS implementation leads to an underspecified logistic model and therefore we report the results only for the fully specified model.

The balance is not difficult to obtain because the donor and recipient databases have a good intrinsic balance so that in our data the balance is not influenced by the matching algorithm chosen as shown in Figure 2 (left panel).

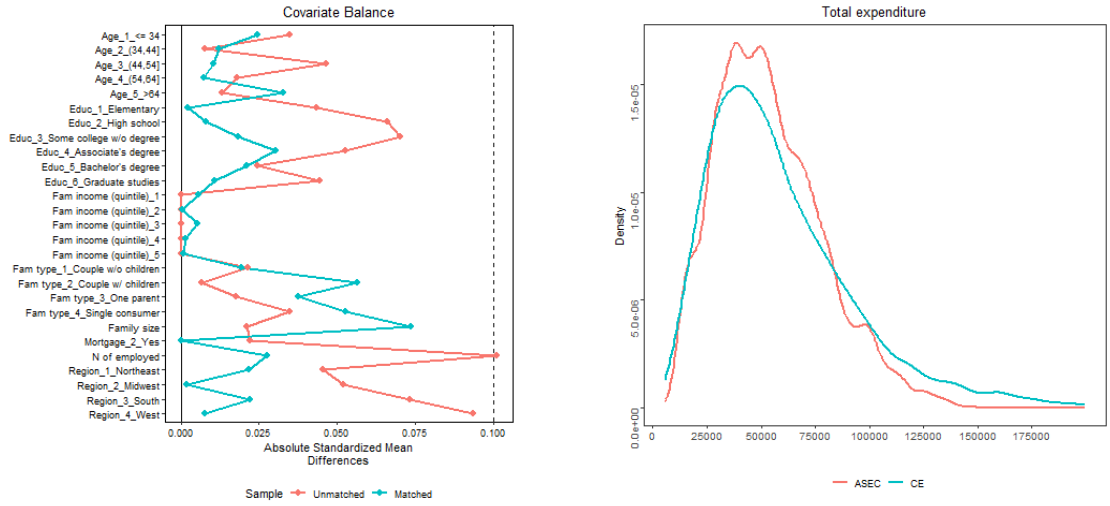

Figure 2 Covariate balance before and after matching (left panel) and Distribution of total expenditure in fused data set (ASEC) and CE data set (right panel)

To examine the matching quality, we inspect the distribution of the extra information (Z) that we transfer from the donor sample to obtain the fused ASEC data set. We control both if in the recipient sample these variables preserve the same distribution as the donor sample, and then we look at the marginal distribution of the imputed variable by the single value of the covariates used to estimate the PS in both databases. For illustrative purposes in Figure 2 (right panel) we report the marginal distribution only for total expenditure that is well preserved. To compare the marginal distribution in the recipient and donor data sets we compute both the ratio of mean and the ratio of median calculated as the ratio between the quantity in the recipient and in the donor sample. There is not a specific threshold

supporting that the information in the two samples can be considered similar, but the closer the ratio is to 1, the greatest the correspondence. The marginal distribution of the common covariates is well preserved in the fused database compared to the donor data set. Major discrepancies are observed in the lower and in the highest income category, in the lower level of education and in families with one parent.

5. Conclusions

This empirical exercise compares hotdeck and propensity score statistical matching (SM) procedures. We hope that our results will provide useful guidance to researchers interested in the implementation of SM methods who can now be reassured because both methods are statistically robust and perform SM satisfactorily. We do warn though that the implementation of the propensity score method needs much more care in the execution of the matching steps. Failing to do so may expose the procedure to significant biases.

Abstract

The Italian National Institute of Statistics is producing some figures of population Census directly based on counts compute on the Base Register of Individuals, a collection of individuals obtained by the integration of several administrative sources and sample surveys. In this paper, we propose an algorithm for the computation of count's estimates and their precision jointly considering measurement, coverage and sampling errors. Experimental studies are carried out on real data.

Keywords: Register-based statistics, under-coverage, over-coverage, misclassification error

1. Introduction

The Italian National Institute of Statistics (Istat) is producing some figures of population Census directly based on the counts computed on the Base Register of Individuals (BRI), a collection of individuals obtained by the integration of several administrative sources and sample survey data. Register-based statistics can be affected by several error's typologies, see e.g., (2), (5) and (6). We propose an estimator considering measurement, coverage and sampling errors, and an algorithm for its uncertainty evaluation.

The official Italian population counts are obtained by correcting BRI counts for over and under coverage errors, that is, for a domain h, count estimates are given by the sum of the weights d_k of the units $k = 1, \ldots, N_h^R$ belonging to the h-domain in BRI

$$N_h = \sum_{k=1}^{N_h^R} d_k, \tag{1}$$

where $d_k = \frac{(1-p_k^o)}{1-p_k^u}$ and p_k^o and p_k^u are the over and under coverage probabilities respectively.

In this paper, d_k are estimated with logistic regression models with random effects applied to a sample survey carried out for census. This implies the presence of a sampling error that affects the accuracy of the estimator and it should be considered in the uncertainty evaluation of estimates. Concerning measurement errors, we remind that values in BRI - that are used for defining domain estimation - are obtained by integrating different administrative sources and may be affected by an error. Disregarding this error in the computation of estimates may lead to a bias (see e.g., (3) and (1)). For example, let us suppose our goal is to provide population count by citizenship $C = c$, with $c = 1, 2$ from the observed count N_1^R of individuals in BRI with citizenship 1, and N_2^R the count of people with citizenship 2, with

$N_1^R + N_2^R = N^R$. If citizenship is misclassified, we have that some people with $C = 2$ should have been classified with $C = 1$. The correct number of units with citizenhip $C = 1$ is $N_1 = N_{1|1} + N_{1|2}$, i .e., all observed units N_1^R in BRI correctly classified ($N_{1|1}$) plus the observed units in BRI with citizenship $C = 2$ which are not corretly classified ($N_{1|2}$).

$N_{1|1}$ and $N_{1|2}$ are independent r.v.s and can be modeled as $N_{1|1} \sim Bin(N_1^R, p_{1|1})$ and $N_{1|2} \sim Bin(N_2^R, p_{1|2})$ with classification probabilities $p_{1|1}$ (the probability that the true citizenship is $C = 1$ given that in BRI is $C = 1$) and $p_{1|2}$ (the probability that the true citizenship is $C = 1$ given that in BRI is $C = 2$) estimated from the cross-classification table obtained comparing BRI and sample data, under the assumption that sample data are not affected by measurement errors (4).

The proposed estimation algorithm that deals with misclassification errors and coverage errors as well is illustrated in Section 2. The algorithm gives also a measure of the precision of the estimator. An experimental study based on 2018 BRI and population survey data is described in Section 3. The application is studied according to different measurement error hypothesis to assess the impact of different rates on the quality of the estimator. To quantify the improvements of the proposal, results are compared with an estimation method dealing only with only coverage errors, disregarding measurement errors in BRI.

2. Algorithm for the estimation of population counts

The algorithm is based on estimates of over and under coverage and misclassification error probabilities. In the Italian permanent census, two surveys are conducted: S_L that is a sample from BRI used for the evaluation of over-coverage, and S_A an area sample used for the evaluation of under-coverage. Part of the S_L and S_A units, i.e., the not over- and not under-coveraged individuals respectively $NS = BRI \cap (S_L \cup S_A)$, can be used for the evaluation of misclassification probabilities. The cross-classification table 1 is computed comparing the citizenship information reported in BRI, measurement error affected, and the error free information from surveys. The general term m_{ij} represents the number of units observed in BRI and NS with $C = i$ in BRI and $C = j$ in NS.

Table 1: Cross-classification table of citizenship of units in BRI and in $S_L \cup S_A$ (respectively BRI_{NS} and $(S_L \cup S_A)_{NS}$)

		$(S_L \cup S_A)_{NS}$	
		$C = 1$	$C = 2$
BRI_{NS}	$C = 1$	m_{11}	m_{12}
	$C = 2$	m_{21}	m_{22}

The algorithm is aimed at estimating population counts by removing coverage and measurement errors, and at evaluating the precision of estimates. In the first step, a pseudo-register free of measurement errors is built, then a pseudo-population free of coverage errors is created. In the third part - to take into account sampling variability - samples are drawn from the pseudo-population. The process is repeated and the results are averaged over those replicates.

The steps of the algorithm are the following:

1 **Correct the register for measurement error**
For each profile x, the counts of subjects in BRI, $N_{1,x}^R$ and $N_{2,x}^R$, are affected by measurement errors. Using the cross-classification table 1 and the Bayes theorem, we obtain the $p_{1|1}$ and $p_{1|2}$

estimates. The corrected $N^{Rc}_{1,x}$ and $N^{Rc}_{2,x}$ are randomly generated from a binomial distribution:

$$N^{Rc}_{1|1,x} \sim Bin(N^{R}_{1,x}, p_{1|1})$$
$$N^{Rc}_{1|2,x} \sim Bin(N^{R}_{2,x}, p_{1|2})$$

Then $N^{Rc}_{1,x} = N^{Rc}_{1|1,x} + N^{Rc}_{1|2,x}$ and $N^{Rc}_{2,x} = (N^{R}_{1,x} - N^{Rc}_{1|1,x}) + (N^{R}_{2,x} - N^{Rc}_{1|2,x})$ are the BRI counts corrected for measurement error [1].

2 **Pseudo-population generation**

Generation of non-overcovered component of population
Simulate for each profile x, the counts of subject that correctly are in the register using the relative frequency $f^{SLc}_{\overline{o},x}$ of not over-covered subjects in the survey from the list . Those counts are randomly generated from a binomial distribution.

$$N^{Rc}_{\overline{o},x} \sim Bin(N^{Rc}_{x}, f^{SLc}_{\overline{o},x})$$

with $N^{Rc}_{o,x} = N^{Rc}_{x} - N^{Rc}_{\overline{o},x}$ the counts of over coveraged subjects in the register.

Generation of under-covered component of population
Simulate for each profile x the count of subjects under covered present in the register (remark: the counts of not over and not under covered are the same in the register) using the relative frequency $f^{SA}_{\overline{u},x}$ of not under-covered subjects in the survey on area. Those counts are randomly generated from a negative binomial distribution.

$$N^{Rc}_{u,x} \sim NegBin(N^{Rc}_{\overline{o},x}, f^{SA}_{\overline{u},x})$$

3 **Correct the register for coverage error**
At this point a complete pseudo-population data set is available and K under and over coverage samples are drawn from the municipalities considered in the original census round. The estimates of probabilities for an individual with profile x to be over ($\hat{p}^{o}_{x}$) and under ($\hat{p}^{u}_{x}$) covered are obtained via logistic regressions on the samples and combined in a ratio corrector applied to the register counts:

$$\hat{N}_x = N^{Rc}_{x} \cdot \frac{1 - \hat{p}^{o}_{x}}{1 - \hat{p}^{u}_{x}} \tag{2}$$

Steps **1-3** are repeated M times obtaining $K \times M$ estimates $\hat{N} = \sum_x \hat{N}_x$ for each municipality. Variance of the estimator is computed by using the variance of estimates computed over the iterations.

3. Experimental study

In the experimental study, we compare the results of the algorithm in Section 2. with an approach that does not take into account measurement errors, but only coverage errors. Estimation procedures are applied to the Emilia-Romagna region data, year 2018, to the 272 municipalities with a population between 1,000 and 18,000 individuals. Two possible levels of measurement error in the 2018 data are introduced on the citizenship variable to evaluate the impact on the estimation algorithm. The first level is calculated using the observed misclassification frequency computed on the linked observations data reported in Table 2.

[1] We note that the citizenship information available for over covered subject in the survey from list come from register then we correct this for measurement error too

Table 2: Cross-classification table of citizenship of units in BRI_{NS} and $(S_L \cup S_A)_{NS}$

		$(S_L \cup S_A)_{NS}$ $C=1$	$C=2$	$Tot.$
BRI_{NS}	$C=1$	190545	386	190931
	$C=2$	180	20008	20188
	$Tot.$	190725	20394	211119

The measurement error probabilities obtained are:

$$Pr(C_{\text{BRI}}=1|C_{\text{NS}}=1)=0.999; Pr(C_{\text{BRI}}=1|C_{\text{NS}}=2)=0.019;$$
$$Pr(C_{\text{BRI}}=2|C_{\text{NS}}=1)=0.001; Pr(C_{\text{BRI}}=2|C_{\text{NS}}=2)=0.981 \quad (3)$$

The second level of measurement error is fixed considering the values in Table 2, subtracting 0.1 from $Pr(C_{\text{BRI}}=1|C_{\text{NS}}=1)$ and $Pr(C_{\text{BRI}}=2|C_{\text{NS}}=2)$ and maintaining the values of the marginal probabilities for C_{NS}, attaining:

$$Pr(C_{\text{BRI}}=1|C_{\text{NS}}=1)=0.899; Pr(C_{\text{BRI}}=1|C_{\text{NS}}=2)=0.119;$$
$$Pr(C_{\text{BRI}}=2|C_{\text{NS}}=1)=0.101; Pr(C_{\text{BRI}}=2|C_{\text{NS}}=2)=0.881. \quad (4)$$

No many changes are expected on the citizenship distribution in the first *scenario*, whereas for the second measurement error *scenario*, the frequency of incorrect assignment of citizenship is more evident.
An experimental population with the desired level of measurement error in citizenship is generated by a 3-step procedure:

- **I.** Using the procedure described in step 2 of Section 2, a pseudo-population is generated from the 2018 BRI, S_L and S_A which are all free of measurement errors.

- **II.** Errors are introduced to obtain a pseudo-register. For each profile x of the 2018 BRI, decomposed in the subset of over covered and not over covered data, the counts of subjects $N^{18}_{C=1,x}$ and $N^{18}_{C=2,x}$ are used to generate $N_{1|1,x}$ and $N_{1|2,x}$ affected by measurement error:

$$N_{1|1,x} \sim Bin(N^{18}_{1,x}, p^E_{1|1})$$
$$N_{1|2,x} \sim Bin(N^{18}_{2,x}, p^E_{1|2})$$

  where: $p^E_{1|1}=Pr(C_{\text{BRI}}=1|C_{\text{NS}}=1)$ and $p^E_{1|2}=Pr(C_{\text{BRI}}=1|C_{\text{NS}}=2)$; $N_{1|1,x}+N_{1|2,x}=N_{1,x}$ and $N_{2|1,x}+N_{2|2,x}=N_{2,x}$.

- **III.** Under and over coverage samples are drawn from the pseudo-register generated at step II. Samples are drawn by considering municipalities used in the sample survey census round.

The estimation algorithm described in Section 2. (henceforth Sim) is applied to those data that at this stage are affected by measurement errors: the pseudo-register of step II and sample S_L and S_A of step III.
For each pseudo-population, 100 under coverage and 100 over coverage samples are drawn, and 100 pseudo-populations are created. After the runs, 100 x 100 estimates are available for each municipality.
In order to assess the improvement obtained with our procedure, for comparison, we also developed a procedure that does not take into account measurement errors. It is based on a classic bootstrap procedure ($BootC$) applied to the S_L and S_A sample surveys. More in detail, 10,000 random samples with

replacement are drawn from S_L and S_A. The factor for the correction of coverage errors is computed for each couple of samples and applied to BRI to compute the estimate as described formula 2 in step 3 of Section 2. At the end of this process, 10,000 estimate of the population counts are available to compute an approximation of the expected value of the estimator and its variance.
We remark that in this experiment, we start from known values of population counts, that are indeed our objective. Estimates can be compared with those true values in order to compute their MSE. In table 3, the mean and median percentage of the relative root MSE (RRMSE) is showed, considering the two possible measurement error $scenarios$.

Table 3: Median and Mean of RRMSE by level of measurement error, estimate method and C domains

		$ScenarioI$		$ScenarioII$	
Met.	C	$Median\%$	$Mean\%$	$Median\%$	$Mean\%$
Sim	all	0.58	0.74	0.74	0.91
	1	0.56	0.72	1.37	1.59
	2	3.12	4.26	10.04	15.31
BootC	all	0.58	0.72	0.74	0.85
	1	0.54	0.71	4.25	4.18
	2	1.98	3.50	42.77	49.60

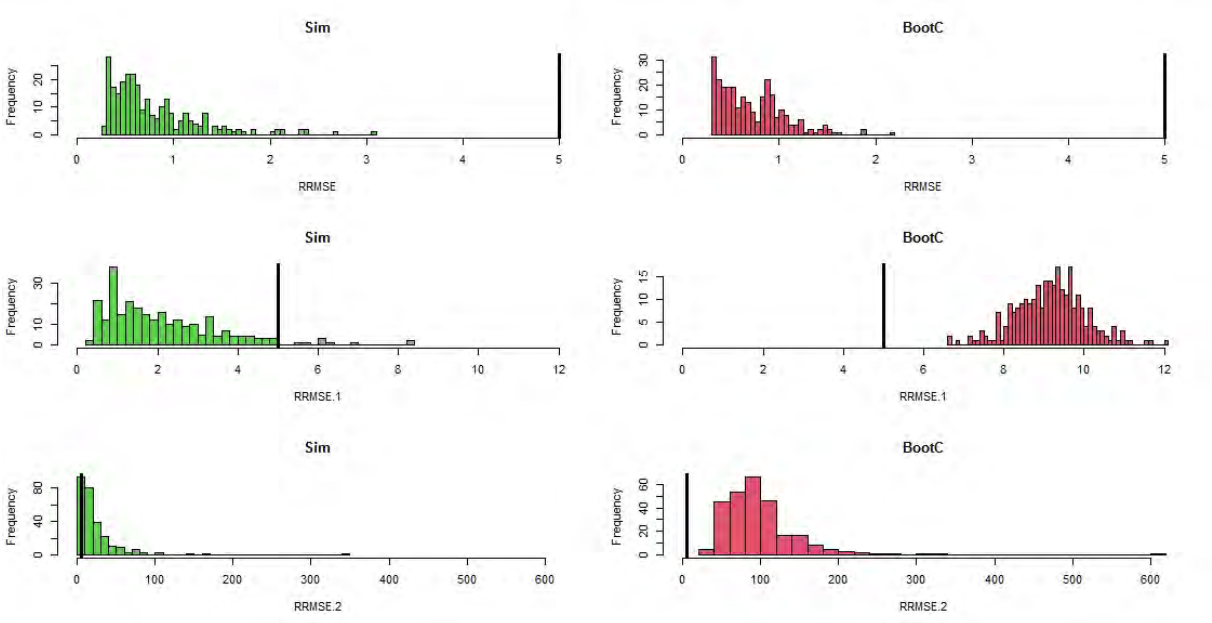

Figure 1: RRMSE percentage by methods (Sim in green; BootC in red) and domains (from top to bottom rows: all citizenship; citizenship = 1 or italian; citizenship = 2 or not italian) for $Scenario$ II (high level) of measurement error. Vertical line in black corresponding to the 5% of RRMSE

Results show that measurement error has a small impact on population counts when citizenship is not considered as a stratification variable ($C = all$). This is true independently of the levels of measurement errors and of estimation procedures. In *Scenario* I, with a low level of measurement error, the two

methods provide estimates with a similar behaviour, suggesting that measurement errors has a small impact on the accuracy of estimator. In the case of a high level of measurement errors (*Scenario* II), the Sim method allows to improve the accuracy of the estimator. In particular for $C = 2$ the median RRMSE decreases from 43% to 10%.

The histograms in Figure 1 shows the distribution of RRMSE (in percentage) for the two methods by citizenship. Considering the entire population, both Sim and $BootC$ show RRMSE percentage lower than 5%. For the Italian sub-population (C=1), all the RRMSE percentages from $BootC$ are greater than 5%, while only the tail of the Sim distribution is greater. Finally, for the not Italian sub-population (C=2) all the $BootC$ RRMSE percentage values are greater than the 5%, while for the Sim method the bulk of the distribution is around this value. To conclude, the algorithm is certainly useful because it is able to remove a large part of the error and because it provides a method for estimating the impact of all those errors on the quality of count estimates, following the idea of total error. More studies will be devoted to understand the characteristic of the remaining part of the error, for instance whether it is mainly due either to measurement or coverage errors, or to an interaction of these components.

Abstract

A hierarchical spatio-temporal model that infers the latent spectral shape from a set of bio-acoustic signals by means of the Nearest neighbour Gaussian process is proposed. The model aims to account for the effects of the relative relationship between time and the spectral shape of the recorded vocalizations and that of time discretization. The goal is to obtain a representative model of the inherent acoustic structure of the species.

Keywords: Bio-acoustic, time-frequency, spatio-temporal model, nearest neighbour Gaussian process, spectral shape

1. Motivation & Data

In comparative bio-acoustic studies, one area of interest is to understand the vocalizations of non-human primates in order to provide insights into the evolutionary mechanism of the communication systems of our closest relatives. Since bioacoustic data are almost always represented in the form of a spectrogram, bioacoustic analysis is therefore a form of time-frequency analysis that requires computational methods to process and learn from the bio-acoustic signals in large quantities. The most commonplace practice is to apply feature engineering methods in order to select and compare a set of basis-features. Such methods often treat the time-frequency bins of spectrograms as independent features and are known to entail perceptual bias due to the reliance on biologists to manually select relevant features. The identification and interpretation of meaningful features are usually costly to acquire and difficult to generalize for cross-species comparison. Furthermore, feature engineering methods in bioacoustic analysis, whether supervised or unsupervised, almost always ignore the effects of time by assuming that all the time-frequency bins from various recorded bio-acoustic signals are independent of each other. The aim of this project is to propose a spatio-temporal model that accounts for the effects of time in bio-acoustic analysis.

The available dataset for this work is a set of vocal signals of lemurs that were recorded in Madagascar. The format of the dataset is similar to those in (2). Each recorded analogue digital signals is

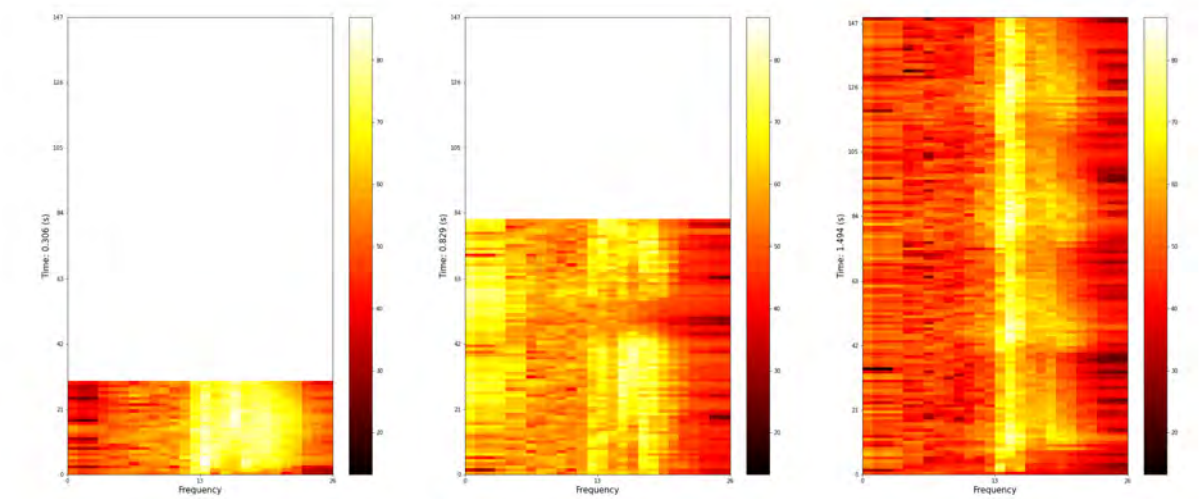

Figure 1: The spectrograms of three recorded signals labelled by the same species label and the same call-type from the dataset. The x-axis and y-axis represent the discretized frequency and time domain, respectively. Each discrete sound point of the discretized recording is measured in decibel scale on the third dimension of the spectrogram. Each axis is labelled by the number of discrete time and frequency coordinates. The number of frequency coordinates on the x-axis is the same for all recorded signals, while the number of time coordinates on the y-axis differ. This discernible disparity between the numbers of time coordinates on the y-axes is a result of the difference between the durations of the three signals. The unique duration of each signal is indicated on the label of the y-axis, which are 0.306, 0.829 and 1.494 seconds respectively (from left to right). The corresponding numbers of time coordinates are 30, 82, and 149 respectively, while all have 26 frequency coordinates.

discretized using a constant time-step of 0.01 seconds during the initial stage of signal pre-processing. Figure 1 is a spectrogram representation of 3 discretized recorded signals of different durations from the dataset. Each signal is categorized by one species label and one call-type label. The species label is the acronym of the scientific name of the lemur that emitted the recorded signal, whereas the call-type label of each recording is assigned according to the behaviour of the animal during the emission of the signal.

2. The Model

Assume that the recordings that are characterized by the same species but different behavioural call types are independent from each other. The model specification is then restricted to the recorded signals that are labelled by a single call type from a single species. Let N be the total number of signals that are classified by the same combination of species and call type with $i = 1, \cdots, N$. As per Figure 1, each recorded signal is represented by a spectrogram with one axis representing the time domain and another representing the frequency domain. Assume that each i-th recorded signal is a realization of a two-dimensional process $\mathcal{Y}_i(t, h) \in \mathbb{R}$ where $t \in \mathbb{R}_{\geq 0}$, $h \in \mathbb{R}$ over an observed regular grid. Let $n_{t,i}$ denote the number of time coordinates on the discrete time axis $\mathcal{T}_i^* \subset [0, l_i]$ where l_i is the duration of the signal and let n_h denote the number of log-frequency bins on the frequency axis $\mathcal{H}$, respectively. The regular grid of the i-th recorded signal is then composed of $n_i = n_{t,i} \times n_h$ time-frequency coordinates in total. In order to compare the recorded signals of different durations, the time domain of each recorded

signal $\mathcal{T}_i^* \subset [0, l_i]$ is rescaled into a new time domain, denoted by $\mathcal{T}_i \subset [0, 1]$, such that it is always one in duration. By contrast, the number of frequency coordinates n_h is constant for all signals and so, it follows that the log-frequency bands that are denoted by the frequency coordinates on $\mathcal{H}$ are also the same for all recorded signals. Hence, let the realization of the process $\mathcal{Y}_i(t, h)$ on a regular grid be denoted by $\boldsymbol{y}_i = \{y_{i,t,h}\}_{t \in \mathcal{T}_i, h \in \mathcal{H}}$ where

$$\mathcal{T}_i = \left\{ \frac{k-1}{n_{t,i}-1} | k = 1, \ldots, n_{t,i} \right\}, \quad \mathcal{H} = \{0.23k + \log 63 | k = 1, \ldots, n_h\} \tag{1}$$

Clearly, each observed spectrogram represented by the $n_{t,i} \times n_h$ regular grid $\mathcal{T}_i \times \mathcal{H}$ is unique in its own right as a consequence of the varying numbers of time coordinates $n_{t,i}$. As explained earlier on, the aim of the model is to infer the latent spectral shape of vocalizations from a dataset of N recorded signals that share the same species and call type labels. It is reasonable to assume that all N recorded acoustic signals have the same inherent spectral shape which can be described by the same latent Gaussian process. This ideal representation of the inherent spectral shape of the vocalizations from a single species of a single call type is henceforth termed the "mother call". Let $\mathcal{W}_i(t, h)$ be the latent process that describes the mother call. Assume that if $(i, t, h) \neq (i', t', h')$, then $\mathcal{Y}_i(t, h)$ and $\mathcal{Y}_{i'}(t', h')$ are conditionally independent given the mother call. The model is:

$$\begin{aligned} \mathcal{Y}_i(t, h) &= \mu_i + \mathcal{W}(t, h) + \epsilon_i(t, h) \\ \mathcal{W}(t, h) &\sim \text{GP}(0, C(\cdot, \cdot | \boldsymbol{\theta})) \\ \epsilon_i(t, h) &\sim \text{GP}(0, \tau_i^2) \end{aligned} \tag{2}$$

where $\mu_i \in \mathbb{R}$ is the mean sound intensity of the i-th recorded signal, $\mathcal{W}(t, h)$ is the latent process over the domain of the mother call, $\epsilon_i(t, h) \sim \text{GP}(0, \tau_i^2)$ is the $i.i.d.$ random noise, and

$$C((t, h), (t', h') | \boldsymbol{\theta}) = Cov(\mathcal{W}(t, h), \mathcal{W}(t', h')) : \mathbb{R}^2 \times \mathbb{R}^2 \to \mathbb{R}^+ \tag{3}$$

is the cross-covariance function for the latent process $\mathcal{W}(\cdot, \cdot)$ that is dependent on the vector of parameters $\boldsymbol{\theta}$. The covariance function $C(\cdot, \cdot | \boldsymbol{\theta})$ for the latent process $\mathcal{W}(\cdot, \cdot)$ is defined by

$$C((t, h), (t', h') | \boldsymbol{\theta}) = \sigma^2 \text{exp}(-\phi_t |t - t'| + \phi_h |h - h'|) \tag{4}$$

such that $\boldsymbol{\theta} = (\sigma, \phi_t, \phi_h)$. The parameters that need to be inferred are the time-frequency decay ϕ_t, ϕ_h and the variance σ, respectively. Note that the equivalent formulation is the generative model $\mathcal{Y}_i(t, h) \mid \mathcal{W}(t, h) \sim \text{GP}\big(\mu_i + \mathcal{W}(t, h), \tau_i^2\big)$. Dependence between the entire set of recorded signals is thus introduced through the latent process $\mathcal{W}(t, h)$ which describes the mother call. That is, if the model in equation (2) is marginalized over the latent process, then the observed processes are dependent on each other. Subsequently, the acoustic structures of each recorded signal is composed of the natural change in the spectral shape across the observed time-frequency grid with independent error τ_i^2, which need to be accounted for by an additional component on the diagonal of the covariance matrix for the observed processes. This is the nugget effect that arises from the covariance of the variables in each observed process. Let $\mathbb{I}(\cdot)$ be an indicator function, then the covariance function for the observed processes is:

$$Cov\big(\mathcal{Y}_i(t, h), \mathcal{Y}_{i'}(t', h')\big) = C((t, h), (t', h') | \boldsymbol{\theta}) + \tau_i^2 \mathbb{I}((i, t, h) = (i', t', h')) \tag{5}$$

Since direct implementation of the generative model in equation (2) is computationally infeasible due to the fact that it requires the mother call to be sampled for every single recorded sound point in the dataset, the marginalized model is implemented instead. To simplify notations, re-write each single recorded sound point $y_{i,t,h} = y_{i,j}$ where $y_{i,j}$ is the realization of $\mathcal{Y}_i(t, h)$. Define $\boldsymbol{y}_i = \{y_{i,j} | j = 1, \cdots, n_i\}$ as the vector of realizations from the i-th recorded signal such that the elements are sorted in the ascending order of time and the increasing value of log-frequencies within each time. Define $\mathbf{1}_i$ as the $n_i \times 1$ vector of ones. Write $\boldsymbol{\Sigma}_i$ as the exact covariance matrix of $\boldsymbol{y}_i$ and write $\boldsymbol{\Sigma}_{i,i'}$ as the exact

cross-covariance matrix of $\boldsymbol{y}_i$ and $\boldsymbol{y}_{i'}$ that are given by the covariance function in equation (5). The joint density of all realizations can be expressed by:

$$\begin{matrix}\boldsymbol{y}_1\\ \boldsymbol{y}_2\\ \vdots\\ \boldsymbol{y}_N\end{matrix} \sim \mathrm{N}\left(\begin{pmatrix}\mu_1\mathbf{1}_1\\ \mu_2\mathbf{1}_2\\ \vdots\\ \mu_3\mathbf{1}_N\end{pmatrix}, \begin{pmatrix}\boldsymbol{\Sigma}_1 & \boldsymbol{\Sigma}_{1,2} & \cdots & \boldsymbol{\Sigma}_{1,N}\\ \boldsymbol{\Sigma}_{2,1} & \boldsymbol{\Sigma}_2 & \cdots & \boldsymbol{\Sigma}_{2,N}\\ \vdots & \cdots & \ddots & \vdots\\ \boldsymbol{\Sigma}_{N,1} & \boldsymbol{\Sigma}_{N,2} & \cdots & \boldsymbol{\Sigma}_N\end{pmatrix}\right) \tag{6}$$

In a more compact form, write $\boldsymbol{y} = \{\boldsymbol{y}_i\}_{i=1,\cdots,N}$ as the collection of all realizations and re-write formula (6) into $\boldsymbol{y} \sim \mathrm{N}(\boldsymbol{\mu}, \boldsymbol{\Sigma}_{\boldsymbol{y}})$.

3. Implementation

The available dataset of lemur signals for this paper has a total number of time-frequency coordinates of $n = \sum_i^N n_{t,i} n_h$. With a computational cost of $\mathcal{O}(n^3)$, the inversion of the exact covariance matrix in equation (6) is too computationally expensive; accordingly, one of the methods for efficiently and accurately approximating Gaussian processes, namely the Nearest Neighbours Gaussian Process (NNGP) method, is adopted in this work. Let $f(\boldsymbol{y}|\boldsymbol{\theta})$ denote the density of the realizations $\boldsymbol{y}$ that depends on the parameters $\boldsymbol{\theta}$ which can be decomposed by conditioning as follow:

$$\begin{aligned} f(\boldsymbol{y}|\boldsymbol{\theta}) &= f(\boldsymbol{y}_1|\boldsymbol{\theta}) \prod_{i=2}^{N} f(\boldsymbol{y}_i|\boldsymbol{\theta}) \\ &= f(y_{1,1}|\boldsymbol{\theta}) \prod_{j=2}^{n_1} f(y_{1,j}|y_{1,j-1}, y_{1,j-2}, \cdots, y_{1,1}, \boldsymbol{\theta}) \times \\ &\prod_{i=2}^{N} f(y_{i,1}|\boldsymbol{y}_{i-1}, \boldsymbol{y}_{i-2}, \cdots, \boldsymbol{y}_1, \boldsymbol{\theta}) \prod_{j=2}^{n_i} f(y_{i,j}|y_{i,j-1}, y_{i,j-2}, \cdots, y_{i,1}, \boldsymbol{y}_{i-1}, \boldsymbol{y}_{i-2}, \cdots, \boldsymbol{y}_1, \boldsymbol{\theta}) \end{aligned} \tag{7}$$

The idea of the NNGP method is that for a Gaussian process which is stationary, if the covariance function is monotonic with respect to the distances between the spatio-temporal coordinates, then only the immediate neighbourhoods rather than the entire conditional sets are necessary to approximate the likelihoods of the realizations of the process. Define $\mathcal{N}_{i,j}$ as a subset of variables in the conditional set of $y_{i,j}$ which is the immediate neighbourhood called the neighbour set. The elements of the neighbour set are called neighbours. Since the covariance function in equation (4) is monotonically decreasing with respect to the form of distance that it depends on, the neighbours in the neighbour set should have minimal non-zero distances and the formation of the neighbour set should be characterized by a distance function that measures the absolute time-frequency lags on the time-frequency domain. The above density of $\boldsymbol{y}$ can then be approximated into:

$$f(\boldsymbol{y}|\boldsymbol{\theta},) \approx \prod_{i=1}^{N} \prod_{j=1}^{n_i} f(y_{i,j}|\mathcal{N}_{i,j}, \boldsymbol{\theta}) \tag{8}$$

with $\mathcal{N}_{1,1}$ being an non-empty neighbour set. The distance function that gives rise to the neighbour set is defined by :

$$d((t,h),(t',h')) = |t-t'| + |h-h'| \tag{9}$$

It is more reasonable to select neighbours for $y_{i,j}$ from both the same i-th signal and the previous $i-1$-th signal instead of just the same recorded signal alone on the grounds that the realizations $\boldsymbol{y}_i$ and $\boldsymbol{y}_{i-1}$ are not independent in spite of the product form of the approximated density in the above equation (8). Spatio-temporal dependence between the two different recordings has to be re-introduced

into the approximated density through the neighbour sets. For the j-th observed sound variable of the i-th recorded signal, denote the neighbour set with elements selected only from the i-th signal by $\mathcal{N}_{i,j}^{i}$ and similarly, denote the neighbour set with elements selected only from the previous $i-1$-th signal by $\mathcal{N}_{i,j}^{i-1}$. The definition of the neighbour set for the realized variable $y_{i,j}$ is:

$$\mathcal{N}_{i,j} = \mathcal{N}_{i,j}^{i} \cup \mathcal{N}_{i,j}^{i-1} \tag{10}$$

Following (1), setting the size of the neighbour set in between 10 to 20 should enable an accurate approximation of the original process. Finally, the main objective of this work is to obtain the representative acoustic structure of the vocalizations that belong to the same species and call-type, the mother call, which is the finite realizations of $\mathcal{W}(t,h)$ over a specified grid. By the NNGP method, the approximated precision matrix $\boldsymbol{\Sigma}_{\boldsymbol{y}}^{-1}$ admits a Cholesky decomposition and enables standard posterior sampling. Let $\boldsymbol{\Sigma}_{w,\boldsymbol{y}}$ be the $1 \times n$ cross-covariance vector of $\mathcal{W}(t,h)$ and $\boldsymbol{y}$. The realization of the latent process $\mathcal{W}(t,h)$ at any location can then be obtained by:

$$\mathcal{W}(t,h)|\boldsymbol{y},\boldsymbol{\theta} \sim \mathrm{N}\big(\boldsymbol{\Sigma}_{w,\boldsymbol{y}}\boldsymbol{\Sigma}_{\boldsymbol{y}}^{-1}(\boldsymbol{y}-\boldsymbol{\mu}),\ \sigma^2 - \boldsymbol{\Sigma}_{w,\boldsymbol{y}}\boldsymbol{\Sigma}_{\boldsymbol{y}}^{-1}\boldsymbol{\Sigma}_{w,\boldsymbol{y}}^{\top}\big) \tag{11}$$

4. Discussion

As this is an ongoing and multidisciplinary work, the current proposed model is a preliminary version of the complete model and as such, further progress to the final results is being made. Another preliminary and less refined version of this work has been communicated to the 36th International Workshop on Statistical Modelling in the form of a poster presentation and the submitted abstract was published in the proceedings that is available in (3).

The current preliminary model in this paper, although incomplete, starkly contrasts many contemporary methods in bio-acoustic analysis. The model accounts for the effects of the time-varying components in the observed vocalizations by using the entire bio-acoustic dataset as realizations of a spatio-temporal process, rather than reducing the high-dimensional time-frequency data into some independent features, such as absolute pitches, with arbitrarily assigned meanings. The main contribution is that the resulting mother call, i.e. the representative acoustic structure of a particular call-type from a species, can subsequently be used to measure the distances between the inherent acoustic structures of different species in the animal kingdom. Such quantitative measures can hopefully ease cross-species comparison in bio-acoustic analysis and facilitate biological studies on the evolutionary basis for the variations of the vocal repertoires of various species. The next steps being taken in this work are summarized as follow.

A closer inspection of the spectrograms of the observed signals in Figure 1 reveals that there are two major issues with the preliminary model in equation (2): (i.) the noticeable distortions of the observed time domains with respect to each other caused by the unique duration of each recordings. Though each recorded signal can be thought of a marginal realization of the same latent process over the observed regular grid, the unique duration of each recording entails distortions of the observed time-axis with respect to each other, and perhaps misalignments of the time domain for the observed process with respect to the time domain for the latent mother call process. The same earliest recorded time coordinate from the 1st recorded signal might not coincide with the very same earliest recorded time coordinate from another signal, for instance. In fact, each observed time domain may be treated as a somewhat stretched portion of the latent time domain for the mother call. (ii.) the oscillations along the time axis on the lower frequency spectrum that arises from time discretization and signal reconstruction during the initial stage of analogue signal pre-processing. When analogue signals are being discretized in time, if the time-step is less than the period of the true waveform of the low frequency, then the sampled frequency becomes an artifact because it does not capture the original periodicty of the true waveform of the sound. This leads to a periodic artefact that oscillates along the time domain of the reconstructured, discretized signal on the lower frequency spectrum.

Both (i.) and (ii.) render the model specification and inference for the mother call more difficult as the challenges posed by the misalignments of the time domains as well as the presence of the artefacts must be resolved. In light of (i.), the preliminary model and its separable covariance function must be

extended to incorporate a time-distortion function with parameters that can describe and quantify the distortions of the time domains of the observed processes with respect to the latent time domain of the mother call. In view of (ii.), an additional component that can explain the periodicity of the artefacts must be included into the covariance function of the observed processes. Considering that the sampling artefacts appear solely in the recorded discretized signals, care must be taken to ensure that only the covariance for the observed processes must possess this additional component, but not the covariance for the mother call. The parameters of the time-distortion function and this additional component must be part of the inference. Once the final model is formulated, it is tested on simulated data in order to demonstrate its efficacy and to recognize if the model suffers from the problem of non-identifiability or any other technical issue in the implementation stage. After all the implementation details are sorted, the final model is then ready to be implemented on the real dataset.

Abstract

We introduce a clustering method for time series based on tail dependence. Such a method considers spatial constraints by means of a suitable dissimilarity index that merges temporal and spatial dependence via extreme-value copulas. The proposed approach is applied to the study of rainfall extremes.

Keywords: Copula, Hierarchical clustering, Tail Dependence.

1. Introduction

In the last two decades, correlation-based clustering of time series has been exploited for describing the co-movement of time series that, especially in finance, have helped in risk assessment, portfolio diversification and trading strategies (see, e.g., (16)). Traditionally, such methods have focused only on linear dependence in the bivariate context (see, e.g., (1)). However, since the seminal paper (2), tail-dependence indices have been also used in order to capture the risk of the joint occurrence of extreme phenomena; see, for instance, (3; 4; 7) and references therein.

Here, we focus on agglomerative hierarchical clustering methods based on tail dependence coefficients. Specifically, we consider methods that depend only on the copula linking the random variables of interest according to the framework described in (10). Such methods are usually based on the definition of a suitable dissimilarity index that, following (7), is assumed here to be related to the upper tail dependence coefficient (2; 3; 7) - when the lower tail is of interest it is enough to change the sign to the variables of interest. As a specific novelty of the proposed approach, we suggest to extend the applicability of such methods to take explicitly into account the spatial information (8). In fact, the geographical contiguity may reflect the inherent structure of the phenomena in various cases. For instance, the spatial dependence between rainfall extremes or flood events can deliver information on which gauges often behave similarly across a given geographical region. Similarly, in the financial context the spatial dependencies between the underlying entities can provide deeper insights into the dependence structure of stock returns (see, e.g., (14)).

According to (17), clustering with spatial constraints may proceed in two main steps: (a) first, compute the dissimilarities between all pairs of time series; (b) then, these dissimilarities are modified by weighting with a function of the geographical distance to form new dissimilarities. In a copula setting, the latter approach has been developed, for instance, in (5; 6).

In the same spirit, here we proceed as follows: (a) we assume that the temporal dependence can be conveniently represented by an *extreme-value copula* C, which is naturally linked to extremal coefficients; (b) then we propose a dissimilarity index based on a modification of the tail dependence

coefficient of C that takes into account spatial information. The modification introduces a tuning parameter $\alpha \in [0,1]$ that determines the influence of the spatial component. This new methodology is fully described in Sect. 2, while Sect. 3.is devoted to an illustrative example.

2. The methodology

Our aim is to cluster n different units, each of them represented by a univariate time series (the temporal feature), and a vector of (spatial) features that record the information about geographic location and/or economic information. For instance, the units represent rainfall information, while the spatial information is about the geographical location of each weather station where the measurements are collected.

Thus, the starting point is represented by:

- a $(T \times n)$ (temporal) matrix, $\mathbf{X} = (x_{ti})$, whose element x_{ti} represents the value of the i-th unit $(i = 1, \ldots, n)$ at time t $(t = 1, \ldots, T)$. Each column of $\mathbf{X}$ is a time series.
- a $(n \times n)$ (spatial) matrix $\mathbf{S} = (s_{ij})$, whose element s_{ij} represents the (Euclidean) distance between the features of the i-th unit and the j-th unit $(i, j = 1, \ldots, n)$.

The clustering procedure consists of the following steps: (1) modeling of the temporal dependence within each univariate series; (2) extraction of the cross-sectional dependence; (3) extraction of the spatial information; (4) construction of an appropriate dissimilarity matrix that glues temporal and spatial dependence; (5) selection of a dissimilarity-based clustering algorithm; (6) selection of the best partition and cluster validation. Now, while steps (5) and (6) are performed as in (7) by choosing a suitable agglomerative hierarchical clustering algorithm (for instance, linkage-based), here we focus on a modified version of the first four steps.

In particular, following a classical copula-based time series model (18), we assume that, for $i = 1, \ldots, n$, the i–th time series $(x_{ti})_{t=1,\ldots,T}$ is generated by the stochastic process

$$X_{ti} = \mu_i(\mathbf{Z}_{t-1}) + \sigma_i(\mathbf{Z}_{t-1})\varepsilon_{ti}, \tag{1}$$

where $\mu_i(\cdot)$ and $\sigma_i(\cdot)$ are the (time-varying) conditional mean and standard deviation, respectively, and $\mathbf{Z}_{t-1}$ depends on $\mathcal{F}_{t-1}$, the available information up to time $t-1$. The innovations ε_{ti} are distributed according to a marginal law $F_{ti} = F_i$, for every t, having mean zero and variance one, and such that, for every t, the joint distribution function of $(\varepsilon_{t1}, \ldots, \varepsilon_{tn})$ can be expressed in the form $C(F_1, \ldots, F_n)$ for some copula C.

Here, we assume that C is an extreme-value (shortly, EV) copula in order to model dependence between all the pairs of time series. Notice that such an assumption is natural when the time series are related to observed maxima (see (12)). However, the proposed methodology can be adapted to the case when C may not be EV itself, but it belongs to the domain of attraction of an EV copula (see (7; 9)). We recall that any bivariate extreme-value copula C can be represented, for all $(u, v) \in [0,1]^2$, by

$$C(u, v) = uv^{A(\ln(v)/\ln(uv))}, \tag{2}$$

for a convex function $A\colon [0,1] \to [1/2, 1]$, called *dependence function*. In particular, the upper tail dependence coefficient of C is expressed as

$$\lambda_U(C) = 2(1 - A(1/2)). \tag{3}$$

The main idea of the proposed methodology is to model the spatial dependence using another EV copula D that can embed the information contained in the spatial matrix $\mathbf{S}$. Then, we combine D with the copula C defined above. In (6) a similar approach is considered, and the two copulas are merged via a convex combination. However, since the class $\mathcal{C}_{EV}$ of EV copulas is not closed under convex combinations, this latter approach cannot be replicated here. However, we could adopt the operation known as Khoudraji's device (see also (15)), given by

$$\varphi_\alpha\colon \mathcal{C}_{EV} \times \mathcal{C}_{EV} \to \mathcal{C}_{EV}, \quad \varphi_\alpha(C_1, C_2)(u, v) = C_1(u^{1-\alpha}, v^{1-\alpha})C_2(u^\alpha, v^\alpha) \tag{4}$$

for $\alpha \in [0,1]$, in order to combine two extreme-value copulas. It turns out that the dependence function associated with this operation is given by the convex combination of the dependence functions A_1 and A_2 associated with C_1 and C_2 (see also (11)). Therefore, the upper tail dependence coefficient of $\varphi_\alpha(C_1, C_2)$ is given by

$$\lambda_U(\varphi_\alpha(C_1, C_2)) = (1-\alpha)\lambda_U(C_1) + \alpha\lambda_U(C_2). \tag{5}$$

2.1 The clustering procedure

The steps to perform the proposed tail dependence clustering are detailed below.

Step 1: Data preprocessing. Before applying the clustering algorithm, it is necessary to disentangle the dependence from the marginal effects. To this end, we proceed as follows:

(i) In order to remove serial dependence, trend or seasonal cycles from each time series, we fit a model of type (1) (e.g. ARIMA, ARMA-GARCH, etc.) to each univariate time series. The model selection can be carried out via classical criteria, such as AIC and BIC.

(ii) The estimated standardized residuals extracted from the previous step, $(\widehat{\varepsilon}_{ti})_t$, are hence transformed into the pseudo-observations, $z_{ti} = F_i(\widehat{\varepsilon}_{ti})$, where F_i may be estimated from a parametric model (Gaussian, Student t, etc.) or by using the empirical distribution function.

As a result, $(z_{t1}, \ldots, z_{tn})_{t=1,\ldots,T}$ contains the information about the link (i.e. the copula) among the time series under consideration (see, e.g., (19)) and can be used for estimating the associated tail dependence.

Step 2: Extracting the cross-sectional dependence. For each pair of time series i and i', with $i, i' \in \{1, \ldots, n\}$, the pseudo-observations are used to estimate the upper tail dependence coefficient of the extreme-value copula $C_{ii'}$ as in Eq.(3). To this aim, the CFG estimator of the related dependence function $A_{ii'}$ as described in (13) is adopted.

Step 3: Extracting the spatial information. With respec t to the spatial information, our aim is to determine a copula $D_{ii'}$ that may represent the spatial distance between units i and i' and that depends on $\mathbf{S} = (s_{ij})$. To this end, we suggest to consider the EV copula

$$D_{ii'}(u,v) = \Pi(u^{\beta_{ii'}}, v^{\beta_{ii'}}) M(u^{1-\beta_{ii'}}, v^{1-\beta_{ii'}}) \tag{6}$$

where $\beta_{ii'} = \dfrac{s_{ii'}}{\max_{k,k'} s_{kk'}}$, for all $k, k' \in \{1, \ldots, n\}$. Note that the copula in (6) is the geometric mean of the copula $\Pi(u,v) = uv$, which describes independence, and the comonotonic copula $M(u,v) = \min(u,v)$. Thus, $\beta_{ii'} = 0$ is associated with maximal dependence, while $\beta_{ii'} = 1$ is associated with independence. The dependence function associated with $D_{ii'}$ is given, for every $s \in [0,1]$, by

$$A(s) = \begin{cases} 1 - (1-\beta_{ii'})s, & 0 \le s \le 1/2, \\ 1 - (1-\beta_{ii'})(1-s), & 1/2 \le s \le 1. \end{cases}$$

From Eq.(3) the related upper tail dependence coefficient is $\lambda_U(D_{ii'}) = 1 - \beta_{ii'}$.

Step 4: Define the dissimilarity matrix. The dissimilarity between with units i and i' is obtained by merging the two copulas $C_{ii'}$ and $D_{ii'}$ in a suitable way. Then, from the resulting copula, we will extract the associated tail dependence coefficient. For every i, i' and every $\alpha \in [0,1]$, the dissimilarity $\Delta^\alpha_{ii'}$ of the i-th and i'-th time series can be defined as a function that takes value 0 if both temporal and spatial copula coincides with the comonotonic copula M. A natural choice consists of considering the operation defined in Eq.(4) and, hence, make a suitable transformation of the coefficient in Eq.(5):

$$\begin{aligned} \Delta^\alpha_{ii'} &= -\ln(\lambda_U(\varphi_\alpha(C_{ii'}, D_{ii'}))) \\ &= -\ln((1-\alpha)\lambda_U(C_{ii'}) + \alpha(1-\beta_{ii'})). \end{aligned}$$

Table 1: Geographical coordinates and elevation (m) of the locations in the data set

	Station	Lat	Lon	Elev
1	Trieste	45.65	13.75	1
2	Sgonico	45.74	13.74	268
3	Fossalon	45.71	13.46	0
4	Gradisca	45.89	13.48	29
5	Capriva	45.96	13.51	85
6	Cervignano	45.85	13.34	8
7	Palazzolo	45.81	13.05	5
8	Talmassons	45.88	13.16	16
9	Udine	46.04	13.23	91
10	Fagagna	46.10	13.07	148
11	Sanvito	45.90	12.81	21
12	Pordenone	45.95	12.68	23
13	Vivaro	46.08	12.77	142
14	Brugnera	45.92	12.54	22
15	Enemonzo	46.41	12.86	438

Notice that $\Delta^{\alpha}_{ii'} = +\infty$ when both temporal and spatial copula describes independence. The dissimilarity matrix $\Delta^{\alpha} = (\Delta^{\alpha}_{ii'})$ can be used as an input for a dissimilarity-based clustering algorithm. In the following, we will illustrate the case of agglomerative hierarchical clustering methods, whose properties have been formalized in a copula framework in (10).

3. Illustration

We used accumulated daily precipitation height measurements (in mm) from 15 sites in the Italian Region Friuli Venezia Giulia (see Table 1). The data was acquired through the Regional Meteorological Service Arpa FVG (https://www.arpa.fvg.it/). The analyzed data covers the period January 2002 – December 2021. From these time series, rainfall monthly maxima were computed, resulting in a data set with $n = 15$ time series and $T = 240$ observations (see Fig. 1).

From the series of maxima, we proceed into two steps. First, we remove the seasonality by fitting a seasonal ARIMA model of seasonal order $(1, 0, 1)$ to each time series. Second, we extract the residuals and transform them into pseudo-observations in order to estimate the dependence structure among the involved time series. The dissimilarity matrix Δ^{α} is derived according to the procedure described in Sect. 2.1. Fig. 2 displays the final clustering solutions for the case $\alpha = 0$ (Fig. 2-left), where only the copula between the time series is considered, and $\alpha = 0.3$ (Fig. 2-right) where the spatial copula is also present.

The effect of considering the spatial information is evident from the different allocation of the units in the final groups since the algorithm with α tends to favor the aggregation of stations with similar elevation in the same geographical area. In general, from a practical side, we notice that the proposed method imposes only a soft constraint on the clustering procedure without however reinforcing the spatial contiguity between resulting clusters.

Abstract

The focus on innovation has increased over the past few years due to its established role as an engine of economic growth, as well as its rising contribution in fostering sustainable development. By using the number of patent applications to measure innovation activity, the paper identifies a set of variables influencing innovation and quantifies their spatial spillover effects within Italian provinces in the period from 2010 to 2017. Panel data models are extended with spatial data estimation techniques to assess the innovation patterns over time under the assumption of global spillover effects. As a result of the study, a wide range of factors contributes to local innovation capacity, from education levels to institutional characteristics, from economic resources to productive structure, as well as the externalities associated with agglomeration economies.

Keywords: local innovation, spatial panel, spillover effects, sustainable development

1. Introduction

The topic of innovation is increasingly debated worldwide, as it is one of the key engines for economic growth and competitiveness (Huggins and Thompson, 2015; Capello and Nijkamp 2009). Scholars have discussed innovation from different perspectives, given the phenomenon's multifaceted nature and its effect on the many dimensions of a country's development. Supporting innovation is one of the goals of the 2030 Agenda for Sustainable Development Goals (SDGs), adopted by the United Nations in 2015. Goal 9 stresses the crucial role of resilient infrastructure, inclusive and sustainable industrialisation, and innovation in achieving economic development, creating job opportunities, and fostering sustainable growth. Therefore, innovation plays a crucial role not only in promoting growth but also in sustainable development since it is the factor through which organisations, industries, communities, regions, and countries can implement innovative multidisciplinary approaches to solve the current sustainability challenges (Silvestre, 2015a). To improve sustainability performance, processes, products, and management approaches need to be adapted and innovated. The literature recognises the prominent role of innovation-focused approaches in addressing the topic of sustainable development (Silvestre, 2015b). Traditionally, firms have considered sustainability as a potential obstacle to their growth and competitiveness (Andersen, 2004). Nowadays, consumers' environmental awareness as well as social and government pressure on companies to reduce their environmental impact are increasing (Bocken et al., 2011). In this regard, companies steadily direct their innovation process from a sustainable perspective. As a result, innovation and sustainability in the broadest sense have become increasingly intertwined, so much so that they feed off each other.

Based on the above, this paper aims to assess and quantify the spatial direct and spillover effects of several determinants of innovation processes in Italian provinces.

Our approach to identifying a suitable statistical model for analysing innovation patterns is based on the well-established assumption that innovation is a spatially embedded phenomenon characterised by global spillovers (Furková, 2019; Paci et al., 2014). Further, it results from a series of processes and investments that occur over time and which take time to manifest into innovations (Capello and Lenzi, 2018). This implies that the double dimension of the phenomenon, both spatial and temporal, cannot be neglected, along with the control of all time-invariant and time-specific effects. In this regard, panel

data models are extended to account for spatial interactions between units by estimating the panel spatial Durbin model extended with spatial and time-period specific effects.

It is necessary to delve into the drivers of innovation to provide private actors and governments with information on the key levers to be forced to foster the innovation process from a sustainable growth perspective. Several authors have attempted to explain innovation and its drivers in the existing literature, mainly focusing on the role of (i) agglomeration economies within Jacob and Marshall's theory of externalities (De Groot et al., 2016) (ii) investments in R&D and human capital endowments based on the regional knowledge production function (RKPF) theoretical approach (Aronica et al., 2022; Paci et al., 2014). The present study proposes a contribution to the literature by investigating whether Jacob's or Marshall's externalities prevail in stimulating innovation in the Italian provinces, jointly considering the spatial and temporal dimensions. Furthermore, the contribution of socio-economic variables as well as their spatial lag to local innovative activity are assessed within the framework of global spillover effects.

The remainder of the article is structured as follows: Section 2 provides an overview of the reference framework; Section 3 discusses the statistical methodology and presents the data used in the analysis; finally, Section 4 concludes by presenting and discussing the empirical findings of the research.

2. Framework

A wide variety of factors contribute to a firm's innovativeness, such as internal resources or firm-specific characteristics, as well as the interaction between the firm and its external operating environment. A comprehensive analysis of innovative patterns cannot fail to consider the spatial scope of the agglomeration externalities. Economic theory has long recognised that agglomeration economies help determine and improve a territory's productive structure by fostering processes of spatial concentration of productive activity.

The theoretical framework proposed by Marshall (1890), Arrow (1962) and Romer (1986) considers agglomeration economies that result from the geographic proximity of firms in the same industry. These externalities, also referred to as MAR externalities by the Marshall-Arrow-Romer model, result from increased industrial specialisation within a specific region that facilitates knowledge sharing among firms and promotes innovativeness in the region. Geographic proximity and labour mobility facilitate the transmission of knowledge between spatially concentrated enterprises and among workers, constituting an engine of innovation development and productivity growth. Moreover, creating a local market for skilled workers advantages both firms and workers.

In opposition to MAR, Jacobs' (1969) theory argues that the spatial concentration of firms from different industries within a region promotes innovation. These economies of diversification, called Jacobs' externalities, are based on the idea that the diversity and variety of neighbouring firms promote information transfers and productivity growth through the exchange of complementary knowledge among heterogeneous agents. The literature, however, continues to be inconclusive in determining which of these two concepts is likely to create a more a more conducive environment for innovation in the long run.

Finally, the contribution of spatial interactions in determining innovation patterns cannot be neglected. The results of innovativeness in one unit can spread to other units, influencing their innovation performance, and geographic proximity allows for faster knowledge diffusion. Thus, innovation processes in a given area generate global spillover effects that trigger chain reactions in other spatial units (potentially in all of them). Spatial interactions are nowadays an intrinsic feature of an innovation-oriented economy where globalising contexts prompt a wide array of spatial spillovers. Consequently, local innovation patterns require spatial econometric techniques to be assessed and to address the spatial dependence (Silvestre and Ţîrcă, 2019; Cabrer-Borras and Serrano-Domingo, 2007).

3. Methodology and Data

The spatial dependence between panel units cannot be ignored, making it necessary to use appropriate estimation techniques to consider the data structure. With this in mind, we extend panel data models to spatial specification to follow the spatio-temporal patterns of innovation over time. Spatial interactions are modelled by taking into account the assumption of global spillover effects of innovativeness by estimating the Spatial Durbin Model (SDM). It is a spatial model configuration that entails global and flexible spillover effects (Elhorst and Halleck Vega, 2017; Firmino Costa da Silva et

al., 2017) obtained through the introduction of spatially lagged dependent and independent variables, which account for the endogenous interaction effect of the dependent variable and the exogenous interaction effects of the independent variables, respectively.

The SDM model extended with spatial specific and time-period specific effects is written as (Elhorst 2014):

$$Y_t = \rho W Y_t + \alpha \iota_N + X_t \beta + W X_t \theta + \mu + \xi_t \iota_N + \varepsilon_t$$
$$\varepsilon_{it} \backsim N(0, \sigma^2) \quad i.i.d$$
$$\mu = (\mu_1, \dots, \mu_N)^T \tag{1}$$

Where Y_t is an $N \times 1$ vector consisting of one observation on the patent intensity for each province during year t (i = 1, …, N; t = 1, ..., T); W is a non-negative and non-stochastic $N \times N$ spatial weights matrix whose generic element w_{ij} is set to 1 if the generic observations i and j share an administrative boundary of non-zero length or have borders that touch the first-order neighbours and to 0 otherwise; ι_N is the $N \times 1$ vector of ones associated with the constant term α; β is the $K \times 1$ vector of parameters for exogenous covariates X_t $(N \times K)$; ρ and θ are, respectively, the scalar for the endogenous interaction effect (WY) referred to as spatial autoregressive coefficient and the $K \times 1$ vector of parameters for the exogenous interaction effects in the regressors WX; μ is the vector of spatial specific fixed effects, while ξ_t denotes the time-period specific fixed effects; ε_t is the vector of independently and identically distributed error terms with zero mean and constant variance.

Spatial-specific effects control for all time-invariant variables whose omission could bias the estimates in a typical cross-sectional study, while time-period specific effects control for all time-specific effects whose omission could bias the estimates in a typical time–series study (Baltagi, 2008).

The presence of spatially lagged variables does not allow the parameters to be interpreted as in the usual framework of the linear model since the change in a covariate in a given spatial unit affects the dependent variable in that unit itself (direct effects) and the dependent variables in other units (spillover effects). Therefore, the direct and indirect effects of the SDM model associated with each independent variable will be presented and discussed, rather than the model parameter estimates.

The average direct effect associated with the generic k_{th} explanatory variable is given by the sum of the diagonal elements of the partial derivatives' matrix (2) of the expected value of the dependent variable, $E(Y_t)$, for that variable. Conversely, the sum of the off-diagonal elements represents the average spillover effect (LeSage and Pace, 2009).

$$\left[\frac{\partial E(Y_t)}{\partial X_{1k_t}} \dots \frac{\partial E(Y_t)}{\partial X_{Nk_t}}\right] = (I_N - \rho W)^{-1}(I_N \beta_k + W \theta_k) \tag{2}$$

The space-time analysis of innovation activities in the 107 Italian provinces is performed on panel data obtained from official sources over the time span from 2010 to 2017. Innovation output is proxied by patent intensity, defined as the number of patent applications to the European Patent Office (EPO) per million population. Despite some limitations associated with patent intensity as an indicator of innovation production, it is considered to provide a reliable measure of innovative territorial activity (Acs et al., 2002) and a direct measure of innovation output (Ascani et al., 2020). The potential explanatory variables of innovation activities (Table 1) are taken from Istat (Italian Institute of Statistics) and SIEPI (Italian Society of Economics and Industrial Policy)

Table 1: Explanatory variables of innovation activities

Label	Indicator	Description	Source
EDU	Higher education rate	Share of the population (aged 24-39) with tertiary-level education.	Istat
IQI	Institutional Quality Index	A measure of Italian institutional quality that ranges between 0 and 1. The closer the IQI is to 1, the higher the quality of the local institution. It is composed of five dimensions: Voice and accountability; Government effectiveness; Regulatory quality; Rule of law; Corruption.	SIEPI
R&D	Research and development.	Expenditure on R&D expressed as a percentage of gross domestic product (GDP).	Istat
GDP	Change in gross domestic product	Relative one-year-change in provincial GDP	Istat
NEET	Youth not in	Share of the young population (aged 15- 29) who are	Istat

	employment, education, or training	not in education, employment, or training to the population of the corresponding age group 15 to 29.	
REG	Registered companies	Share of registered enterprises minus terminated enterprises in the total number of enterprises in the commercial register.	Istat
SPE	Specialisation Index	An index of dissimilarity that takes the value 0 if the local unit has the same employment composition by sectors as its neighbouring units (no specialisation) and, on the contrary, the value 1 if all the employees of the local unit are concentrated in a single sector, unlike its neighbourhood.	Own elaboration of Istat data

4. Results and Conclusions

The assumed global spillover effects of innovation are confirmed by the results of the locally robust panel Lagrange Multiplier tests (Elhorst, 2014; Anselin et al., 1996) for spatial lag (LM_{lag}=12.836, p-value < 0.001) or spatial error (LM_{err}=0.006, p-value=0.940) dependence. The advisability of using the SDM model with fixed effects rather than random effects is tested through Hausman's robust test (Hausman, 1978) of spatial autocorrelation (Mutl and Pfaffermayr, 2011). Given the statistic test of 108.42 (p-value=0.000), the random effects model is inconsistent; thus, a fixed effect model was chosen.

Table 2 shows the estimated direct and indirect effects of the SDM model extended with spatial specific and time-period specific effects (eq. 1). According to a stepwise procedure, the covariates presented in Table 1 were properly selected, also checking for multicollinearity. The significant spatial autoregressive coefficient (ρ) confirms that interaction between local units contributes to shaping their innovative profiles. Therefore, spatial analysis techniques best modelling the innovation patterns since they capture ties within provincial networks that promote the transfer of knowledge, expertise, and experience (Baycan et al., 2017). All explanatory variables exert significant direct effects on local innovation and, most of them, potentially influence the innovativeness of all other provinces due to significant global spillover effects.

Table 2: Direct and Spillover Effects for SDM

The education rate (EDU), a proxy for the level of human capital, positively influences provincial innovativeness both directly and indirectly. Higher levels of education mean greater skills and knowledge that can be leveraged to generate innovation. Furthermore, education is considered to be both an "engine of innovation" and a "catalyst for sustainability" (Cai et al., 2020) due to the growing focus of universities and educational institutions on providing sustainability-oriented training. Supporting this result are those showing that better innovative performances are in the provinces characterised by a lower share of NEETs and a higher R&D expenditure. It is worth noting that better education systems can facilitate local development by widening access to education, human capital development and highly skilled labour (Raileanu Szeles and Simionescu, 2022). NEETs' lower access to the necessary knowledge and tools to foster innovation clearly inhibits innovative processes in contexts with a higher share of NEETs in the population. Additionally, researchers have shown that companies led by qualified

administrators holding a degree or post-graduate degree invest more in R&D (Wang et al., 2019), thereby increasing the percentage of patentable innovations (Gallié and Legros, 2012).

As regards the links between institutions and innovation, IQI positively affects provincial innovativeness, meaning that an increase in institutional quality leads, on average, to an increase in patent applications. Stable institutions and effective government regulations can profoundly influence and foster innovation activities. Conversely, political uncertainty, deficient rule of law, high corruption, and weak regulatory quality strongly undermine innovation probability and intensity (Bhattacharya et al., 2017; Rodríguez-Pose and Zhang, 2020). The spillover effects of IQI also significantly affect innovation patterns. That is, better local institutions in neighbouring areas foster innovation intensity in the area of interest. Therefore, stable local governments' cooperation and mutual influence can form a competitive environment capable of experimenting with sustainable and lasting innovation patterns (He and Tian, 2020).

The change in GDP expresses the economic growth of an area and as expected, positively affects the local propensity to innovate. It is assumed that wealthier provinces have more resources and economic incentives to invest in innovation to trigger innovation-oriented virtuous mechanisms (Gössling and Rutten, 2007). While the innovation propensity of a province is directly affected by its GDP, it is negatively impacted by the GDP of its neighbouring provinces. In light of this result, it appears that economic growth within one local unit may attract highly-skilled employees and draw resources, and potential investments away from neighbouring units, thereby hindering their ability to innovate. Entrepreneurs can recognise opportunities in more prosperous areas and move resources there that can support economic development and promote innovation (Feldman, 2014).

The net share of registered companies in each province (REG) is a driver of innovation both in the province of reference and the surrounding provinces. The proximity of a larger number of firms within the same province can produce positive externalities that facilitate the diffusion of knowledge and the development of local innovative activities (Glaeser et al., 1992). In particular, the specialisation index (SPE) has a negative impact on patenting propensity both directly and indirectly. Therefore, the more provinces have a different employment composition per sector than their neighbours (no specialisation - direct effect), and the more their neighbouring provinces have a different employment composition from each other (no specialisation - spillover effect), the more local innovativeness increases. Although the debate on whether a specialised or diversified productive structure fosters innovation remains open and requires further empirical evidence, the analysis shows that a diversified production structure within the same province can stimulate territorial innovation capacity. Therefore, a diversified environment promoting Jacobs' externalities can stimulate patenting activity as the output of innovation activities.

Abstract

In this work, we use three sources of mobile phone data to monitor traffic between three neighboring small areas - three "Aree di Censimento" (ACE) - in the Province of Brescia. Two indicators aimed at capturing crowding and traffic intensity are defined and their relationship is analyzed. Then, their impact on traffic flows is investigated. To this scope, traffic flows between pairs of ACEs are estimated by means of a vector autoregressive model with crowding and traffic intensity indicators as regressors. Moreover, seasonal components are included in the model as exogenous variables modeled as dynamic harmonic regressions. We find that our model always satisfactorily captures traffic flows, although the effect of the seasonal components varies considerably among the pairs.

Keywords: Vector AutoRegressive model, Dynamic harmonic regression, Traffic monitoring, Small area estimation, Miminization Drive Test.

1. Introduction

The Italian Government has recently set the goal of implementing an advanced digital system to monitor traffic in Italy as part of the National Recovery and Resilience Plan, which is part of the Next Generation EU Programme. Achieving this goal is of main relevance, as it would also constitute an important step toward the achievement of some of the United Nations Sustainable Development Goals (in particular goal 11, "Sustainable cities and communities"). To this aim, mobile phone data might play a key role. Indeed, they allow for capturing both the temporal and spatial dynamics that characterize social phenomena in urban areas. For this reason, they are increasingly adopted in the statistical literature for the analysis of people's presences and movements (e.g., 1; 2; 3; 4; 5; 6; 7; 11).

In this paper, we explore the potential of mobile phone data in traffic monitoring by analyzing their ability in forecasting flows between small areas. We consider three "Aree di CEnsimento" (ACE) (which correspond to small municipalities) in the Province of Brescia, namely Gussago, Castegnato, and Rodengo Saiano (see the left map of Figure 1), and estimate the traffic flows between pairs of them. To this aim, we refer to the Vector AutoRegressive model with eXogenous variables (VARX) with complex seasonality by (8), which we extend by introducing regressors defined over different types of mobile phone data. More in detail, we use "Origin-Destination" (OD) data to represent the number of people moving between the ACEs, the "Mobile Phone Density" (MPD) data to capture crowdings in the ACEs, and the "Minimization of Drive Test" (MDT) data to capture the level of traffic intensity. As we will

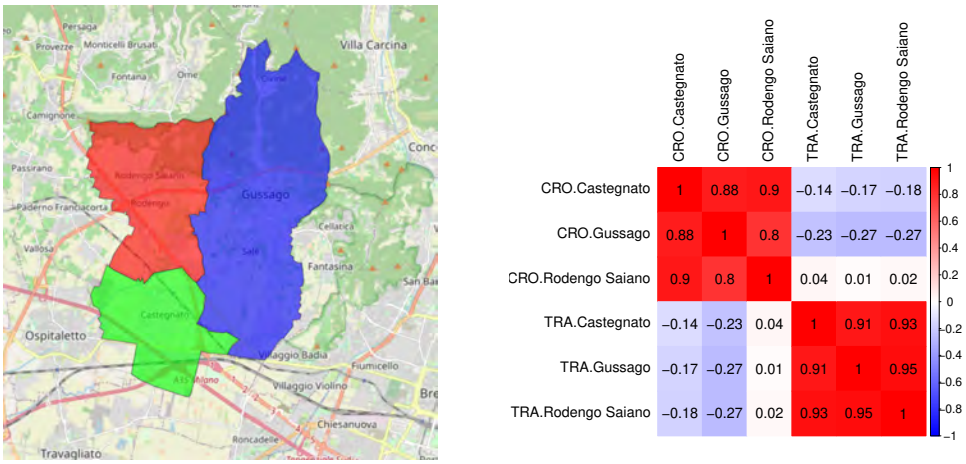

Figure 1: Left: Map of the three ACEs: Rodengo Saiano (red), Castegnato (green), and Gussago (blue). Right: Correlation plot of the indicators CRO and TRA.

discuss in detail in the next Section, the three sources of data present different temporal and spatial characteristics, which allow us to capture different important features of the phenomena, but also require proper preprocessing to be combined. Indeed, this constitutes a further contribution of this work to the literature.

The paper organizes as follows: Section 2 presents the data; Section 3 defines the model; Section 4 shows the results; Section 5 concludes.

2. Data

Three sources of data have been used for the analysis: the OD, MPD, and MDT data. All the data refer to users subscribed to TIM but have been provided to the DMS Statlab in the context of different projects. Specifically, the MPD data was provided by the Municipality of Brescia in the context of a territorial monitoring project between 2014 and 2016, while the OD and MDT data have been provided by Olivetti S.p.A. (www.olivetti.com) with the support of FasterNet S.r.l. (www.fasternet.it) for the MoSoRe Project 2020-2022. For this reason, the three datasets cover different periods of time: the MPD data refer to April 2014 - August 2016, the OD to September 2020 - August 2021, and the MDT to 5 days of November 2021 (namely Wednesday 10^{th}, Friday 19^{th}, Saturday 20^{th}, Sunday 21^{st}, and Monday 22^{nd}). To guarantee the comparability of the data, we restrict our attention to traffic flows between October 1^{st}, 2020 and March 31^{st}, 2021. Three variables based on mobile phone data have been included in the model: the traffic flows, the crowding indicator, and the traffic intensity indicator. The three variables are described in detail in the next paragraphs.

Traffic flows (y_{ijt}) The flows of people y_{ijt} are captured by the OD data, which report the number of SIM cards moving from ACE i to ACE j during the hour t. Unusual traffic flows characterize holidays. Therefore, according to (8), flows corresponding to holidays have been replaced with the corresponding values observed seven days before (the previous same day of the week). Substituted days are November 1^{st}, December 8^{th}, 25^{th}, and 26^{th}, and January 1^{st} and 6^{th}.

Crowding indicator (CRO_{id}) The crowding indicator CRO_{id} represents the average number of individuals in ACE i during the d-th hour of the day of the week (i. e., Monday at hour 00-01 AM, Monday at 01-02 AM, ...). For the construction of this indicator, the MPD data have been used. Specifically, the MPD database reports the average number of mobile phone SIM cards in a 150×150 squared meters cell of a pixel grid during a 15-minute interval. Following the approach in (9), we restricted our attention to human SIM cards (i.e., machine SIM cards have been excluded) and to observations in November to

guarantee comparability with the MDT data. Then, for each 15-minute interval t' the number of SIMs (MPD) in the i-th ACE has been computed by overlaying the pixel grid to a map of the administrative boundaries of the Province of Brescia and aggregating the portions of cells of the grid overlapping i. At last, observations have been averaged among hours and days of the week:

$$CRO_{id} = \sum_{t' \in d} \frac{1}{N_{t'}} \sum_{k} MPD_{kt'} \cdot \frac{Area(ACE_i \cap Cell_k)}{Area(Cell_k)} \tag{1}$$

where $N_{t'}$ is the number of 15-minute intervals of November 2020 corresponding to the d-th hour of the day of the week.

Traffic intensity indicator (TRA_{id}) The traffic intensity indicator TRA_{id} has been defined using the MDT data, which collects the number of signals (i.e., phone calls, text messages, internet browsing, or technical operations on the network) transmitted over the 3G/4G mobile network from/to terminal devices with GPS enabled. The signals are collected in 15-minute intervals and geo-referenced on a grid of pixels measuring 10 meters per side. MDT data only represents a sample of users and a mobile phone can produce multiple signals in 15 minutes. However, the high accuracy in georeferencing allows for estimation at the small area level. Following (9), we overlay the grid of pixels with a polygon-based street map and identify the cells of the grid that correspond to streets. For each ACE i and time interval t', we count the number of street cells from which at least one signal originated during a 15-minute interval. Then, values have been averaged in intervals of length 1 hour. Therefore, we obtained 24 observations per each of the 5 observed days of the week:

$$TRA_{id} = \frac{1}{4} \sum_{t' \in d} (\text{Number of Street Cells with MDT signals}_{it'} \in ACE_i) \tag{2}$$

Since the data at our disposal do not include Tuesday and Thursday, values for each hour of the two days are set equal to the corresponding average of Monday, Wednesday, and Friday.

The relationship between the indicators CRO_{id} and TRA_{id} has been investigated. As shown in the right plot of Figure 1, the two indicators do not appear correlated. However, high positive values of the Pearson correlation emerge between the values of each indicator observed in the three ACEs. This evidence is not particularly surprising, as traffic conditions in neighboring ACEs are likely to be related and so do crowdings.

3. The model

To model traffic flows between pairs of ACEs, we refer to the vector autoregressive model with dynamic harmonic components defined by (8), to which we apply two major modifications. First, (8) focuses on the analysis of one ACE and models its inflows from and outflows to other 38 ACEs as well as its internal flows. Since we are interested in flows between ACEs, we do not model the internal flows. Second, the original work only includes lags of traffic flows and some dummies as regressors; here, we also introduce the indicators CRO and TRA.

The estimated VARX model is:

$$\boldsymbol{y}_t = \boldsymbol{\nu} + \sum_{h} \boldsymbol{A}_h \boldsymbol{y}_{t-h} + \boldsymbol{B}\boldsymbol{x}_t + \boldsymbol{C}\boldsymbol{z}_t + \boldsymbol{\epsilon}_t \tag{3}$$

where $\boldsymbol{\nu}$ is a 2×1 vector of constants, $\boldsymbol{y}_t$ is a 2×1 vector containing the flows between and within ACEs i and j, namely y_{ijt}, y_{jit}, and $\boldsymbol{\epsilon}_t$ is a 2×1 vector of the error terms at time t. h indicates a set of lags of y_{ijt} and y_{jit}. For this parameter, we refer to the analyzes in (8) and include 3 daily and 4 weekly lags, therefore we have $h = (24, 48, 72, 168, 336, 504, 672)$. For each value of h there is a 2×2 matrix of coefficients $\boldsymbol{A}_h$ to be estimated. $\boldsymbol{x}_t$ is a vector of exogenous variables containing the crowding and

	R^2	
Model	with CRO, TRA	no CRO, TRA
Castegnato - Gussago	[0.939, 0.936]	[0.936, 0.933]
Rodengo - Gussago	[0.949, 0.948]	[0.942, 0.940]
Rodengo - Castegnato	[0.942, 0.941]	[0.939, 0.939]

Table 1: R^2 of the estimated models. Each row represents a pair of ACEs, column "with CRO, TRA" indicates the model in Eq.s (3)-(4), and column "no CRO, TRA" the model in (8). For each model and each pair of ACEs, two values of the R^2 are reported (one per each flow in Eq. 3, i.e., y_{ij} and y_{ji}).

traffic indicators, 6 daily dummies (from Tuesday to Sunday), and 5 monthly dummies (from November 2020 to March 2021). In order to avoid multicollinearity issues, the average values of the two indicators in the ACEs i and j at time d are considered, namely $\overline{CRO}_{ijd}$ and $\overline{TRA}_{ijd}$. $\boldsymbol{B}$ is the 2×13 matrix of coefficients associated to $\boldsymbol{x}_t$. At last, $\boldsymbol{z}_t$ is a $l \times 1$ vector of exogenous variables capturing seasonality, and $\boldsymbol{C}$ is the corresponding $2 \times l$ matrix of coefficients. The elements of the vector $\boldsymbol{C}\boldsymbol{z}_t$ are modeled using the dynamic harmonic regression components:

$$\beta_0^{(r)} + \sum_{k=1}^{K} \left[\alpha_k^{(r)} sin\left(\frac{2\pi kt}{m}\right) + \gamma_k^{(r)} cos\left(\frac{2\pi kt}{m}\right) \right], \qquad r = 1, 2 \tag{4}$$

where β_0 is a constant term, K is the optimal numbers of Fourier bases, α_k and γ_k are regression coefficients to be estimated, and m is the seasonal period. Note that β_0, α_k, and γ_k are allowed to assume different values in the two flows y_{ijt} and y_{jit}. Since we account for both daily and weekly seasonal components, we include two sets of Fourier basis, one considering $m = 24$ and one with $m = 168$.

At last, all the dependent variables in the model excluding dummies and Fourier bases have been transformed into z-scores such that we can compare the effect of the variables on different pairs of ACEs.

4. Results

The model defined in Eq.s (3)-(4) has been estimated on pairs of ACEs, namely: Gussago-Rondengo Saiano, Castegnato-Gussago, and Castegnato-Rodengo Saiano. The performance of the here proposed model has been evaluated with respect to the original model in (8) where regressors $\overline{CRO}$ and $\overline{TRA}$ were not included. In this respect, Table 1 shows the R^2 for the two equations of the VARX model (Eq. 3) (i.e., flows from the i-th to the j-th ACE and flows from j to i). It could be noticed that, for each combination of ACEs, the values of the R^2 just slightly increase when $\overline{CRO}$ and $\overline{TRA}$ are included. Although the improvement in the R^2 is not so high, the Akaike and Bayesian Information Criteria decrease when $\overline{CRO}$ and $\overline{TRA}$ are introduced, as shown in Table 2. Therefore, we find evidence that our model should be preferred, and that accounting for crowding and traffic intensity improves the estimates.

The estimated parameters are shown in Figure 2. In general, we find that the monthly and daily dummies are among the main determinants of traffic flows y_{ijt}. Along with the dummies, highly significative coefficients are also found for the indicator $\overline{TRA}$. The crowding indicator $\overline{CRO}$ also generally appears significant, although it plays a minor negative effect. As far as these variables are concerned, the estimated coefficients appear stable among the pairs of ACEs. By contrast, major differences among the three cases emerge in the lagged variables $\boldsymbol{y}_{t-h}$. Indeed, each pair appears affected by different lags h. However, many lagged variables are associated with coefficients close to 0 or large confidence intervals and are therefore not significant. This is particularly the case of the flows between Gussago and Rodengo Saiano.

	AIC		BIC	
Model	with CRO, TRA	no CRO, TRA	with CRO, TRA	no CRO, TRA
Castegnato - Gussago	-8.464	- 8.421	-8.306	- 8.269
Rodengo - Gussago	-8.443	-8.301	-8.285	-8.150
Rodengo - Castegnato	-7.797	-7.736	-7.640	-7.584

Table 2: Comparison of the performance of the model in Eq.s (3)-(4) (i.e., with regressors $\overline{CRO}$ and $\overline{TRA}$) and the model in (8) (i.e., without $\overline{CRO}$ and $\overline{TRA}$) estimated on the three pairs of ACEs. The second and third columns report the Akaike Information Criterion (AIC), and the last two columns the Bayesian Information Criterion (BIC).

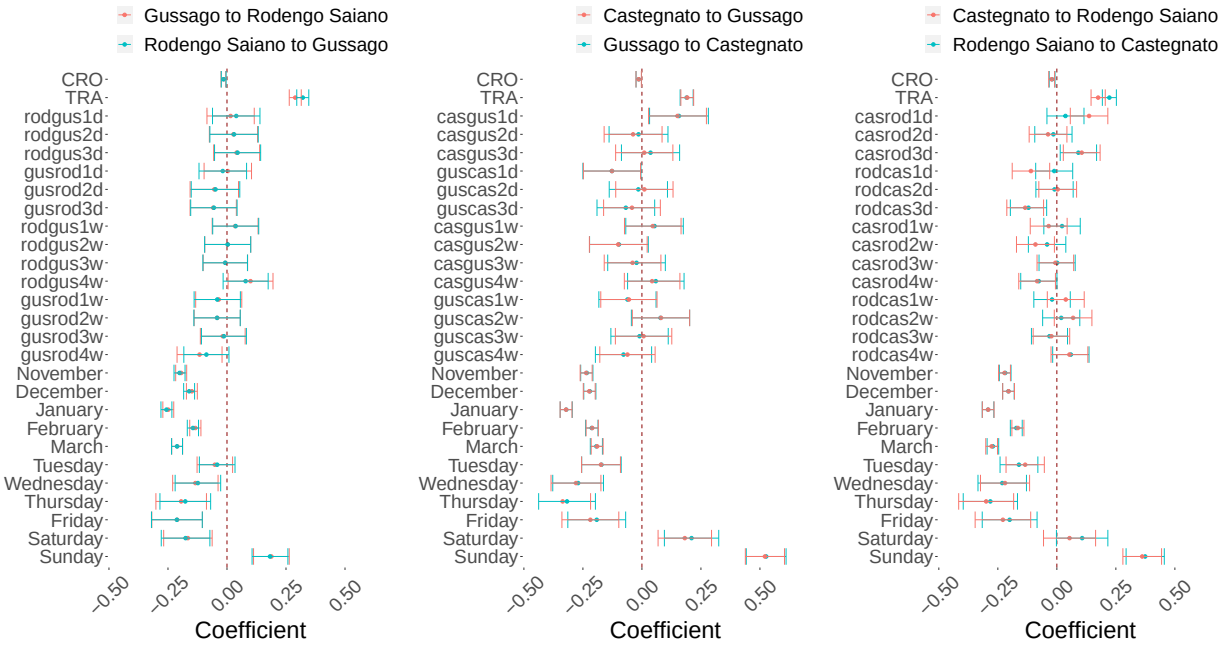

Figure 2: Estimated coefficients of the model in Eq.s (3)-(4). Each column represents one of the analyzed pairs of ACEs. For each pair, the variables included in the model are reported in this order: a $\overline{CRO}$ indicator, a $\overline{TRA}$ indicator, 14 lagged flows, 5 monthly dummies, and 6 daily dummies. Lagged variables are indicated by the three initial letters of the ACEs of origin and destination (e.g., rodgus = flows from Rodengo Saiano to Gussago) and two digits representing the lag (1d corresponds to $h = 24$, 2d to $h = 48$, 3d to $h = 72$, 1w to $h = 168$, 2w to $h = 336$, 3w to $h = 504$, 4w to $h = 672$). For each variable, the point represents the estimated coefficient, and the line reports the associated confidence interval.

5. Conclusion

A VARX model with complex seasonality and regressors representing crowding and traffic has been proposed for traffic flow estimation based on mobile phone data. The model has been applied to three ACEs in the Province of Brescia, with satisfactory results. In particular, we found that the two mobile phone data indicators of crowding and traffic intensity are among the main determinants of traffic flows. The seasonal component also appears to affect the flows, and its effect is captured by both monthly and daily dummies and the lagged flows. We find similar results for the three pairs of ACEs, although each pair appears affected by different lags of the flows. As a future development, the model forecasting ability will be analyzed using a blocked k-folds cross-validation along with the mean absolute percentage error and the hit rate.

Abstract

Synthetic control methods are commonly used in panel data settings to evaluate the effect of an intervention. In many of these cases, the treated and control time series correspond to spatial areas such as regions or neighborhoods. Synthetic control methods can be used to evaluate the effect that the treatment had in the treated area, but it is often unclear how far the treatment's effect propagates, as this approach ignores the spatial structure of the data, and can lead to efficiency loss in spatial settings. We propose to deal with these issues by developing a Bayesian spatial matrix completion framework that allows us to predict the missing potential outcomes in the different areas around the intervention point while accounting for the spatial structure of the data. Specifically, the missing time series in the absence of treatment for the treated areas of all sizes are imputed using a weighted average of control time series, where the weights are assumed to vary smoothly over space according to a Gaussian process.

Keywords: Causal inference, Spatial Econometrics, Synthetic Control Method, Gaussian Process, Potential Outcomes

1. Introduction

The Synthetic Control method (SCM hereinafter) is a widespread methodology to estimate causal effects in presence of a single treated unit and many control units, observed over time (2). With this method, the impact of an intervention is evaluated as the difference between the observed value of some primary outcome and its counterfactual value, imputed by using a weighted average of control units.

Evidence of interest in SCM is the flurry of methodological developments. Recently, the exploration of SCM alternatives heads toward Bayesian regression models. (6), (5), (7) and (8) use Bayesian methods for causal effects estimation, illustrating a simple and effective proposal for inference in SCM-like settings. Finally, recent work from (3) investigates the use of multitask Gaussian Processes for weights estimations. In Many fields where SCM is commonly used study outcomes which are measured in spatial areas such as municipalities, states or regions. (1) suggests these as the specific framework of application for SCM-like methods. In such contexts, it is common to see treatment assigned to a single area, and the focus being to estimate the treatment effect on this treated unit. Usually, scholars consider no second-round effects from the treatment, neither in terms of spillovers nor in terms of effect propagation. However, no previous work has addressed spatial treatment effect propagation explicitly within the scope of SCM. In practice, researchers often evaluate the extent to which treatment effects propagate through space by applying SCM to areas of different sizes around the treated location. In this work, we propose a Bayesian estimator for missing potential outcomes in presence of spatial correlation among treated units. We exploit a Gaussian process prior for the vertical regression coefficients that take into

account spatial correlation, encouraging regression coefficients across similar areas to be similar. We aim to exploit this spatial information to estimate counterfactual quantities that are still unbiased, but have improved properties in terms of mean bias and mean square error of the point estimate with respect to the separated SCM or vertical regression methods. We refer to this method as *Spatial Matrix Completion* or SMaC. Our motivating application is the impact evaluation arising from the construction of the first line of the Florentine tramway network. In particular, we wish to assess the infrastructural impact on the commercial vitality of the treated neighbourhood, measured as the number of stores located within some distance d from a tramway stop.

2. Causal Framework

Consider a space Ω that can be partitioned into N areas, indexed in $i \in \mathbf{N} = \{1, \ldots, i, \ldots, N\}$, such that $\bigcup_{i=1}^{N} \Omega^i = \Omega$ and $\Omega^i \cap \Omega^j = \emptyset$ for each couple $i, j \in \{1, \ldots, N\}$. In our study, we consider the natural partition of our sample space into the clusters representing the Florentine neighbourhoods. We observe treatment arising from some specific locations $\boldsymbol{\omega}_1 \in \Omega_1$. We can consider treatment locations as a point treatment (e.g.: pollution created by a power plant), a linear treatment or even a polygonal treatment. Let be $\boldsymbol{\omega}^1$ the set of treatment locations, in our application we consider $\boldsymbol{\omega}^1$ as the tramway stops located in the treated area. We also consider sets of locations $\boldsymbol{\omega}^i, i \in \{2, \ldots, N\}$ as sets of locations located in neighbourhoods located far away from the tramway line, in streets similar to the one that receives the treatment. We define our observation units as the areas around the treatment sites $\boldsymbol{\omega}$. Therefore, for each neighbourhood i we construct a set of buffers areas $\boldsymbol{A}_i = \{A_i^1, \ldots, A_i^d, \ldots A_i^H\}$ around the treatment locations $\boldsymbol{\omega}_i$, using the vector of distances $\mathbf{D} = (d_1, \ldots, d_h, \ldots, d_H)$ representing the distance of the $h-$th area from the treatment site. We sort units and distances such that $d_{h+1} \geq d_h \quad \forall h \in (1, 2, \ldots, H-1)$. Let also d denote a generic distance between a treated area and the treatment site. We repeatedly observe units over time, so we consider a panel data setting, with $H \times N$ areas observed for $T^0 = (1, \ldots, t_0 - 1)$ pre-treatment periods, and $T^1 = (t_0, \ldots, T)$ post-treatment periods. Let $Y_{i,t}^d$ be our primary outcome, the number of stores in neighbourhood i within distance d from the tramway stops in each time period $t \in T$. Let be $\boldsymbol{z} = \{z_i^d\}_{i \in N}^{d \in D} \quad z_i^d \in \{0, 1\}$ be a neighbourhood-level treatment for each area A_i^d considered. Thus following, units belonging to the same cluster i can be only treated or not-treated together. We consider two alternative situations for $\boldsymbol{z}$: $\boldsymbol{z}^1$ is the scenario in which each area $A_1^d \in \Omega_1$ receives the treatment, and no one outside. Instead, $\boldsymbol{z}^0$ represents the scenario in which no area results treated, in our scenario the situation in which the tramway was never built in Florence. We consider that areas $\boldsymbol{A}_1 = \{A_1^1, \ldots, A_1^d, \ldots, A_1^H\} \in \Omega_1$ will receive the treatment starting from the period t_0, and remain treated afterwards. In our application, we consider the treated space as the Legnaia neighbourhood in which the tramway stops are located, and t_0 =2006. Units located in other part of Florence will be considered non-treated units with $\boldsymbol{A}^0 = \{A_2^1, \ldots, A_i^d, \ldots, A_N^H\} \notin \Omega_1$. We adopt the potential outcome approach to causal inference (9). Under consistency assumption, for each unit A_i^d in each period t we define the following couple of potential outcomes: $Y_{i,t}^d(1) \equiv Y_{i,t}(\boldsymbol{z}^1) \quad$ as the potential outcome under $\boldsymbol{z}^1$ assignment and $Y_{i,t}^d(0) \equiv Y_{i,t}(\boldsymbol{z}^0) \quad$ as the potential outcome under $\boldsymbol{z}^0$ assignment. In contexts with cluster-level treatment allocation, scholars often invoke a partial interference assumption (10), which rules that interference may occur, but not within groups. Moreover, we exploit the *non-anticipating treatment* assumption to rule out anticipatory effects. We define the causal effect for the treated units as

$$\Delta_{1,t}^d = Y_{1,t}^d(\boldsymbol{z}^1) - Y_{1,t}^d(\boldsymbol{z}^0) \quad \forall t \in T^1, d \in \mathbf{D} \tag{1}$$

For the treated units we observe $Y_{1,t}^d = Y_{1,t}^d(\boldsymbol{z}^1)$ when $t \geq t_0$, so we need to impute the missing quantity $Y_{1,t}^d(\boldsymbol{z}^0)$. From the comparison of effects at different distances from the treatment site, we can get precious insights into the transmission of treatment effects through space. In general, we could expect decaying treatment effects up to some boundary of spatial treatment.

3. Estimation of causal effects

One might be interested in understanding the effect that treating the specific location ω_i had on the area comprised within a specific distance $d \in \mathbf{D}$ versus not treating it. To do this, they can use synthetic control methodology. Specifically, one can find $\beta_{0d} \in \mathbb{R}$ and $\boldsymbol{\beta}_d = (\beta_{2d}, \ldots, \beta_{Nd})^T \in \mathbb{R}^{N-1}$ such that:

$$\begin{pmatrix} \beta_{0d} \\ \boldsymbol{\beta}_d^T \end{pmatrix} = \underset{\boldsymbol{\beta}_d \in \mathbb{R}^N}{\operatorname{argmin}} \left\{ \sum_{t=1}^{t_0-1} \left(Y_{1,t}^d - (1 \ \mathbf{Y}_{i,t}^T)^T \boldsymbol{\beta}_d \right)^2 \right\}. \tag{2}$$

The synthetic control weights and vertical regression coefficients can be calculated separately for different choices of $d \in (d_1, d_H)$. For example, to find the synthetic control weights at distances $d_1 < d_2 < \cdots < d_H$, one could solve the minimization problem in 2 using a constrained optimization procedure, separately for each of these distances. Alternatively, the H different minimization problems could be stacked, and one could solve the combined minimization problem

$$\begin{pmatrix} \beta_{0d_1} \\ \boldsymbol{\beta}_{d_H}^T \\ \beta_{0d_2} \\ \boldsymbol{\beta}_{d_2}^T \\ \vdots \\ \beta_{0d_H} \\ \boldsymbol{\beta}_{d_H}^T \end{pmatrix} = \underset{\boldsymbol{\beta}_0, \boldsymbol{\beta}_2, \ldots, \boldsymbol{\beta}_N \in \mathbb{R}^N}{\operatorname{argmin}} \left\{ \sum_{d=1}^{H} \sum_{t=1}^{T_0-1} \left(Y_{1,t}^d - (1 \ \mathbf{Y}_{i.t}^T)^T \boldsymbol{\beta}_i \right)^2 \right\} \tag{3}$$

which will return the exact same solutions as solving 2 separately for each distance. Thus we can obtain weights that minimise the pre-treatment distance between treated unit and the synthetic control, but ignore the spatial structure of data.

Exploting the spatial structure of data, we introduce the Bayesian framework we will use to impute the missing outcome $Y_{1,t}^d(\boldsymbol{z}^0)$. Building on the vertical regression idea (2, (4)) we will propose a matrix completion algorithm that smooths regression coefficient values through contiguous treated units.

In order to consider the spatial structures of the observed treated units, yet being flexible in the parameter estimation, we follow a Bayesian regression approach to solve the optimization problem in 3, using Gaussian processes as priors for control unit coefficients. In our setting, Gaussian processes can be particularly useful, as we could exploit the spatial information in our data for the specification of regression coefficients. We consider β varying smoothly through space, in particular, the vector of coefficients β^d will be more similar for physically close units. We specify such structure by using a Gaussian process prior for β such that

$$\boldsymbol{\beta}_i(\mathbf{D}) \sim \mathcal{GP}\left(\mathbf{0}, \mathcal{K}_{\alpha_i,\rho_i}(\mathbf{D})\right)$$

with $\mathcal{K}_{\alpha_i,\rho_i}(\mathbf{D})$ as a quadratic exponential smoothing kernel with parameter ρ_i. Thus, the (p, q) entry of $\mathcal{K}_{\alpha_i,\rho_i}(\mathbf{D})$ is

$$[\mathcal{K}_{\alpha_i,\rho_i}(\mathbf{D})]_{pq} = \alpha_i \exp\left\{ -\frac{(d_p - d_q)^2}{2\rho_i^2} \right\}$$

As stated above, other kernel specifications are possible, in order to consider different correlation structures between the treated units. To solve the pooled regression problem in 3, we specify the total vector of coefficients $\boldsymbol{\beta} = (\boldsymbol{\beta}_2, \ldots, \boldsymbol{\beta}_i, \ldots, \boldsymbol{\beta}_N)$ with $\boldsymbol{\beta} \sim \mathcal{MVN}(0, \Sigma)$, where Σ is an appropriate block covariance matrix for the pooled coefficient estimation for multiple treated units. With $\mathcal{K}_{\alpha_i,\rho_i}(\mathbf{D})$ on the

block diagonal. We define the Bayesian regression model as

$$\begin{aligned}
\mathbf{Y} &\sim \mathcal{N}(\beta^T \mathbf{X}, \sigma_y \mathbf{I}) \\
\beta_i &\sim \mathcal{GP}(\mathbf{0}, \mathcal{K}_{\alpha_i, \rho_i}(\mathbf{D})) \\
\alpha_i &\sim \Gamma^{-1}(50, 5) \\
\rho_i &\sim \Gamma^{-1}(5, 5) \\
\sigma_y &\sim \Gamma^{-1}(5, 5)
\end{aligned}$$

This framework has simple yet powerful relapses. In context with spatially correlated units, Gaussian process priors can improve the point estimate quality both in terms of bias and in terms of efficiency. Moreover, from the posterior distribution of $\beta_{\mathbf{i}}$ we can derive the smoothed path of the coefficient for some control unit i across the treated units $d \in \mathbf{D}$. Lastly, we can easily derive credibility intervals for the posterior distribution of the causal effect, retrieving it from the posterior distribution of β_i.

4. Estimating the effect of the Florentine tramway construction

Figure 1 show the results of our computation. Our results show that the tramway has provoked generally an increase in the commercial vitality of the area considered. These results are particularly significant for the areas closer to the tramway stops, as we find significant average treatment effects for the areas within 50 and 100 meters of the treatment sites. The positive, yet non-statistically significant effects are present for the outer areas, from 150 to 400 meters away from the tramway stops. Worksites have not extensively damaged the commercial environment of the treated area. We can note a significant and negative effect for the area within 100 meters during the period 2006-2010. That time span was the construction period of the tramway, and thus we could expect worse outcomes for areas close to the construction site. However, the number of stores steadily recovered in 2010, the inauguration year, and the overall effect, even for this particularly affected area, is still positive. For this purpose, it is worth noting that in the closer area to the treatment site, the positive effect is present since the start of the construction period, some retailers anticipate their competitors by locating the shops in the most served areas even before the start of tramway operations. The effect on the outer bands is similar to the ones found for inner areas. In particular, we notice that worksites has not affected the commercial environment of the outer areas, while the tramway has improved the accessibility of the area, leading to an increase in the number of shops present. The estimated causal effect has a growing tendency, especially for the outer areas, that exhibits statistically significant effects in the last observational periods. Concluding, in this work we propose a framework for matrix completion with spatial data, an open challenge in policy evaluation literature. We provide convincing results for our motivating application, showing the spatial diffusion of the causal effect. Simulation results, not provided here, confirms the good properties of the proposed estimation framework.

The impact of traffic flow and road signs on road accidents: an approach based on spatiotemporal point pattern analysis on linear networks

Andrea Gilardi[a] and Riccardo Borgoni[a]

andrea.gilardi@unimib.it, riccardo.borgoni@unimib.it

Abstract

Road accidents represent a concern for modern societies, especially in poor and developing countries. In this paper, we develop a road safety model assuming that the car crashes recorded in Milan (Italy) during 2019 can be appropriately modelled as a realisation of a spatio-temporal point process on a linear network. We adopt a separable first-order intensity function with spatial and temporal components. The temporal dimension is estimated semi-parametrically using an additive Poisson regression model. The spatial dimension is estimated semi-parametrically considering a b-spline transformation of two potentially relevant space-varying covariates, namely the traffic flows and the distance to the closest road sign. This approach permits us to analyse traffic accidents at a very granular spatial scale, hence avoiding potential biases due to data aggregation.

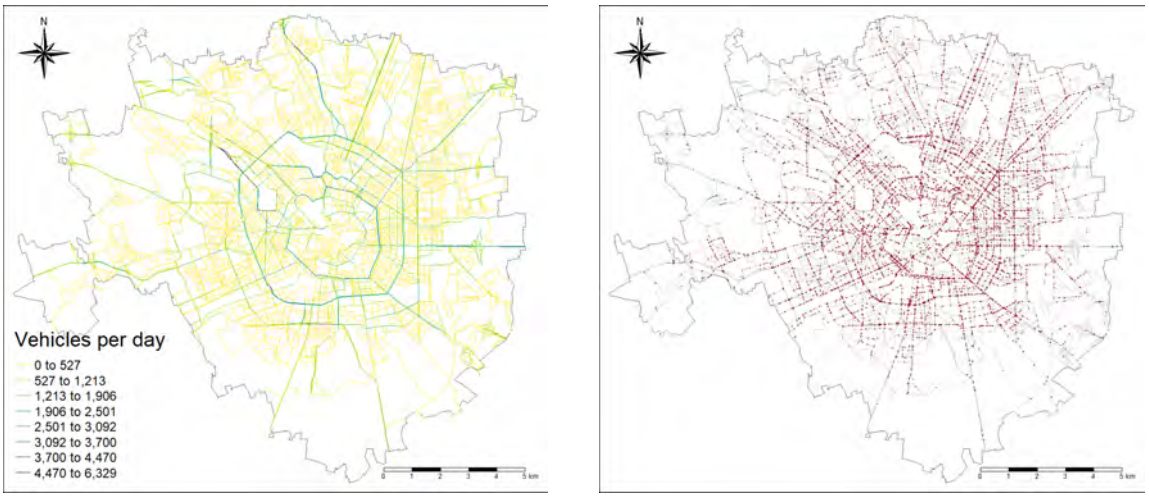
Keywords: Car crashes, Linear network, Poisson process

1. Introduction

According to the World Health Organisation, car crashes are responsible for more than 1 million casualties each year, representing "the leading cause of death for children and young adults aged 5-29 years" (7). The statistics highlight that the burden is disproportionally borne by vulnerable road users (such as cyclists or pedestrians) and that these problems are particularly relevant in low- and middle-income countries. Therefore, road injuries were named "neglected and silent epidemic", demanding evidence-based interventions and innovative approaches to understand how to reduce the huge annual death toll and establish its determinants.

Car accidents represent a typical example of a point pattern occurring on a linear network, i.e. a set of linear features corresponding to the street segments of a road network. In the last years, we observed a surge of interest in the statistical analysis of such processes, which typically exhibit several complexities due to the restricted spatial domain and the geometrical complexity of the network. The first approaches were introduced in a purely spatial context, mainly focusing on non-parametric techniques for estimating the intensity function (8). More recently, a few authors focused on defining a parametric model for the first-order intensity function that takes into account a set of spatially-varying covariates (3). Following their work, this paper proposes a spatio-temporal semi-parametric Poisson model to analyse the car crashes that occurred in the road network of Milan (Italy) during 2019, relating the intensity function with two variables representing traffic flows and (shortest-path) distances to road signs.

The rest of the article is structured as follows. The car crashes database and the relevant covariates are presented in Section 2. The statistical model is introduced in Section 3, whereas the results are summarised in Section 4, which ends the paper.



(a) (b)

Figure 1: (a) Choropleth map displaying the estimates of daily traffic volumes at the street segment level in the city of Milan. (b) Location of all car crashes that occurred in 2019 and required an ambulance intervention.

2. Data and covariate construction

The datasets analysed in this paper come from three different geo-referenced sources that were combined together into a unique object suitable for estimating the statistical model detailed below. In the remaining part of this section, we briefly introduce each provider and describe the procedures adopted to pre-process the data.

Traffic flows: The street network and the GPS counts, representing respectively the spatial domain and one of the covariates included in our model, were obtained from TomTom Move service (https://move.tomtom.com/). The network is composed of 33244 geo-referenced segments that are associated with traffic volume estimates obtained from mobile devices connected to cars and anonymous GPS-equipped smartphones. Traffic volumes on Milan's road network are depicted in Figure 1a. As we can see, the traffic estimates are provided with a very granular spatial coverage.

Car crashes data: We considered all car crashes that occurred in the city of Milan (IT) from 2019-01-01 to 2019-12-13 and required an ambulance intervention. The raw dataset was provided by the regional Emergency Medical System agency and it was processed by applying the following operations. First, we removed all records with missing spatial or temporal coordinates. Then, we excluded the events farther than 30 metres from the closest segment in the linear network since they are assumed to occur in streets not included in our database. The final sample included 8586 road accidents that were projected into the network. Accident locations are depicted in Figure 1b.

Road signs: The information regarding the road signs in the city of Milan was taken from Open Street Map (9). Geographical coordinates of traffic lights, pedestrian crossings and speed bumps were retrieved from the OSM servers and projected onto the spatial network. Similarly to the previous case, we adopted a threshold of 30m to decide which points must be excluded from our dataset. Eventually, we ended up with 21820 observations. The shortest path distance from each point in the network to the closest of these points has been calculated and included as a covariate in the statistical model.

3. Spatio-temporal modelling of the road accidents point process

As already mentioned, we modelled the car crashes occurrences as a spatio-temporal point pattern on a linear network. Formally, a linear network L is defined as the union of a finite number of segments, say l_i, lying in a planar region S:

$$l_i = [\mathbf{u}_i, \mathbf{v}_i] = \{\mathbf{s} : \mathbf{s} = c\mathbf{u}_i + (1-c)\mathbf{v}_i;\ 0 \leq c \leq 1\},$$

where $\mathbf{u}_i$ and $\mathbf{v}_i$ denote the endpoints of l_i stored using an appropriate coordinate reference system. Let $\mathcal{T} = \{1, 2, \ldots, T\}$ be a discrete temporal dimension divided into intervals of, say, two hours. A spatio-temporal point pattern on L is a finite realisation of a stochastic process on $L \times \mathcal{T}$. In this paper, we assume that for each $t \in \mathcal{T}$, the observed events represent a realisation of a *non-homogeneous Poisson Process* (NHPP) with *intensity function* $\lambda_t(\boldsymbol{s})$ (1; 4).

Following a classical hypothesis in the literature of spatio-temporal point patterns (4), we further assume the separability of the intensity function

$$\lambda_t(\boldsymbol{s}) = \mu_t g(\boldsymbol{s}) \quad \text{for } t \in \mathcal{T} \text{ and } \boldsymbol{s} \in L, \tag{1}$$

where μ_t and $g(\boldsymbol{s})$ represent the temporal and spatial dimension of the process at time t, respectively. More precisely, if we denote by y_t the number of events at time t, under the NHPP assumption we have $y_t|\lambda_t \sim \text{Poisson}(\mu_t)$, implying that μ_t represents the *expected volume* of road crashes occurring all over the network at time t. Similarly, denoting by $\boldsymbol{s}_{t,i}$ the location of the ith, $\{\boldsymbol{s}_{t,i}\}|\lambda_t, y_t \overset{\text{iid}}{\sim} g(\boldsymbol{s})$, highlighting that $g(\boldsymbol{s})$ represents the (common) *spatial density function* of the road accidents. Hereinafter, we introduce two statistical models for μ_t and $g(\boldsymbol{s})$, respectively.

3.1 The temporal model

As mentioned above, μ_t represents the expected number of car crashes observed over the network during a two-hours interval t. Following the suggestions in (5), we modelled the bi-hourly counts using Poisson regression considering the hour of the day, the day of the week, and the week of the year as predictors. To incorporate smoothness into the model, Generalized Additive Models (GAMs) are used in the estimation process (10). GAMs extend Generalized Linear Models allowing for non-linear relationships between the response variable and the covariates.

Considering the previous assumptions, the (log-linear) Poisson additive regression model is given by

$$\log \mu_t = \beta_0 + \text{dow}_t + \text{dow}_t \times \beta_1(\text{hour}_t) + \beta_2(\text{week}_t), \tag{2}$$

where β_0 is the intercept, dow_t is a factor variable denoting the day of the week, hour_t represents the hour of the day (taking values from 0 to 23) while week_t represents the week of the year (taking values from 1 to 53). The terms $\beta_j(x),\ j = 1, 2$, represent spline transformations, i.e. $\beta_j(x) = \sum_{r=1}^{k_j} b_{jr}\gamma_{jr}(x)$, where $\gamma_{jr}(x), r = 1, \ldots, k_j$ are the basis functions and b_{jr} the unknown coefficients. In particular, a cyclic cubic regression spline is adopted since in our context it is appropriate to assume a smooth transition between the last hour of one day and the first hour of the next day as well as between the last week of one year and the first week of the next year.

3.2 The spatial model

The spatial component of the intensity function at location $\boldsymbol{s} \in L$, previously denoted by $g(\boldsymbol{s})$, is modelled semi-parametrically as a function of the two covariates described in Section 2: the traffic counts in the road segments (Z_1) and the shortest-path distance to a traffic sign (Z_2). The model of the spatial component reads

$$\log g(\boldsymbol{s}) = \alpha_0 + \alpha_1(\log Z_1(\boldsymbol{s})) + \alpha_2(Z_2(\boldsymbol{s})) \tag{3}$$

where α_0 is an intercept and $\alpha_j(x),\ j = 1, 2$ are spline transformations defined as before.

The parameters in Equation (3) were estimated using a likelihood-based approach. In general, the log-likelihood function for an NHPP on a linear network L writes as

$$\log L(\boldsymbol{\theta}) = \sum_{i=1}^{n} \log g(\boldsymbol{s}_i; \boldsymbol{\theta}) - \int_L g(\boldsymbol{s}; \boldsymbol{\theta}) \, \mathrm{d}_1 \boldsymbol{s} \tag{4}$$

where $n = \sum_{t \in \mathcal{T}} y_t$ represents the total number of points, $\boldsymbol{\theta}$ is the set of model parameters, and $\mathrm{d}_1 \boldsymbol{s}$ denotes integration with respect to arc-length measure (1). The MLE $\hat{\boldsymbol{\theta}}$ is typically not available in closed form since it depends on the form of $g(\boldsymbol{s}; \boldsymbol{\theta})$ and must be derived using numerical approximation techniques. In particular, in this paper, we employed a strategy named *Berman - Turner device*, originally developed for planar point patterns in (2) and recently extended to linear network data (1).

The first step of the aforementioned procedure involves approximating the integral in Equation (4) by a weighted sum over *quadrature points* $\{\tilde{\boldsymbol{s}}_j\}_{j=1}^m$ with weights $\{w_j\}_{j=1}^m$

$$\int_L g(\boldsymbol{s}; \boldsymbol{\theta}) \, \mathrm{d}_1(\boldsymbol{s}) \approx \sum_{j=1}^{m} w_j g(\tilde{\boldsymbol{s}}_j; \boldsymbol{\theta})$$

yielding to the following approximation for the log-likelihood function

$$\log L(\boldsymbol{\theta}) \approx \sum_{i=1}^{n} \log g(\boldsymbol{s}_i; \boldsymbol{\theta}) - \sum_{j=1}^{m} w_j g(\tilde{\boldsymbol{s}}_j; \boldsymbol{\theta}). \tag{5}$$

Then, the key part of the Berman-Turner device is observing that if the quadrature points $\{\tilde{\boldsymbol{s}}_j\}_{j=1}^m$ contain the n observed events, Equation (5) can be rewritten as

$$\log L(\boldsymbol{\theta}) \approx \sum_{j=1}^{m} \Big(Z_j \log g(\tilde{\boldsymbol{s}}_j; \boldsymbol{\theta}) - g(\tilde{\boldsymbol{s}}_j; \boldsymbol{\theta}) \Big) w_j \tag{6}$$

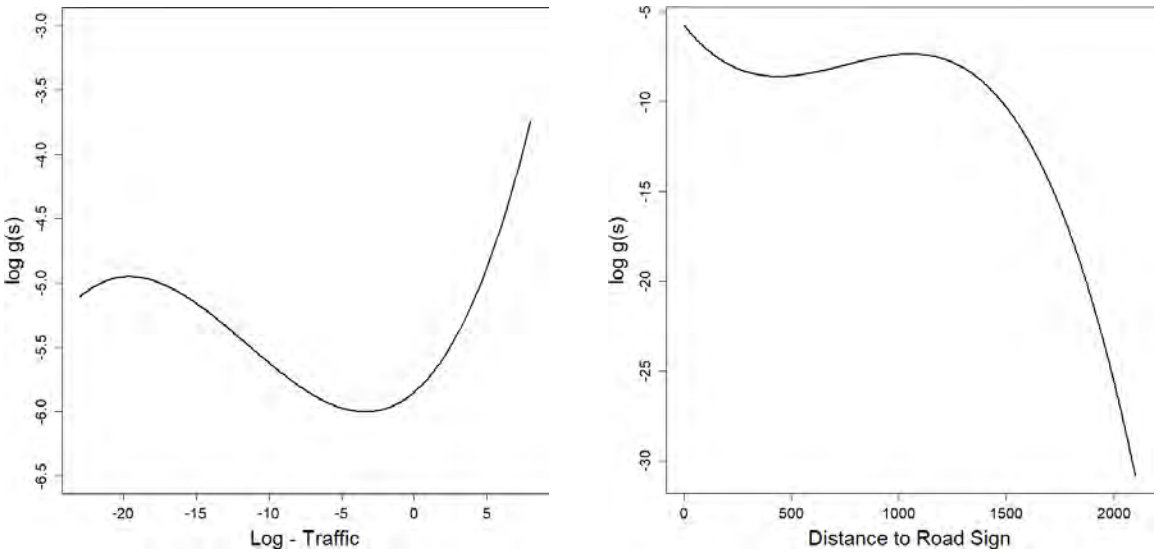
where $Z_j = I_j / w_j$ and I_j is an indicator function which is equal to 1 if $\tilde{\boldsymbol{s}}_j$ denotes an observed event (instead of a quadrature point) and 0 otherwise. Equation (6) represents the likelihood function of m independent Poisson random variables with mean $g(\tilde{\boldsymbol{s}}; \boldsymbol{\theta})$ and weight w_j, implying that $\hat{\boldsymbol{\theta}}$ can be derived using standard GLM tools.

4. Results and Conclusions

We can now present the results obtained after applying the methodology described in Section 3. to the accident data presented in Section 2.

Figure 2a and 2b display the effects on the spatial density $g(\boldsymbol{s})$ due to variations in traffic flows and distance to the closest road sign. For low traffic flow, the accident density tends to increase slightly. It can be argued that low traffic flows are typically found in residential streets where, despite mild vehicular traffic, accidents can be present due to intensive pedestrian and cyclist activities. When the traffic gets moderate, which is typical in medium-sized streets, this effect declines. Finally, the car crashes density increases substantially on traffic-intensive roads. Figure 2b shows the impact of the distance to the (closest) road sign. It clearly appears that being away from a pedestrian crossing, a traffic light or a speed bump has a protective effect against accidents with a striking decline when the distance gets larger than, say, 1-1.5km, which is typical in fast roads and highways.

The methodology proposed in this paper allows us to estimate the proneness of accidents in the road network of the city of Milan. More specifically, by combining the estimated version of model (2) and (3), we are able to calculate the estimate of the intensity function of the spatio-temporal point process at any desired location of the network and time of the day. Hence, after discretising the linear network by a fine pixel grid, intensity estimates can be computed efficiently at any grid location of the raster to produce a map that graphically displays the spatio-temporal dynamic.



(a) (b)

Figure 2: Covariates' effects obtained after applying a spline transformation. a) road traffic (log scale); b) distance to the closest road sign (metre).

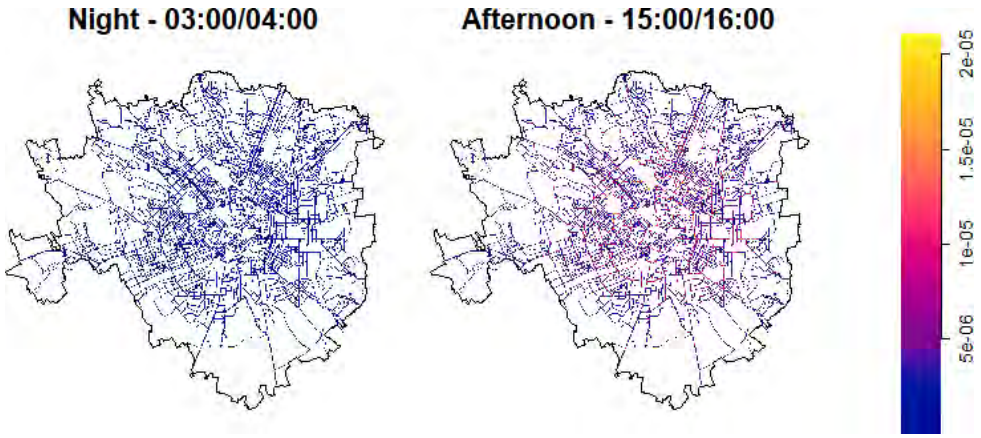


Figure 3: Choropleth maps showing the estimated intensity of events occurring in the street network of Milan for two particular time periods. The colour scale represents the expected number of car crashes occurring in a small linear neighbourhood around a point of the network.

Figure 3 represents the map obtained using this approach for two different temporal occasions. The values reported in the maps represent the expected number of car crashes occurring in a small linear neighbourhood around a point taken in the network.

We finally observed that our dataset does not include all those accidents that did not require medical intervention, hence the intensity function can be somewhat underestimated. However, these events are expected to be of lower severity, hence less crucial for a road safety program. In addition, we acknowledge that the separability assumption of our model is a bit simplistic since the spatial configuration of car crashes can, to some extent, change over time. This aspect has been considered by (6) in a similar context using a kernel-based non-parametric approach. Tackling this issue in a parametric or semi-parametric setting, however, is not an easy task and is material for future research.

Abstract

A new clustering model for skew-symmetric matrices is introduced to analyse flow data. This model aims to find clusters of objects that have a significant flow, interpreted as exchange intensity. The model analyses the within-clusters effects between objects and provides the directions of the flows within clusters. Formally, it is based on the decomposition of the data skew-symmetric matrix into within-cluster components, i.e. the skew-symmetric matrix is decomposed into a sum of diagonal block skew-symmetric matrices. The model is estimated in a least-squares sense through the SVD of the skew-symmetric matrices. An application to the international student mobility is discussed.

Keywords: Flow data, Skew-symmetry, Within-cluster effects

1. Motivating example and Introduction

In order to analyse the international mobility of students in the OECD countries, flow data models can be useful tools for identifying clusters of countries where international students come from and move to in order to enrol in different education programs abroad.

Studying abroad has become a key differentiating experience for university students, and international student mobility has received increasing policy attention in recent years. Studying abroad is an opportunity to access a high-quality education, acquiring skills that may not be taught in the country of origin and it is also seen as a way to broaden one's knowledge and improve language skills, especially English. For their countries of origin, mobile students could be seen as lost talent (the classic "brain drain"). However, they can contribute to knowledge improvement and technological upgrading in their origin country. Mobile students acquire knowledge that is often shared through direct personal interactions and can enable their origin country to integrate into global knowledge networks. Some research suggests that students abroad are a good predictor of future flows of scientists, providing evidence for the "brain circulation" effect. Student mobility appears to shape international scientific cooperation networks more profoundly than a common language or geographical or scientific proximity (3).

In this context, in order to analyse whether a country has more international students in incoming or outgoing mobility, it becomes useful to understand if there exist clusters of countries that exchange more mobile students with each other and above all it is important to provide the directions of such flows. To this end, in this work, we introduce a new model to identify clusters of countries that are similar in terms of flows within clusters and able to give information also on what are the directions within each cluster. Specifically, the model proposed here analyses the within-cluster effects of a skew-symmetric matrix describing the exchanges between objects within clusters. In order to estimate the model, singular value decompositions (SVD) are considered which are implemented in an Alternating

Least Squares algorithm. Furthermore, this model allows for a graphical interpretation of the results in terms of amounts and directions of the imbalances within clusters.

The rest of the work is organized as follows: in Section 2. the model is formalized, and in Section 3. an application to the flows of the international student mobility in tertiary education in the OECD founding countries is analysed by studying the number of students enrolled by country of origin and destination.

2. The Model

Let $\mathbf{K} = (k_{ij})$ be a $(N \times N)$ skew-symmetric matrix, i.e. $k_{ij} = -k_{ji}$, for all $i, j = 1, \ldots, N$ (for a review on methodologies for studying asymmetric and skew-symmetric data see (1)). Clustering models for fitting skew-symmetries have been proposed in (4) and (5) following different approaches to account for both within and between cluster effects.

Here, we introduce a clustering model that takes into account the within cluster effects and aims to cluster the skew-symmetric matrix $\mathbf{K}$ by considering a partition of the N objects into C disjoint clusters which can be identified by an $(N \times C)$ binary membership matrix $\mathbf{U} = (u_{ic})$ for $i = 1, \ldots N$ and $c = 1, \ldots, C$.

Given a partition $\mathbf{U}$, we are interested in modelling the imbalances within clusters as follows

$$\mathbf{K} = \mathbf{W} + \mathbf{E}, \tag{1}$$

where $\mathbf{W}$ is the $(N \times N)$ skew-symmetric diagonal block matrix of the imbalances *within* clusters.

The within matrix $\mathbf{W}$ can be decomposed as

$$\mathbf{W} = \sum_{c=1}^{C} \mathbf{W}^{(c)}, \tag{2}$$

where $\mathbf{W}^{(c)}$ is the $(N \times N)$ skew-symmetric matrix of the exchanges within cluster c. Any skew-symmetric matrix $\mathbf{W}^{(c)}$ can be approximated as

$$\mathbf{W}^{(c)} = \mathbf{v}_1^{(c)}\mathbf{v}_2^{(c)\prime} - \mathbf{v}_2^{(c)}\mathbf{v}_1^{(c)\prime} + \mathbf{E}_W^{(c)}, \qquad \text{for } c = 1, \ldots, C, \tag{3}$$

where, $\mathbf{v}_1^{(c)}$ and $\mathbf{v}_2^{(c)}$ are orthogonal vectors of size N, and $\mathbf{E}_W^{(c)}$ is the $(N \times N)$ residual matrix.

Therefore, model (1) can be written as

$$\mathbf{K} = \sum_{c=1}^{C} \left[\mathbf{v}_1^{(c)}\mathbf{v}_2^{(c)\prime} - \mathbf{v}_2^{(c)}\mathbf{v}_1^{(c)\prime}\right] + \mathbf{\Xi}, \tag{4}$$

subject to

$$u_{ic} \in \{0, 1\}, \quad \sum_{c=1}^{C} u_{ic} = 1, \text{ for } c = 1, \ldots, C, \quad i = 1, \ldots, N,$$

$$\mathbf{v}_1^{(c)\prime}\mathbf{v}_2^{(c)} = 0, \text{ for } c = 1, \ldots, C.$$

Model (4) is fitted in the least squares-sense thanks to the SVD of any within skew-symmetric matrix.

3. A case of study: the international student mobility flow in OECD countries

In this section, model (4) is fitted to study the flow of the enrolment of international students between countries. Specifically, the data can be downloaded from the website http://www.oecd.

org/education/education-at-a-glance/ and refer to the number of students enrolled in different education programs abroad by country of origin and destination in 2017 for the 20 founding countries of the OECD, namely, Austria, Belgium, Canada, Denmark, France, Germany, Greece, Iceland, Ireland, Italy, Luxembourg, Netherlands, Norway, Portugal, Spain, Sweden, Switzerland, Turkey, UK, USA, which represent around 84% of the international university student mobility flows within all OECD countries in 2017.

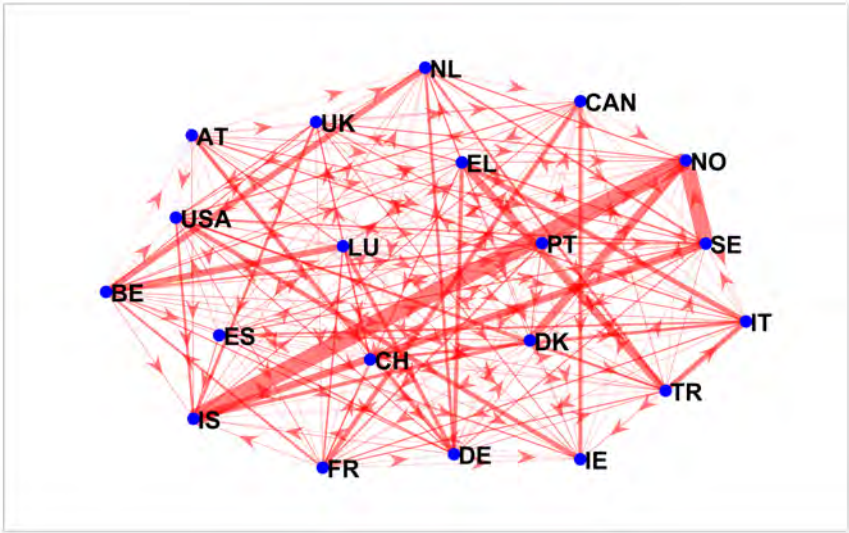

Figure 1: Directed graph of the skew-symmetric matrix **K** of the international student flows for the 20 founding countries of the OECD in 2017.

The original mobility data of the asymmetric origin/destination matrix **A** have been firstly pre-processed to incorporate the information on the amounts of the flows, and then transformed into a skew-symmetric matrix **K** as follows

$$A^*_{ij} = \frac{A_{ij} \sum_{i=1}^{20} \sum_{j=1}^{20} A_{ij}}{\sum_{i=1}^{20} A_{ij} \sum_{j=1}^{20} A_{ij}}, \qquad \text{for } i, j = 1, \ldots, 20,$$

$$K_{ij} = \frac{A^*_{ij} - A^*_{ji}}{2}, \qquad \text{for } i, j = 1, \ldots, 20.$$

Once computed matrix **K**, the clustering model (4) has been fitted. Matrix **K** is displayed in the graph in Fig.1 where some relations between countries are quite evident. In fact, it is possible to distinguish high mobility flows between some pairs of countries, such as Iceland-Norway or Turkey-Greece.

The proposed model (4) has been fitted by varying $C = 1, \ldots, 8$ and, from the loss function values, the model suggests to select 4 clusters of countries with a goodness-of-fit equal to 85%. The clustering results are described in Table 1 and the directions of the international student mobility within clusters of countries are represented in Fig.3.

Table 1: Clustering of the founding OECD countries.

CLUSTERS	**COUNTRIES**
C_1	Spain, Sweden, Island, Norway, UK, Denmark
C_2	Greece, Turkey, Switzerland, Italy
C_3	USA, Canada, Ireland, France
C_4	Netherlands, Germany, Belgium, Luxembourg, Austria, Portugal

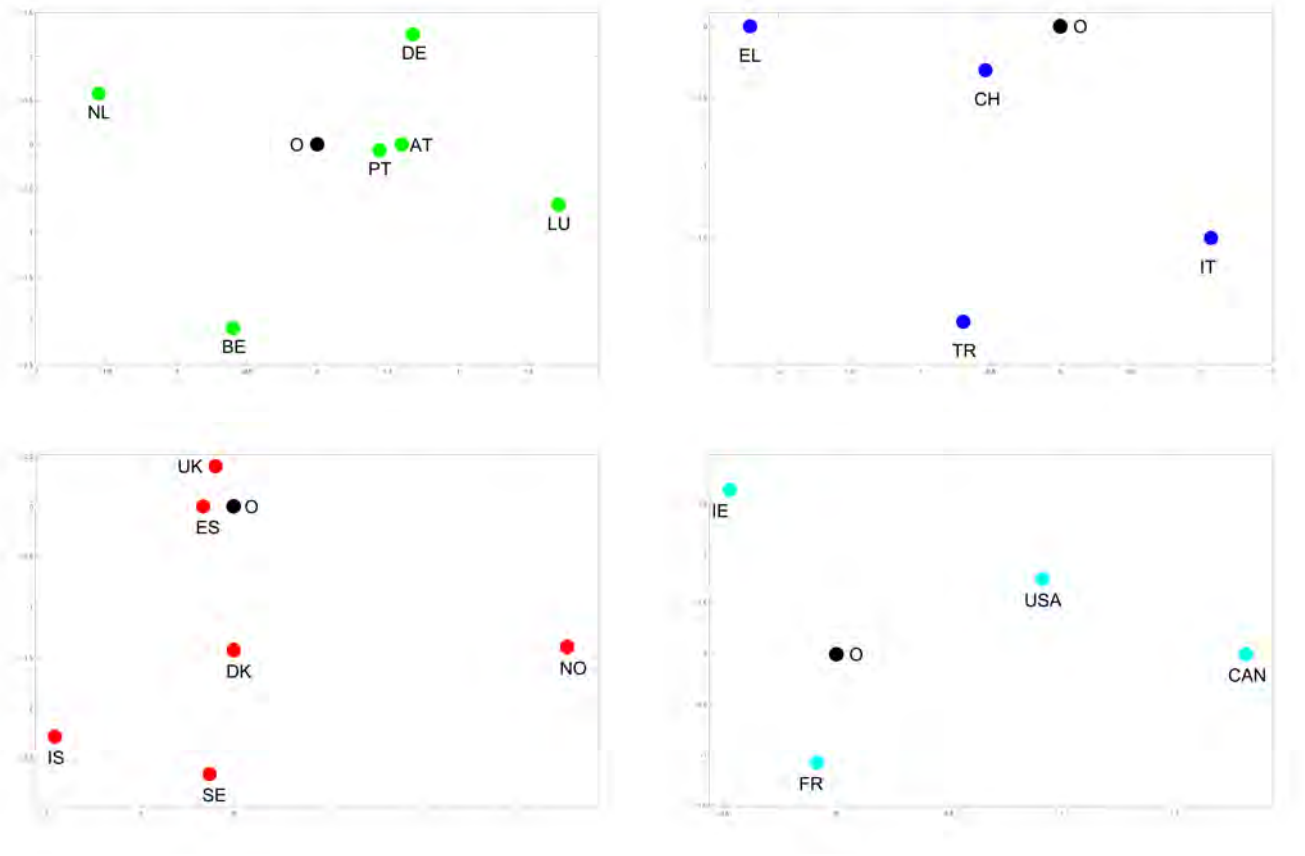

Figure 2: Scatter plot of the OECD countries. Colours identify countries in same clusters

One of the advantages of this model is the possibility to make a graphical representation and provide an interpretation in terms of directions and amounts of the skew-symmetries within clusters (2), (1). Therefore, in Fig.2 the positions of the countries can be interpreted in terms of areas: the areas of the triangles that all pairs of countries form with the origin O are approximatively proportional to the amounts of the skew-symmetries, i.e. to the imbalances between flows of international students between countries. Moreover, it is possible to give an interpretation in terms of directions: by convention, 1) a clockwise direction denotes a negative skew-symmetry, i.e. the destination country of the student flow; 2) an anticlockwise direction indicates a positive skew-symmetry, i.e. the country from which the student flow originates. Thus, according to the interpretation of the Gower diagram (2), from Fig.2 we can deduce the directions of the student mobility within each cluster of countries summarized in Fig.3. In particular, in Fig.2 we point out that Spain-UK, Portugal-Austria have small skew-symmetries because are positioned close to the origin: there is a low flow of students between these two pairs of countries, i.e., for example, few Portuguese students go to study in Austria. Similarly, it can be noted that Netherlands, Portugal, and Luxembourg are nearly collinear with the origin, so they represent small skew-symmetries, i.e. there is a low flow of students between these countries. Moreover, it can be seen that the area of the triangle between Norway, Sweden, and the origin is very large and Norway has a clockwise direction towards Sweden, which means that there are many student exchanges from Sweden to Norway. In general, Fig.2 reveals a large flow of students between the Scandinavian countries. Similar considerations can be made for Turkey and Greece, as the student flow from Greece to Turkey is high. These findings are easily interpretable due to both the geographical proximity of the countries and their culture. Finally, it is also important to point out that USA, Canada and Ireland have a rather high flow of students exchanged between them, both for geographical proximity and for the common language: the clockwise direction from Ireland to USA connotes Ireland as a country of destination from USA, while the anticlockwise direction from Canada to USA qualifies Canada as the origin country for students going to the United States. Another group of countries clearly closely linked to the geographical aspect

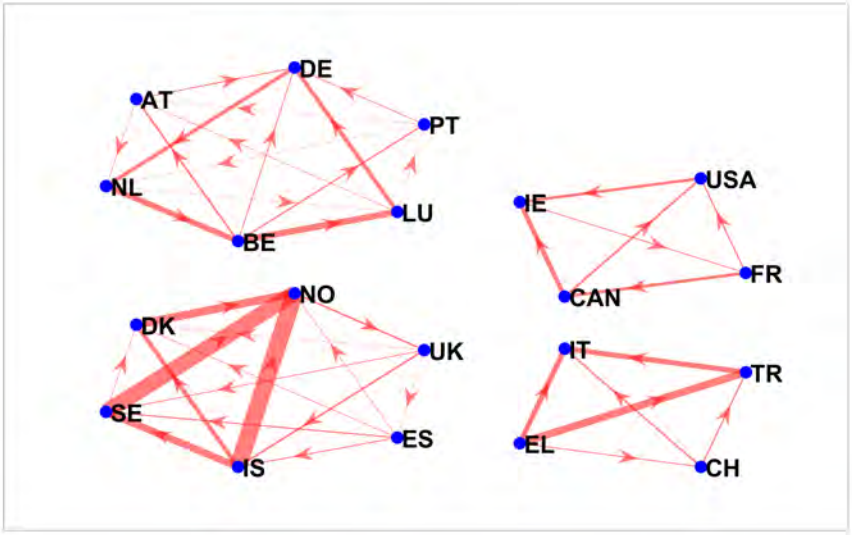

Figure 3: Directions of the flows within each cluster.

and the language spoken is group C_4 which mainly contains countries where French and German are spoken and which are bordering each other. All in all, the clustering results (Fig.3) summarize the main links of Fig.1 which agree with the OECD report (3).

Abstract

In this work, we analyze the connection between contingency table analysis and copulas in a discrete framework. We focus on the impact of structural zeros on the general theory presented by Geenens (2020) based on a new idea of copula models for discrete variables. Through examples, we investigate the pros and cons of applying the theory developed by Geenens (2020) and discuss some open questions for future research.

Keywords: Bubble plot, Categorical data analysis, Discrete copulas, Iterated Proportional Fitting (IPF), Structural zeros

1. Introduction

Contingency tables appear in many applied fields, such as biology, health care, and social science. Due to their importance in application, the analysis of such tables was studied in statistics, where researchers developed methodological tools to extract information about the relation between the variables involved (9). Recent work by Geenens (4) highlights interesting connections between standard methods in contingency table analysis and *copulas* in a discrete setting. Copulas are popular tools to model dependencies between random variables. Their popularity is due to Sklar's theorem (11), which states that, for every $(x_1, \ldots, x_d) \in \mathbb{R}^d$, the joint distribution function $F_{\mathbf{X}}$ of any d-dimensional random vector $\mathbf{X} = (X_1, \ldots, X_d)$ can be written as $F_{\mathbf{X}}(x_1, \ldots, x_d) = C(F_{X_1}(x_1), \ldots, F_{X_d}(x_d))$, where the function $C : [0,1]^d \to [0,1]$ is a *d-dimensional copula* and $F_{X_1}, \ldots, F_{X_d}$ are univariate marginal distributions. In a nutshell, copulas can be seen as joint probability distributions with uniform margins in $[0,1]$. When the random vector $\mathbf{X}$ is discrete, the copula associated with $F_{\mathbf{X}}$ is uniquely defined on the $\text{Range}(F_{X_1}) \times \cdots \times \text{Range}(F_{X_d})$. Thus, it is possible to associate any contingency table with the restriction of a full-domain copula on a grid domain, i.e., a so-called *discrete copula*; see, e.g., (6; 7) and references therein. Any discrete copula can be extended into a full-domain copula by simply spreading the probability mass on each hyper-rectangle of their grid domain. However, the extension is not unique (1), which leads to problems while applying copula theory in discrete settings. In this work, we elaborate on a novel approach to using copulas in contingency table analysis presented in (4). In Sect. 2, we recall basic definitions (in the bivariate case) and results on the topic with special attention to contingency tables with structural zeros, and we discuss the connections with some classical log-linear models for incomplete tables. Some interesting examples are illustrated in Sect. 3, where we also discuss some open questions for future research on the topic.

2. Background

In this section, we provide the mathematical framework and notation to work with discrete copulas. We consider $R \in \mathbb{Z}_{>0}$ and denote $I_R = \{0, 1/R, \ldots, (R-1)/R, 1\}$, $[R] = \{1, \ldots, R\}$, and $\langle R \rangle = \{0, \ldots, R\}$. For R and S in $\mathbb{Z}_{>0}$, we define $U_R = \{u_0 = 0, u_1, \ldots, u_{R-1}, u_R = 1\}$, $u_0 < \ldots < u_R$ and $V_S = \{v_0 = 0, v_1, \ldots, v_{S-1}, v_S = 1\}$, $v_0 < \ldots < v_S$ as two finite grid partitions of the unit interval. A discrete copula C_{U_R,V_S} is a function defined on $U_R \times V_S$ that satisfies the properties of a copula function on the grid domain $U_R \times V_S$. As highlighted in (6), there are interesting connections between the space of discrete copulas and convex polytopes called *transportation polytopes*, which are also linked with contingency tables analysis (2) . Namely, considering two vectors $\tilde{u} = (\tilde{u}_1, \ldots, \tilde{u}_R) \in \mathbb{R}^R_{>0}$ and $\tilde{v} = (\tilde{v}_1, \ldots, \tilde{v}_S) \in \mathbb{R}^S_{>0}$, we can define the transportation polytope $\mathcal{T}(\tilde{u}, \tilde{v})$ as the convex polytope in the RS variables $x_{i,j}$ satisfying, for all $i \in [R]$ and $j \in [S]$, the following conditions: $x_{i,j} \geq 0$, $\sum_{h=1}^{S} x_{i,h} = \tilde{u}_i$, $\sum_{\ell=1}^{R} x_{\ell,j} = \tilde{v}_j$. The two vectors $\tilde{u}$ and $\tilde{v}$ are called the margins of $\mathcal{T}(\tilde{u}, \tilde{v})$. In (8), the authors show that any discrete copula C_{U_R,V_S} corresponds to a matrix within a transportation polytope $\mathcal{T}(\tilde{u}, \tilde{v})$, and viceversa. Intuitively, the transportation matrix directly relates to the probability mass function of the discrete random vector, while the corresponding discrete copula relates to the cumulative distribution function.

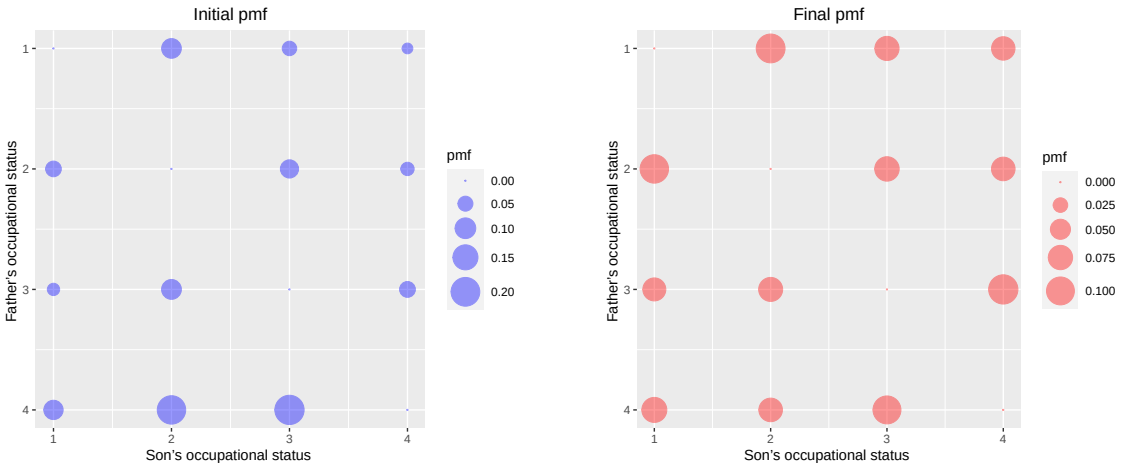
We now show how to derive the discrete copula associated with a given contingency table. We consider an example taken from (10) whose data is reported in Table 1. The table shows the cross-classification of a father's and his son's occupational status categories in Japan in 1955. There are four categories (1: Professional and Managers; 2: Clerical and Sales; 3: Skilled manual and Semiskilled manual; 4: Unskilled manual and Farmers). Since this table is analyzed in (10) under quasi-symmetry models, we have removed the diagonal, because the diagonal cells are fitted exactly, and thus there is no variability. We get $N = 799$ values. In this example, $R = S = 4$, the vectors $\tilde{u}$ and $\tilde{v}$ are the margins of the contingency table, i.e., $\tilde{u} = (128, 136, 144, 391)$ and $\tilde{v} = (139, 301, 264, 95)$, while the defining grids of the corresponding discrete copula are $U_R = \frac{1}{N}\{0, \tilde{u}_1, \tilde{u}_1 + \tilde{u}_2, \ldots\} = \{0, 0.16, 0.33, 0.51, 1\}$ and $V_S = \{0, 0.17, 0.55, 0.88, 1\}$. The entries of the discrete copula $C_1 = C_{U_R,V_S} = (c_{i,j})$, $i \in [R]$ and $j \in [S]$ are computed from the entries of the contingency table $(x_{i,j})$ by summing up and normalizing, i.e., $c_{i,j} = \frac{1}{N}\sum_{\ell=1}^{i}\sum_{h=1}^{j} x_{\ell,h}$, while $c_{0,0} = c_{i,0} = c_{0,j} = 0$, for $i \in [R]$ and $j \in [S]$.

In (4), the author highlights the difficulty of drawing conclusions on the dependence from tables that have non-uniform margins as the one reported in Table 1. Therefore, in the spirit of copula theory for continuous random variables, the author suggests searching for a representative $\bar{\mathbf{p}}$ of all $(R \times S)$ probability distributions that (1) preserves the inter-dependencies of a contingency table in terms of odds-ratios, and (2) has uniform margins equal to $1/R$ and $1/S$. In discrete copula terms, this is equivalent to searching for a discrete copula defined on the rectangular grid $I_R \times I_S$ which preserves the dependence structure of the original discrete copula computed from a given contingency table. Looking at the example above, we would search for a discrete copula $\tilde{C}_1$ with support $I_4 \times I_4$ and margins I_4 associated with C_1 in a meaningful way. A natural question that arises is whether or not such an element exists and is unique. The answer to this question is given in the theorem below presented in (4). We here report the cases that are relevant to our examples while the original formulation of the theorem is more general and presents more scenarios. The cardinality of a set A is denoted by $|A|$.

Theorem 1. *Let* $\mathbf{p}$ *be in the set* $\mathcal{P}_{R\times S}$ *of all* $(R \times S)$ *probability distributions. We define Supp*$(\mathbf{p}) = \{(i,j) \in [R]\times[S]$ *s.t.* $p_{i,j} > 0\}$ *and N*$(\mathbf{p}) = \{(v_X \times v_Y) : v_X \subset [R], v_Y \subset [S]$*s.t.* $\sum_{(i,j)\in v_X \times v_Y} p_{i,j} = 0\}$, *the set of rectangular subset of* $[R] \times [S]$ *where* $\mathbf{p}$ *is null.*

1. *Suppose that for all* $(v_X \times v_Y) \in N(\mathbf{p})$, $\frac{|v_X|}{R} + \frac{|v_Y|}{S} < 1$, *then there exists a unique* $\bar{\mathbf{p}}$ *with uniform margins, same odds-ratio structure of* $\mathbf{p}$, *and associated with a discrete copula* $C_{I_R\times I_S}$.
2. *Suppose that there exists* $\tilde{\tilde{v}}_X \times \tilde{\tilde{v}}_Y \in N(\mathbf{p})$ *such that* $\frac{|\tilde{\tilde{v}}_X|}{R} + \frac{|\tilde{\tilde{v}}_Y|}{S} > 1$. *Then there is no element* $\bar{\mathbf{p}}$ *with uniform margins such that it has same odds-ratio structure of* $\mathbf{p}$ *and is associated with a discrete copula* $C_{I_R\times I_S}$.

The element $\bar{\mathbf{p}}$ can be obtained by using the iterated proportional fitting (IPF) procedure, which is a standard method in contingency table analysis for a meaningful comparison of tables with different



(a) observed pmf

(b) final pmf as output of IPF

Figure 1: Bubble plots of the probability mass functions

margins and same dependence structure in terms of corresponding odds-ratios (4; 9). Theorem 1 states that zero-count cells in a contingency table impact the existence of the element $\bar{\mathbf{p}}$ of interest.

When a contingency table contains structural zeros, classical statistical methods become difficult to apply. Some of the odds-ratios can not be defined, and the standard independence model can not be used, because it implies a sample space in the form of a Cartesian product $[R] \times [S]$. For the analysis of incomplete square tables with structural zeros on the main diagonal, as in the example in Table 2, one can use quasi-independence or quasi-symmetry log-linear models. The latter is defined by

$$\log(p_{i,j}) = \lambda + \lambda_i^{(X)} + \lambda_j^{(Y)} + \lambda_{i,j}^{(XY)} \tag{1}$$

for $(i, j) \in [R] \times [S]$, where λ is a mean parameter, $\lambda_i^{(X)}$ are the row-parameters, $\lambda_j^{(Y)}$ are the column-parameters, and $\lambda_{i,j}^{(XY)}$, with the constraints $\lambda_{i,j}^{(XY)} = \lambda_{j,i}^{(XY)}$, measure the symmetry beyond the marginal contributions. Although the expression of the model is simple, the practical interpretation of the values of the λ parameters is not easy, and usually, log-linear models of this kind are used only for a global goodness-of-fit test. Using the discrete copulas and their graphical visualization through the bubble plots as the ones reported in Fig. 1, we will be able to focus on the dependence described by the $\lambda_{i,j}^{(XY)}$ parameters. In the next section, we further explore this aspect by analyzing two examples of contingency tables with special zero-count cell structures.

Table 1: Father's and son's occupational status categories in Japan in 1955, adapted from (10). Observed data in the left panel (dashes denote structural zeros), and associated discrete copula in the right panel.

	Son				
Father	1	2	3	4	Total
1	–	72	37	19	128
2	44	–	61	31	136
3	26	73	–	45	144
4	69	156	166	–	391
Total	139	301	264	95	799

$$C_1 = \begin{pmatrix} 0 & 0.00 & 0.00 & 0.00 & 0.00 \\ 0 & 0.00 & 0.09 & 0.14 & 0.16 \\ 0 & 0.06 & 0.15 & 0.27 & 0.33 \\ 0 & 0.09 & 0.27 & 0.39 & 0.51 \\ 0 & 0.17 & 0.55 & 0.88 & 1.00 \end{pmatrix}$$

3. Examples and discussion

The first example we consider here is taken from (10) and we have already described it in Section 2. The corresponding data are reported in Table 1. We have $R = S = 4$, $\mathrm{N}(\mathbf{p}) = \{(v_X \times v_Y) : v_X = v_Y = \{i\}, i = 1, \ldots, 4\}$ and for all $(v_X \times v_Y) \in N(\mathbf{p})$, $\frac{|v_X|}{R} + \frac{|v_Y|}{S} = 1/4 + 1/4 < 1$. This example falls under case 1 of Theorem 1. As expected, we are able to find a representative element $\bar{\mathbf{p}}$ with uniform margins $1/4$ and a corresponding discrete copula $\tilde{C}_1$ defined on the uniform grid I_4^2. The results are reported in Table 2. Fig. 1 displays the bubble plots for this example, a graphical representation of the probability mass function (pmf) for the observed data and the transformed pmf obtained through IPF. In the right-hand panel, exploiting the IPF algorithm, we have removed the effects of marginal non-homogeneity and the red plot unveils the symmetry structure, which is masked in the blue panel by the different values of the marginal frequencies. The role of the frequencies in the right-hand panel, i.e., to unveil symmetry beyond marginal non-homogeneity, is the same role of the residuals in the log-linear quasi-symmetry model in Eq. (1). Nevertheless, the graphical representation of the discrete copula is immediate to read and provides an easy way to detect symmetries in the data table. In this example, we can observe that the bubbles in symmetric cells have nearly the same radius, and thus the data table has a strong symmetry.

The second example is taken from (3), and the data are displayed in Table 3. The table here differ from previous case, as here we do not have a square table. The data concern the relationship between the locular composition (the number of locules of the ovary with odd or even numbers of ovules) and radial symmetry (root mean square deviation of the number of ovules from the mean number in the individual ovary) for the fruit of the American Bladder Nut, *Staphylea trifolia*, which has three locules per ovary. Some of the combinations are biologically impossible, which implies that the table has structural zeros. Note that after a reordering of the rows and columns, the observed table in Table 3 can be split into two separate complete sub-tables without structural zeros. This approach has been developed in, e.g., (5). We have retained the original structure since ordinal random variables are relevant in the copula framework.

This example falls under the assumption of case 2 in Theorem 1. Indeed, we have $R = 4$, $S = 9$ and with $v(X) = \{1, 4\}$, $v(Y) = \{2, 3, 5, 6, 8\}$ we get a sub-table with structural zeros with $|v(X)|/R + |v(Y)|/S = 2/4 + 5/9 > 1$. Therefore, the existence of a unique discrete copula is not guaranteed. Running the IPF algorithm on the original table, we obtain the probabilities in Table 4, top panel, where only the row variable is uniform. Running the IPF algorithm on the transposed of the observed table, we obtain the probabilities in Table 4, bottom panel, where, again, only the row variable is uniform. Thus, we have two solutions. Both of them share the same odd-ratio structure of the observed table due to the properties of the IPF algorithm. However, it is not possible to construct a unique discrete copula on $I_4 \times I_9$ (or on $I_9 \times I_4$) which is associated to the table. This implies that the identifiability issue of a unique copula model in a discrete setting is not completely solved by the approach presented in (4). More research is needed to shed light on such cases and further inquire into other invariant properties of the discrete copulas that can be relevant for more scenarios.

In this work we have only discussed two examples. Though, the theory is far more rich and several interesting examples do not fall within the cases of Theorem 1. For instance, we have not explored here the situation where $\frac{|v_X|}{R} + \frac{|v_Y|}{S} \leq 1$ for all $(v_X \times v_Y) \in N(\mathbf{p})$, but there are $\tilde{v}_X, \tilde{v}_Y$ such that

Levels Merging in the Latent Class Model

Christophe Biernacki[a]

[a]Inria, Univ. Lille, CNRS, UMR 8524 - Laboratoire Paul Painlevé, F-59000 Lille, France
christophe.biernacki@inria.fr,

Abstract

The latent class model (LCM), dedicated to cluster categorical variables, suffers for the curse of dimension when the number of levels is large, situation frequently encountered in practice. We propose to extent LCM to a natural modeling which limits the number of levels by merging them, process which is also equivalent to a specific levels clustering. Related estimation and model selection processes are also presented and discussed.

Keywords: Mixture models, categorical data, numerous levels, model selection

1. Introduction

Cluster analysis is one of the main data analysis method. It aims at partitioning into K groups a data set $\mathbf{x} = (\mathbf{x}_1, \ldots, \mathbf{x}_n)$ composed by n individuals and lying in a space $\mathcal{X}$ of dimension d. This partition is denoted by $\mathbf{z} = (\mathbf{z}_1, \ldots, \mathbf{z}_n)$, lying in a space $\mathcal{Z}$, where $\mathbf{z}_i = (z_{i1}, \ldots, z_{iK})'$ is a vector of $\{0,1\}^K$ such that $z_{ik} = 1$ if individual $\mathbf{x}_i$ belongs to the kth group, and $z_{ik} = 0$ otherwise ($i = 1, \ldots, n$, $k = 1, \ldots, K$). Model-based clustering allows to reformulate cluster analysis as a well-posed estimation problem both for the partition $\mathbf{z}$ and for the number K of groups. See for instance (13) among many other references on this topic.

Thanks to the nice mathematical background it provides, model-based clustering has led also to numerous and significant practical successes, even in some challenging situations. It is typically the case for the high dimensional context ("large" d value), which is very pregnant in applications such as transcriptomics, image analysis, text analysis, and so on. We can for instance refer to (5) and references therein. However, in the categorical data case, meaning that $\mathcal{X}$ corresponds to d categorical variables, the jth one having m_j response levels, another kind of dimensionality curse can appear as soon as some m_js are large. This situation appears in many practical situations also, for instance for features related to the states in the US, to the French departments, to the professional social categories, to medical nomenclature, and so on. But, existing modelings as the standard latent class model (LCM, (9)), are not really adapted to this problematic situation. As far as we know, this question is seldom addressed until now, except some early work in (11) (see a description later in the paper) and also a current practice which usually simplifies data set at hand by merging manually some levels before the clustering step itself. In this work, we thus propose to formalize this empirical procedure by a specific variant of LCM which includes natively a levels merging process, which can also be equivalently re-interpret like a levels partioning process, as we will explain later in the paper. Our proposal can also be seen as an extension of (11).

We will present this LCM extension in Section 2, before to estimate parameters (Section 3) and to select the levels partitioning re-interpreted as a model selection process (Section 4). Section 5. presents preliminary numerical experiments and draws possible extensions of this preliminary work.

2. A Latent Class Model (LCM) in case of numerous levels

2.1 The classical LCM and variants

We consider data sets $\mathbf{x} = (\mathbf{x}_1, \ldots, \mathbf{x}_n)$, each $\mathbf{x}_i$ containing d categorical variables, the jth having m_j response levels. The coding $\mathbf{x}_i = (x_i^{jh}; j = 1, \ldots, d; h = 1, \ldots, m_j)$ indicates that $x_i^{jh} = 1$ if i has response level h for variable j and $x_i^{jh} = 0$ otherwise. The standard model for clustering observations described through categorical variables is the so-called latent class model (see for instance (9)). Data are assumed to arise independently from a mixture of K multivariate multinomial distributions with pdf

$$\mathrm{p}(\mathbf{x}_i; \boldsymbol{\theta}) = \sum_{k=1}^{K} \pi_k \prod_{j=1}^{d} \prod_{h=1}^{m_j} (\alpha_k^{jh})^{x_i^{jh}}, \tag{1}$$

where $\boldsymbol{\theta} = (\boldsymbol{\pi}, \boldsymbol{\alpha})$ denotes the vector parameter of the latent class model to be estimated, with $\boldsymbol{\alpha} = (\boldsymbol{\alpha}_1, \ldots, \boldsymbol{\alpha}_K)$ and $\boldsymbol{\alpha}_k = (\alpha_k^{jh}; j = 1, \ldots, d; h = 1, \ldots, m_j)$, α_k^{jh} denoting the probability that variable j has level h if object i is in cluster k. Thus, the latent class model assumes that the variables are *conditionally independent* knowing the latent groups.

The number of parameters for LCM is equal to $K - 1 + K \sum_{j=1}^{d} (m_j - 1)$. For limiting the effect of dimension d, some approaches proposed parsimonious variants including for instance variable selection or variable clustering (see (5) for an overview). However, the effect of d and the m_js are similar on the number of parameters count, thus it makes sense also to limit the number of levels for each variable. Less works are focused in this direction, except an early one of (11) which proposes four parsimonious versions of LCM. They correspond to an extension of the parameterization of Bernoulli distributions used by (7) for clustering and also by (1) for kernel discriminant analysis. The basic idea is to impose the vector $\boldsymbol{\alpha}_k^j = (\alpha_k^{j1}, \ldots, \alpha_k^{jm_j})$ to take the form $(\beta_k^j, \ldots, \beta_k^j, \gamma_k^j, \beta_k^j, \ldots, \beta_k^j)$ with $\gamma_k^j > \beta_k^j$. Since $\sum_{h=1}^{m_j} \alpha_k^{jh} = 1$, we have $(m_j - 1)\beta_k^j + \gamma_k^j = 1$ and, consequently, $\beta_k^j = (1 - \gamma_k^j)/(m_j - 1)$. The constraint $\gamma_k^j > \beta_k^j$ becomes finally $\gamma_k^j > 1/m_j$. It leads to a very parsimonious (only $K - 1 + Kd$ parameters) but poor flexible model, and three other still more parsimonious and less flexible variants are also proposed. Thus, there is a need for a new modeling allowing to tune more finely the trade-off between parsimony and flexibility concerning the number of free levels by variable.

2.2 A parsimonious LCM by levels merging (LCM-LM)

We propose to follow the previous idea of constraining some levels to share the same parameter value, but we drastically extend it. More precisely, for each variable $j = 1, \ldots, d$, we define L_j clusters of levels through a vector $\mathbf{w}_j = (\mathbf{w}_j^1, \ldots, \mathbf{w}_j^{m_j})$. Here $\mathbf{w}_j^h = (w_j^{h1}, \ldots, w_j^{hL_j})$ is a binary vector such $w_j^{h\ell} = 1$ if the level h of the variable j belongs to the level cluster ℓ ($\ell = 1, \ldots, L_j$), and $w_j^{h\ell} = 0$ otherwise. The LCM parameters are linked to this levels clustering $\mathbf{w} = (\mathbf{w}_1, \ldots, \mathbf{w}_d)$ as follows: $\alpha_k^{jh} = \beta_k^{j\ell} / (\sum_{h'=1}^{m_j} w_j^{h'\ell}) \propto \beta_k^{j\ell}$ if $w_j^{h\ell} = 1$, where $\sum_{\ell=1}^{L_j} \beta_k^{j\ell} = 1$. The new parameters of this constraint multinomial model are then gathered in $\boldsymbol{\beta} = (\boldsymbol{\beta}_1, \ldots, \boldsymbol{\beta}_K)$, with $\boldsymbol{\beta}_k = (\beta_k^{j\ell}; j = 1, \ldots, d; \ell = 1, \ldots, L_j)$. Denoting by $\boldsymbol{\vartheta} = (\boldsymbol{\pi}, \boldsymbol{\beta})$ the new mixture parameter, the pdf of this novel LCM is expressed as

$$\mathrm{p}(\mathbf{x}_i | \mathbf{w}; \boldsymbol{\vartheta}) = \sum_{k=1}^{K} \pi_k \prod_{j=1}^{d} \prod_{\ell=1}^{L_j} \left(\frac{\beta_k^{j\ell}}{\sum_{h=1}^{m_j} w_j^{h\ell}} \right)^{\sum_{h=1}^{m_j} w_j^{h\ell} x_i^{jh}}. \tag{2}$$

The number of parameters associated to this constraint model is equal to $K - 1 + K \sum_{j=1}^{d} (L_j - 1)$, thus showing a varying parsimony degree depending on the numbers of clusters L_js. We call hereafter this constraint LCM as LCM-LM for *Latent Class Model by Levels Merging*.

Remark Notice that the extreme parsimonious version of LCM-LM where $L_j = 1$ could be interpreted as having no effect of variable j on the clustering. Consequently, it is also a model where variable j has no effect on the clustering, playing the role of a specific variable selection process.

3. Parameter estimation of LCM-LM

3.1 Reformulating the log-likelihood of LCM-LM as a classical LCM

We propose to estimate $\boldsymbol{\vartheta}$ through $\hat{\boldsymbol{\vartheta}}_{\mathbf{w}}$ which maximizes the observed log-likelihood

$$L(\boldsymbol{\vartheta}|\mathbf{w};\mathbf{x}) = \sum_{i=1}^{n} \ln \left(\sum_{k=1}^{K} \pi_k \prod_{j=1}^{d} \prod_{\ell=1}^{L_j} \left(\frac{\beta_k^{j\ell}}{\sum_{h=1}^{m_j} w_j^{h\ell}} \right)^{\sum_{h=1}^{m_j} w_j^{h\ell} x_i^{jh}} \right). \tag{3}$$

But it is of practical interest to notice at this step that the log-likelihood $L(\boldsymbol{\vartheta}|\mathbf{w};\mathbf{x})$ of LCM-LM can be reformulated as the log-likelihood $L(\boldsymbol{\vartheta}|\mathbf{w};\mathbf{y})$[1] of a classical LCM where the levels of the same cluster ℓ are merged into a unique new level with an additional term $c_{\mathbf{w}}$ independent of the parameter $\boldsymbol{\vartheta}$. Indeed, we can write

$$\begin{aligned}
L(\boldsymbol{\vartheta}|\mathbf{w};\mathbf{x}) &= \sum_{i=1}^{n} \ln \left(\sum_{k=1}^{K} \pi_k \prod_{j=1}^{d} \prod_{\ell=1}^{L_j} \left(\beta_k^{j\ell} \right)^{y_{\mathbf{w},i}^{jl}} \right) + c_{\mathbf{w}} && (4)\\
&= \sum_{i=1}^{n} \ln \left(\sum_{k=1}^{K} \pi_k \mathrm{p}(\mathbf{y}_{\mathbf{w},i};\boldsymbol{\beta}_k) \right) + c_{\mathbf{w}} && (5)\\
&= \sum_{i=1}^{n} \ln \mathrm{p}(\mathbf{y}_{\mathbf{w},i};\boldsymbol{\vartheta}) + c_{\mathbf{w}} && (6)\\
&= L(\boldsymbol{\vartheta};\mathbf{y}_{\mathbf{w}}) + c_{\mathbf{w}} && (7)
\end{aligned}$$

where $c_{\mathbf{w}} = -\sum_{i=1}^{n} \sum_{j=1}^{d} \sum_{\ell=1}^{L_j} y_{\mathbf{w},i}^{j\ell} \ln \left(\sum_{h=1}^{m_j} w_j^{h\ell} \right)$ is a constant with regards to the parameter $\boldsymbol{\vartheta}$ and where $y_{\mathbf{w},i}^{j\ell} = \sum_{h=1}^{m_j} w_j^{h\ell} x_i^{jh}$, $\mathbf{y}_{\mathbf{w},i} = (y_{\mathbf{w},i}^{j\ell}; j = 1,\ldots,d; \ell = 1,\ldots,L_j)$ and $\mathbf{y}_{\mathbf{w}} = (\mathbf{y}_{\mathbf{w},1},\ldots,\mathbf{y}_{\mathbf{w},n})$.

3.2 EM algorithm description

As a consequence of the preeceeding remark, estimating $\boldsymbol{\vartheta}$ can be performed by any classical EM algorithm (8) for LCM implemented in any classical existing package (for instance Rmixmod (11) or RMixtComp[2]). Concretely, starting from $\boldsymbol{\vartheta}^0 = (\boldsymbol{\pi}^0, \boldsymbol{\beta}^0)$, iteration $r > 0$ of this EM is expressed as:

E step: Conditional probability that individual i arose from cluster k

$$t_{ik}(\boldsymbol{\vartheta}^r) = \frac{\pi_k^r \mathrm{p}(\mathbf{y}_{\mathbf{w},i};\boldsymbol{\beta}_k^r)}{\mathrm{p}(\mathbf{y}_{\mathbf{w},i};\boldsymbol{\vartheta}^r)}. \tag{8}$$

M step: Updating the mixture parameter estimates by maximizing the expected complete log-likelihood

$$\pi_k^{r+1} = \frac{\sum_i t_{ik}(\boldsymbol{\vartheta}^r)}{n} \quad \text{and} \quad (\beta_k^{j\ell})^{r+1} = \frac{\sum_{i=1}^{n} t_{ik}(\boldsymbol{\vartheta}^r) y_{\mathbf{w},i}^{j\ell}}{\sum_{i=1}^{n} t_{ik}(\boldsymbol{\vartheta}^r)}. \tag{9}$$

The stopping rule can rely on a plateau of the log-likelihood (equally $L(\boldsymbol{\vartheta};\mathbf{y}_{\mathbf{w}})$ or $L(\boldsymbol{\vartheta}|\mathbf{w};\mathbf{x})$) or a given iteration number. Several runs should be performed also from different starting parameters for avoiding local maxima traps.

[1] For simplifying notations, both p and L stand for *generic* pdf and log-likelihood functions, respectively.
[2] https://cran.r-project.org/web/packages/RMixtComp/index.html

4. Model selection for LCM-LM

4.1 Exact ICL criterion for LCM-LM

Beyond parameter estimation, there is a need also to estimate the number of individual clusters K and the levels partioning $\mathbf{w}$ (which includes itself the levels clusters L_js). Hereafter we omit the (implicit) index K in notations for focalizing attention on the index $\mathbf{w}$ which is the novel part of this work.

Usually, the BIC criterion (16) or the ICLbic criterion[3] (3) appear to give a reasonable answer to the model selection problem in mixtures, especially the ICLbic criterion when the clustering point of view is of first interest. However, some previous works dealing with LCM (see for instance (15) or (4)) suggest that both BIC and ICLbic need particular large sample sizes to reach its expected asymptotic behaviour in practical situations. In (4), it is taken profit from the possibility to avoid the asymptotic approximation ICLbic of the observed integrated likelihood to propose an alternative non-asymptotic ICL criterion, leading to a subsequent improvement in model selection for moderate sample sizes, while having a particular easy to calculate closed-form expression of the corresponding ICL. We propose thus to adapt now this non-asymptotic ICL criterion calculation from LCM to the new modeling LCM-LM.

Denoting by $\hat{\mathbf{z}}_{\mathbf{w}}$ the maximum *a posteriori* (MAP) estimate of $\mathbf{z}$[4] and by $\Theta_{\mathbf{w}}$ the space of $\boldsymbol{\vartheta}$ when considering the model $\mathbf{w}$, the ICL criterion for LCM-LM is defined as

$$\begin{aligned}
\mathrm{ICL}_{\mathbf{w}}^{\text{LCM-LM}} &= \ln \mathrm{p}(\mathbf{x}, \hat{\mathbf{z}}_{\mathbf{w}}|\mathbf{w}) && (10)\\
&= \ln \int_{\Theta_{\mathbf{w}}} \mathrm{p}(\mathbf{x}, \hat{\mathbf{z}}_{\mathbf{w}}|\mathbf{w};\boldsymbol{\vartheta})\mathrm{p}(\boldsymbol{\vartheta}|\mathbf{w})d\boldsymbol{\vartheta} && (11)\\
&= \ln \int_{\Theta_{\mathbf{w}}} \mathrm{p}(\mathbf{y}_{\mathbf{w}}, \hat{\mathbf{z}}_{\mathbf{w}};\boldsymbol{\vartheta})\mathrm{p}(\boldsymbol{\vartheta}|\mathbf{w})d\boldsymbol{\vartheta} + c_{\mathbf{w}} && (12)\\
&= \mathrm{ICL}_{\mathbf{w}}^{\text{LCM}} + c_{\mathbf{w}} && (13)
\end{aligned}$$

where we have used a similar development as in 7 for obtaining this last expression, and where $\mathrm{ICL}_{\mathbf{w}}^{\text{LCM}}$ is the ICL criterion for LCM. This latter is classically defined as follows (see for instance (4))

$$\begin{aligned}
\mathrm{ICL}_{\mathbf{w}}^{\text{LCM}} = \sum_{k=1}^{K}\sum_{j=1}^{d}\left\{\sum_{\ell=1}^{L_j}\ln\Gamma\left(\hat{n}_{\mathbf{w},k}^{j\ell}+\tfrac{1}{2}\right) - \ln\Gamma(\hat{n}_{\mathbf{w},k}+\tfrac{L_j}{2})\right\} - \ln\Gamma(n+\tfrac{K}{2}) + \ln\Gamma(\tfrac{K}{2})\\
+K\sum_{j=1}^{d}\left\{\ln\Gamma(\tfrac{L_j}{2}) - L_j\ln\Gamma(\tfrac{1}{2})\right\} + \sum_{k=1}^{K}\ln\Gamma(\hat{n}_{\mathbf{w},k}+\tfrac{1}{2}) - K\ln\Gamma(\tfrac{1}{2}), \qquad (14)
\end{aligned}$$

where $\hat{n}_{\mathbf{w},k} = \#\{i : \hat{z}_{\mathbf{w},ik} = 1\}$ and $\hat{n}_{\mathbf{w},k}^{j\ell} = \#\{i : \hat{z}_{\mathbf{w},ik} = 1, y_{\mathbf{w},i}^{j\ell} = 1\}$. As a consequence from 13, the $\mathrm{ICL}_{\mathbf{w}}^{\text{LCM-LM}}$ is itself easily calculated also.

4.2 Labels partitioning estimation without multiple parameter estimation

Since the space $\mathcal{W}$ where lie models $\mathbf{w}$ is extremely large (including or not the number labels clusters L_j), it is obviously impossible to calculate the value of $\mathrm{ICL}_{\mathbf{w}}^{\text{LCM-LM}}$ for each of them. In addition, a single evaluation of $\mathrm{ICL}_{\mathbf{w}}^{\text{LCM-LM}}$ requires the availability of $\hat{\mathbf{z}}_{\mathbf{w}}$, thus to perform potentially a full run of the EM algorithm for evaluating $\hat{\boldsymbol{\vartheta}}_{\mathbf{w}}$.

An original strategy is proposed by (12) for avoiding parameter estimation for all models which compete, thus limiting the computing time. Then a parameter estimation is just performed for the retained model at the end of their process. Their strategy is applied to mixture models where the within component variable independence is assumed, as it the case in LCM.

[3] ICLbic corresponds to the classical asymptotic approximation of the ICL (*Integrated Complete-data Likelihood*) criterion.

[4] It means that $\hat{z}_{\mathbf{w},ik} = 1$ iif $k \in \arg\max_{k'} t_{ik'}(\hat{\boldsymbol{\vartheta}}_{\mathbf{w}})$.

Their strategy relies on a variant of the ICL criterion, the so-called MICL criterion (*Maximum Integrated Complete-data Likelihood*), and defined in our case by

$$\text{MICL}_{\mathbf{w}}^{\text{LCM-LM}} = \ln \text{p}(\mathbf{x}, \mathbf{z}_{\mathbf{w}}^*|\mathbf{w}) \quad \text{with} \quad \mathbf{z}_{\mathbf{w}}^* = \arg\max_{\mathbf{z}\in\mathcal{Z}} \ln \text{p}(\mathbf{x}, \mathbf{z}|\mathbf{w}).$$

Then, the model $\mathbf{w}^*$ maximizing $\text{MICL}_{\mathbf{w}}^{\text{LCM-LM}}$ is retained:

$$\mathbf{w}^* = \arg\max_{\mathbf{w}\in\mathcal{W}} \text{MICL}_{\mathbf{w}}.$$

We expect that MICL is consistent for choosing $\mathbf{w}$, at least when the cluster numbers (K and L_js) are known, as being an extension of the proof of (12) available in a more restricted by quite similar situation.

The question of maximizing $\text{MICL}_{\mathbf{w}}^{\text{LCM-LM}}$ on $\mathbf{w}$ is obviously the crucial difficulty. Thus, mimiking the idea of (12), we implement the following simple alternate procedure, for a fixed K value (thus this algorithm has to be run for different candidate values of K). Starting from a value $\mathbf{w}^0$ uniformly sampled in the corresponding space and then a value $\mathbf{z}^0$ being deduced from the MAP rule of the associated maximum likelihood estimate, iteration $s > 0$ of the algorithm is composed by the following two steps:

Partition step Fix $\mathbf{z}^{s+1}$ such that $\ln \text{p}(\mathbf{x}, \mathbf{z}^{s+1}|\mathbf{w}^s) \geq \ln \text{p}(\mathbf{x}, \mathbf{z}^s|\mathbf{w}^s)$.
Model step Fix $\mathbf{w}^{s+1}$ such that $\ln \text{p}(\mathbf{x}, \mathbf{z}^{s+1}|\mathbf{w}^{s+1}) \geq \ln \text{p}(\mathbf{x}, \mathbf{z}^{s+1}|\mathbf{w}^s)$.

In practice, the partition step can be performed by sampling uniformly an individual which is affiliated to the component maximizing the integrated complete-data likelihood, while the other component memberships are unchanged (details are given in (12)). The model step can be performed in two successive phases: First, estimate all $\boldsymbol{\beta}_k$ in the case where all $L_j = m_j$ (no labels partitioning case), which is obtained in closed-form since the individual partition $\mathbf{z}^{s+1}$ is fixed; Second, different labels partition candidates $\mathbf{w}$ can be proposed thanks to a simple kmeans of $\boldsymbol{\beta}_k$, variable by variable, for different values of L_js. Note that this procedure can be trapped within local maxima and thus several run are required.

5. Preliminary numerical experiments and conclusion

Here are some early numerical experiments on a real data set for evaluating the practical interest of our LCM-LM proposal. Authors in (10) (see also (14) p. 139–142) considered the clustering of patients on the basis of petrial variates alone for the prostate cancer clinical trial data of (6) which is reproduced in (2) p. 261–274. This data set was obtained from a randomized clinical trial comparing four treatments for $n = 506$ patients with prostatic cancer grouped on clinical criteria into two Stages 3 and 4 of the disease (there are 62 missing values, so about 1% of the whole sample). As reported by (6), Stage 3 represents local extension of the disease without evidence of distance metastasis, while Stage 4 represents distant metastasis as evidenced by elevated acid phosphatase, X-ray evidence, or both. Twelve pre-trial variates were measured on each patient, composed by eight continuous variables and four categorical variables with various numbers of levels. We limit here our study to these latter, namely performance rating (so-called PF, with 4 levels), cardiovascular disease history (HX, 2 levels), electrocardiogram code (EKG, 7 levels) and bone metastases (BM, 2 levels). Invoking the RMixtcomp package[5], which is a clustering package able implementing LCM categorical data (and also dealing with missing values), we obtain a classification error equal to 49.2% and an ICL value equal to -1728.4 (we have fixed $K = 2$, because there are two stages of the desease).

We see below the frequency of each level for all these variables (missing values are denoted by a "?" and appear below as a level, but mathematical speaking it is not a level obviously).

```
    PF       HX           EKG       BM
?:  4   ?:  4   1      :168   ?:  4
1:450   1:289   5      :150   1:420
2: 37   2:213   6      : 75   2: 82
3: 13          3      : 51
4:  2          4      : 26
               2      : 23
               (Other): 13
```

[5] https://cran.r-project.org/web/packages/RMixtComp/index.html

As observed through this level distribution, level 4 of variable PF is under-represented, thus we propose to merge it with level 3 of the same variable. Running the corresponding LCM-LM (still through RMixtcomp) on this new data set, we obtain now a classification error equal to 28.8% and an ICL value equal to -1618.4 (we used the ICL formulation given in Section 4. in such a way that this LCM-LM ICL value can be compared to the ICL value of LCM). We thus observe that merging these two levels of PF leads to a very significant improvement of both the error rate and the ICL value, illustrating in that way all the potential interest of the proposed LCM-LM model for the clustering of categorical variables.

This paper should be considered as a preliminary work for levels clustering in the LCM context. We need now to numerically experiment the LCM-LM proposal on simulated and real data sets. We expect however that the alternating algorithm proposed for implementing the MICL criterion could be quite low. An extension could thus be to reinterpret LCM-LM within a new co-clustering paradigm where the levels partitioning should replace the classical variable partitioning involved in co-clustering. In that way, we could consider levels partitioning as a latent variable, and use in this context an efficient Variational EM algorithm for instance.

Abstract

A model-based clustering algorithm based on finite mixture of negative binomial Lévy processes is proposed. The algorithm models heterogeneous long-time count process data that can have multiple change points. The design of the algorithm involves several stages to avoid the infeasible exhaustive search. The proposed model is applied to the COVID ICU cases in the state of California USA with promising results.

.

Keywords: Categorical data analysis, Model-based clustering...

1. Introduction

The field of change point has a long history and most of the papers study the existence of single change point. Multiple change point estimation was first proposed by [1] and can be found in more recent literature. Model-based clustering [4] is an unsupervised learning tool for partitioning a heterogeneous population. Model-based clustering for stochastic process data in its functional form has recently received a lot of attention. Specifically, [3] proposed a novel extension of the Poisson mixture model for clustering count process data using intensity functions. To the authors' knowledge, change point estimation and model-based clustering methodologies have only been studied in the common framework by [5]. The method relies on matrix-variate mixture and exhaustively searches for a shift in the mean or variance. In this paper, our focus is on long-time count process data that can have multiple change points. An exhaustive search would be computationally infeasible. The authors take an alternative approach and search for an optimal interval at each step of the algorithm which contains a change point most likely. Then the change point is exhaustively tested in the interval. We assume a mixed type of change point where there is a gap between two logit-transformed segments.

2. Methodology

2.1 Lévy processes

A stochastic process $\boldsymbol{X} = \{X_t, t \geq 0\}$ is called a Lévy process, if it has right continuous left limited path with independent, stationary increments. The Poisson process is the most popular example of a

Lévy process used for count data. Since the Poisson distribution has a strong restriction that its mean and variance are equal, a negative binomial (NB) process with parameters $r = \alpha$ and $p = 1/(\beta + 1)$ is usually adopted with more flexibility. p can be considered as the success probability that some event happened and r is viewed as the number of failures until the experiment is stopped. In this paper, we consider a negative binomial time-inhomogeneous process whose increments are independent, but not stationary.

2.2 Finite mixture model of negative binomial process

Assume $\underline{\boldsymbol{y}} = \{\boldsymbol{y}_1, \ldots, \boldsymbol{y}_n\}$ is an observed random sample from a mixture model

$$g(\boldsymbol{y}; \boldsymbol{\Psi}) = \sum_{k=1}^{K} \tau_k f_k(\boldsymbol{y}; \boldsymbol{\Psi}_k) \tag{2.1}$$

with K components. Time interval $(t_0, t_T]$ is split into small intervals of equal length t given by $\{(t_0, t_1], \ldots, (t_{T-1}, t_T]\}$. Let $\boldsymbol{y}_i = \{y_{ij}\}_{j=1}^{T}$ denote a count process associated to subject i where y_{ij} is the number of events happening in interval $(t_{j-1}, t_j]$. We assume that $f_k(\boldsymbol{y}; \boldsymbol{\Psi}_k)$ from Equation 2.1 is a negative binomial (NB) process with the following form

$$f_k(\boldsymbol{y}; \boldsymbol{\Psi}_k) = \prod_{j=1}^{T} \binom{r_k + y_{ij} - 1}{y_{ij}} (1 - p_k)^{r_k} p_k^{y_{ij}}, \tag{2.2}$$

with parameters $r_k (\geq 0)$ and p_k $(0 \leq p_k \leq 1)$. The complete-data likelihood function is given by:

$$\mathcal{L}_c(\boldsymbol{\Psi}; \underline{\boldsymbol{y}}, \boldsymbol{Z}) = \prod_{i=1}^{n} \prod_{k=1}^{K} \left(\tau_k \prod_{j=1}^{T} \binom{r_k + y_{ij} - 1}{y_{ij}} (1 - p_k)^{r_k} p_k^{y_{ij}} \right)^{I(Z_i = k)}, \tag{2.3}$$

where Z_i denotes the unknown membership of the i^{th} count process. We model the changes in process through the success probability (p_k). During the observed time interval $(t_0, t_T]$, suppose there are m_k change points $(0 \leq m_k < T)$ denoted as $\zeta_{k1}, \ldots, \zeta_{km_k}$ and the shift occurs at the beginning of the m_k sub intervals of the form $(t_{j-1}, t_j]$; $j = 1, 2, \ldots, T-1$. The change in the process is introduced through the change in the logit of $(1 - p_k)$ as follows

$$\log\left(\frac{1 - p_k}{p_k}\right) = \begin{cases} \eta_{k0} + \nu_{k0} j, & \text{if } \zeta_{k0} < j \leq \zeta_{k1} \\ \eta_{k1} + \nu_{k1} j, & \text{if } \zeta_{k1} < j \leq \zeta_{k2} \\ \vdots & \\ \eta_{km} + \nu_{km} j, & \text{if } \zeta_{km} < j \leq \zeta_{k(m_k+1)}. \end{cases} \tag{2.4}$$

The logit of $(1 - p_k)$ is assumed to be a linear function of time. The parameters associated to this function indicate the change in the process.

Denote p_{kl} as the success probability in the interval $(\zeta_{kl}, \zeta_{k(l+1)}]$. The complete data likelihood becomes

$$\mathcal{L}_c(\boldsymbol{\Psi}; \underline{\boldsymbol{y}}, \boldsymbol{Z}) = \prod_{i=1}^{n} \prod_{k=1}^{K} \left(\tau_k \prod_{l=0}^{m_k} \prod_{j=\zeta_{kl}+1}^{\zeta_{k(l+1)}} \binom{r_k + y_{ij} - 1}{y_{ij}} (1 - p_{kl})^{r_k} p_{kl}^{y_{ij}} \right)^{I(Z_i = k)}. \tag{2.5}$$

The posterior probabilities are given by

$$\ddot{\pi}_{ik} = \frac{\dot{\tau}_k f_k(\boldsymbol{y}_i; \dot{\boldsymbol{\Psi}}_k)}{\sum_{k'=1}^{K} \dot{\tau}_{k'} f_{k'}(\boldsymbol{y}_i; \dot{\boldsymbol{\Psi}}_{k'})} \tag{2.6}$$

in the E-step. In the M-step, the mixing proportion $\ddot{\tau}_k$ is obtained as $\frac{1}{n}\sum_{i=1}^{n}\ddot{\pi}_{ik}$. The maximum likelihood estimates of η_{kl} and ν_{kl} can be found by numerically maximizing

$$Q_{kl} = \sum_{i=1}^{n} \ddot{\pi}_{ik} \sum_{j=\zeta_{kl}+1}^{\zeta_{k(l+1)}} (\dot{r}_k \log(1-\dot{p}_{kl}) + y_{ij}\log(\dot{p}_{kl})). \tag{2.7}$$

For estimating r_k

$$\begin{aligned} Q_k = &\sum_{i=1}^{n} \ddot{\pi}_{ik} \Bigg(\sum_{j=1}^{T} \log \binom{\dot{r}_k + y_{ij} - 1}{y_{ij}} \\ &+ \sum_{l=0}^{m_k} \sum_{j=\zeta_{kl}+1}^{\zeta_{k(l+1)}} \dot{r}_k \log(1-\ddot{p}_{kl}) \Bigg) \end{aligned} \tag{2.8}$$

needs to be numerically maximized. If there is no change point associated to the k^{th} component *i.e.* if $m_k = 0$, Equation 2.5 becomes equivalent to Equation 2.3.

2.3 Algorithm for finding multiple change points

For change point estimation in a time series with moderate length, an exhaustive search at each time point is extremely time consuming and maybe computationally infeasible. Employing a sequential approach for multiple change point estimation has been suggested by the studies of [2]. Application of segmentation algorithm that involves partitioning the entire time series into smaller pockets [3] is particularly useful in this context.

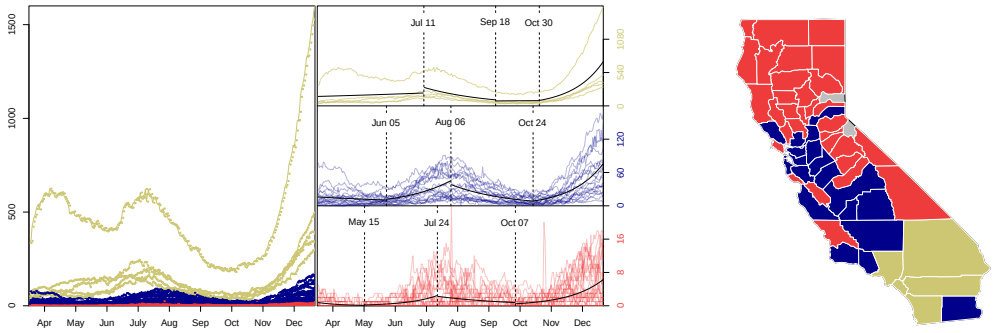
In the beginning, the list of change points $\mathcal{CP}list$ is $NULL$ and a null model $\mathcal{M}_{null}$ with no change point is fitted according to Equation 2.3. The observed interval is partitioned into smaller intervals of length h with break points $\{b_0, \ldots, b_d\}$ where $b_0 = t_0$, $b_d = t_T$ and $d = \lfloor T/h \rfloor + 1$. Here, the $\lfloor . \rfloor$ operator returns the integer part of a real number. For each mixture component, $d-2$ models according to Equation 2.5 are fitted with the assumption that there exist change points at$\{b_i, b_{i+1}\} \cup \mathcal{CP}list$ where $1 \leq i \leq d-2$. The best c models (c is user specified) among these $d-2$ candidates are chosen based on BIC value. The intervals associated to these c models are combined to get a favorable interval ($\mathcal{I}_{fav}$). An exhaustive search is performed for each time point within the interval which involves fitting $c(h+1)$ models with the assumption that change points exist at $\{cp\} \cup \mathcal{CP}list$ where $cp \in \mathcal{I}_{fav}$. If the BIC value for a fitted model is less than the BIC value of $\mathcal{M}_{null}$, the associated time point $\mathcal{CP}_{est}$ is added to $\mathcal{CP}list$ for the specific mixture component and the corresponding model is denoted as $\mathcal{M}_{current}$. This process is repeated for each component. Then a search for the next set of change points is conducted until all searches yield higher BIC.

2.4 Computational issues

In this paper, we use k-means with one iteration to initialize the algorithm. Several random starts are run till convergence and the solution with the minimum BIC is adopted as the null model. During the search for change points, each alternative model is initialized by the model adopted in the previous step so that the iteration required for convergence is much fewer than if initialized randomly. The computational time for analyzing one dataset (in the following application section) with $n = 56$ and $T = 275$ is 50327.706 seconds (14 hours).

3. Application

We apply the proposed methodology to the California county COVID-19 daily ICU data which includes a total of 275 days in 2022. Models are fitted for $K = 1, 2, 3, \ldots$ components and $\hat{K} = 3$ is the



(a) (b)

Figure 1: (a) Grouped daily ICU positive patients curves for 56 counties in California, (b) 3-cluster solution presented on California map.

chosen mixture order based on its lowest entropy value [1]. Figure 1 (a) demonstrates the obtained partition on the left. The khaki group has the highest daily ICU positive patients, followed by the blue one. The red group has the lowest ICU counts. The corresponding geographical location of these counties are shown in California map in Figure 1 (b). South California counties are mostly khaki with highest positive patients. The blue group along the west coast including the Bay area has moderate control of cases. The North California area, which consists of red counties, has the lowest transmission rate.

The change points estimated by the algorithm are reflected by dashed lines in Figure 1 (a). The solid black lines represent mean profiles fitted by the model. There are three change points detected in each group and they happen at different times across different groups. Generally speaking, the numbers are stable (slightly dipped for the red and blue groups) due to regulations and stay-at-home orders from the state governor. After those orders get lifted, the numbers increased for all three groups during May – July. The state slowly reopened public places in an attempt to recover from economy depression. During the mid of summer, several close-down orders were re-imposed.

In khaki counties, this results in a decline in numbers starting from July 11. On August 28, the state governor released the "Blueprint for a Safer Economy" guideline which classified all counties into 4 tiers based on the number of daily cases and current test positivity rate. The assignment can move to a lower or higher tier if recent numbers change. Re-openings will be permitted according to the assigned category. This smart movement effectively controlled the numbers during September – October. We can clearly see an increasing trend for all three groups towards the end of the year starting from October, which is probably driven by the holiday season and the presidential election.

Similarity Measures and Internal Evaluation Criteria in Hierarchical Clustering of Categorical Data

Jana Cibulková[a], Zdeněk Šulc[a], Hana Řezanková[a], and Jaroslav Horníček[a]

[a] Prague University of Economics and Business, Department of Statistics and Probability, W. Churchill Sq. 4, 130 67 Prague 3, Czech Republic;
jana.cibulkova@vse.cz, zdenek.sulc@vse.cz, hana.rezankova@vse.cz, jaroslav.hornicek@vse.cz

Abstract

The contribution focuses on the hierarchical clustering of objects characterized by categorical variables and on the evaluation of the obtained results by selected internal criteria. The aim is to assess the dependence of the evaluation criteria on the dataset properties and the used similarity measure. In the experiment, 270 generated datasets (with the controlled number of variables, between-cluster distances, and the number of clusters) are analysed using the average linkage method and twelve similarity measures. Moreover, the correlation of obtained values of the five examined internal criteria is studied as well. We apply the ANOVA method to assess the dependence of evaluation criteria on the dataset parameters and the similarity measure. We found that the number of clusters influences the dependence intensity of internal criteria on the type of similarity measure. The dependence intensity of internal criteria on the dataset properties varies greatly according to the particular dataset parameter and the type of evaluation criteria.

Keywords: categorical data, cluster analysis, similarity measures, evaluation criteria

1. Introduction

For the investigation of the data structure, cluster analysis is often used. This type of data analysis includes many different techniques. The most frequent task of clustering is the identification of groups (clusters) of similar objects, whereas each object is represented by a vector of variables. The usual input for analyses is a data matrix in which each row characterizes one object, and each column represents one variable. Methods of cluster analysis can be classified according to what types of variables they can handle.

This contribution focuses on the analysis of datasets with categorical variables whose values are on a nominal scale, i.e., unordered. For this type of data, several kinds of methods were proposed. In our research, we investigate methods of hierarchical cluster analysis, which are based on a proximity matrix with the distances for each pair of objects. In the case of categorical data, dissimilarities are used instead of distances. In the further text, we will use the term "distance" in a broader sense, including also dissimilarity.

The relationships of two objects characterized by values of categorical variables are usually expressed by a similarity, which is transformed into the distance for the purpose of cluster analysis. Recently, different similarity measures were proposed for categorical data. Šulc and Řezanková (2019) proposed two new similarity measures and compared them with similarity measures proposed by some other authors in terms of the quality of the obtained clusters. All these measures are implemented in the *nomclust* R package (Šulc et al., 2022) in the R environment (R Core Team, 2020).

The main aim of this contribution is to assess the dependence of the selected internal evaluation criteria on the properties of the datasets and the used similarity measure. The internal evaluation criteria

are usually constructed to satisfy the principles of compactness and separation of the obtained clusters (e.g., Liu et al., 2010). We also investigate dependencies and differences between the examined internal criteria.

2. Theoretical Background of Experiment

In this section, we describe the way of dataset generation, cluster analysis using different similarity measure, and used internal evaluation criteria. The generated datasets for the experiment were obtained using the *genRandomClust* function from the *clusterGeneration* R package (Qiu and Joe, 2020) and the discretize function from the *arules* R package (Hahsler et al., 2021). The generation process is realized in two steps. In the first step, a dataset with quantitative variables and a multidimensional correlation structure reflecting the studied dataset properties is created. In the second step, the variables are categorized using the equal-width intervals approach.

2.1 Hierarchical Cluster Analysis and Similarity Measures for Categorical Data

For cluster analysis, we applied the average linkage method and twelve similarity measures for categorical data. The average linkage method was chosen, since it avoids the extremes of either large or tight compact clusters and of unwanted chain effect. There are the Goodall 1 (G1), Goodall 2 (G2), Goodall 3 (G3), and Goodall 4 (G4) based on the original Goodall measure (Goodall, 1966), and Lin 1 (LIN1), which were introduced by Boriah et al. (2008). The names of the other measures are Eskin (ES) proposed by Eskin et al. (2002), Lin (LIN) introduced by Lin (1998), the simple matching coefficient (SM) proposed by Sokal and Michener (1958), the measures occurrence frequency (OF) and inverse occurrence frequency (IOF) introduced by Spärck Jones (1972), and the measures variable entropy (VE) and variable mutability (VM) proposed by Šulc and Řezanková (2019).

When two objects are compared, for each variable, two values for the examined two objects are compared. In the case of the categorical data, we can only distinguish whether the two values are the same or not. Thus, for the expression of object similarity, two certain values (e.g. 1 or 0) or ways of their calculations are given: one for the equality, and the second for the inequality of the variable values.

For a certain similarity measure, the relationship of the objects $\boldsymbol{x}_i$ and $\boldsymbol{x}_j$ can be computed either as

$$S(\boldsymbol{x}_i, \boldsymbol{x}_j) = \frac{\sum_{c=1}^{m} S_c(x_{ic}, x_{jc})}{m}\ , \tag{1}$$

or as

$$S(\boldsymbol{x}_i, \boldsymbol{x}_j) = \frac{\sum_{c=1}^{m} S_c(x_{ic}, x_{jc})}{\sum_{c=1}^{m} \left(\ln p(x_{ic}) + \ln p(x_{jc})\right)}\ , \tag{2}$$

where c is the index of a certain variable, S_c is the comparative value for the cth variable, x_{ic} is the value for the ith object in the cth variable, m is the number of variables, and $p(x_{ic})$ is the relative frequency of the value x_{ic} (similarly for x_{jc}).

For the similarity measures that take on values from zero to one, the distance between the objects $\boldsymbol{x}_i$ and $\boldsymbol{x}_j$ is computed as

$$D(\boldsymbol{x}_i, \boldsymbol{x}_j) = 1 - S(\boldsymbol{x}_i, \boldsymbol{x}_j). \tag{3}$$

For the similarity measures whose maximum is lower than one, the distance between the objects $\boldsymbol{x}_i$ and $\boldsymbol{x}_j$ is calculated as

$$D(\boldsymbol{x}_i, \boldsymbol{x}_j) = \frac{1}{S(\boldsymbol{x}_i, \boldsymbol{x}_j)} - 1. \tag{4}$$

2.2 Internal Evaluation Criteria for Clustering Results with Categorical Data

For the evaluation of clustering results, we used five internal criteria, two of them are based on the comparison of within-cluster and between-cluster variability, two criteria are based on the likelihood, and the last criterion is based on the distances. Distance based criteria are usually applied when quantitative data are analysed. Their obtained values depend on the used type of the distance measure.

2.2.1 Variability-based Criteria

When data with categorical variables are analysed, special variability measure should be applied. There are usually the Gini measure (mutability) and entropy. Mutability of the whole dataset (the total mutability) is expressed as

$$TM = \sum_{c=1}^{m}\left(1 - \sum_{u=1}^{K_c}\left(\frac{n_{cu}}{n}\right)^2\right), \tag{5}$$

where c is the index of a certain variable, m is the number of variables, u is the index of a certain category (a certain value from the set of unique values of the analysed variable), K_c is the number of categories of the cth variable, n_{cu} is the number of values equal to the uth category of the cth variable, and n is the number of objects in the dataset. Entropy of the whole dataset (the total entropy) is then expressed as

$$TE = \sum_{c=1}^{m}\left(-\sum_{u=1}^{K_c}\left(\frac{n_{cu}}{n}\ln\frac{n_{cu}}{n}\right)\right). \tag{6}$$

The within-cluster mutability for k-cluster solution of clustering is calculated as

$$WCM(k) = \sum_{g=1}^{k}\frac{n_g}{n}\sum_{c=1}^{m}\left(1 - \sum_{u=1}^{K_c}\left(\frac{n_{gcu}}{n_g}\right)^2\right), \tag{7}$$

where g is the index of a certain cluster, n_g is the number of objects in the gth cluster, and n_{gcu} is the number of values equal to the uth category of the cth variable in the gth cluster. Similarly, the within-cluster entropy for k-cluster solution is calculated as

$$WCE(k) = \sum_{g=1}^{k}\frac{n_g}{n}\sum_{c=1}^{m}\left(-\sum_{u=1}^{K_c}\left(\frac{n_{gcu}}{n_g}\ln\frac{n_{gcu}}{n_g}\right)\right). \tag{8}$$

On the basis of the formulas mentioned above, the pseudo F coefficients (for k clusters) inspired by Milligan and Cooper (1987) can be expressed either as the pseudo F coefficient based on mutability

$$PSFM(k) = \frac{(n-k)(TM - WCM(k))}{(k-1)WCM(k)} \tag{9}$$

or as the pseudo F coefficient based on mutability

$$PSFE(k) = \frac{(n-k)(TE - WCE(k))}{(k-1)WCE(k)}\ . \tag{10}$$

These modifications of the pseudo F coefficient were proposed by Řezanková et al. (2011). The maximal value across all the examined cluster solutions suggests the optimal number of clusters for both criteria.

2.2.2 Likelihood-based Criteria

We applied two criteria based on the likelihood in our experiment: the Akaike information criterion (AIC) and the Bayesian information criterion (BIC). Clustering evaluation by these criteria is explained by Bacher (2004). Both the criteria indicate the optimal number of clusters by their minimal value.

With the notation mentioned above, we can write the AIC (Akaike, 1973) as

$$AIC(k) = 2\sum_{g=1}^{k} n_g \sum_{c=1}^{m}\left(-\sum_{u=1}^{K_c}\left(\frac{n_{gcu}}{n_g}\ln\frac{n_{gcu}}{n_g}\right)\right) + 2k\ \sum_{c=1}^{m}(K_c - 1) \quad (11)$$

and the BIC (Schwarz, 1978) as

$$BIC(k) = 2\sum_{g=1}^{k} n_g \sum_{c=1}^{m}\left(-\sum_{u=1}^{K_c}\left(\frac{n_{gcu}}{n_g}\ln\frac{n_{gcu}}{n_g}\right)\right) + k\sum_{c=1}^{m}(K_c - 1)\ln n\ . \quad (12)$$

2.2.3 A Distance-based Criterion

As a representative of distance-based criteria, we used the silhouette index (SI), proposed by Rousseeuw (1987) as the average silhouette width. It takes on values from –1 to 1. Values close to one indicate well-separated clusters with low within-cluster distances and high between-cluster distances. The maximal value of the criterion across all the examined cluster solutions indicates the optimal number of clusters. It is calculated as

$$SI(k) = \frac{1}{n}\sum_{i=1}^{n}\frac{b(i)-a(i)}{\max(a(i),b(i))}, \quad (13)$$

where $a(i)$ is the average distance of the ith object from the other objects in the same cluster, and $b(i)$ is the minimal average distance of the ith object from other objects in any cluster not containing the ith object. For the analysis and for result evaluation, the same type of the distance measure should be used.

3. Results of Experiment

The datasets with two, four and six clusters were generated. The other parameters of the datasets were a number of variables (4, 7, and 10) a between-cluster distance (0.21, 0.34, and 0.5). The number of categories was five for all variables. For the experiment, 27 different dataset settings were used. Each dataset setting combination was replicated ten times, it means that 270 datasets were generated. Each dataset was analysed using twelve similarity measures.

Correlation analysis was performed to determine whether the applied evaluation criteria assess the quality of clusters in a similar way. We found that the values of the correlation coefficient express medium to high linear dependences between the examined criteria. There was almost a direct linear dependence (r = 0.998) between the AIC and BIC and between PSFE and PSFM (r = 0.99). Therefore, only one representative for each group of evaluation criteria, namely PSFE, BIC, and SI, are presented for the following analyses.

Table 1 shows the values of the eta coefficient expressing the dependence intensity of a particular evaluation criterion on the similarity measure. The values are obtained based on the ratio of the between-group and total variability in the ANOVA method. The method compares the between-group sum of squares (SS_B) with the within-group sum of squares (SS_W). The higher the SS_B variability, the more strongly the quantitative variable depends on the categorical one. The *eta coefficient* can be expressed by the formula

$$\eta(v,a) = \sqrt{\frac{SS_B}{SS_B+SS_W}}, \quad (14)$$

where v is a partition with values of an evaluation criterion, a is the categorical variable expressing a given property of the clustered dataset, e.g., the number of clusters or variables.

The outputs are broken down by the number of generated clusters. Whereas the BIC values barely depend on the used similarity measure, the SI values are strongly determined by it. The eta coefficient values decrease with the increasing number of clusters.

Table 1: Eta coefficient values evaluating the dependence intensity of internal criteria on the type of the similarity measure (broken down by the number of clusters)

Criterion	2 clusters	4 clusters	6 clusters	Total
PSFE	0.529	0.427	0.320	0.345
BIC	0.214	0.193	0.187	0.190
SI	0.887	0.653	0.489	0.632

Table 2 shows the values of the eta coefficient expressing the dependence intensity of a particular evaluation criterion on the parameters of the dataset, namely the between-cluster distance (clu_dist), the number of variables (n_var), and the number of clusters (n_clu). The outputs are broken down by the similarity measure. We can see that the dependence intensity of internal criteria on the dataset properties varies greatly according to the particular dataset parameter and the type of evaluation criteria.

Table 2: Eta coefficient values evaluating the dependence intensity of internal criteria on the dataset parameters (broken down by the similarity measure)

	PSFE			BIC			SI		
Measure	clu_dist	n_var	n_clu	clu_dist	n_var	n_clu	clu_dist	n_var	n_clu
ES	0.430	0.445	0.669	0.199	0.966	0.031	0.504	0.603	0.420
G1	0.451	0.507	0.631	0.190	0.969	0.070	0.535	0.652	0.320
G2	0.419	0.440	0.691	0.199	0.965	0.025	0.465	0.595	0.502
G3	0.433	0.507	0.646	0.184	0.971	0.046	0.507	0.648	0.369
G4	0.346	0.200	0.266	0.114	0.967	0.031	0.123	0.294	0.105
IOF	0.438	0.419	0.688	0.196	0.969	0.024	0.408	0.369	0.724
LIN	0.441	0.420	0.636	0.191	0.968	0.083	0.577	0.555	0.389
LIN1	0.363	0.702	0.176	0.068	0.976	0.163	0.243	0.809	0.090
OF	0.432	0.430	0.464	0.209	0.949	0.048	0.460	0.517	0.468
SM	0.427	0.449	0.669	0.198	0.966	0.031	0.511	0.616	0.415
VE	0.418	0.467	0.683	0.185	0.970	0.018	0.470	0.639	0.414
VM	0.424	0.469	0.675	0.192	0.969	0.022	0.485	0.636	0.417
Total	0.388	0.407	0.554	0.172	0.948	0.038	0.333	0.405	0.316

The total dependence of the BIC criterion on the number of variables (eta = 0.948) is more than twice as strong as by PSFE (eta = 0.407) and SI (eta = 0.405) criteria. On the other hand, the total dependence of this criterion on the between-cluster distance is weak, and the dependency on the number of clusters is minimal. The eta value for this criterion is highest with the number of variables for all similarity measures.

For most similarity measures, the values of PSFE depend mostly on the number of clusters. However, moderate dependences are also with the number of variables and between-cluster distance. For almost all similarity measures, the values of PSFE depend mostly on the number of variables. However, moderate dependences are also with the between-cluster distance and number of variables.

4. Conclusion

The results show that the dependence intensity of internal criteria on the type of similarity measure is influenced by the number of clusters. The dependence intensity of internal criteria on the dataset properties varies greatly according to the particular dataset parameter and the type of evaluation criteria. The highest values of the eta coefficient evaluating these dependences were found in the case of the BIC criterion and the number of variables – for all twelve examined similarity measures.

In the case of SI, the values of the eta coefficient are mostly the highest in the case of the number of variables, too. However, the dependence intensity is twice as small in comparison with the BIS criterion. In the case of PSFE, the values of the eta coefficient are mostly the highest in the case of the number of clusters. For this evaluation criterion, comparing the values of the eta coefficient for the particular similarity measures, the values for the LIN1 measure are very different from the others. Due to space limitations, this contribution considers average linkage only. However, it could be extended to study and compare dependence intensity of internal criteria on the type of similarity measure across multiple linkage methods. It is expected by authors, based on the preliminary studies, that the results presented in this contribution would be stable across various linkage methods.

Abstract

Several statistical methods are based on distances, that is, the quantification of the differences among observed values in a set of attributes. The definition of distance is not unique as it depends on the attributes describing the observations, and on the problem at hand. Spectral clustering, that takes as input the pair-wise distances between observations, makes no exception: its performance will depend on the considered distance measure. Computing distances with respect to continuous attributes only is intuitive, not so in case of categorical and mixed data. In this paper an association-based distance for mixed data is proposed, within the spectral clustering framework.

Keywords: mixed-type data, spectral clustering, association-based distance

1. Introduction

Several unsupervised learning methods, such as spectral clustering (10, SC), partition around medoids (9), or probabilistic distance clustering (1), take pairwise distances as input: the overall method performance depends on the distance measure of choice. The distance between two observations is the quantification of the differences between the two observed vectors of values, and its definition is not unique: it depends on the attributes describing the observations and on the problem at hand. Computing distances for continuous attributes is intuitive, as they depend on distances among the observed values; an example is the squared Euclidean distance, the sum of the squared differences in the attribute values. Measuring distances between a pair of observations described by categorical attributes or by a combination of continuous and categorical attributes is less straightforward. Practitioners may compute distances by coding the categories as numbers and then using the Euclidean distance, but such an approach would be simplistic at best. A plethora of distance measures for categorical data has been proposed in the literature; these go beyond counting the times two observations present different entries. Recently, (11) proposed a unified framework that includes the best-known distance measures for categorical data.

However, the abundance of available measures makes choosing the one to adopt challenging. When it comes to the mixed data case, choosing a distance measure becomes even more complex; two appropriate distance measures must be chosen for continuous and categorical attributes, respectively, and then they have to be suitably combined in a single measure. The best-known measure is Gower's general dissimilarity coefficient (3), where the dissimilarity between two rows is the weighted mean of the contributions of each attribute.

Extending unsupervised learning methods to mixed data sets can be done by rendering homogeneous attributes (via discretization of the continuous attributes or the quantification of the categorical attributes) at the cost of information loss. More enhanced solutions come from *ad hoc* approaches. The paper aims to propose an implementation of SC for mixed data by using an association-based distance that considers the interaction between categorical and continuous attributes.

The remainder of the paper is structured as follows: Section 2. recalls the main concepts of SC and association-based distance; in Section 3. the association-based distance for mixed data is described; in Section 4. alternative SC implementations are compared on some synthetic datasets.

2. Background

2.1 Spectral clustering

SC can be seen as a graph partitioning problem (13). The $n \times p$ data matrix $\mathbf{X}$ is represented as a similarity graph $G(V, E)$ of the data where the n objects are represented as the vertices/nodes V and the edges E that connect the vertices are based on some measure of similarity between the n points. SC was firstly proposed for continuous data; in such a case the similarity matrix is obtained as a transformation of a distance matrix, the most commonly used metric is the Euclidean distance. There are several SC algorithms. A commonly used one is the NJW algorithm by (8). After calculating the symmetric Euclidean distance matrix $\mathbf{S}$, with all zeros on the diagonal, most SC algorithms transform the matrix $\mathbf{S}$ into a similarity matrix. Specifically, the NJW algorithm computes the affinity matrix $\mathbf{A}$ as a weighted negative exponential of $\mathbf{S}$ after which the diagonal entries A_{ii} are set to zero. A second matrix is then computed, the diagonal matrix $\mathbf{D}$ with D_{ii} equal to the sum of the elements of row i of $\mathbf{A}$. The graph Laplacian matrix $\mathbf{L}$ can then be calculated from $\mathbf{A}$ and $\mathbf{D}$ as $\mathbf{L} = \mathbf{I} - \mathbf{D}^{-1/2}\mathbf{A}\mathbf{D}^{1/2}$. The following step is to create the $n \times k$ matrix $\tilde{\mathbf{Y}}$ using the eigenvectors corresponding to the k largest eigenvalues obtained with the spectral decomposition of the Laplacian matrix $\mathbf{L}$. Each row of $\tilde{\mathbf{Y}}$ is re-normalized to unit length to give $\mathbf{Y}$. The matrix $\mathbf{Y}$ is characterized by well-separated clusters and, therefore, many different clustering algorithms can be used to partition the data. The most commonly used is k-means clustering (4). The cluster assignments for the n rows of Y are the cluster assignments for the original corresponding n objects. For some examples and comparisons of SC with other well-known clustering techniques, see (7).

The definition of the starting distance matrix is key to extend the SC to non-continuous attributes: some recent work focused on extending SC for mixed-type data. SpectralCaT (2) automatically transforms the data into categorical values and then applies a dimension reduction version of SC. SC for mixed data (5), instead, uses Euclidean distance for continuous variables, matching coefficient for categorical, and a tuning algorithm to determine the weights. Lastly (6) proposes the use of an extended Mahalanobis distance based on mutual information within SC.

2.2 Association-based distance for categorical data

Let $\mathbf{X}_{cat}$ be an $n \times p$ matrix of categorical attributes, each with q_i categories, $i = 1, \ldots, p$, and let $\mathbf{Z}_i$ be the one-hot encoded version of the i^{th} attribute and $\mathbf{Z} = [\mathbf{Z}_1, \mathbf{Z}_2, \ldots, \mathbf{Z}_p]$. The pair-wise distance between categorical observations is given by

$$\mathbf{D}_{cat} = \mathbf{Z}\boldsymbol{\Delta}\mathbf{Z}^{\mathsf{T}}$$

where $\mathbf{\Delta}$ is a block-wise diagonal matrix: each diagonal block $\mathbf{\Delta}_i$ is of size $q_i \times q_i$, $i = 1, \ldots, p$. The definition of $\mathbf{\Delta}$ determines the distance of choice.
In the framework described in (11), a distinction is made between *independent* and *association-based* category dissimilarities; in the former case, a single weight is associated to each category of the categorical attributes and the corresponding $\mathbf{\Delta}$ matrix is diagonal. The general idea of association-based measures for categorical data is similar to the Mahalanobis distance for continuous attributes: differences in categories with similar association with the other attributes are less informative and should have a limited contribution to the distance value. For each attribute, the weight assigned to the difference between a pair of categories a and b depends on the distributions of the the other attributes conditional to a and b: the higher the similarity, the lower the weight. Consider the matrix of co-occurrence proportions

$$\mathbf{P} = \frac{1}{n}\mathbf{Z}^{\mathsf{T}}\mathbf{Z},$$

and the matrix of conditional distributions as

$$\mathbf{R} = \mathbf{P}_d^{-1}\left(\mathbf{P} - \mathbf{P}_d\right),$$

where $\mathbf{P}_d = diag(\mathbf{P})$ and $\mathbf{R}_{ij}$ is the $q_i \times q_j$ general off-diagonal block of $\mathbf{R}$. In particular, the a^{th} row of $\mathbf{R}_{ij}$, $\mathbf{r}_a^{ij}$, is the conditional distribution of the j^{th} variable, given the a^{th} category of the i^{th} variable.
Now, for each pair of categories a and b from the i^{th} categorical variable, their overall dissimilarity $\delta^i(a, b)$ is

$$\delta^i(a, b) = \sum_{i \neq j}^{q} w_{ij}\Phi^{ij}(\mathbf{r}_a^{ij}, \mathbf{r}_b^{ij}).$$

It follows that $\delta^i(a, b)$ is the off diagonal entry of $\mathbf{\Delta}_i$. The association-based measure of choice boils down to how $\Phi^{ij}(\mathbf{r}_a^{ij}, \mathbf{r}_b^{ij})$ is computed. To use the total variation distance between two discrete probability distributions, $\Phi^{ij}()$, is given by

$$\Phi^{ij}(\mathbf{r}_a^{ij}, \mathbf{r}_b^{ij}) = \frac{1}{2}\sum_{\ell=1}^{q_j} |\mathbf{r}_{\ell a}^{ij} - \mathbf{r}_{\ell b}^{ij}|.$$

Other options are available, and are described in (11).

3. Association-based distance for mixed data

A straightforward way to generalize the association-based measures from the categorical to the mixed data case is to compute the Mahalanobis distance on the continuous attributes, and the total variation distance on the categorical attributes. The mixed data distance is then computed as a convex combination of the two obtained distance measures. While this approach is coherent as the two distances share the same rationale, it does not take into account the relation between categorical and continuous variables. As a step forward, we propose to incorporate, in the computation of $\mathbf{\Delta}$, the effect of the continuous attributes on each categorical attribute. In particular, we measure the impact of continuous attribute(s) on the difference between a pair of categories using their discriminant power. More specifically, for each pair of categories, we consider a two-class classification problem, with the continuous variables as predictors. We then compute the accuracy of the nearest neighbors (NN) classifier: the higher the accuracy, the higher the impact of the continuous variables on the considered category pair.
Formally, let us consider a pair of categories a and b from the i^{th} categorical variable, and their proportion π_a and π_b, computed with respect to n_{ab}, the number of observations that present the category a OR the category b.
For each observation of the categories a and b, with a proportion of occurrence π_a and π_b, respectively, we compute a set of neighbors $\mathcal{N}_a$ of size $k\pi_a$ and a set of neighbors $\mathcal{N}_b$ of size $k\pi_b$. We refer to $\hat{\pi}_a$ and $\hat{\pi}_b$ as the observed proportions of a and b, respectively, within $\mathcal{N}_a$ and $\mathcal{N}_b$. For each observation of the category a, if $\hat{\pi}_a \geq .5$, then the observation is well classified. Same goes for the observations of

the category b. The Φ_{ab}^{ij} and Φ_{ab}^{ij} measures represent the improvement of the NN classifier over the pure chance $(.5)$, that is

$$\Phi_{ab}^{ij} = \frac{1}{k\pi_a} \sum_{s \in \mathcal{N}_a} I(\hat{\pi}_{a(s)} > .5) - .5,$$

$$\Phi_{ba}^{ij} = \frac{1}{k\pi_b} \sum_{s \in \mathcal{N}_b} I(\hat{\pi}_{b(s)} > .5) - .5;$$

Finally, the general measure for the category pair (a, b) is

$$\Phi^{ij}\,(ab) = \frac{1}{2}(\Phi_{ab}^{ij} + \Phi_{ba}^{ij}).$$

Figure 1 shows the Φ_{ab}^{ij} values corresponding to four different scenarios: the factors involved are the overlap and the convexity of the group of observations defined by a and b. For the non-overlapping cases, $\Phi_{ab}^{ij} = 1$, irrespective to the convexity of the classes. For the overlapping cases, the obtained values are $\Phi_{ab}^{ij} < .25$.

Figure 1: Values of Φ_{ab}^{ij} in different scenarios: convex (top) and non convex groups, without (left) and with overlap. In the non overlapping cases $\Phi_{ab}^{ij} = 1$ as the observations labeled a and b are perfectly separated. In case of overlap, the value of Φ_{ab}^{ij} drops to less than .25

4. Experiments

An extensive experiment to assess the proposed association-based measure for mixed data is beyond the scope of the paper. We report an illustrative comparison of the SC performance using different approaches to the pairwise distances computation. We consider up to 10 attributes, some categorical and some continuous. In particular, the categorical attributes are generated with mild to high degree of association with cluster membership, according to the procedure described in (12). The continuous attributes with structure are generated via a bivariate Gaussian distribution with a different mean in each cluster and the same diagonal covariance matrix; the other continuous attributes are Gaussian noise. The factors

considered are *association* (mild/high) and *noise* (mild/high). The former refers to the strength of the association of the categorical attributes to the cluster membership, the latter to the number of considered noise attributes (two continuous and two categorical, or four of each type). We assess the SC performance via the ARI computed with respect to the *t*rue cluster membership. The proposed approach is compared to other three approaches: a Gower distance-based approach; a simple convex combination of matching and Euclidean distance as in (5) (referred to as *matching*); a convex combination of the total variation and the Euclidean distances (referred to as *total_variation*). Note that, for the sake of simplicity, the weight of the considered convex combinations, including the newly proposed method, is fixed: the choice of such hyper-parameter is sensitive and should be tuned as, e.g., in (5). The number of neighbors for the computations of the $\phi^{ij}(ab)$'s is also kept fixed: this hyper-parameter showed less impact on the results, therefore one could use a rule of thumb (e.g. a constant proportion $(.05)$ of n), and skip the tuning process.
The results are reported in Figure 2: for high association and mild noise, any distance method would produce the same high performance; when the association is mild, the proposed association-based measure provide better results, even compared to the total variation distance: taking into account the impact of the continuous on the categorical attributes is beneficial, especially when the association within the categorical attributes is mild. Furthermore, performances related to the proposed association-based measure are less affected to the increased number of noise attributes.

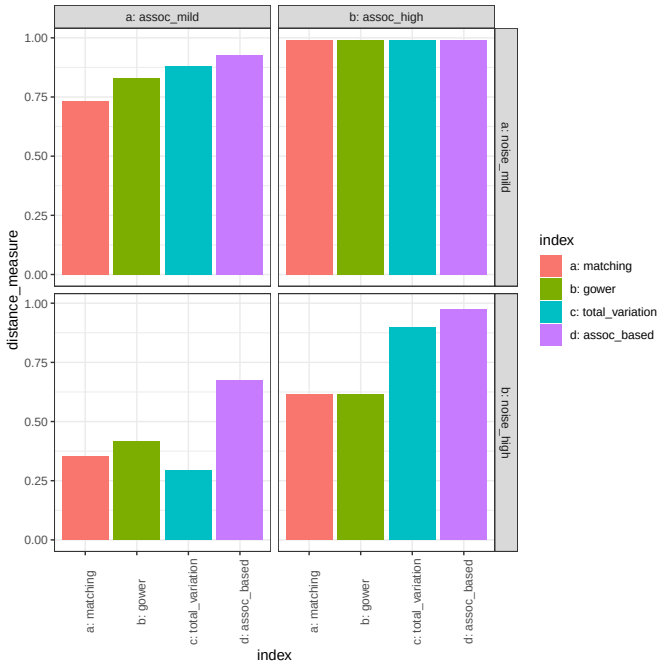

Figure 2: ARI results for SC solution based on different distance measures for the categorical/mixed attributes: matching, Gower, total variation distance, association-based distance for mixed data.

In spite of the fairly promising preliminary results, future work is very much needed to assess and perfect the proposed measure. A larger scale experiments is to be carried out. Also, at the moment, the interaction continuous/categorical is accounted for just one-way: only the impact of the continuous attributes on each pair of categories is measured, and not the other way around. A further development to account for the impact of the categorical attributes on the pairwise distance of the continuous ones is in the works.

A graph based convolution Neural Network approach for forecast reconciliation

Andrea Marcocchia[a] and Pierpaolo Brutti[a]

[a]La Sapienza University of Rome; name.surname@uniroma1.it

Abstract

Forecast reconciliation for hierarchies of time series, whose idea is that observed responses at each level have to add up to those observed at higher levels, is a theme of growing interest in the scientific community. The challenge is to exploit the high signal-to-noise ratio that characterizes the most aggregated data to boost the forecast on the more granular data. In this work, a new family of techniques is developed to solve the problem in a multi-hierarchical scenario, embracing both temporal and classical hierarchies. The idea is to leverage the predictive power and the flexibility of Graph Convolutional Neural Networks (GCN) by designing an architecture with the goal of making all the hierarchies simultaneously consistent. This approach has been tested on real and simulated datasets, and the new architectures achieve promising results.

Keywords: forecasting, time series, forecast reconciliation, hierarchical time series, convolution, deep learning, graph neural network

1. Introduction

The goal of forecast reconciliation is that forecasted values at a level of the hierarchy add up to the predicted demands at higher levels. If forecasting at the different levels is done independently, we have forecast incoherence, meaning that the bottom level forecasts do not add up. The various components of the hierarchy can interact in a variety of complex ways: a change in one series can have an impact on other series at the same level, as well as on series at higher or lower levels. Reconciliation is the process that fixes incoherent forecasts.

In this work a new approach is proposed that exploits convolution techniques to perform reconciliation in the case of multiple hierarchies at the same time, so that all the hierarchies are exploited simultaneously to produce the best possible reconciled values. Most of the techniques in the literature are built to work with a single hierarchy. However, there are numerous real-world cases in which multiple hierarchies are valid simultaneously, and the information contained in such data structures and the gain they can bring must be exploited in the best possible way. The idea is to introduce an architecture that allows to work with multiple hierarchies in a Deep Learning framework, such that the output values are coherent for multiple hierarchies at once. This process is embedded in an end-to-end architecture, so that all information is also leveraged during the forecasting phase, and the two steps are not unnecessarily separated, returning in ouput coherent values. The hierarchies can be both classical or temporal.

The innovative and most important aspect of the presented technique is the use of Graph Neural Network to represent the hierarchical structures. Using a graph representation it is possible to link all the time-series in a flexible way, sharing the information in the hierarchy in an effective way.

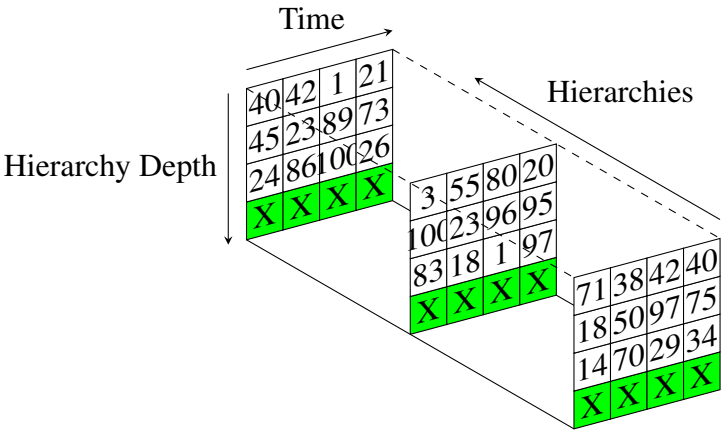

Figure 1: Multi-channel matrix representation of hierarchies

2. Architecture

The proposed method makes use of Deep Learning, and it is specifically proposed as an end-to-end architecture. This means that a single loss function is optimized that keeps together both the forecasting and the reconciliation steps, instead of choosing a different loss and hyper-parametrer setting for the forecast and reconciliation stage. In roder to perform both the forecasting and the reconciliation task with a single model, it is necessarily to develop an architecture that is able to join all the information from the different levels of the hierarchy and to perform the forecasting step. The complete proposed method exploits an architecture similar to CNN + LSTM, in which in a first step there are layers that allow the information contained in the hierarchy to be shared through a convolution step, and then there is a forecast step exploiting techniques such as LSTM. The loss function can be evaluated in two different ways: focusing on the bottom level series (and rebuilding the whole hierarchy using a Bottom-up approach) or focusing on all the levels of the hierarchy. Considering that the general purposes when forecast reconciliation techniques are used are to improve the quality of the bottom level series, the first approach is used in the experiments. The focus of this work is on the convolutional step, since here the hierarchical structure is more involved and it is crucial for the overall goodness of fit. In this stage the Graph Neural Network are introduced.

The more intuitive idea to represent the hierarchy in a format that is suitable for a Deep Learning algorithm is through the use of a matrix, stacking all the series together or using a multi-channel approach, as in the next image:

where the X values are the bottom level series, that are the same for each training sample. The advantage of this architecture is that it allows to apply a filter that includes all the information simultaneously.

Anyway, the matrices data structure is very rigid, while the problem to be modeled requires more flexibility. The representation that best fits this type of data is a graph representation where each node represents a time series and there is an edge between two nodes if and only if the two time series are adjacent in the hierarchy. It is possible to save within each node some features, and in this case the time series analyzed are saved. The nodes in the graph will be both the series at the bottom level and the aggregated series. In this representation there is a link between all nodes at an adjacent level of the hierarchy. The graph is indirect since the relationship between the two nodes is reciprocal. In such a graph, there can be no completely disconnected nodes. In the next image it is reported an example of graph created from two hierarchies:

The provided graph representation can easily be extended to more than two hierarchies just adding other nodes and edges.

Once the hierarchical structure is represented using a graph, it is necessary to perform a convolutional step over the graph. There are several ways to perform convolutions on graphs: these techniques belong to the field of Graph Neural Network. The idea behind these methods is that a convolution step involves updating the information of each node with that of its neighbors. The updating of information can be

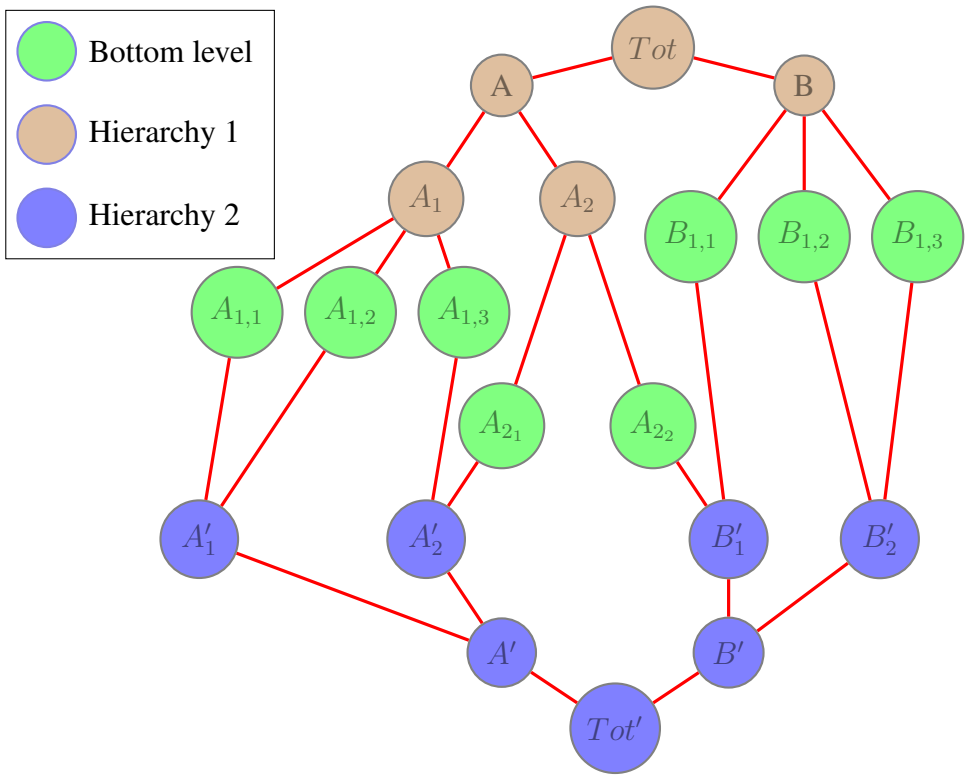

Figure 2: Graph representation of hierarchies

done by exploiting several functions: average, sum, concatenation and others. By taking advantage of this architecture, known as Message Passing Algorithms, it is then possible to share the information from the more aggregated series with the less aggregated series, achieving the desired benefits. At the end of a convolution step on graphs, the topology of the graph will be unchanged. The number of nodes and edges will be the same as the input dataset. What will have changed is the time-series information within each node, which will contain the updated information. The number of convolution layers is a hyperparameter of the architecture: the greater the number of layers, the greater the depth of the graph with which each node will share information.

There are multiple algorithms to perform the Graph Convolutional step:

- **Message Passing**: it is more general implementation of the convolution operator over graphs. In formula it can be defined as follows:

$$x_i^{(k)} = \gamma^{(k)}\big(x_i^{(k-1)}, \Psi_{j \in \mathbf{N}(i)} \phi\big(x_i^{(k-1)}, x_j^{(k-1)}, \mathbf{e}_{j,i}\big)\big)$$

  where i is a generic node, k a generic layer and $x_i^{(k-1)}$ the feature of node i in the layer $k-1$. The value $\mathbf{e}_{j,i}$ represents the edge features from node i to node j: this value is optional and in our implementation it is not considered. Ψ denotes a differentiable, permutation invariant function such as the mean, the sum or others. γ and ϕ are differentiable functions such as a simple Multi-Layer Perceptrons. The idea behind this formule is simple: each node in the graph has a feature vector. For each node $x_i^{(t)}$, it is performed an aggregation function of the feature vectors of all neighbouring nodes with the node $x_i^{(t)}$: this quantity is known as message. Then, the feature vector of the node $x_i^{(t)}$ is updated using the obtained message and the previous feature vector of that node;
- **Graph attentional operator**: the *attention* mechanism is a well known field of literature in Machine Learning that shows important results in the field of Deep Learning, in particular with the Transformer architectures. The idea behind this layer, which differentiates it from the classic message passing algorithm, is that the weight of each neighboring node is a parameter that has to be

estimated, and therefore not all nodes have the same importance in sharing information between nodes;
- **Gated graph convolution**: The GatedGCN architecture(2) is an anisotropic message-passing-based GNN that employs residual connections, batch normalization, and edge gates. This method makes use of gated recurrent units.

Once the convolutional step is performed, a set of dense and LSTM layers are stacked in order to perform the forecasting step. This forecasting step is performed for each node on the graph. Once the forecasted values are obtained, it is possible to rebuild the whole hierarchy focusing on the bottom level series.

The training methodology also deserves a closer look: in particular, it is important to analyze how to handle the training, test and validation split. In fact, to perform the convolution step on graphs it is required that edges and nodes are all simultaneously available within the same batch, otherwise there is the risk of removing important links. To solve this problem, it is necessary to analyze in more detail how the split between training, testing and validation can be done. There are basically two ways:

- **Inside the nodes**: in this option, the splitting between frames is done within each node: the time-series saved within the node is split into training, test and validation. In output we have that some timestamps appear in the training dataset, others (later in time) in the test dataset, and still others in the validation dataset.
- **Between the nodes**: in this other method, the time series within nodes are not split. In fact, the splitting is performed directly at the node level. Thus we have some nodes belonging to training, some to testing and some to validation. This methodology involves complications in case there are edges between nodes that belong to different groups: it can be a problem to remove one or more edges since it can lead to disconnected nodes or it can change the graph structure too much.

In the development of this work, the splitting at node level is performed. It is done since the dataset used for testing have few observations for each time-series, so it not easy to divide the data at the series level. In addition, most of the other works in the field of forecast reconciliation are evaluated at the node level. The problem was solved by splitting at the beginning of the training procedure, thus assigning each node its own label (training/test/validation). During training, the entire graph was simultaneously loaded into memory, without removing any edge. The forward step is then always performed for all nodes (so for all the time series), without distinction regarding the set they belong to. The membership set comes into play when the backpropagation step (in training) or the metrics evaluation step (in the case of test or validation) is performed. At this stage, nodes that do not belong to the selected set are "turned off", assigning them a weight of 0. In this way, these nodes do not come into play during the calculations and do not affect the value of the loss or metrics under consideration.

3. Results

The proposed architecture has been tested over multiple dataset: the M5 dataset (3) of the Makridakis competitions and a simulated dataset. In the M5 dataset, the time-series represent the hierarchical unit sales of the world's largest retail company by revenue, Walmart, and the data comprise 3049 individual products from 3 categories and 7 departments, sold in 10 stores in 3 different states: the two hierarchy are built looking at the administrative organization and at the product classification. The simulated dataset has a hierarchical structure that mirrors the M5 structure, but the time-series inside have an easier pattern: all the information are generated using an ARMA process. Both the dataset have multiple hierarchies defined. The common goal in analyzing the performances across datasets is to verify if the use of reconciliation techniques is useful in improving the quality of the original forecasts. In particular, the focus has been on the bottom level series, as these are the most complex and at the same time the most interesting forecasts. The results are evaluated according to the Mean Absolute Error (MAE). The proposed architecture is compared with multiple methods proposed in the literature, such as Optimal Reconciliation methods with OLS Estimator or WLS Estimator (1), Mint (6), Top-down and Bottom-up

(4). The Top-down approach is tested with three different approaches: Top-down with forecast proportions (TD-FP), average of the historical proportions (TD-GSA) and proportions based on the historical averages (TD-GSF).

To properly perform the experiments, all the dataset are divided into training, test and validation. Specifically, 30% of the dataset is isolated to evaluate the test set, 20% as validation and the remainder as training. The splitting is performed on the bottom level series. In the next table the results on the test dataset are reported:

Table 1: MAE performances on test set

Model	Simulated	M5
Graph Conv.	0.0710	0.0915
Matrix Conv (multiple hierarchies)	0.0670	0.0921
MINT	0.0578	0.0971
WLS	0.0598	0.0974
OLS	0.0609	0.0981
BU	0.0571	0.0976
TD-FP	0.0810	0.1507
TD-GSF	0.0950	0.1099
TD-GSA	0.0890	0.1119

In all the considered datasets, the performances are evaluated by focusing on the series at the bottom level, since these are the ones of greatest interest. All the methods that require a base forecast algorithm to perform the reconciliation step (all except the end-to-end architectures that use Deep Learning) use an Arima model to perform the base forecast. For the methods that work with only one hierarchy, one of the defined hierarchical structure is chosen to perform the reconciliation step.

In the simulated dataset, the best result is obtained with the Bottom-Up method: this is quite intuitive since with this approach the focus is all on the series at the bottom level, and any errors that need to be corrected in the reconciliation stage affect the series at the higher levels of the hierarchy. The MINT algorithm also performs well for the reconciliation, but all the Optimal-reconciliation methods seem to be good. It is important to keep in mind that for the simulated dataset the generation process and the base forecast algorithm is the same, so it justifies the better performances of the classical methods with respect to the end-to-end architectures. Analyzing the M5 dataset, as can be seen from the previous table, the methods that make use of neural networks outperforms all the others. The result is due to the fact that in this case the data are much more complicated in their structure, so a simple Arima model is not enough to provide good base forecast. On the other hand, the end-to-end architecture provides a more flexible and power system to perform the forecast and the reconciliation. Looking at the two Neural Network based approaches (the one with graph and the one with multi-channel matrix), it is possible to see how the graph-based outperforms the other. This is due to the better representation of the data, and the lower redundancy of information that the graph representation allows compared to the matrix representation.

4. Conclusions

Regarding the new reconciliation techniques that exploit convolution over multiple hierarchies through the use of graphs or matrices, it has been observed that the results are in line, and sometimes better, with other methods in the literature. The introduction of a new way of representing the hierarchical structure, using graphs, seems really interesting and more applications will be developed in future researches to check the performances of this approach.

It should be emphasized, however, how computationally complex is to train these models in terms of the hardware resources required. Experiments on the M5 dataset are carried out by sampling the data in order to obtain a large number of time series to train the model robustly and generically in the Neural Network approaches. It is necessary because the proposed model have a large number of parameters, and

the convolution steps are really computationally expansive: the use of the whole dataset is not feasible with the hardware resources at our disposal. To solve this problem, the most immediate solution is to have more powerful machines so that a larger amount of data can be trained. However, considering that more hardware power also requires a larger budget, this solution is not scalable. A currently highly debated topic in the field of Graph Neural Networks is that of Graph Summarization, which allows the information contained in one graph to be condensed into another graph of smaller size, but with the same information capacity: in this way, at least for the GNN approach, it might be possible to train larger data with the same hardware capacity.
A field to continue the research work is about the possibility to improve the quality of the forecasts by exploiting external information. Although these kinds of improvements are not directly related to the reconciliation task, it is still important to make the proposed end-to-end architecture able also to support external covariates and in general supporting more complex use cases. This case is applicable to the M5 dataset, where is possible to improve the quality of the forecasts by exploiting external information that are provided with the competition data.

Abstract

The analysis of multivariate time series of pollutant concentrations is complicated by the complex interactions between pollutants, which may not be constant over over time. We propose to approximate the joint data distribution by a parsimonious finite mixture of vector auto-regressive models, whose parameters are driven by the evolution of a latent semi-Markov process. This results in a vector auto-regressive hidden semi-Markov model that is capable to (1) describe the exposure to pollution in terms of a few latent regimes, (2) associate these regimes with specific combinations of pollutant concentration levels as well as distinct correlation structures between concentrations, and (3) provide estimates of sojourn times in each regime and transition probabilities between regimes. We apply the proposed model to the daily time-series of nine pollutant concentrations recorded at the Marylebone Road station, in London, between 2012 to 2017.

Keywords: air quality, EM algorithm, hidden Markov model, semi-Markov process, penalized regression

1. Introduction

Environmental risks are defined as all the external physical, chemical, biological, and work related factors that affect a person's health and well-being. They include pollution, radiation, noise, land use patterns, work environment, and climate change, that are all well-recognised as important causes of disease burden for populations and National Health Systems. Among them, air pollution is classified as one of the greatest environmental risks to health by the WHO[1], causing millions premature deaths worldwide every year (7). Its extent can be measured by the concentrations of various pollutants in the air (10), making its nature intrinsically multi-dimensional.

Here, we propose a multivariate model-based approach, belonging to the class of multivariate vector auto-regressive Hidden Semi-Markov Models (HSMMs; (2)), that can capture the dynamic evolution of environmental risk factors determined by multiple time and cross-dependent components.

HSMMs are recognised as a promising tool driving the assessment of environmental risk building procedure. Specifically, they allow for policy makers to differentiate the overall air-pollution risk exposure depending on the state of the environment identified by the latent process. This synthesis resembles other existing composite metrics such as the air quality index proposed by the US EPA that provides six

[1]see https://www.who.int/news-room/fact-sheets/detail/ambient-(outdoor)-air-quality-and-health

risk levels: “good”, “moderate”, “unhealthy for sensitive groups”, “unhealthy”, “very unhealthy”, “hazardous”. Furthermore, HSMMs are intrinsically dynamic and provide a conditional framework for the quantification of the environmental risk calculated on the resulting predictive distribution. HSMMs can be also viewed as a structured Hidden Markov Models (8; 11) and the predictive distribution is a finite mixture of the semi-Markovian emission distributions. Thus, they allow an analytical assessment of the overall current and future environmental risk conditional on the past values of the process, making them invaluable monitoring tools for regulatory agencies.

Nevertheless, the specification of our model poses two notable statistical challenges: (i) the typical model selection issue related to the order of the autoregression; (ii) the large number of parameters in the state-specific covariance matrices that generate unstable estimates and increasing computational burden. We propose a penalized likelihood approach to HSMMs to deal with these issues, following similar works in the field (3; 4). Here, we contribute to this literature by applying the LASSO regularization on both the hidden state covariance matrix and the vector autoregressive coefficients.

The remainder of the paper is organized as follows. Section 2. summarizes the modeling framework and the estimation process. Section 3. describes the application and the results on the air quality indicators (AQIs) recorded at the Marylebone Road station, in London (UK), from 2012 to 2017. Finally, Section 5. contains some final comments and further developments.

2. A model for multivariate times series of pollutant concentrations

The data that motivated our proposal are in the form of a multivariate time series $(\boldsymbol{y}_t, t \geq 0)$, where the vector $\boldsymbol{y}_t = [y_{t1}, \ldots, y_{tp}]$ includes the concentrations of p pollutants at time t, $t = 1, \ldots, T$. A popular modelling approach in this setting is provided by the class of vector auto-regressive (VAR) models with lag H, where the conditional distribution of the process at time t given the past $\mathcal{H}_t = \{\boldsymbol{y}_\tau,\ \tau = 1, \ldots, t-1\}$:

$$f_{\boldsymbol{Y}_t}(\boldsymbol{y}_t|\mathcal{H}_t) = f_{\boldsymbol{Y}_t}\left(\boldsymbol{y}_t \mid \boldsymbol{Y}_{t-1} = \boldsymbol{y}_{t-1}, \ldots, \boldsymbol{Y}_{t-H} = \boldsymbol{y}_{t-H}\right), \quad \boldsymbol{y}_t \in \mathbb{R}^p,\ t = 1, \ldots, T.$$

is a multivariate normal distribution with mean

$$\boldsymbol{\mu}_t = \boldsymbol{\beta}_0' + \sum_{h=1}^{H} \boldsymbol{\alpha}_h' \boldsymbol{y}_{t-h}, \tag{1}$$

and covariance matrix Σ. Under a traditional VAR model, the effect of past values on the process is time-constant and measured by the autoregressive coefficients $\boldsymbol{\alpha}$. It is however well known that the dynamic of air quality is affected by unobserved, time-varying weather conditions. This source of latent heterogeneity can be captured by assuming that the conditional distribution of the process given the past is a mixture of K VARs (5). A mixed VAR can be seen as a hierarchical VAR, whose parameters evolve according to the values taken by a sequence of independent multinomial distributions. Such an independence assumption is an obvious limitation of the model, which can be relaxed by allowing latent multinomial distributions to be temporally correlated. Such extension can be easily obtained by specifying the latent multinomial process as a homogeneous Markov chain. A mixture of VARs whose parameters evolve according to a latent Markov chain are known in the literature as multivariate hidden Markov models, and they have been already exploited for the analysis of multivariate environmental time series (9). Under a multivariate hidden Markov model, the sojourn times that the latent process spends in a specific state follow a Geometric distribution. Although this assumption can be realistic in some settings, it can be a serious shortcoming in the analysis of urban pollution, where sojourn times of specific air quality regimes may well show more complicated patterns. To avoid this source of misspecification, we propose a finite mixture of VARs whose parameters vary according to the states of a semi-Markov process. A discrete-time semi-Markov process $(S_t, t \geq 0)$ taking values in a finite state space, say $\{1, 2, \ldots K\}$, can be defined as follows. First, let $(U_t, t \geq 0)$ be a homogeneous Markov chain with a special transition probabilities matrix having all diagonal entries equal to zero (i.e the chain is not allowed to remain in the same state in two subsequent times). A realization of a semi-Markov process is

obtained by replacing the state k of the Markov chain at time t by a run of d copies of state k, where d is drawn from a state-specific dwell-time distribution d_k. When the dwell time-distributions are all equal to a geometric distribution, then a semi-Markov process reduces to a Markov chain. Otherwise, it extends the Markov chain framework by allowing for flexible dwell times.

Let $(S_t, t \geq 0)$ be a latent semi-Markov process, taking values in the set $\{1 \dots K\}$, whose distribution is known up to a $K \times K$ matrix of transition probabilities with zero diagonal entries and a battery of K dwell time distributions that depend on a finite set of parameters. Conditionally on the value k taken by the latent process at time t, we assume that the conditional distribution of the observed process given the past is a multivariate normal distribution with mean

$$\boldsymbol{\mu}_t = \boldsymbol{\beta}'_{k0} + \sum_{h=1}^{H} \boldsymbol{\alpha}'_{kh} \boldsymbol{y}_{t-h}, \tag{2}$$

and covariance matrix Σ_k. We remark that the resulting mixture VAR is stable, hence stationary, if all the companion matrices:

$$\boldsymbol{A}_k = \begin{bmatrix} \boldsymbol{\alpha}_{k1} & \boldsymbol{\alpha}_{k2} & \cdots & \boldsymbol{\alpha}_{kH} \\ \boldsymbol{I}_p & \mathbf{0} & \cdots & \mathbf{0} \\ \mathbf{0} & \ddots & \mathbf{0} & \vdots \\ \mathbf{0} & \mathbf{0} & \boldsymbol{I}_p & \mathbf{0} \end{bmatrix}, \quad k = 1, \dots, K,$$

have all the eigen-values with modulus < 1 (5).

2.1 Estimation

The proposed hidden semi-Markov VAR model can be represented as a multivariate HMM by appropriately augmenting the state sequence, as proposed by Langrock and Zucchini (8). Such representation is exact if all dwell time distributions have finite support. It otherwise provides an approximation with the desired accuracy. An HMM representation of our proposal allows us to exploit the efficient likelihood maximization algorithms that have been developed for HMMs. These algorithms rely on a EM approach, where the maximization of a weighted (data-augmented) log-likelihood function is alternated with weights updating, up to convergence.

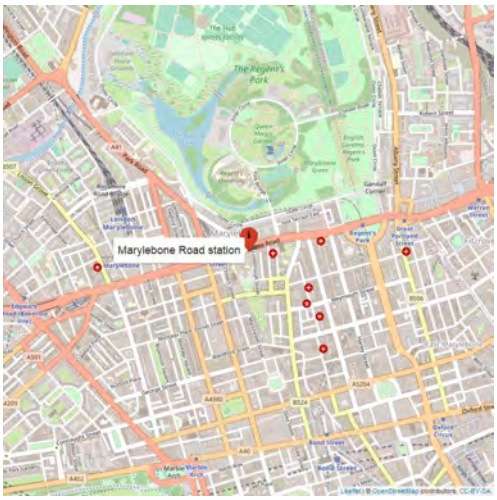
The maximization step is further integrated by considering a penalized approach for the estimation of the covariance matrix. This regularizes the estimation process, favoring the model identifiability and highlighting the most evident correlation patterns across the p outcomes. Following (4), we use a convex combination of the maximum likelihood estimator and a scaled identity matrix with the same trace:

$$\boldsymbol{\Sigma}_k = \frac{1}{1+\lambda_\Sigma} \hat{\boldsymbol{\Sigma}}_{\boldsymbol{k}}^{\boldsymbol{ML}} + \frac{\lambda_\Sigma}{1+\lambda_\Sigma} c\mathbf{I}, \quad \text{with} \quad \mathrm{tr}(\hat{\boldsymbol{\Sigma}}_{\boldsymbol{k}}^{\boldsymbol{ML}}) = tr(c\mathbf{I}).$$

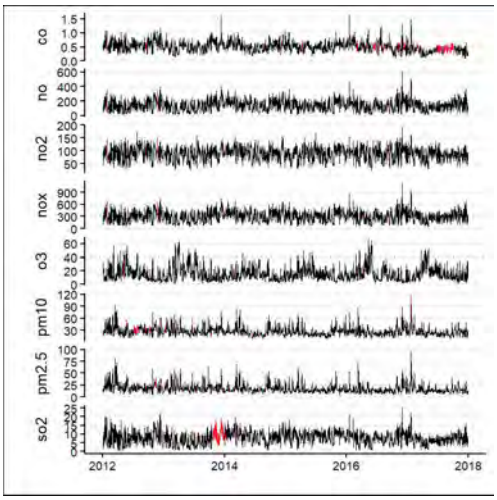
The coefficient $\lambda_\Sigma \geq 0$ is a shrinking parameter that controls for the strength of the penalization. Similarly, we consider a L1-norm penalty on the VAR coefficients and introduce a LASSO shrinking parameter λ_α in order to regularize their estimation and simultaneously select a smaller subset of lags that exhibits the strongest effects.

3. Application to urban pollution

We apply the proposed model to the daily time-series of $p = 9$ air quality indicators (AQIs) that have been recorded at the Marylebone Road station from 2012 to 2017 in London, for a total of $T = 2,192$ days of observation. This station is placed in the north-western part of the city on a very busy urban road (part of the London ring) and is close to Regent's park (see Figure 1a). Data have been downloaded from the `openair R` package (1), which provides several tools for the analysis of air pollution data, and include the concentrations of the following: carbon monoxide (co), nitrogen dioxide (no2), nitrogen



(a)



(b)

Figure 1: (a) Location of MY1 (Marylebone Road station); (b) daily time-series of the AQIs, including imputed missing values (red line); (c) marginal distribution of the AQIs.

oxide (no), ozone (o3), sulfur dioxide (so2), volatile and non-volatile matter at $2.5\mu m$ (v2.5, nv2.5) and at $10\mu m$ (v10, nv10). As it is common in such applications, the raw data however contained some missing values, perhaps arising from the malfunctioning of the monitoring device. Note that missing values are not necessarily concomitant and the missing data patterns may vary across the AQIs. In our application, we assume that the missing data pattern is Missing at Random (MAR) for each AQI, and there is independence in the missing data mechanism across AQI (i.e. the probability of recording a missing value for one indicator does not depend on concomitant or previous missing values of another indicator). Overall, we counted a total of 804 missing out of $T \times p = 17,536$ values ($< 5\%$), with a percentage of missingness going from a minimum of $\approx 2\%$ for no and no2, up to $\approx 10\%$ for co. Given these low percentages, we used the `Amelia R` package (6) that combines bootstrapping and EM algorithms to provide efficient multiple imputation of incomplete set of data, including time-series data. Here, we use 50 multiple imputations and averaged all the results to get the final estimate of the missing values. A more rigorous approach would rely on integrating the missing value imputation within the proposed EM algorithm, at the price of an additional computational burden. The obtained time-series are shown in Figure 1b, where the imputed values are coloured in red. The series appear stationary through the whole considered time-window and show substantial correlation, particularly when spikes of high concentrations are recorded.

4. Results

We run a preliminary analysis on the data described in Section 3. We set the shrinking parameter of the covariance matrix $\lambda_\Sigma = 0.1$ and use cross-validation within the EM algorithm to adaptively select the best LASSO shrinking parameter λ_α at each iteration. We set $K = 3$ as to test the hypothesis of observing three possible patterns: pollutants below, in the mid-range, or above average. We consider only the effect of one lag, i.e. $H = 1$. The estimated conditional averages of pollutant concentrations in each state are reported in Table 1. Looking at the point estimates, state 2 can be interpreted as the high-pollution state, showing the largest pollutant average concentrations, except for ozone, which is however uncorrelated with all other pollutants (see Figure 2b). On the other hand, state 3 is the low-pollution state, state 1 is the intermediate state. We estimate 931 days in state 1, 39 days in state 2 and 1222 days in state 3. As expected, the dwell time distribution of state n. 3 is more skewed to the right than the other two distributions, as shown in Figure 3. The LASSO shuts down the effect of carbon oxide on all other pollutants.

state	co	no	no2	nv10	nv2.5	o3	so2	v10	v2.5
2	0.79	289.83	123.56	42.43	30.36	6.34	14.57	6.63	5.93
1	0.6	186.92	105.78	27.77	18.49	10.52	9.94	3.89	3.16
3	0.42	95.44	75.38	18.94	12.04	19.08	5.97	2.91	2.19

5. Conclusions and further developments

The proposed model is able to describe complex multivariate patterns that present temporal and cross-variable correlation. The non-parametric HSMM specification makes it able to detect and estimate the lower-dimensional structure controlling the different regimes of the multivariate process. The shrinking factors control for the substantial complexity of its specification. Indeed, the full model envisions a faceted dependence structure which depends on a great number of parameters. The adoption of regularized estimation methods becomes a necessity more than an opportunity. An interesting byproduct of the LASSO penalty is its ability to perform selection together with the shrinking. This allows highlighting the most relevant auto-regressive patterns across different components of the multivariate process.

The preliminary analysis on the time-series of pollutants recorded at the Marylebone Road station in London returns promising results. In the near future we aim at implementing a specific selection proce-

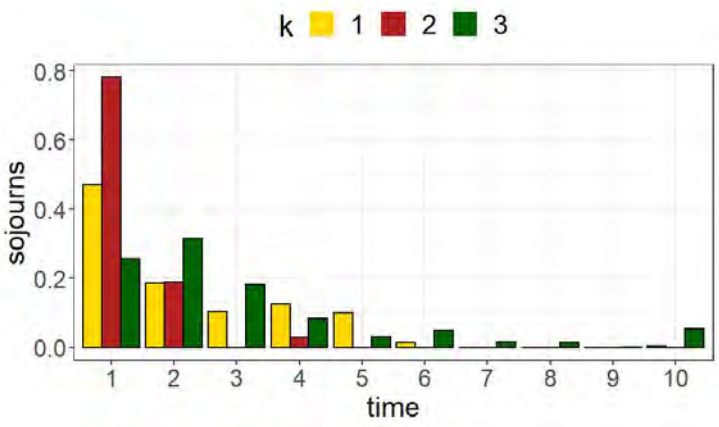

Figure 3: Estimated sojourn probabilities.

dure for the best number of states K. Furthermore, we can enrich the results analysis by accompanying them with risk and conditional risk measures, other than associating to each state the probabilities to exceed the risk thresholds fixed by the WHO.

A smooth transition autoregressive model for matrix-variate time series

Andrea Bucci[a]

[a]Department of Economics and Law, University of Macerata; andrea.bucci@unimc.it

Abstract

In many applications, data are observed as matrices with temporal dependence. Matrix-variate time series modeling is a new branch of econometrics. Although stylized facts in several fields, the existing models do not account for regime switches in the dynamics of matrices that are not abrupt. In this paper, we extend linear matrix-variate autoregressive models by introducing a regime-switching model capable of accounting for smooth changes, the matrix smooth transition autoregressive (MSTAR) model. We provide a thorough examination of the estimation process and evaluate the finite-sample performance of the MSTAR model estimators with simulated data.

Keywords: Matrix-valued time series; Smooth transition; Multivariate time series

1. Introduction

Time series processes are present in many fields, including econometrics, finance, biology, and ecology. The typical classification of time series analysis is between univariate and multivariate data, and both have been extensively studied in the related literature (10). There exists a third possible specification in the temporal domain which involves multidimensional datasets (2). Of particular interest are bi-dimensional data where the variables are organized in matrices that vary over time. While matrix-valued data has been studied in several papers (12), only recently the matrix-variate autoregressive (MAR) model proposed by Wang et al. (11) and Chen et al. (4) has opened up new territories for modeling the temporal dependency in matrix-variate problems with a twofold advantage with respect to the more used stacked vectorization form: the original matrix structure is preserved meaning that the coefficient matrices can be interpreted row- and column-wisely (4); the number of parameters is drastically decreased.

Most of the research in this field has focused on linear autoregressive matrix-variate models. However, economic and financial systems have often been shown to exhibit both structural and behavioral changes. Accordingly, Liu and Chen (7) have recently introduced a threshold version of the MAR model that accounts for abrupt changes in the matrices of parameters, while Billio et al. (3) propose a smooth transition model for temporal networks estimated through a Bayesian approach. In this paper, we suppose that the regime changes can be smooth and we introduce the matrix-variate smooth transition (MSTAR) model inspired by the vector smooth transition autoregressive (VSTAR) model (9). Although a typical assumption is that the transition variable is weakly stationary, we also analyse the case in which a regime changes coincides with a structural break, meaning that the temporal trend is used as a transition variable. This may help identifying common breaks in matrix-valued problems. We investigate the estimation process that allows to both estimate the coefficient matrices and the parameters of the transition function. The finite sample performance of the estimators is assessed through a simulation study.

The remainder of the paper is organized as follows. Section 2 introduces the MSTAR model. A numerical study is conducted in Section 3 to assess the finite-sample properties of the estimators, while Section 4 concludes.

2. Matrix smooth transition autoregressive model

Consider an $m \times n$ matrix $\mathbf{Y}_t$ observed at time t, for $t = 1, \ldots, T$. Let vec$(\cdot)$ be the vectorization of a matrix by stacking its columns. One way to introduce some nonlinearity in the dynamics of $\mathbf{Y}_t$ is generalising to the matrix-variate framework the threshold autoregressive model proposed by Quandt (8), as done in Liu and Chen (7). Another possible nonlinear extension may foresee the use of a smooth transition mechanism, as done for multivariate time series in Anderson and Vahid (1), and Tërasvirta and Yang (9). Supposing the absence of exogenous variables and a single lag, the zero-mean 2-regime vector smooth transition autoregressive (VSTAR) model can be defined as follows

$$\text{vec}(\mathbf{Y}_t) = \mathbf{\Phi}_0 \text{vec}(\mathbf{Y}_{t-1}) + \mathbf{G}(\gamma, \mathbf{c}; \mathbf{s}_t) \left(\mathbf{\Phi}_1 \text{vec}(\mathbf{Y}_{t-1})\right) + \text{vec}(\mathbf{E}_t) \tag{1}$$

where $\mathbf{\Phi}_k$ are $mn \times mn$ parameter matrices, for $k = 0, 1$, $\mathbf{E}_t$ is an $m \times n$ matrix of errors, and $\mathbf{G}(\gamma, \mathbf{c}; \mathbf{s}_t)$ is an $mn \times mn$ diagonal matrix, such that

$$\mathbf{G}(\gamma, \mathbf{c}; \mathbf{s}_t) = \text{diag}\left\{g_1(\gamma_1, c_1; s_{1,t}), \ldots, g_{mn}(\gamma_{mn}, c_{mn}; s_{mn,t})\right\}, \tag{2}$$

where $g(\cdot)$ is typically a standard logistic function, $g_i(\gamma_i, c_i; s_{i,t}) = \left[1 + \exp\left\{-\gamma_i \left(s_{i,t} - c_i\right)\right\}\right]^{-1}$, and $s_{i,t}$, for $i = 1, \ldots, mn$, is a weakly stationary transition variable usually chosen among the set of variables in vec$(\mathbf{Y}_{t-1})$, although exogenous variables are possible as well (5). Special cases of the model in (1) foresee a common transition variable for all the mn equations or, more strictly, a unique transition function that drives the regime changes of the autoregressive parameters. Extending to the matrix-variate framework the smooth transition version the MAR model may imply introducing a regime-switching either for the parameters related to the column-wise effect, those related to the row-wise effect or both. However, the interpretation of the parameters in such models becomes extremely difficult, since the transition variables and the parameters of the function can differ for each element of the matrices in the second regime. A simpler version of the aforementioned models foresees that the transition variables, as well as the parameters of the transition functions, are the same for all the equations (6). For its simplicity, its popularity in most of the macroeconomic problems and its similarity with a threshold autoregressive model as the one introduced in Liu and Chen (7), we use this specification to extend in a matrix-variate context the VSTAR model. Supposing a two-regime model (*i.e.*, a single transition function), we extend the MAR model by introducing an additive nonlinear component, such that

$$\mathbf{Y}_t = \mathbf{A}\mathbf{Y}_{t-1}\mathbf{B}' + g_t(\gamma, c; s_t)(\mathbf{C}\mathbf{Y}_{t-1}\mathbf{D}') + \mathbf{E}_t, \tag{3}$$

where $g_t(\gamma, c, ; s_t)$ is, as before, a standard logistic function (for ease of notation we will refer to this function as g_t). Obviously, more than two regimes are also allowed even if in practice a number of regimes greater than 3 is of scarce interest. This matrix smooth transition autoregressive (MSTAR) model implies that the conditional mean of the entire matrix changes the regime based on the values of the unique transition variable, s_t. Nevertheless, finding a common transition variable that drives the dynamics of the entire matrix is not always easy, especially when the entries of the matrix are different indices. For this reason, a more interesting candidate transition variable is the normalized temporal trend, $s_t = t/T$. In this case, model (1) becomes a linear vector regression with a smooth structural break (5). It follows that, if we use $s_t = t/T$ as a transition variable in the MSTAR model proposed in this article, the estimation of the threshold parameter c implies a single structural break detection for all the matrix-valued time series.

2.1 Estimation of the MSTAR model

In a general MAR model, assuming that the entries of $\mathbf{E}_t$ are i.i.d. normal with mean zero and a constant variance, the estimates of the parameters are the solution of the least squares problem

$$\min_{\mathbf{A},\mathbf{B}} \sum_t \| \mathbf{Y}_t - \mathbf{A}\mathbf{Y}_{t-1}\mathbf{B}' \|_F^2 . \tag{4}$$

Chen et al. (4) show that the estimates of the matrices of parameters can be obtained either through a projection method, maximum likelihood and iterative least squares. In the estimation process of the nonlinear extension of the MAR, we focus on the latter method. The estimation of the MSTAR model is more complicated than a simple MAR model for the presence of the threshold and the slope parameters. Moreover, the splitting algorithm used for the iterative least squares estimates used for a matrix-variate threshold autoregressive model (7) is not applicable. One way to solve these shortcomings is using the same algorithm proposed in Hubrich and Tërasvirta (6) which foresees the minimization of the objective function conditionally on γ and c. Let the optimization problem be

$$\min_{\mathbf{A},\mathbf{B},\mathbf{C},\mathbf{D}} \sum_t \parallel \mathbf{Y}_t - \mathbf{A}\mathbf{Y}_{t-1}\mathbf{B}' - g_t\mathbf{C}\mathbf{Y}_{t-1}\mathbf{D}' \parallel_F^2, \tag{5}$$

which leads to the following loss function to be minimized:

$$Q = \text{tr}\left(\sum_t \left(\mathbf{Y}_t - \mathbf{A}\mathbf{Y}_{t-1}\mathbf{B}' - g_t\mathbf{C}\mathbf{Y}_{t-1}\mathbf{D}'\right)'\left(\mathbf{Y}_t - \mathbf{A}\mathbf{Y}_{t-1}\mathbf{B}' - g_t\mathbf{C}\mathbf{Y}_{t-1}\mathbf{D}'\right)\right). \tag{6}$$

It is clear that if all the coefficients are zeros, than the parameters γ and c are non-identifiable. A typical assumption to solve this issue is that not all the coefficients are zeros. Therefore, conditionally on the values of the transition function, the minimization of the loss function in Eq. (6) is guaranteed to have at least one global minimum and can be simply solved by taking its first derivatives where g_t is treated as a known scalar. As in the case of the MAR, the solution of (5) is found by iteratively updating one at a time the matrices $\hat{\mathbf{A}}$, $\hat{\mathbf{B}}$, $\hat{\mathbf{C}}$, and $\hat{\mathbf{D}}$, while keeping the others fixed, starting with some initial matrices.

Once obtained the following iterative least squares estimates of the autoregressive coefficient matrices

$$\begin{aligned}
\mathbf{A} &\leftarrow \left(\sum_t \mathbf{Y}_t\mathbf{B}\mathbf{Y}_{t-1}' - g_t\mathbf{C}\mathbf{Y}_{t-1}\mathbf{D}'\mathbf{B}\mathbf{Y}_{t-1}'\right)\left(\sum_t \mathbf{Y}_{t-1}\mathbf{B}'\mathbf{B}\mathbf{Y}_{t-1}'\right)^{-1} \\
\mathbf{B} &\leftarrow \left(\sum_t \mathbf{Y}_t'\mathbf{A}\mathbf{Y}_{t-1} - g_t\mathbf{D}\mathbf{Y}_{t-1}'\mathbf{C}'\mathbf{A}\mathbf{Y}_{t-1}\right)\left(\sum_t \mathbf{Y}_{t-1}'\mathbf{A}'\mathbf{A}\mathbf{Y}_{t-1}\right)^{-1} \\
\mathbf{C} &\leftarrow \left(\sum_t g_t\mathbf{Y}_t\mathbf{D}\mathbf{Y}_{t-1}' - g_t\mathbf{A}\mathbf{Y}_{t-1}\mathbf{B}'\mathbf{D}\mathbf{Y}_{t-1}'\right)\left(\sum_t g_t^2\mathbf{Y}_{t-1}\mathbf{D}'\mathbf{D}\mathbf{Y}_{t-1}'\right)^{-1} \\
\mathbf{D} &\leftarrow \left(\sum_t g_t\mathbf{Y}_t'\mathbf{C}\mathbf{Y}_{t-1} - g_t\mathbf{B}\mathbf{Y}_{t-1}'\mathbf{A}'\mathbf{C}\mathbf{Y}_{t-1}\right)\left(\sum_t g_t^2\mathbf{Y}_{t-1}'\mathbf{C}'\mathbf{C}\mathbf{Y}_{t-1}\right)^{-1},
\end{aligned}$$

the optimization problem foresees the minimization of the loss in Eq. (5) with respect to γ and c. Finding the optimum of such a function is performed analytically. In practice, the numerical algorithm may be slow and may converge to some local minimum. For this reason, we apply the same method proposed by (6) which implies the use of a grid search among a set of possible values for γ and c. We construct a discrete grid in the parameter space of the transition function parameters and we estimate as before the autoregressive coefficients, conditionally on the pair of values on the grid. The estimation of the parameters in $\mathbf{A}$, $\mathbf{B}$, $\mathbf{C}$ and $\mathbf{D}$ is carried out for all the values in the grid and the residuals sum of squares

$$\text{SSQ} = \text{tr}\left(\sum_t \text{vec}(\mathbf{Y}_t - \mathbf{A}\mathbf{Y}_{t-1}\mathbf{B}' - g_t\mathbf{C}\mathbf{Y}_{t-1}\mathbf{D}')'\text{vec}(\mathbf{Y}_t - \mathbf{A}\mathbf{Y}_{t-1}\mathbf{B}' - g_t\mathbf{C}\mathbf{Y}_{t-1}\mathbf{D}')\right) \tag{7}$$

is collected. We then choose as starting values for the iterative least squares presented above the pair of values (γ, c) that produces the smallest SSQ. Once obtained the estimates of the autoregressive coefficient parameters, the algorithm proceeds with the estimation of γ and c fixing all the parameters in $\mathbf{A}$, $\mathbf{B}$, $\mathbf{C}$ and $\mathbf{D}$. This continues until convergence.

3. Simulation study

To study the finite-sample properties of the model introduced in this article, we perform a simulation study in which we generate $R = 100$ replications using different settings in terms of dimensionality of the matrix (*i.e.*, with different m and n), and the length of the time series, with $T = 400, 600, 1000$.

$\mathbf{Y}_t$ is generated from model (3), where $\mathbf{A}$ and $\mathbf{B}$ are diagonal matrices with 0.20 entries on their diagonal, while $\mathbf{C}$ and $\mathbf{D}$ are computed as a diagonal matrix with entries 0.75. For all the replications we use the same coefficient matrices and we let $\mathbf{E}_t$ vary. This guarantees that $\rho(\mathbf{A}) \cdot \rho(\mathbf{B}) < 1$ and $\rho(\mathbf{C}) \cdot \rho(\mathbf{D}) < 1$, then all the DGPs are stationary. Since the iterative algorithm for the estimation of the matrices foresees a set of initial values for the matrices $\mathbf{B}$, $\mathbf{C}$ and $\mathbf{D}$, we sample the value of $\mathbf{B}$ from a uniform distribution $\mathcal{U}(0, 0.2)$, while the entries of the initial $\mathbf{C}$ and $\mathbf{D}$ are sampled from a uniform distribution $\mathcal{U}(0, 0.5)$. In addition, we let γ range between 1 and 50 and c between 0 and 1 to compute the searching grid algorithm. The innovation matrix, $\mathbf{E}_t$, is sampled from a matrix normal distribution, with the $mn \times mn$ covariance matrix equal to $\mathbf{\Sigma} = \mathbf{I}_m \otimes \mathbf{I}_n$. We choose to use as a transition variable the scaled temporal trend, *i.e.*, $s_t = t/T$, we set $c = 0.65$ and $\gamma = 10$.

We also estimate the stacked version of the model, this means estimating a VLSTAR model on $\text{vec}(\mathbf{Y}_t)$, and for both the models we compute the box-plot among the 100 replications of the following loss functions

$$\| \hat{\mathbf{B}} \otimes \hat{\mathbf{A}} - \mathbf{B} \otimes \mathbf{A} \|_F^2 \text{ and } \| \hat{\mathbf{D}} \otimes \hat{\mathbf{C}} - \mathbf{D} \otimes \mathbf{C} \|_F^2 . \tag{8}$$

Figure 1 shows the simulation results in terms of the measures in (8) for an increasing number of observations (from left to right) and an increasing dimension (from top to bottom) taking values in $(m, n) = (2, 3)$, and $(4, 6)$. For each simulation setting, we report in Figure 2 and 3 the box-plot of the difference of the estimated and observed threshold and slope parameters in the 100 replications.

From Figure 1 it emerges that, for each simulation setting, the MSTAR model strongly outperforms the VLSTAR model in the estimation of the coefficient matrices for both the regimes when the dimension of the matrix is $(4, 6)$. Moreover, it always overperforms the VLSTAR model in the estimation of the coefficient matrix in the first regime with mixed evidence in terms of the coefficient matrix in the second regime. In Figure 2, it can be observed that for $(m, n) = (2, 3)$, the median difference between the estimated and the observed threshold is extremely close to zero regardless of the sample size (last row in the Figure), meaning that the threshold is correctly estimated. Overall, the estimated thresholds are in line with the observed value for both the methods, and the difference between the two methods is often negligible. Still, for larger matrices and larger samples, the MSTAR model seems to outperform the VLSTAR one also in terms of threshold estimation. Figure 3 reports the box-plots among the R replicates of the slope parameter γ. It can be observed that the two models perform similarly well in the estimation of the slope parameter when the dimension of the matrix is $(2, 3)$. When the matrix dimension and the sample size increase, the difference between the estimated and the observed slope parameter is strictly close to zero for the MSTAR model, while it diverges for the VLSTAR.

4. Conclusions

In this article, we have proposed a smooth transition autoregressive model for matrix-variate time series which extends the VLSTAR model. In a numerical study, we show that the MSTAR model is able to outperform the stacked vectorization form through a VLSTAR in terms of estimated coefficients, threshold and slope parameters. This is mostly true for larger samples and larger matrices.

There are several open questions that could be solved in future works. For instance, a linearity test of the matrix-variate time series could avoid the use of a nonlinear specification when a linear one is needed. Moreover, a proper procedure for the detection of the regimes in a smooth transition model would be helpful.

Figure 1: Comparison of the estimated coefficient matrices for the MSTAR and VLSTAR models. The rows identify an increasing matrix dimension of $(m, n) = (2, 3), (4, 6)$, while the number of observations in the sample grows by column. For each subfigure, the plot on the left denotes the first regime, while the plot on the right reports the measure for the second regime.

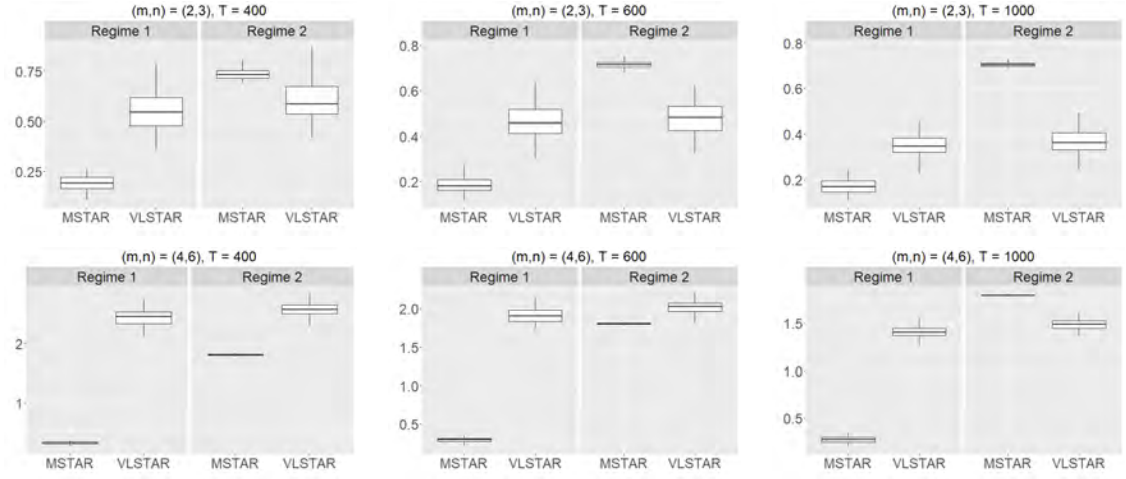

Figure 2: Comparison of the differences between the estimated and real ($c = 0.65$) threshold parameters for the MSTAR and VLSTAR models. The rows identify an increasing matrix dimension of $(m, n) = (2, 3), (4, 6)$, while the number of observations in the sample grows by column.

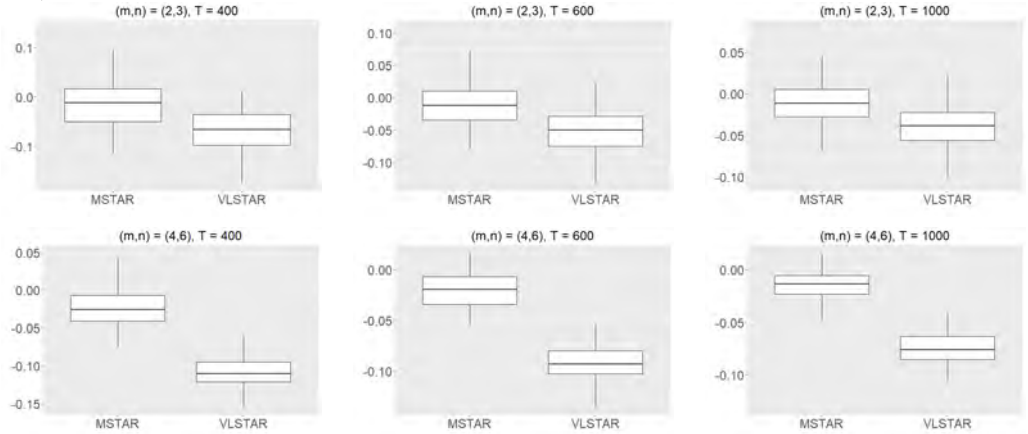

Figure 3: Comparison of the differences between the estimated and real ($\gamma = 10$) slope parameters for the MSTAR and VLSTAR models. The rows identify an increasing matrix of $(m, n) = (2, 3), (4, 6)$, while the number of observations in the sample grows by column.

Abstract

We develop a class of random effect models for dynamic networks aiming to account for a time-varying network topology. Ignoring this aspect may lead to a bias in the parameters estimate of the model for the edges, since, in principle, an edge is not observable when the related couple of nodes does not belong to the network. A Bayesian conjugate approach is proposed for the inference of this class of models based on the Pólya-Gamma latent variable method. A preliminary simulation study has been implemented to investigate the empirical performances of the proposed approach.

Keywords: Bayesian inference, Mixture model, Zero-inflation.

1. Introduction

Networks are used to represent complex data structures, that arise in different fields of science, including economics, biology, and sociology, among others. These data encode the relationships between different units or actors, stimulating interesting research questions and new methodological approaches. For a general introduction to network science, see Newman (2018). Networks are often not static objects, since they can evolve over time and this dynamic behaviour adds a further level of complexity. Most existing methods only consider a single snapshot of the network at a given time, making it difficult to study the network evolution. In this context, developing advanced statistical models for dynamic network analysis becomes relevant. Main approaches available in the literature belong to the broad class of latent variable models, which are latent space models and stochastic blockmodels. For a general overview of both frameworks, see Kim et al. (2018). Another popular class of models used for temporal networks are continuous-time Markov processes and temporal exponential random graph, we refer to Goldenberg et al. (2009) and references therein for an introduction to the topic. However, most of the approaches mentioned above model the dynamic behaviour of edges without considering that the network's topology may vary over time. We expect that ignoring this issue can lead to distortion for the parameter estimates of the network model since the model is not able to distinguish between observed missing edges and lacks of edges for pairs of nodes which do not belong to the network topology at a given time.
To address this relevant issue, we develop a fully dynamic modelling framework that takes into account both the node and edge temporal behaviour. Inspired by the dynamic version of latent factor model for undirected binary networks (Durante and Dunson, 2014), we propose a class of zero-inflated Bernoulli models for the network edges, which discriminates between structural zeros for missing edges and those produced by observing a lack of edges between pairs of observed nodes. The inference approach for this class of models is developed within the Bayesian paradigm and relies on a Gibbs sampling algorithm

with Pólya-Gamma the data augmentation scheme, introduced by Polson et al. (2013). The performance of our approach is explored through a preliminary simulation study. The remainder of this contribution is organized as follows. Section 2. describes the model formulation in detail. In Section 3, we develop a Gibbs sampling algorithm for inference. Section 4. provides some preliminary results of our simulation study. Finally, Section 5. contains concluding remarks and further extensions for the proposed approach.

2. Dynamic network model

A time-varying graph $\{\mathcal{G}_t\}_{t=1}^{T} = \{(\mathcal{N}_t, \mathcal{E}_t)\}_{t=1}^{T}$, is represented by a set of *nodes* or *vertices* $\mathcal{N}_t = \{1, \ldots, V_t\}$ and an *edge*'s set $\mathcal{E}_t \subseteq \{(i,j) : i,j \in \mathcal{N}_t, i > j\}$, for $t = 1, \ldots, T$. The entire graph structure is encoded by a sequence of adjacency matrices $\boldsymbol{\mathcal{Y}} = \{\mathbf{Y}_1, \ldots, \mathbf{Y}_T\}$ that provide a full representation of the *dynamic network*. Each $\mathbf{Y}_t = \{Y_{ijt}\}$ denotes an $V_t \times V_t$ symmetric matrix, characterizing the *undirected* binary network connectivity with no self-loops. The realization of Y_{ijt} is denoted by $Y_{ijt} = y_{jit}$, which is equal to 1 if nodes i and j share a connection at time t and is equal to 0 otherwise. In order to take into account the vertex dynamics, we define the maximum network size $V_{\max} = |\mathcal{N}_{\max}|$, where $\mathcal{N}_{\max}$ is a set of all nodes until T, such that $\mathcal{N}_t \subseteq \mathcal{N}_{\max}$, for $t = 1, \ldots, T$. Therefore, our network at time t is represented by an $V_{\max} \times V_{\max}$ adjacency matrix $\mathbf{Y}_t$, where the set of links $\mathcal{E}_t \subseteq \mathcal{N}_{\max} \times \mathcal{N}_{\max}$ and entries are defined as before.

2.1 Model formulation

Let $\boldsymbol{Z}_i = (Z_{i1}, Z_{i2}, \ldots, Z_{iT}) \in \mathbb{R}^T$ denotes the T- dimensional vector, such that $Z_{it} = 1$ if $i \in \mathcal{N}_t$, and 0 otherwise. Assuming independence between Z_{it} and Z_{jt} with $i \neq j$, the joint presence/absence of pair of nodes in the network at time t, can be described by $\boldsymbol{Z}^{\star}_{ij} = \boldsymbol{Z}_i \circ \boldsymbol{Z}_j, \in \mathbb{R}^T$, where $\circ$ denotes the element-wise vector product operator. This new variable follows a Bernoulli distribution with probability equal to λ_{ijt}, i.e. $Z^{\star}_{ijt} \sim \mathcal{B}(\lambda_{ijt})$. The dynamic network's topology is fully characterized by the sequence $\boldsymbol{\mathcal{Z}}^{\star} = \{\boldsymbol{Z}^{\star}_1, \boldsymbol{Z}^{\star}_2, \ldots, \boldsymbol{Z}^{\star}_{V_{\max}(V_{\max}-1)/2}\}$, which means that $Y_{ijt} = 0$ if $Z^{\star}_{ijt} = 0$ at time t, otherwise Y_{ijt} follows a Bernoulli distribution, i.e., $Y_{ijt} \sim \mathcal{B}(\pi_{ijt})$. As a consequence, we can define the following zero-inflated distribution:

$$Y_{ijt} | Z^{\star}_{ijt}, \lambda_{ijt}, \pi_{ijt} \sim \begin{cases} 0\,, & \text{with probability} \quad 1 - \lambda_{ijt} \\ \mathcal{B}(\pi_{ijt})\,, & \text{with probability} \quad \lambda_{ijt}. \end{cases} \tag{1}$$

where π_{ijt} the denotes dynamic edge probability, for $t = 1, \ldots, T$ and $i > j, \in \mathcal{N}_{\max}$. This model can be reformulated as a two-component mixture model where the first part addresses the structural zero, due to the absence of a pair of nodes at time t and the second part is related to the edge probability through a Bernoulli distribution, "adjusted"for the presence of that pair, at given time t. Therefore, we can write (1) as a two-component finite mixture model:

$$Y_{ijt} \sim (1 - \lambda_{ijt})\, \mathbb{1}_{\left(z^{\star}_{ijt} = 0\,,\, y_{ijt} = 0\right)} + \lambda_{ijt}\, \mathcal{B}\left(\pi_{ijt}\right) \mathbb{1}_{(z^{\star}_{ijt} = 1)}, \quad \begin{array}{l} t = 1, \ldots, T, \\ i = 2, \ldots, V_{\max}, j = 1, \ldots, i-1 \end{array} \tag{2}$$

where $\mathbb{1}_{(\cdot)}$ is the indicator function and $z^{\star}_{ijt}$ is an observable binary variable such that with probability $(1 - \lambda_{ijt})$, $z^{\star}_{ijt} = y_{ijt} = 0$ implying the absence of a pair of nodes and edge connecting them.

Moreover, with probability λ_{ijt}, we model the joint presence of node's pair, i.e $z^{\star}_{ijt} = 1$ and y_{ijt} is in turn drawn from a Bernoulli distribution with probability π_{ijt}. This representation is very convenient as $Z^{\star}_{ijt}$ is an observable process and in this manner, we are able to discriminate structural zeros due to the topology of the network from those related to the absence of an edge between a pair of nodes. Furthermore, we assume that both edges and nodes probabilities are modelled via logistic regression models:

(*i*) $\text{logit}(\pi_{ijt}) = \mathbf{x}_{ijt}^{\intercal}\boldsymbol{\beta}$, where $\mathbf{x}_{ijt} = (x_{ijt1}, x_{ijt2}, \ldots, x_{ijtp})^{\intercal}$ is a set of p dyad edges covariates and $\boldsymbol{\beta} = (\beta, \ldots, \beta_p)^{\intercal}$ is the $p \times 1$ vector.

(*ii*) $\text{logit}(\lambda_{ijt}) = \mathbf{w}_{ijt}^{\intercal}\boldsymbol{\gamma}$, where $\mathbf{w}_{ijt} = (w_{ijt1}, w_{ijt2}, \ldots, w_{ijtq})^{\intercal}$ is a set of q dyad nodes covariates and $\boldsymbol{\gamma} = (\gamma, \ldots, \gamma_q)^{\intercal}$ is the $q \times 1$ vector.

Following the model assumptions outlined above, the complete-data likelihood can be written as:

$$\mathcal{L}(\boldsymbol{\beta}, \boldsymbol{\gamma}; \boldsymbol{\mathcal{Y}}, \boldsymbol{\mathcal{Z}}^{\star}) = \prod_{t=1}^{T} \prod_{i>j \in \mathcal{N}_{\text{max}}} \left(\lambda_{ijt}^{z^{\star}_{ijt}} (1-\lambda_{ijt})^{1-z^{\star}_{ijt}}\right) \left(\pi_{ijt}^{y_{ijt}} (1-\pi_{ijt})^{1-y_{ijt}}\right)^{z^{\star}_{ijt}} \tag{3}$$

This model can be generalized with the inclusion of further components, including for instance a spatial/temporal latent factor or a latent space component, on both edges and nodes processes. In the next Section, we propose a first attempt of the dynamic model with random effects.

3. Inference

Let us define two independent random effects denoted by $\phi_{1,ij}|\xi_1^{(ij)} \sim \mathcal{N}(0, \xi_1^{(ij)})$ and $\phi_{2,ij}|\xi_2^{(ij)} \sim \mathcal{N}(0, \xi_2^{(ij)})$, with $\xi_1^{(ij)}, \xi_2^{(ij)} \in \mathbb{R}^{+}$. These components capture the heterogeneity of the nodes interaction and edges connectivity patterns. As before, we assume:

$$\begin{aligned} \text{logit}(\pi_{ijt}) &= \mathbf{x}_{ijt}^{\intercal}\boldsymbol{\beta} + \phi_{1,ij} \\ \text{logit}(\lambda_{ijt}) &= \mathbf{w}_{ijt}^{\intercal}\boldsymbol{\gamma} + \phi_{2,ij}\,, \end{aligned} \tag{4}$$

where the lagged observation of $z^{\star}_{ij\,t-1}$ is included in the covariate set $\mathbf{w}_{ijt}$ to account for the dynamic trend of the nodes, for $t = 1, \ldots, T$ and $i = 2, \ldots, V_{\text{max}}, j = 1, \ldots, i-1$. For estimation purposes, we follow the Bayesian approach. The Bayesian inferential procedure requires the specification of the prior distribution for the unknown vector of parameters $\boldsymbol{\vartheta} = (\boldsymbol{\gamma}^{\intercal}, \boldsymbol{\beta}^{\intercal}, \xi_1^{(ij)}, \xi_2^{(ij)})^{\intercal}$. Posterior sampling is performed with a Gibbs sampler via Pólya-Gamma data augmentation scheme, that allows a conjugated inference in this specific framework. Therefore, we define $\boldsymbol{\Omega}_t = \text{blockdiag}(\boldsymbol{\Omega}_t^{(z^{\star})}, \boldsymbol{\Omega}_t^{(y)})$, where $\boldsymbol{\Omega}_t^{(\cdot)} = \text{diag}(\boldsymbol{\omega}_t^{(\cdot)}) = (\omega_{12,t}, \omega_{13,t}, \ldots, \omega_{(V_{\text{max}}-1)V_{\text{max}}/2,t})$ and each $\omega_{ijt}^{(\cdot)} \sim \text{PG}(1, 0)$. The sequence of latent variables is denoted by $\boldsymbol{\Omega}^{\star} = (\boldsymbol{\Omega}_1, \ldots, \boldsymbol{\Omega}_T)$.

Edges process	Nodes process
$\boldsymbol{\beta} \sim \mathcal{N}(\boldsymbol{\mu}_{\beta,0}, \boldsymbol{\Sigma}_{\beta,0})$	$\boldsymbol{\gamma} \sim \mathcal{N}(\boldsymbol{\mu}_{\gamma,0}, \boldsymbol{\Sigma}_{\gamma,0})$
$\xi_1^{(ij)} \sim \mathcal{IG}(a_{ij}^{(\phi_1)}, b_{ij}^{(\phi_1)})$	$\xi_2^{(ij)} \sim \mathcal{IG}(c_{ij}^{(\phi_2)}, d_{ij}^{(\phi_2)})$

Table 1: Prior probability distributions.

The augmented likelihood can be written as (see Polson et al., 2013):

$$
\begin{aligned}
p(\boldsymbol{\mathcal{Y}}, \boldsymbol{\mathcal{Z}}^\star, \boldsymbol{\Omega}^\star | \mathbf{X}, \mathbf{W}, \boldsymbol{\vartheta}) = & \prod_{t=1}^{T} \prod_{i>j} \left[\left(\frac{\mathrm{e}^{\mathbf{x}_{ijt}^\intercal \boldsymbol{\beta} + \phi_{1,ij}}}{1 + \mathrm{e}^{\mathbf{x}_{ijt}^\intercal \boldsymbol{\beta} + \phi_{1,ij}}} \right)^{y_{ijt}} \left(1 - \frac{\mathrm{e}^{\mathbf{x}_{ijt}^\intercal \boldsymbol{\beta} + \phi_{1,ij}}}{1 + \mathrm{e}^{\mathbf{x}_{ijt}^\intercal \boldsymbol{\beta} + \phi_{1,ij}}} \right)^{1 - y_{ijt}} p\left(\omega_{ijt}^{(y)}\right) \right]^{z_{ijt}^\star} \\
& \times \left[\left(\frac{\mathrm{e}^{\mathbf{w}_{ijt}^\intercal \boldsymbol{\gamma} + \phi_{2,ij}}}{1 + \mathrm{e}^{\mathbf{w}_{ijt}^\intercal \boldsymbol{\gamma} + \phi_{2,ij}}} \right)^{z_{ijt}^\star} \left(1 - \frac{\mathrm{e}^{\mathbf{w}_{ijt}^\intercal \boldsymbol{\gamma} + \phi_{2,ij}}}{1 + \mathrm{e}^{\mathbf{w}_{ijt}^\intercal \boldsymbol{\gamma} + \phi_{2,ij}}} \right)^{1 - z_{ijt}^\star} \right] p\left(\omega_{ijt}^{(z^\star)}\right) \\
= & \prod_{t=1}^{T} \prod_{i>j} \left[\frac{(\mathrm{e}^{\mathbf{x}_{ijt}^\intercal \boldsymbol{\beta} + \phi_{1,ij}})^{y_{ijt}}}{1 + \mathrm{e}^{\mathbf{x}_{ijt}^\intercal \boldsymbol{\beta} + \phi_{1,ij}}} p\left(\omega_{ijt}^{(y)}\right) \right]^{z_{ijt}^\star} \\
& \times \left[\frac{(\mathrm{e}^{\mathbf{w}_{ijt}^\intercal \boldsymbol{\gamma} + \phi_{2,ij}})^{z_{ijt}^\star}}{1 + \mathrm{e}^{\mathbf{w}_{ijt}^\intercal \boldsymbol{\gamma} + \phi_{2,ij}}} \right] p\left(\omega_{ijt}^{(z^\star)}\right) , \qquad (5)
\end{aligned}
$$

which can be easily exploited to find the full conditional distributions of the parameters and latent factors. The resulting Gibbs sampling algorithm is made of the following steps:

(*a*) sample $\omega_{ijt}^{(z^\star)} \sim \mathrm{PG}(1, \mathbf{w}_{ijt}^\intercal \boldsymbol{\gamma} + \phi_{2,ij})$ and update $\boldsymbol{\gamma}$ and $\phi_{2,ij}$.

(*b*) conditional on $z_{ijt}^\star = 1$, draw $\omega_{ijt}^{(y)} \sim \mathrm{PG}(1, \mathbf{x}_{ijt}^\intercal \boldsymbol{\beta} + \phi_{1,ij})$ and update $\boldsymbol{\beta}$ and $\phi_{1,ij}$.

These steps are updates of the Bayesian logistic regression model, with a slight modification when $z_{ijt}^\star = 1$. In particular, we apply the standard update results for $\boldsymbol{\beta}$ and $\phi_{1,ij}$, if $z_{ijt}^\star = 1$ for each pair (i, j), at time t. Regarding the random effect $\phi_{1,ij}$, we simulate from its prior when a specific pair of nodes (i, j) does not belong to the network.

4. Preliminary simulation study

We perform a simulation study to evaluate the empirical performance of the proposed algorithm. In particular, we are interested in the full conditional distributions of the parameters for the edges model when the topology of the nodes changes over time. The main goal of this simulation study is to compare our method, which takes into account the dynamic network's topology with a standard approach that ignores this aspect. The detailed setting of the simulation study is reported below.

4.1 Simulation setup

We perform a simulation study by drawing a sample of $T = 100$ observations for $V_{\max} = 20$ nodes, according to the model defined in equation (4), in which the lagged variable $z_{ij\,t-1}^\star$ was included among the covariates of the nodes. In particular, we have fixed $\boldsymbol{\gamma} = (-0.8, 0.2, 0.8)^\intercal$, $\boldsymbol{\beta} = (2, 1)^\intercal$ and $\xi_1^{(ij)} = \xi_2^{(ij)} = 1$ for the random effect variances. These values produce around 51% of zeros on the network topology.

Table 2: Summaries of the posterior distribution for the parameters

	Mean	Std. Dev	$\mathrm{CI}_{95\%}$
β_0	1.93	0.13	(1.68,2.18)
β_1	0.97	0.06	(0.86,1.08)
γ_0	-0.80	0.08	(-0.97,-0.64)
γ_1	0.18	0.04	(0.14,0.21)
γ_2	0.81	0.04	(0.75,0.89)
$\xi_1^{(ij)}$	1.00	0.11	(0.80,1.24)
$\xi_2^{(ij)}$	0.98	0.19	(0.64, 1.38)

(a) Toplogy correction.

	Mean	Std. Dev	$\mathrm{CI}_{95\%}$
β_0	-0.32	0.10	(-0.50,-0.13)
β_1	0.08	0.02	(0.05, 0.11)
γ_0	-0.79	0.09	(-0.97,-0.61)
γ_1	0.18	0.02	(0.14,0.21)
γ_2	0.79	0.04	(0.72,0.86)
$\xi_1^{(ij)}$	1.07	0.12	(0.84, 1.31)
$\xi_2^{(ij)}$	1.29	0.14	(1.02, 1.58)

(b) Without correction.

For posterior inference, we ran the Gibbs sampler for $R = 30000$ iterations, discarding the first 5000 as burn-in and thinned the iterations by keeping every 10^{th} sample. Table (2) shows some statistics for our MCMC posterior sample, both for our method which takes into account the topology structure of the network and for the same one, which ignores this aspect.

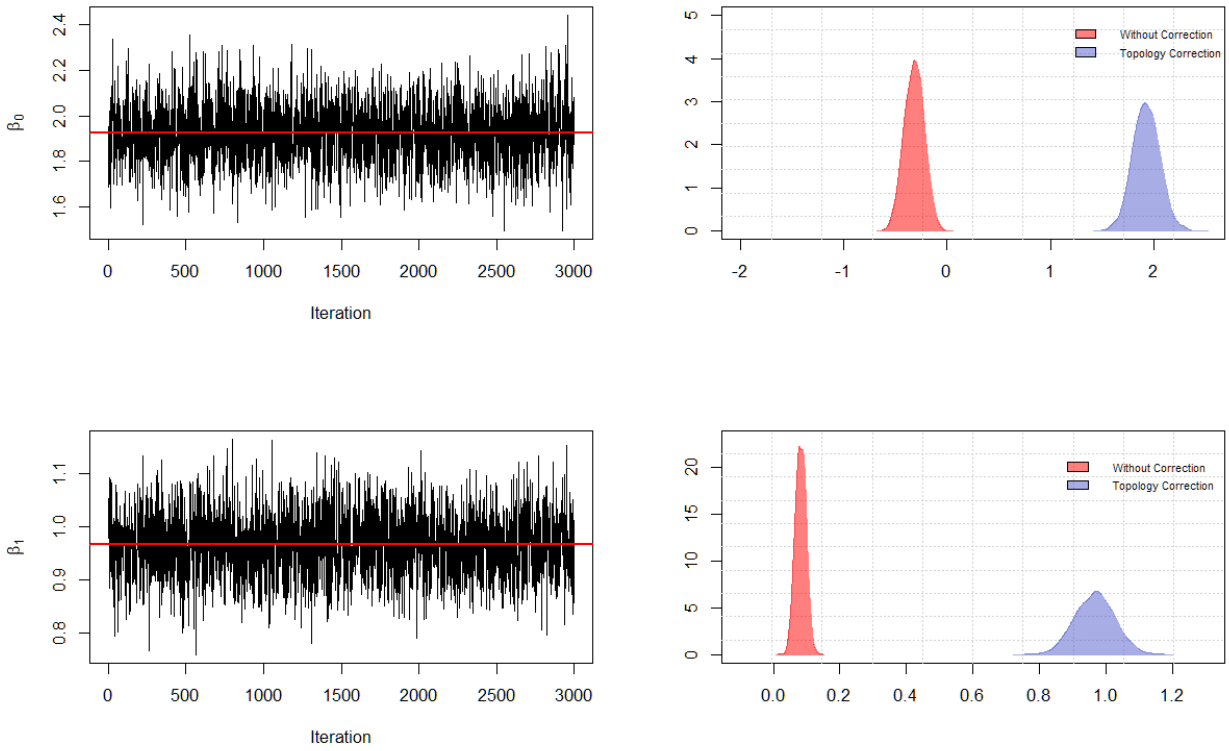

Figure 1: Trace plots for (β_0, β_1) (topology correction), with a true value in red (left panel) and density plots of full conditionals distribution for (β_0, β_1), where the red one is related to a model without correction and the blue one is referred to a model with a topology correction.

Figure (1) (right panel) compares the full conditionals distribution for both methods, showing that our methods provide more concentrated distributions around the true values with slight additional variability. These results suggest that even for moderate sample sizes with a large percentage of zeros, the proposed Bayesian approach provides unbiased estimates for $\boldsymbol{\beta}$, emphasising that the network topology is an important aspect to take into account. Clearly, if $\lambda_{ijt} \to 1$ this bias vanishes.

5. Concluding remarks

We propose a very general approach for modelling a fully dynamic network characterized by vertex and edge dynamics. In particular, using a zero-inflated Bernoulli representation we are able to capture the network connectivity patterns, taking into account the entire topology of the dynamic network. We have performed a preliminary simulation study to assess our model specification and proposed inference. The results show that if we do not consider the node's behaviour, the parameters associated with link probabilities results are completely underestimated. This novel class of methods can be extended by adding a temporal latent factor on the nodes and edges dynamics, including for example a latent space component, which embeds nodes in a lower dimensional space. Finally, we'll apply our method to real temporal network datasets in order to study their dynamic behaviour over time.

Time lapse analysis of nuclear calcium spiking in plant cells during symbiotic signaling

Ivan Sciascia[a], Andrea Crosino[a], and Andrea Genre[a]

[a]Università di Torino Department of Life Sciences and Systems biology;
ivan.sciascia@unito.it

Abstract

The analysis of the time lapse series of nuclear calcium concentration obtained with FRET-based confocal microscopy imaging was performed with spectral analysis, to look for periodicities in the calcium peaks. The results demonstrate that for our dataset it is not possible to distinguish a periodicity in the calcium peaks. Further studies with larger datasets will better investigate this result for confocal microscopy time lapse analysis.

Keywords: time-lapse, microscopy, spectral analysis

1. Introduction

The confocal microscope is a fluorescence microscope that can perform tomographic scans of biological samples, focusing on individual optical planes (optical sections). As a result, the confocal microscope outputs a three-dimensional high resolution image even from relatively thick samples, including living organisms. As such, confocal imaging has been widely used not only to obtain 3D reconstructions of biological tissues and organs, but also for the live imaging of cellular and physiological processes as they develop in living cells. This is the case for calcium-mediated signaling, a very common mechanism of signal transduction across eukaryotes. In plants, a remarkable example of such calcium-mediated signals has long been studied in root symbiotic interactions with nitrogen-fixing bacteria and arbuscular mycorrhizal fungi [9]. In both cases, the early perception of microbe-derived molecules by the root epidermal cells triggers prolonged oscillations in nuclear calcium concentration, known as calcium spiking and required for the appropriate regulation of gene expression and cellular as well as systemic responses that allow symbiosis establishment [1], [3]. In this study we have analyzed nuclear calcium spiking traces recorded in root epidermal cells after their stimulation with short-chain chito-oligosaccharides, the so-called Myc-factors that arbuscular mycorrhizal fungi release to alert host plants of their vicinity. Such calcium spiking traces are characterized by a series of peaks in calcium concentration that start a few minutes after Myc-factor application and continue for over 30 minutes [12]. Intriguingly, the peak sequence is markedly irregular, which has previously been proposed as a characteristic signature of Myc-factor induced signaling, compared to the more regulat spiking described in legumes in response to rhizobial Nod-factors.

2. Materials and Methods

Signal molecules included exudates from germinated arbuscular mycorrhizal (AM) fungal spores (GSE), generally referred to as Myc factors, activate a symbiotic signalling pathway that includesnucleus-

associated Ca2+ signals and trigger plant symbiotic responses [3], such as transcriptional regulation, lateral root formation and starch accumulation in roots ([11], [8], [10]). These pre-symbiotic responses [3] have been defined as part of an anticipation program, which prepares the host for a successful association [5] .In our case, we use the confocal microscope to detect variations in Ca2+ ions concentration within nuclei of Medicago truncatula root cells after chito-oligosaccharides treatment[2]. Recent studies on AM fungal exudates characterized chito-oligosasccharides as bioactive molecules responsible for the activation of AM symbiotic responses in the host plant. These molecules trigger responses [9] in the host roots, like Ca2+ spiking and time-series analyzes have been performed in several studies [12], [6], [7], [4].

We used transformed root organ cultures (ROCs) of M. truncatula expressing the NupYC construct. The YC construct is a chimeric protein obtained from fusion between a fluorescent protein with blue light emission spectrum (ECFP), a Ca2+ sensitive calmodulin domain (CaM), the M13 spacer peptide and a second fluorescent protein with yellow light emission spectrum (EYFP). YC construct can detect variation of Ca2+ concentration in a range from 10-8 to 10-2 M by a phenomenon called FRET (Förster Resonance Energy Transfer): resonance energy transfer between fluorophores, that occurs when donor fluorophore emission wavelength and acceptor fluorophore absorption wavelength substantially overlap. When fluorophores are a few dozen Å far from each other, the donor excitement causes resonance energy transfer to the acceptor, which is therefore the only molecule to emit fluorescence. In the YC construct, this process is used to visualize variations in cellular Ca2+ concentration: in Ca2+ lacking, the fluorophores are not such close to give rise to FRET phenomenon, they thus absorb and emit light independently; but in presence of cellular ca2+, it binds to CaM, which folds up moving close the 2 fluorophores ECFP and EYFP and allowing FRET; a downturn in the blue fluorescence and an increase in the yellow one will be observed. For our analyses we used a nucleoplasmin-tagged cameleon (NupYC2.1), which permits to observe the variations of ca2+ within the cellular nuclei. Confocal microscope analyses were conducted treating excised 1-2cm-long lateral roots with 10-6 M chito-oligosaccharides (COs) solution, sterile distilled water was used as negative control. Each root was excised and placed in a silicon micro-chamber (Invitrogen) to avoid the root damage caused by compression against the coverslip glass. A sterile distilled water drop was added for preventing root tissues desiccation. A Leica TCS SP2 AOBS confocal laser-scanning microscope, equipped with a 40x water-immersion objective, was used for these experiments. Roots were first observed in bright field to identify epidermal cells devoid of root hairs (atrichoblasts), focusing on their nuclei. Images were recorded setting the pinhole diameter at 6 Airy units, to obtain high-thickness optical sections in order to entirely include the diameter of focused nuclei. After balancing the intensity level of YFP and CFP, water on microchamber was then removed employing filter paper and substituted with 200 μl of CO solution using a micro-pipette. Images were scanned at a resolution of 512 X 512 pixels and collected every 5 seconds over a period of 30 min after treatment. The average intensity of yellow and cyan emitted fluorescence was recorded for each nucleus. Such values were exported in a .txt file, which was then elaborated in Microsoft Excel to calculate the ratio between yellow and cyan fluorescence: this ratio corresponds to FRET intensity within the YC protein and was plotted over time to visualize variations in ca2+ concentration for each nucleus during the 30 minutes acquisition.

3. Results

The results of the analyzes can be broken down into disaggregated analyzes and aggregate analyses. In the disaggregate analyses, described in Figure 1 the nuclei that make spike peaks are analyzed by single portion of root and treatment, while the aggragated data allow the analysis of the Ca2+ peaks by sum of roots for each single treatment. The data were considered for the WT and DMI2 experimental sets by proceeding first with the autocorrelation analysis (autocorrelation function, ACF) and then with the cross correlation analysis (cross correlation function, CCF). The results demonstrate autocorrelation within the same series as in Figure 3, decreased between series of different experimental sets as described in Figure 4. The periodogram useful for identifying periodicity demonstrates the presence of an initial

peak indicating that the series do not appear to have a periodicity as described in Figure 2.

Two-stage weighted least squares estimator of multivariate conditional mean observation-driven time series models

Mirko Armillotta[a]

[a]Department of Econometrics and Data Science, Vrije Universiteit Amsterdam;
m.armillotta@vu.nl

Abstract

We introduce a general parametric multivariate model where the first two conditional moments are assumed to be multivariate time series. The focus of the estimation is the conditional mean parameter vector. Quasi-Maximum Likelihood Estimators (QMLEs) based on the linear exponential family are typically employed for such estimation problems when the true multivariate conditional probability distribution is unknown or too complex. Although QMLEs provide consistent estimates they may be inefficient. In this paper we study a two-stage Multivariate Weighted Least Square Estimators (MWLSEs), which enjoy the same consistency property as the QMLEs and provides efficiency gain with suitable choice of the covariance matrix. We compare the estimation performance of the QMLEs and MWLSEs through simulation experiments.

Keywords: Quasi-likelihood, Multivariate Integer-valued GARCH, Multivariate Poisson.

1. Inefficiency of QMLE

Consider a multivariate stationary and ergodic sequence of real-valued processes $\{\mathbf{Y}_t\}_{t\in\mathbf{Z}}$ with first conditional moment given by

$$\mathrm{E}(\mathbf{Y}_t|\mathcal{F}_{t-1}) = \lambda(\mathbf{Y}_{t-1}, \mathbf{Y}_{t-2}, \ldots; \boldsymbol{\theta}_0) = \boldsymbol{\lambda}_t(\boldsymbol{\theta}_0)\,, \quad t \in \mathbf{Z} \tag{1}$$

where $\mathbf{Z}$ is the set of integers, $\mathcal{F}_t$ denotes the σ-field generated by $\{\mathbf{Y}_s\,,\ s \le t\}$, $\lambda : \mathbf{R}^\infty \times \Theta \to \mathbf{R}^d$ is a known measurable function, with $\boldsymbol{\theta}_0$ unknown parameter vector belonging to some compact parameter space $\Theta \subset \mathbf{R}^m$. The vector $\boldsymbol{\theta}_0$ is quite general as it is not constrained to have a specific structure; Sometimes the specification of model (1) can be completed by setting a function of the data $\mathbf{Y}_t = f(\boldsymbol{\lambda}_t, \boldsymbol{\varepsilon}_t; \boldsymbol{\theta}_0)$ where $\{\boldsymbol{\varepsilon}_t\}_{t\in\mathbf{Z}}$ is an iid sequence. It is the case of the Vector Autoregressive Moving-Average models (VARMA), see Lütkepohl (8, Ch. 11), or also the Multivariate Generalized Autoregressive Conditional Heteroskedasticity model (MGARCH); see Francq and Zakoian (5, Ch. 10). However, although the Maximum Likelihood Estimator (MLE) is sometimes readily computable when the joint conditional distribution function (cdf) can be specified (as in the case of VARMA and MGARCH models) this may not always be the case. For example, when count time series models are analyzed, for models encompassed in eq. (1) such as the Multivariate Integer-valued GARCH (MINGARCH), Fokianos et al. (4), a Poisson distribution can be specified for the marginal probability mass functions (pmf) of the univariate process $Y_{i,t}$, for $i = 1, \ldots, d$. However, to obtain a complete joint cdf a particular joint pmf needs to be specified as well. The functional form of such joint pmf can be unknown or too complex to be employed

for the MLE. Indeed, the development of a multivariate count time series model would be based on specification of a joint pmf distribution, so that the standard likelihood inference and testing procedures can be developed. Although several alternatives have been proposed in the literature, see the review in Fokianos (3, Sec. 2), the choice of a suitable multivariate version of the Poisson pmf is a challenging problem. In fact, multivariate Poisson-type pmfs have usually complicated closed form and the associated likelihood inference is theoretically and computationally cumbersome. Furthermore, in many cases, the available multivariate Poisson-type pmfs implicitly imply restricted models, which are of limited use in applications (e.g. covariances always positive, constant pairwise covariances). See Inouye et al. (6) and Fokianos (3) for a discussion on the choice of multivariate count distributions and several alternatives. Other approaches try to avoid the problem of specifying a multivariate Poisson distribution, like in Fokianos et al. (4), where the joint distribution of the vector $\{\mathbf{Y}_t\}$ is constructed by following a copula approach where all marginal distributions of $Y_{i,t}$ are univariate Poisson, conditionally to the past, with mean process $\lambda_{i,t}$, for $i = 1, \dots, d$. However, this approach does not allow to perform a ML estimation but requires appealing the class of Quasi-Maximum Likelihood Estimators (QMLEs) based on the linear exponential family that assumes independence between the univariate processes $Y_{i,t}$, for $i = 1, \dots, d$, see eq. (10) in Fokianos et al. (4). The QML estimator $\hat{\boldsymbol{\theta}}_Q$ can be seen as the vector which solves the first order conditions that typically take the form

$$\mathbf{S}_T^Q(\boldsymbol{\theta}) = \frac{1}{T}\sum_{t=1}^{T} \frac{\partial \boldsymbol{\lambda}_t(\boldsymbol{\theta})}{\partial \boldsymbol{\theta}'} \mathbf{D}_t^{-1}(\boldsymbol{\theta}) \Big(\mathbf{Y}_t - \boldsymbol{\lambda}_t(\boldsymbol{\theta}) \Big) = 0\,, \tag{2}$$

where $\mathbf{S}_T^Q(\boldsymbol{\theta})$ is the score of the QMLEs, $\mathbf{D}_t(\boldsymbol{\theta})$ is the $d \times d$ diagonal matrix with diagonal elements equal to $\nu_{i,t}(\boldsymbol{\theta})$ for $i = 1, \dots, d$ and $\nu_{i,t}(\boldsymbol{\theta}_0)$ is defined in

$$\mathbf{V}(Y_t|\mathcal{F}_{t-1}) = \boldsymbol{\nu}(\mathbf{Y}_{t-1}, \mathbf{Y}_{t-2}, \dots; \boldsymbol{\theta}_0) = \boldsymbol{\nu}_t(\boldsymbol{\theta}_0)\,, \quad t \in \mathbf{Z} \tag{3}$$

which is the vector of conditional variances of the marginal process $Y_{i,t}$ with $\nu : \mathbf{R}^\infty \times \Theta \to [0, +\infty)^d$ being a measurable function. From the property of the linear exponential family we often have that the variance model depends on the mean model, i.e. $\nu_{i,t}(\boldsymbol{\theta}_0) = g(\lambda_{i,t}(\boldsymbol{\theta}_0))$ where $g(\cdot)$ is some measurable function. The possible value of $\nu_{i,t}$ is however restricted by the fact that it must match the conditional variance of an exponential family distribution. For example, in the QMLE employed in Fokianos et al. (4) all marginal distributions of $Y_{i,t}$ are univariate Poisson, conditionally to the past, so the variances processes are $\nu_{i,t}(\boldsymbol{\theta}_0) = \lambda_{i,t}(\boldsymbol{\theta}_0)$, for $i = 1, \dots, d$. In practice, one can easily conceive that the conditional variance may have other forms. Obviously, the choice of a wrong marginal pmf, or probability density function (pdf), may affect the efficiency of the QMLEs. Moreover, it is clear that the score of the QMLE defined in (2) does not directly include any joint dependence between the univariate processes because is computed upon a quasi-likelihood which assumes contemporaneous independence among $Y_{i,t}$, for $i = 1, \dots, d$. Then the QMLEs suffer from two main sources of inefficiency: constrained variance specification and exclusion of joint dependence parameters.

2. Two-stage Multivariate Weighted Least Square Estimators

The present contribution proposes a novel class of two-stage Multivariate Weighted Least Square Estimators (MWLSEs) of the mean parameters $\boldsymbol{\theta}_0$. Given a theoretical matrix weight function $\mathbf{W}_t = \mathbf{W}(\mathbf{Y}_{t-1}, \mathbf{Y}_{t-2}, \dots)$, where $\mathbf{W}$ is a measurable function from $\mathbf{R}^\infty \to \mathbf{R}^{d \times d}$ a first-stage MWLSE is defined by $\hat{\boldsymbol{\theta}}_1 = \arg\min_{\boldsymbol{\theta} \in \Theta} l_T(\boldsymbol{\theta}, \mathbf{W})$ where

$$l_T(\boldsymbol{\theta}, \mathbf{W}) = \frac{1}{T}\sum_{t=1}^{T} l_t(\boldsymbol{\theta}, \mathbf{W}_t)\,, \qquad l_t(\boldsymbol{\theta}, \mathbf{W}_t) = \Big(\mathbf{Y}_t - \boldsymbol{\lambda}_t(\boldsymbol{\theta}) \Big)' \mathbf{W}_t \Big(\mathbf{Y}_t - \boldsymbol{\lambda}_t(\boldsymbol{\theta}) \Big)\,. \tag{4}$$

When $\mathbf{W}_t = \mathbf{I}$ where $\mathbf{I}$ is the identity matrix of suitable dimension, (4) corresponds to the multivariate version of the Conditional Least Squares (CLS) estimator of Klimko and Nelson (7). It is well-known

that the optimal choice of the weights $\mathbf{W}_t$ is inverse of the true conditional covariance matrix of the process, $(\tilde{\mathbf{V}}_t^{-1})_{t\geq 1}$. In practice, the value of $\tilde{\mathbf{V}}_t^{-1}$ is generally unknown. We assume for the conditional covariance matrix a parametric specification of the form $\mathbf{V}_t = \mathbf{V}(\mathbf{Y}_{t-1}, \mathbf{Y}_{t-2}, \ldots; \boldsymbol{\tau}_0)$, where $\mathbf{V}$ is a measurable function defined in $\mathbf{R}^{\infty} \to \mathbf{R}^{d\times d}$ and the true parameter vector $\boldsymbol{\tau}_0$ may contain $\boldsymbol{\theta}_0$ or some of its elements. Then, the optimal sequence of weights is estimated by

$$\hat{\mathbf{W}}_t = \mathbf{V}_t(\hat{\boldsymbol{\tau}})^{-1} = \mathbf{D}_t(\hat{\boldsymbol{\tau}})^{-1/2}\mathbf{P}(\hat{\boldsymbol{\tau}})^{-1}\mathbf{D}_t(\hat{\boldsymbol{\tau}})^{-1/2} \tag{5}$$

where, analogously to Section 1, $\mathbf{D}_t(\hat{\boldsymbol{\tau}})$ is the $d \times d$ diagonal matrix with diagonal elements equal to $\nu_{i,t}(\hat{\boldsymbol{\tau}})$ for $i = 1, \ldots, d$ and $\nu_{i,t}(\hat{\boldsymbol{\tau}})$ is defined as in (3) with obvious rearrangement of the notation and $\mathbf{P}(\hat{\boldsymbol{\tau}})$ is a $d \times d$ correlation matrix whose structure can be defined by the researcher and whose single element has a functional form of the type $r_{i,j}(\hat{\boldsymbol{\tau}}) = r(\mathbf{Y}_1, \ldots, \mathbf{Y}_T; \hat{\boldsymbol{\tau}})$ for $i, j = 1, \ldots, d$ where $r : \mathbf{R}^T \to (-1, 1)$. The estimator $\hat{\boldsymbol{\tau}}$ will be a function of the estimator $\hat{\boldsymbol{\theta}}_1$ of $\boldsymbol{\theta}_0$, and possibly of estimates of some extra parameters $\boldsymbol{\gamma}_0$. In this way $\hat{\boldsymbol{\tau}}$ represents a first-step estimator of $\boldsymbol{\tau}_0$ and the two-stage WLSE is given by

$$\hat{\boldsymbol{\theta}} = \arg\min_{\boldsymbol{\theta}\in\Theta} l_T(\boldsymbol{\theta}, \hat{\mathbf{W}}), \qquad l_T(\boldsymbol{\theta}, \hat{\mathbf{W}}) = \frac{1}{T}\sum_{t=1}^{T} l_t(\boldsymbol{\theta}, \hat{\mathbf{W}}_t) \tag{6}$$

where $l_t(\boldsymbol{\theta}, \hat{\mathbf{W}}_t)$ is defined analogously to (4) and $\hat{\mathbf{W}}_t$ has the form (5). We can see that the MWLSE defined in (6) is the solution of the first order condition system

$$\mathbf{S}_T(\boldsymbol{\theta}) = \frac{1}{T}\sum_{t=1}^{T} \frac{\partial \boldsymbol{\lambda}_t(\boldsymbol{\theta})}{\partial \boldsymbol{\theta}'}\mathbf{V}_t(\hat{\boldsymbol{\tau}})^{-1}\Big(\mathbf{Y}_t - \boldsymbol{\lambda}_t(\boldsymbol{\theta})\Big) = 0\,. \tag{7}$$

The MWLSEs do require only the correct specification of the first conditional moment of the process instead of entirely specifying its conditional distribution. In this sense, they are semi-parametric estimators because, except for the first moment, they are totally agnostic about the distribution of the observations. In this way the estimation is robust against possible misspecification of the conditional distribution and simplifies the inference when the full MLE is undoable or too complex.

The first order conditions (2) and (7) allow for a direct and intuitive comparison between QMLEs and MWLSEs. The first main difference is that in (7) there is no particular constraint on the shape of the univariate conditional variances, $\nu_{i,t}(\hat{\boldsymbol{\tau}})$ whereas in (2) the form of the variances are constrained by the univariate conditional distribution specified in the quasi-likelihood. Consequently, the MWLSE adds more flexibility in the choice of the variances form and this can lead to an improved efficiency estimator. A second difference lies in the possibility of including correlation effects in the estimation system (7) whereas the QMLE simply implies no correlation in the score (2), i.e. $\mathbf{P}^{-1} = \mathbf{I}$. Intuitively, the MWLSE is expected to explain a larger part of the variability connected to the process of study. We will show with a simulated experiment that when a moderate or high degree of contemporaneous dependence is indeed present among the variables $Y_{i,t}$ for $i = 1, \ldots, d$ the MWLSE entails a relevant gain in efficiency with respect to the QMLE.

3. An example with Poisson data

We apply the methodology discussed in the previous section to the Multivariate INGARCH model with Poisson data

$$\mathbf{Y}_t = \mathbf{N}_t(\boldsymbol{\lambda}_t), \quad \boldsymbol{\lambda}_t = \mathbf{c} + \mathbf{A}\boldsymbol{\lambda}_{t-1} + \mathbf{B}\mathbf{Y}_{t-1}\,, \tag{8}$$

where $\mathbf{c}$ is a vectorial intercept of positive unknown parameters and $\mathbf{A}$ and $\mathbf{B}$ are $d \times d$ unknown parameter matrices assumed to be non-negative such that $\lambda_{i,t} > 0$ for all i and t. $\mathbf{N}_t(\boldsymbol{\lambda}_t)$ is a sequence of d-dimensional iid marginally Poisson count processes, with intensity 1, counting the number of events in the interval of time $[0, \lambda_{1,t}] \times \cdots \times [0, \lambda_{d,t}]$ and whose structure of dependence is modelled through

a copula construction $C(\dots)$ on their associated exponential waiting times random variables. The complete structure of the data generating process (dgp) is described in Fokianos et al. (4, p. 474). For the scopes of our example it is just important to state that the joint conditional pmf resulting from (8) does not have a closed form (so the MLE is unfeasible) but the univariate conditional pmfs $q(\cdot)$ are Poisson, i.e. $Y_{i,t}|\mathcal{F}_{t-1} \sim q(\lambda_{i,t}(\boldsymbol{\theta}_0))$, for $i = 1, \dots, d$ and the contemporaneous dependence between the variables $Y_{i,t}$ is modelled through a copula $C(\dots;\rho)$ which depends on one unknown parameter, say ρ, capturing the contemporaneous correlation among the variables. Since the copula construction in the dgp is imposed on latent variables (exponential waiting times) it cannot be included in the likelihood estimation and a Poisson QMLE of the type $l_T^P(\theta) = T^{-1}\sum_{t=1}^{T}\sum_{i=1}^{d} q(\lambda_{i,t}(\boldsymbol{\theta}_0))$ has been carried out in the previous literature; see Fokianos et al. (4, eq. 10), Armillotta and Fokianos (1) and Armillotta and Fokianos (2), among others. The associated QML estimator $\hat{\boldsymbol{\theta}}_P$ is the vector which maximizes $l_T^P(\theta)$ and clearly solves the first order system (2) where the elements on the diagonal matrix $\mathbf{D}_t(\hat{\boldsymbol{\theta}}_P)$ have the form $\lambda_{i,t}(\hat{\boldsymbol{\theta}}_P)$.

We summarize the steps required in order to carry out the two-stage MWLSE.

1. Estimate $\hat{\boldsymbol{\theta}}_1$, the first-stage MWLSE (4) of model (8) by setting $\mathbf{W}_t = \mathbf{I}$.
2. Choose a functional form for $\nu_{i,t}(\boldsymbol{\tau})$.
3. Choose a structure for $\mathbf{P}(\boldsymbol{\tau})$ and a functional form for $r_{i,j}(\boldsymbol{\tau})$.
4. Estimate $\hat{\boldsymbol{\theta}}$ the second-stage MWLSE (6) of model (8) by setting $\hat{\mathbf{W}}_t = \mathbf{V}_t(\hat{\boldsymbol{\theta}}_1)^{-1}$.

For the first-stage estimation a reasonable weighting scheme in absence of any information will be $\mathbf{W}_t = \mathbf{I}$ so that $\hat{\boldsymbol{\theta}}_1$ represents the CLS estimator. For the accomplishment of the second-stage estimation we need to define a suitable weight matrix (5), which is translated in steps 2-3 of the algorithm above. Since the data are marginally Poisson-distributed we set $\nu_{i,t}(\boldsymbol{\tau}) = \lambda_{i,t}(\boldsymbol{\tau})$. In this case no additional parameters $\boldsymbol{\gamma}$ are employed so we have $\hat{\boldsymbol{\tau}} = \hat{\boldsymbol{\theta}}_1$.

Reminding that the copula construction in the dgp is imposed on latent variables and since, in practice, the dependence structure among the integer-valued random variables is completely determined by the copula parameter ρ, the true structure of the conditional correlation matrix $\mathbf{P}(\tau)$ is unknown. In this cases, similarly to the theory of Generalized Estimating Equation (GEE) Zeger and Liang (12), the researcher may choose a working correlation structure for the estimation. There exist several suitable alternatives in the literature; see for example Pan (9, p. 121). Sometimes the inversion of the $d \times d$ matrix $\mathbf{P}(\cdot)$ may be unfeasible for numerical reasons. Furthermore, since only the inverse of such matrix would be required by the proposed estimating procedure, we suggest to pick a correlation structure where an analytical form for the inverse is known. For example, in this work we decide to impose a simple structure like the equicorrelation structure (EQC), $\mathbf{P}(\boldsymbol{\tau}) = (1 - r(\boldsymbol{\tau}))\mathbf{I} + r(\boldsymbol{\tau})\mathbf{J}$, where $\mathbf{J}$ is a $d \times d$ matrix of ones and an equal pairwise correlation $r_{i,j}(\boldsymbol{\tau}) = r(\boldsymbol{\tau})$ is assigned to all the possible couples of the multivariate time series. Such working correlation matrix is appealing since it has an analytical form of the inverse, i.e. $\mathbf{P}^{-1}(\boldsymbol{\tau}) = (a - b)\mathbf{I} + b\mathbf{J}$, with $a = [1 + (d-2)r]/\{(1-r)[1+(d-1)r]\}$ and $b = -r/\{(1-r)[1+(d-1)r]\}$, where we set for simplicity $r(\boldsymbol{\tau}) = r$. For a proof see Rao (10, p. 67)

Borrowing the idea of GEE, the form of the the correlation parameter can be tackled using moment estimators types functions, see for example Zeger and Liang (12, Sec. 4). We consider two alternatives, $\hat{r}_1 = 2\sum_{i=1}^{d}\sum_{j>i}\hat{r}_{ij}(\hat{\boldsymbol{\theta}}_1)$ and $\hat{r}_2 = \max_{i,j=1,\dots,d,\, j>i}\hat{r}_{ij}(\hat{\boldsymbol{\theta}}_1)$, where

$$\hat{r}_{ij}(\hat{\boldsymbol{\theta}}_1) = \frac{\sum_{t=1}^{T}[Y_{i,t} - \lambda_{i,t}(\hat{\boldsymbol{\theta}}_1)][Y_{j,t} - \lambda_{j,t}(\hat{\boldsymbol{\theta}}_1)]}{\sqrt{\sum_{t=1}^{T}[Y_{i,t} - \lambda_{i,t}(\hat{\boldsymbol{\theta}}_1)]^2}\sqrt{\sum_{t=1}^{T}[Y_{j,t} - \lambda_{j,t}(\hat{\boldsymbol{\theta}}_1)]^2}}$$

are the empirical Pearson correlations from the first-stage MWLSE estimation.

To examine the performance of the QMLEs and MWLSEs we run a simulation study, by generating data from model (8), with different dimension d and sample size T, using the algorithm depicted in Fokianos et al. (4, p. 474) and the Gaussian copula for $C(\dots;\rho)$; data are produced by employing a copula parameter ρ selected by an equidistant grid of values in the interval $[0.3, 0.9]$. Then, we compare the estimation performances of the QMLE versus the MWLSE, by measuring their relative efficiency, with the relative Mean Square Error, $e(\hat{\boldsymbol{\theta}}_P, \hat{\boldsymbol{\theta}}) = \sum_{s=1}^{S}||\hat{\boldsymbol{\theta}}_{P,s} - \boldsymbol{\theta}||^2 / \sum_{s=1}^{S}||\hat{\boldsymbol{\theta}}_s - \boldsymbol{\theta}||^2$, where $S = 500$

is the number of simulations performed and $\hat{\boldsymbol{\theta}}_s$ is the estimator associated with the replication s. Clearly, $e(\hat{\boldsymbol{\theta}}_P, \hat{\boldsymbol{\theta}}) > 1$ shows improved efficiency of $\hat{\boldsymbol{\theta}}$ when compared to $\hat{\boldsymbol{\theta}}_P$. The same comparison can be done marginally for each parameter of the model $e(\hat{\boldsymbol{\theta}}_{P,h}, \hat{\boldsymbol{\theta}}_h) = \sum_{s=1}^{S}(\hat{\boldsymbol{\theta}}_{P,h,s} - \boldsymbol{\theta}_h)^2 / \sum_{s=1}^{S}(\hat{\boldsymbol{\theta}}_{h,s} - \boldsymbol{\theta}_h)^2$, for $h = 1, \ldots, m$. The results of the Monte Carlo simulations are summarized in Figure 1. When the

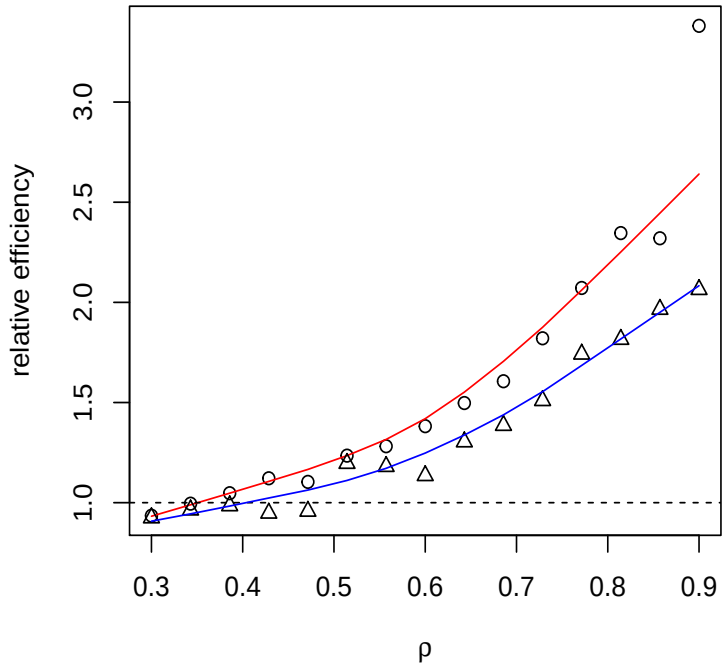

Figure 1: Plot for $e(\hat{\boldsymbol{\theta}}_P, \hat{\boldsymbol{\theta}})$ versus values of copula parameter ρ, with EQC working correlation matrix and $r(\hat{\boldsymbol{\theta}}_1) = \hat{r}_2$. Data generated by model (8) with 500 simulations. Triangles: $d = 2, T = 100$. Points: $d = 4, T = 200$. Blue line: LOWESS smoother at $d = 2, T = 100$. Red line: LOWESS smoother at $d = 4, T = 200$. Dashed line: horizontal line $e(\hat{\boldsymbol{\theta}}_P, \hat{\boldsymbol{\theta}}) = 1$.

data are generated with a low correlation ($\rho < 0.4$) the two estimator show similar performances. However, when the data are generated with a moderate or strong correlation (copula parameter $\rho > 0.4$) the MWLSE is relatively more efficient than the QMLE. The improvement in efficiency is larger as the correlation becomes stronger and tends to grow even by increasing dimension and time size (d, T). This would be expected since the QMLE becomes a poor approximation of the true likelihood as the dependence structure of the multivariate count process $\mathbf{Y}_t$ becomes stronger, whereas the specified MWLSE methodology appears to be able to account for a significant part of the correlations among the counts, even though the working correlation does not reflect the true correlation structure of the data. Similar results are obtained by comparing the marginal efficiencies $e(\hat{\boldsymbol{\theta}}_{P,h}, \hat{\boldsymbol{\theta}}_h)$, therefore are omitted. The employment of the estimator $\hat{r}_1$ gave analogous results but with gain in efficiency less than the gain obtained by used $\hat{r}_2$.

Although the result of the present simulation study are encouraging, the problem of improving the efficiency of the QMLE is only at the initial stage and further studies are required. For example, alternative working correlation structures may be used, like the AR-1 correlation structure $\mathbf{P}(\boldsymbol{\tau}) = (r_{ij})$ where $r_{ij} = r^{|i-j|}$, for $i, j = 1, \ldots, d$ and $i \neq j$. This matrix also have analytical inverse, $\mathbf{P}^{-1}(\boldsymbol{\tau}) = 1/(1-r^2)\mathbf{T}(\boldsymbol{\tau})$, where $\mathbf{T}(\boldsymbol{\tau})$ is a tridiagonal matrix, with the main diagonal consisting of the elements of the $d \times 1$ vector $(1, 1+r^2 \ldots, 1+r^2, 1)$, and the remaining two diagonals are the elements of the

$(d-1) \times 1$ vector of $(-r, \ldots, -r)$; see Sutradhar and Kumar (11, eq. 1.1). Moreover, more complex correlation structures could be considered. In addition, further estimators for the correlation parameter r may be available. Finally, the development of an asymptotic theory for the proposed MWLSE estimator would be of interest.

Abstract

With the aim of performing a counterfactual analysis using the statistical learning method of Matrix Completion (MC) to evaluate the impact of the Emissions Trading System (ETS) - an instrument launched by the European Union in 2005 to reduce CO_2 emissions and mitigate global warming - in this paper we study the performance of recently proposed nuclear norm regularized MC methods for panel data when applied to CO_2 emission data. Results show that the inclusion of individual and time fixed effects in the MC optimization problem, and the pre-processing of the original data, increase the performance of the method.

Keywords: emissions trading system, counterfactual analysis, statistical learning, missing data, causal inference

1. Introduction

CO_2 emissions represent a rising concern in relation to pollution and climate change (7). Economic systems produce large amounts of CO_2 by the use of fossil energy, thereby governments are trying to address the production to new systems aimed at minimizing emissions. In this regard, the European Union implemented a market of emission rights called the Emissions Trading System (ETS) that was launched in 2005.

A counterfactual analysis for policy evaluation permits quantifying the reduction of CO_2 emissions due to ETS is in place. In our ongoing works we adopt an approach based on Matrix Completion (MC) (4), which is a supervised statistical learning method to reconstruct a partially incomplete matrix and whose idea relies on the minimization of a trade-off between the approximation error on a set of observed entries and a proxy of the rank of the reconstructed matrix, e.g., its nuclear norm. We adopt an MC approach because, in the absence of the ETS policy, counterfactual CO_2 emission levels are not known for the treated countries (namely EU countries) in the years of treatment. Hence, based on the method introduced by Athey et al. (1), we use MC to generate estimates of such counterfactual values, and compare them with the actual CO_2 emission levels, with the final aim to estimate the effect of treatment on CO_2 emission levels through the ETS policy.

The MC optimization problem proposed and theoretically investigated by Mazumder et al. (5), which belongs to the class of "nuclear norm regularized" MC methods (because the error minimization is penalized by the nuclear norm of the reconstructed matrix) and which is generally solved using the so-called Soft Impute algorithm, has been widely adopted (e.g., in (6) for the reconstruction of Input-Output tables, or in (3) to analyse economic complexity). When the matrix to reconstruct displays the

countries in rows and the years in columns (as is the case of the CO_2 emissions matrix considered in this work), we are in a panel data set-up. More recently, specific nuclear norm regularized MC methods solved with Soft Impute algorithm and that explicitly take into account for individual and time effects in the MC optimization problem have been proposed for panel data by Athey et al. (1).

A necessary condition for obtaining credible counterfactual results regards a satisfying performance of the MC method in reconstructing the original matrix in absence of any treatment. The aim of this paper is that of assessing and comparing the performance of the above-mentioned MC methods in reconstructing CO_2 emissions matrix. We develop a simulation study where different amounts of unknown entries are allowed and we evaluate the performance in terms of Mean Absolute Percentage Error (MAPE). Because a criterion for an efficient reconstruction lies in the maintenance of the original decomposition of the total deviance in within and between country deviance, an analysis based on such a decomposition in the reconstructed matrix is also conducted.

Results show that, for our simulation study, the MC method proposed by Athey et al. generally outperforms the MC method proposed by Mazumder. When the first method is applied to a l_1 row-normalized matrix, the performance is extremely good even for a large amount of unknown entries. The between and within deviance decomposition is also preserved when the method proposed by Athey et al. is applied to the original matrix (i.e., without l_1 row-normalization).

2. Methods

MC is a statistical method used to predict unobserved entries of a matrix in terms of the set of the remaining observed entries. Given a matrix $\mathbf{M} \in \mathbb{R}^{m\times n}$, MC works by finding a suitable low-rank approximation of $\mathbf{M}$, by assuming the model $\mathbf{M} = \mathbf{C}\mathbf{G}^T + \mathbf{E}$, where $\mathbf{C} \in \mathbb{R}^{m\times r}$, $\mathbf{G} \in \mathbb{R}^{n\times r}$, whereas $\mathbf{E} \in \mathbb{R}^{m\times n}$ is a matrix of errors. According to (5), the rank-r approximating matrix $\mathbf{C}\mathbf{G}^T$ is found by solving the following MC optimization problem based on a LASSO-like nuclear norm penalty:

$$\underset{\hat{\mathbf{M}}\in\mathbb{R}^{m\times n}}{\text{minimize}} \quad \left(\frac{1}{|\Omega^{\text{tr}}|} \sum_{(i,j)\in\Omega^{\text{tr}}} \left(M_{i,j} - \hat{M}_{i,j}\right)^2 + \lambda\|\hat{\mathbf{M}}\|_* \right) , \tag{1}$$

where Ω^{tr} is a subset of pairs of indices (i, j) corresponding to positions of known entries of $\mathbf{M}$, $\hat{\mathbf{M}}$ is the matrix to be optimized, $\lambda \geq 0$ is a regularization constant, and $\|\hat{\mathbf{M}}\|_*$ is the nuclear norm of the matrix $\hat{\mathbf{M}}$. The regularization constant λ controls the trade-off between fitting the known entries of the matrix $\mathbf{M}$ and achieving a small nuclear norm. The "Soft Impute" algorithm has been proposed in (5) to solve equation 1. Penalization parameter λ is chosen by first randomly dividing the set of positions of unobserved entries of the matrix $\mathbf{M}$ into a validation set Ω^{val} and a test set Ω^{test}. Then, the optimization problem is solved for several choices of λ and the optimal λ is that corresponding to the smallest average RMSE on the validation set. Herein after, we call this method MC Baseline (`MCB`).

Athey et al. (1) propose a methodological advancement of Mazumder nuclear norm regularized MC consisting of explicitly including individual and time fixed effects in the optimization problem, specifically intended to use in panel data. The optimization problem to solve is:

$$\begin{aligned} \underset{\hat{\mathbf{L}}\in\mathbb{R}^{m\times n},\hat{\mathbf{\Gamma}}\in\mathbb{R}^{m\times 1},\hat{\mathbf{\Delta}}\in\mathbb{R}^{n\times 1}}{\text{minimize}} \quad & \left(\frac{1}{|\Omega^{\text{tr}}|} \sum_{(i,j)\in\Omega^{\text{tr}}} \left(M_{i,j} - \hat{M}_{i,j}\right)^2 + \lambda\|\hat{\mathbf{L}}\|_* \right) , \\ \text{subject to} \quad & \hat{\mathbf{M}} = \hat{\mathbf{L}} + \hat{\mathbf{\Gamma}}\mathbf{1}_{\boldsymbol{n}}^\top + \mathbf{1}_{\boldsymbol{m}}\hat{\Delta}^\top , \end{aligned} \tag{2}$$

where $\mathbf{1}_{\boldsymbol{n}}$ and $\mathbf{1}_{\boldsymbol{m}}$ are column vectors made respectively of n entries and m entries, all equal to 1; $\hat{\mathbf{M}}$ is decomposed as $\hat{\mathbf{M}} = \hat{\mathbf{L}} + \hat{\mathbf{\Gamma}}\mathbf{1}_{\boldsymbol{n}}^\top + \mathbf{1}_{\boldsymbol{m}}\hat{\Delta}^\top$ (where $\hat{\mathbf{L}}$, $\hat{\mathbf{\Gamma}}$ and $\hat{\Delta}$ have to be chosen in such a way to solve the optimization problem above); $\|\hat{\mathbf{L}}\|_*$ is the nuclear norm of the matrix $\hat{\mathbf{L}}$. $\hat{\mathbf{\Gamma}}\mathbf{1}_{\boldsymbol{n}}^\top$ and $\mathbf{1}_{\boldsymbol{m}}\hat{\Delta}^\top$ model, respectively, row fixed effects (and can be interpreted as individual fixed effects) and column fixed effects

(time fixed effects) in the reconstruction $\hat{\mathbf{M}}$ of $\mathbf{M}$. Differently from MC optimization problem by (5), the nuclear norm $\|\hat{\mathbf{L}}\|_*$ is used instead of $\|\hat{\mathbf{M}}\|_*$ (i.e., the fixed effects $\hat{\mathbf{\Gamma}}\mathbf{1}_n^\top$ and $\mathbf{1}_m\hat{\Delta}^\top$ are not regularized). Herein after, we refer to this method as MC Fixed Effects, or simply `MCFE`. When row fixed effects $\hat{\mathbf{\Gamma}}\mathbf{1}_n^\top$ are constrained to zero, the model includes time fixed effects only. We refer to this case as MC Time Fixed Effects (`MCTFE`).

3. Application to CO_2 Emissions

Adopted data on CO_2 emissions at the national level (2) are freely available at https://op.europa.eu/en/publication-detail/-/publication/df9c194b-81ba-11e9-9f05-01aa75ed71a1/language-en for the period 2000 – 2016 and for 43 countries (30 from the European Union (EU) and 13 extra-EU). In this application, considered time period is from 2000 to 2005, in order to avoid possible treatment effects coming from the ETS. Moreover, we restrict the analysis to 26 countries (14 from the European Union (EU) and 12 extra-EU, which is the result of having dropped out all small countries and all extra-EU countries having special agreements with the EU).

Specifically, in this section we compare the performance of `MCB`, `MCTFE` and `MCFE`. The performance of the methods is assessed both with respect to the original matrix (`raw`) and to a suitably pre-processed matrix (l_1 row-normalization by country). This pre-processing is made with the aim of making comparable the orders of magnitude of all the elements (i.e., the countries) of that matrix. To avoid overfitting, for each row the computation of the l_1 norm takes into account only the elements in the training set and their number. According to the design of the experiments, for any specific percentage of unknown entries (from 0 to 50%, at intervals of 1), 200 replications have been generated, where the unknown entries (test set) are chosen at random according to the desired percentage.

Methods `MCTFE` and `MCFE` have been performed with `mcnnm_cv` function in `MCPanel` R package. The function automatically chooses the optimal value for λ by dividing the observed entries into training and validation sets and by minimizing the average RMSE on the validation set[1]. Method `MCB` has been performed with the same function by constraining both time and individual fixed effects to zero.

Figure 1 displays the optimal λ at increasing percentages of unknown entries (average over 200 replications). The increase in the optimal λ is less pronounced if we include both individual and time effects (`MCFE`). We note that, on the l_1 row-normalized matrix, optimal λ is always low with method `MCFE`, meaning that the penalization by the nuclear norm plays a minor role in cases when time and country fixed effects are taken into account.

To study and compare the performance of the methods, MAPE[2] has been evaluated on the test set as:

$$100 \times \frac{1}{|\Omega^{\text{test}}|} \sum_{i=1}^{|\Omega^{\text{test}}|} \frac{\mid y_i - \hat{y}_i \mid}{y_i},$$

where $|\Omega^{\text{test}}|$ is the dimension of the test set, y and $\hat{y}$ are, respectively, true and estimated values. According to Figure 2, MAPE is low, even for a large amount of unknown entries, on the l_1 row-normalized matrix. In general, method `MCFE` performs slightly better than method `MCB`.

The performance of these methods has been evaluated also with respect to their capability of preserving the original ratio among between and within country deviance. Decomposition of the total deviance in between and within country deviance has been evaluated on the reconstructed matrix according to the

[1] By considering the average RMSE, the comparison of RMSE on validation sets of different dimension is fair.

[2] MAPE in this case has to be preferred over RMSE in order to allow a comparison of the performance of the method on the original and on the normalized matrix.

equation:

$$\underbrace{\sum_{i=1}^{n}\sum_{j=1}^{t}(\hat{y}_{ij}-\hat{y}_{..})^2}_{\text{Total deviance}}=\underbrace{\sum_{i=1}^{n}(\hat{y}_{i.}-\hat{y}_{..})^2}_{\text{Between deviance}}+\underbrace{\sum_{i=1}^{n}\sum_{j=1}^{t}(\hat{y}_{ij}-\hat{y}_{i.})^2}_{\text{Within deviance}},$$

where n and t stay, respectively, for the number of countries and the number of years, $\hat{y}_{ij}$ is the CO_2 emission for the country i at time t, $\hat{y}_{..}$ is the matrix average, $\hat{y}_{i.}$ is the country i average. The same equation holds for the original matrix when estimated values $\hat{y}$ are replaced with the original values y. The Between Deviance Percentage Ratio is evaluated as:

$$\text{BDPR}=\frac{\text{Between deviance}}{\text{Total deviance}}*100\%,$$

in order to understand whether such a ratio departs from that of the original matrix by increasing the amount of unknown entries. In the original matrix, the between deviance stands to 16.4% of the total deviance. By applying MC to the original (i.e., non normalized) matrix, the percentage of 16.4 is maintained for large amounts of unknown entries only using method `MCFE` (Figure 3). When considering the l_1 row-normalized matrix, all methods preserve the original BDPR.

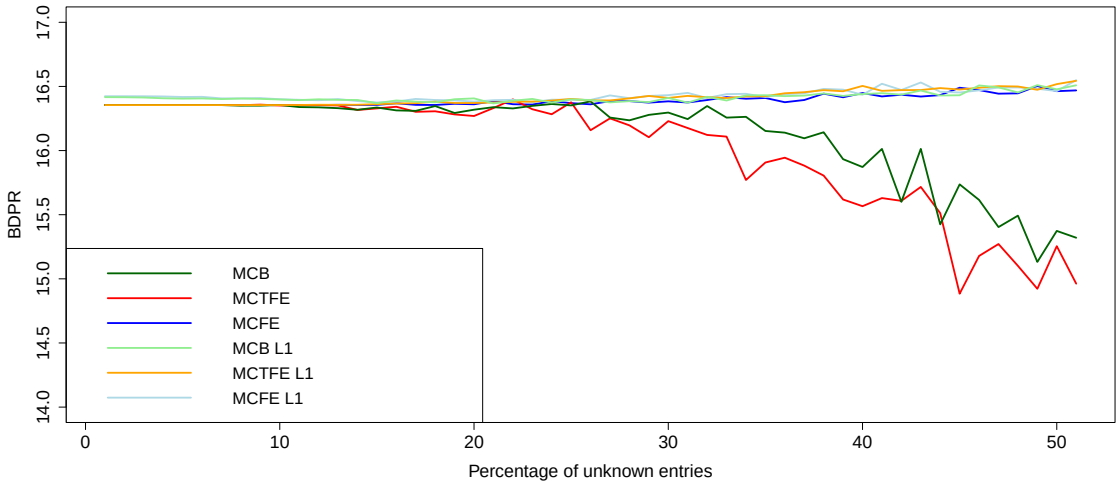

Figure 3: Between deviance percentage ratio (BDPR) at increasing percentages of unknown entries. Median over the 200 replications.

4. Discussion and conclusions

To perform a robust counterfactual analysis on the emission of CO_2 after the Emission Trading System launched by the European Union in 2005, in this paper we assessed the performance of some nuclear norm regularized Matrix Completion (MC) methods in terms of Mean Absolute Percentage Error (MAPE) and in terms of decomposition in within and between country deviance. A study of the optimal λ penalization parameter shows that, at increasing percentages of unknown entries, the increase in the optimal λ is less pronounced for the MC method with both individual and time fixed effects. This means that by better modelling the error minimization component of the MC optimization problem, the component that depends on the nuclear norm decreases in relevance. This is particularly true when applying MC to the l_1 row-normalized matrix. MAPE generally increases by increasing the percentage of unknown entries. However, this increase is less pronounced when using the MC method with both fixed

effects instead of the one that constraint all effects to zero, or if we apply MC to the l_1 row-normalized matrix. The deviance decomposition of the original matrix is generally preserved for low amounts of unknown entries. By adopting the MC method with both fixed effects or by normalizing the rows of the matrix, the decomposition in within and between countries is preserved even for a larger amount of unknown entries. Overall, it can be concluded that the MC method without fixed effects presents good performance when applied to a row-normalized matrix. By using the MC method with both fixed effects, the performance is good even when applying the MC to the original matrix.

Abstract

In recent years, machine learning and deep learning techniques have emerged as effective tools to address the challenges related to smart and sustainable agriculture thanks to their ability to automate the task of processing various types of data (*e.g.*, soil condition data and meteorological information) and transform this data into knowledge that will serve in the decision-making process. The aim of this paper is to showcase through a real case study and an exemplificative application how relevant issues related to the sustainable management of farming activities can be addressed in an effective way by employing deep learning algorithms. The real case study concerns the development of a vineyard yield prediction model using time series of satellite images whereas the exemplificative application showcases how deep learning techniques based on object detection can be usefully exploited to build a plant disease detection system.

Keywords: Smart and Sustainable Agriculture, Yield Prediction, Disease detection, Deep Learning

1. Introduction

Agriculture is a key component in the 2030 Agenda for Sustainable Development to achieve the Sustainable Development Goals (SDGs), since it is the common thread which holds all the SDGs together. The growing population and the complexity of climate change have forced the agriculture sector to data-driven management and automation to increase production while using fewer resources. To achieve the objectives of both the SDGs and the Farm to Fork Strategy, presented in the first quarter of 2020 [11], European farmers need to transform their production processes in a more sustainable way, making the best use of nature-based, technological, digital solutions to properly allocate resources (*e.g.*, water, pesticides, fertilizers), deliver better environmental results and make all productive systems resilient to climate change. Smart Agriculture (SA) supports a data-driven management system for sustainable farming by precisely determining the steps that need to be practiced at its due season through the adoption of modern information technologies, software tools, and smart embedded devices. In such scenario, Machine Learning (ML) and Deep Learning (DL) algorithms can support farmers in making faster decisions on crop management. A main task in crop management is to identify which features (*e.g.*, topography, temperature, soil type, soil quality, rainfall, soil moisture, pH, electrical conductivity, soil nutrients) affect crop yield and the specific requirements to monitor for different phases of crop phenology such as: seeding, growing and maturity, so as to build for example an accurate crop yield prediction model which can help farmers to identify the type of crop to grow and when to grow [25]. ML and DL algorithms can also support farmers to assess agriculture land suitability [21]; measure fruit maturity to identify the suitable harvest moment [5]; detect nutrient status for precision fertilizers management [4]; predict the irrigation schedule and the amount of water to be applied to reduce high water consumption by adapting supplies to the crop needs and avoiding losses [1]. DL algorithms are the most prominent choice for building disease identification systems [15]. They can offer accurate

detection of diseases and weeds to minimize the excessive use of fungicides and pesticides and the need for field scouts [2]; help classify types of plant diseases, since most disease infections are too subtle for the naked eye to be able to perceive [19]; pinpoint which weed infestation areas are most critical, thus allowing farmers to target actions based on environmental customization [3]. This paper aims at showcasing how the adoption of predictive analytics based on DL algorithms can support a knowledge-based crop management system. The paper is organized as follows: Section 2 is devoted to vineyard yield prediction modelling using time series of satellite images; Section 3 illustrates an exemplificative application of DL algorithms for plant disease detection; Conclusion are drawn in Section 4.

2. Vineyard yield prediction

Vineyards for wine production are complex farming systems where aspects related to crop performance and grape and wine compositions are worthy of consideration. In general, with a given climate, vineyard capacity (*i.e.*, grape yield per hectare) is regulated and limited to specific quantities to not exceed certain levels of berry sugar concentrations and dry matter accumulation. An early prediction of the final yield level can be used to establish, and later undertake, farming practices capable of obtaining desired levels of vineyard yield.

2.1 Methodologies

Conventional methods for vineyard yield prediction [14], [23] are based on manual sampling strategies for the estimation of the average number of productive vines (APV), the average number of clusters per productive vine (ACV) and the average cluster weight (ACW). Sampling can be performed on vineyard representative sites at various phenological stages, and yield potential can be estimated using historical data (e.g., ACW at harvest). However, the dependency on historical data regarding cluster weight at harvest is a disadvantage because of climate change environment. An alternative manual method consists of weighing a sample of clusters at the lag phase (just before veraison) while considering a growth factor (generally 2) until full maturation. The lag phase method is based on destructive sampling; its dependency on a berry growth factor, makes it sensitive to growth conditions, cultivar, and management practices. Both methods are labor intensive and time consuming, especially in highly variable vineyards where a higher number of samples is required for an accurate yield estimation; moreover, being dependent on sampling in the field and manual counting, these methods are highly sensitive to spatial variability.

Recently, the adoption of ML and DL techniques tries to overcome the limitations of traditional yield estimation methods. Two alternative approaches are dominant in the specialized literature: (1) combination of object detection algorithms and computer vision systems to build models that try to do an exhaustive enumeration of grape clusters to estimate final vineyard yield and (2) combination of predictive analytics methods and remote sensing techniques that exploit environmental and vegetative status data to predict final yield. In the following we focus on the latter approach since it has many advantages over the former: it is less intrusive in the daily operational context, moreover, remote sensing provides a higher coverage capability and significant low-cost for data acquisition. Long short-term memory (LSTM) neural networks have been successfully applied to crop yield estimation and prediction [22] as they are suitable for learning the relationship between time series data (*e.g.*, temperature and rainfall) and a continuous scalar variable (*e.g.*, final yield). LSTM is a special kind of recurrent neural network (RNN) developed by [9] to tackle the vanishing-gradient-problem that occurs with conventional RNN and leads to the inability to learn long-term dependencies. LSTM is developed to control the whole information flow within neurons, for this purpose, a gating mechanism controls the process of adding and deleting information from an iteratively propagated cell state. Thus, the process of forgetting can be controlled, and a defined memory behavior is realized to model short-term as well as long-term dependencies.

2.2 Data acquisition

The dataset was built collecting vineyard data and satellite time series of atmospheric and vegetation status data considering four different vintages (viz. 2018, 2019, 2020, 2021) of 264 vineyards located in Southern Italy. Vineyard data were obtained from wine Production Declarations of producers which contain records that allow the traceability of the vineyard plot location, grape variety, and final yield. Time series of temperature, precipitation, atmospheric pressure, and Leaf Area Index (LAI) were

obtained using ERA5-Land a database with a spatial resolution of 9 km and a temporal resolution of 1 day. Time series of vegetation indices [26] (i.e., Normal Difference Vegetation Index, NDVI; Modified Soil-Adjusted Vegetation Index, MSAVI; Normalized Difference Moisture Index, NDMI; Enhanced Vegetation Index, EVI) were calculated using a spectral imaging transformation of multispectral images with a spatial resolution of 10 m and a temporal resolution of 10 days obtained from Sentinel-2 a multispectral imaging mission covering 13 spectral bands that range from the visible range to the shortwave infrared (SWIR). Vegetation indices summarize relevant ground information to monitor vineyards, vine growth cycles, nutrient and water stress, thus they are widely employed for better vineyard management in precision agriculture applications [8].

Satellite time series data acquisition was articulated into four phases: obtaining geographical coordinates of vineyards using Google Earth Engine (GEE) code editor; extracting satellite image of the region of interest using GEE API in Python; cleaning satellite image via S2 cloudless cloud detection algorithm [20]; extracting time series of predictors by cutting out the polygon representing the region of vineyard and calculating for each satellite image: average, maximum, minimum of pixels for Temperature; average of pixels for Rainfall and Pressure; average, median, maximum, minimum and standard deviation of pixels for NDVI, EVI, NDMI and MSAVI; and average of pixels for LAI. Climatic and vegetation status time series data were used as predictors to develop the vineyard yield prediction model; each predictor consists of 1056 time series (related to the 264 vineyards observed from 2018 to 2021) extracted at 30 equally spaced time steps with a time span of 10 days. Extracting time series of predictors instead of directly using satellite images as input data stands as the optimal option considering two specificities of the application context: (1) the small number of involved vineyards and available vintages put a constrain on the dataset size and thus limit the effective training of sophisticated prediction models (*e.g.* [12]) able to process satellite images by accounting for both temporal and spatial dependencies; (2) the need to limit costs forced the choice of the satellite Era5 for the acquisition of climatic data; however, the data resolution (9 km grid spacing) allows to obtain a single pixel rather than a pixelated image of the vineyard since the area of this latter is smaller than the pixel size.

2.3 Model Architecture

The model architecture has been defined using optimized parameters obtained via the grid search hyperparameter optimization technique by keeping the value of six parameters as follows: number of layers specified as [2, 4, 6]; number of neurons in the hidden layers specified as [20, 50, 80, 100, 150]; learning rate specified as [0.001, 0.005, 0.01, 0.03, 0.05]; batch size specified as [16, 32, 64, 128]; activation functions in hidden layers specified as sigmoid, hyperbolic tangent (tanh) and rectified linear unit (ReLU); optimizers specified as Stochastic Gradient Descent (SGD), Root Mean Square Propagation (RMSProp) and ADAptive Moment estimation (ADAM).

During the training, early stopping with patience for stagnant progress of 50 epochs has been used. Each training iteration has been allowed to continue for a maximum of 500 epochs. Hyper-parameters tuning and model selection have been carried out using the 5-fold cross-validation. Significantly better results have been obtained with three hidden layers with 80 neurons, batch size of 16, learning rate of 0.01, nonlinear activation function ReLu and ADAM optimizer. The model has been implemented in Python programming language using Keras library, a high-level Neural Network API and the back-end processing TensorFlow library.

The proposed model has been compared to conventional sampling strategy in performing a prediction of the final yield approximately 30 days before harvest. The test sets were based on a sample of 30 vineyards (located in the same region) and performances have been assessed via Mean Absolute Percentage Error (MAPE) which results equal to 15,6 % and 21,6% for the LSTM strategy and the traditional one, respectively. However, besides higher predictive performance, the advantages of the strategy based on LSTM are evident when considering the reduction in product waste, operating costs and time needed to obtain yield estimation. There is still room for performance improvement of the proposed strategy via high resolution satellite images and/or additional key variables as predictors.

3. Grapevine Disease Detection

Plants suffer from different diseases caused by different agents like bacteria, fungi, viruses etc. depending on climate and environmental conditions. The rate of disease spread depends on current crop

conditions and its susceptibility to infection. When plants are affected by diseases, they show a range of symptoms such as colored spots, or streaks that can occur on the leaves, stems, and seeds of the plant. These visual symptoms continuously change in color, shape, and size as per disease progress.

3.1 Methodologies

Plant disease detection is traditionally performed by continuously monitoring crop conditions via visual observation (*i.e.*, direct approach). This strategy is ineffective since growers may not have adequate disease identification knowledge and on the other hand the availability of experts for continuous monitoring is not affordable. In the last decade, scientific literature has shown a substantial increase of indirect approaches for disease detection and classification [6]. Indirect approach uses image processing techniques to identify and classify disease symptoms for different crops. These techniques lead to faster disease detection and diagnosis and allow to determine the exact quantity of pesticides required for a particular disease. The first applications of indirect approach for disease detection adopted more traditional ML algorithms such as support vector machines (SVM) and K-means clustering, however, these methods have shown low detection efficiency because of the complexity of image preprocessing and feature extraction. In recent years, disease identification strategies have been developed using DL algorithms mostly based on Convolutional Neural Networks (CNN), the most frequently used are AlexNet, GoogLeNet, VGG-16, and ResNet-50. These techniques suffer some limitation and drawbacks when used as automatic disease recognition system in field conditions, for this reason DL-based object detection algorithms (*e.g.*, Region-Based Convolutional Neural Network (R-CNN), Fast R-CNN, Faster R-CNN, Yolo and SSD-MobilNet) have been explored as a solution for successful plant disease detection in realistic conditions characterized by images with complex backgrounds or with multiple leaves (diseased or healthy) from different plant species along with different classes.

3.2 Dataset

A total number of 365 images of diseased grapevines was taken from the PlantVillage dataset [10] and EdenLibrary Online Repository [17]. All these images were collected under uncontrolled conditions and without focusing on a particular organ (*e.g.*, clusters or leaves). Table 1 reports for each disease the number of images divided between train and test sets.

Table 1: Number of images per disease

Disease	Train	Test
Esca	108	48
Downy Mildew (DW)	35	24
Powdery Mildew (PW)	66	22
Eriophyes vitis (EV)	45	17
Total	254	111

The total number of diseased leaves annotations amounts to 7475. To increase dimensionality, the training set was enlarged using augmentation techniques that do not negatively influence the detection of diseases: 90°-180°-270° image rotation; brightness variation; image magnification [13]. Finally, a total number of 1157 images and 23421 annotations was obtained.

3.3 Model Architecture

The architecture employed for developing the DL-based object detection model is YOLOv7 [24], one of the best available solutions in terms of speed and accuracy, characterized by high ability to detect small objects like leaf spot diseases (*e.g.*, [18], [7] and [16]).

In the training process, the pre-trained weights of the MS COCO dataset have been used as the initial weights and imported into YOLO architecture.

To generate a robust YOLO model for disease detection, hyper-parameters, such as optimizer (SGD, ADAM), learning rate (0.01, 0.001, 0.0001, 0.00001, 0.0000001) and momentum (0.5, 0.9, 0.99) have been tuned as they can significantly reduce training time and improve the model performance. During training, early stopping with patience for stagnant progress of 50 epochs has been used. The training and test evaluation of each trained model has been performed with hold-out sets. The following

hyperparameters have been selected after tuning: Batch size=16; Image size=1280; Optimizer= ADAM; Momentum=0.937; Learning rate=0.01; Epochs=500.

The model has been implemented in Python using PyTorch framework. For testing purpose, 132 images of healthy grapevines collected from EdenLibrary Repository have been considered.

Table 2: Confusion matrix and performance results

		Predicted							
		Esca	DW	PW	EV	Healthy	Precision	Sensitivity	F1 score
Actual	Esca	48	0	0	0	0	100.00%	100.00%	100.00%
	DW	0	22	0	0	2	100.00%	91.67%	95.65%
	PW	0	0	9	0	13	52.41%	40.90%	45.95%
	EV	0	0	0	14	3	70.00%	82.35%	75.67%
	Healthy	0	0	8	6	118	86.13%	89.39%	87.73%

The results reported in Table 2 show good performance for detection of Esca, DW and EV diseases. The model has difficulties in distinguishing PW from Healthy leaves, in fact PW only partially reduces the leaf aesthetic, unlike the other diseases, which considerably change the color of leaves.

From an operational point of view, it is not important that the model detects all the diseased leaves, but it is sufficient that the model identifies at least one diseased leaf to produce an alert; thus, to assess model performance all bounding boxes related to a diseased leaf have been labeled into a single class. Results in Table 3 show a satisfactory model performance.

Table 3: Performance of grapevine disease detection system

Accuracy	87.00%
Precision	88.00%
Sensitivity	84.00%

4. Conclusion

The use of DL techniques in SA offers a high level of accuracy and outperforms existing traditional ML algorithms, providing flexible tools that can be deployed as an aid for the sustainable management of farming activities. The proposed vineyard yield prediction model based on satellite remote sensed meteorological and vegetation data shows better performance results with respect to conventional strategy based on destructive sampling, and, in addition, it has a positive impact on sustainability in terms of reduction of product waste, costs, labor and time needed for the yield estimation. The grapevine disease detection strategy described in the exemplificative application can be used in real field conditions where images are characterized by complex backgrounds, this is the case for example, of images captured by a drone flying over crops. The integration with Unmanned Aerial Vehicles (UAV) will make possible to automate the detection of diseases in the vineyard in real time to take necessary countermeasures.

Acknowledgments The research has been funded by project SCAE – Smart and Connected Agrifood Ecosystem – F/200119/01/X45.

Abstract

This study investigates the impact of green technology innovation, environmental taxes, renewable energy consumption, along with economic growth, trade openness and urban population, on the ecological sustainability of the G7 countries within the framework of Environmental Kuznets Curve (EKC) hypothesis. To this end, we utilized a combination of second-generation methodologies including quantile regression (QR), augmented mean group (AMG), fully modified ordinary least square (FMOLS), dynamic ordinary least square (DOLS) and fixed effect ordinary least square (FE-OLS). The empirical findings show that green technological innovation, environmental taxes and urban population reduce ecological footprint and enhance environmental sustainability, whereas renewable energy consumption shows a negative and significant relationship with ecological footprint results also confirm the existence of EKC hypothesis in G7 economies. These results indicate that policy makers should encourage investments in green innovation and renewable energy industries.

Keywords: Green technology innovation, Environmental taxes, Renewable energy consumption, Ecological sustainability, Panel quantile regression.

1. Introduction

Many countries are working for mitigating the adverse effects of climate change, land degradation, desertification and other associated human and environmental degradation. After the increasing awareness of the dangerous effects of greenhouse gases (GHGs) on humans and ecosystems, the introduction of carbon tax, innovations and energy-saving and efficient technologies are some of the specific strategies targeted at reducing carbon dioxide (CO_2) emissions and other GHGs [20]. Despite the efforts done, the Intergovernmental Panel on Climate Change reports an increase in CO_2 emissions from 9434.4 to 34,649.4 million tons between 1961 and 2011 [12]. The Energy International Agency also reports that CO_2 emissions increased from 29,714.2 to 33,444 million tons between 1999 and 2017. The Paris Agreement, signed in 2015, reveals that the world's CO_2 emissions grew by 1.3% between 2006 and 2016, and 1.6% in 2017, thus constituting about 81% of greenhouse gases.

Environmental pollution has a multi-dimensional effect on the ecological system; hence, the proxy used for environmental quality has remained mixed. CO_2 emissions are extensively investigated in the literature and remain the core of international climate change agreements; besides, there are some other factors, such as deterioration in the quality of soil, forest and water, which are facing ecological threats [2]. These factors are of great importance and represent an integral part of the ecosystem. Hence, an ecological footprint indicator based on the concept of carrying the capacity of ecosystem represents an important issue in the

ecological system [2]. Moreover, green innovation provides benefits to consumers and organizations and helps reducing the severe environmental effects [18]. It comprises various techniques, including waste recycling, energy-saving, pollution prevention and environmental management [34]. Green technologies are capturing the continuous attention of researchers, resulting from the growing concern of people regarding environmental conditions [18]. The consumption of renewable energy sources is also one of the major determinants in breaking the strong relationship between fuel pollution, CO_2 emissions, and the economy growth. Energy utilization is directly linked with economic growth, which indicates that energy consumption is also responsible for environmental quality [23, 25]. The conventional sources of renewable energy, including hydropower and biomass, reduce a substantial level of CO_2 emissions while contributing to approximately 17% of the overall world demand for energy. Further, environmental taxes represent the most effective policy tool for reducing GHGs [3]. It aims at the taxation of carbon emissions to increase energy efficiency, reduce environmental problems and contribute to environment protection, by internalizing negative externalities in the form of environmental pollution ([21], [4]).

Based on the above discussion, the aim of this study is to investigate the impact of green innovation, environmental taxes and renewable energy consumption, along with economic growth, trade openness and urban population, on the ecological footprint of the G7 economies for the period 1994-2018, in presence of Environmental Kuznets Curve (EKC) hypothesis. This research contributes to the literature in several ways. Firstly, the analysis is focused on the G7 economies. Since the USA is the second-largest emitter of GHGs in the world and accounts for around 13% of global emissions, pollutant emissions from the G7 countries are still high [30]. Moreover, as of 2017, 9% of total GHGs emissions come from the European Union [30], with G7 members including Germany, France, Italy and UK playing a significant role. Therefore, there is still room for discussion on the issue of reducing environmental harms in the G7 countries. Secondly, we use the ecological footprint, which is a more comprehensive indicator of environmental accounting, as a proxy for environmental quality, whereas most of the existing studies have used CO_2 emission. Lastly, the impact of green innovation, environmental taxes and renewable energy consumption on ecological footprint is analysed by utilizing a technique - quantile regression - that considers the conditional distribution of ecological footprint. To our best knowledge, no study has employed the quantile regression approach with fixed effect in the ecological footprint framework.

The paper is organized as follows. Section 2 reviews the relevant literature, Section 3 introduces the methodology used and presents the data used. Section 4 presents the results obtained and Section 5 concludes.

2. Literature review

Many researchers have examined the link between environmental damage and technological advancement. For instance, Chu (2022) has investigated the relationship between green technological innovation and ecological footprint for OECD countries. His findings suggest that promoting the purchase of eco-friendly technologies can help reducing the ecological footprint. Further, Feng et al. (2022) for China, Liu et al. (2022) for ten Asian economies, Sherif et al. (2022) for N-11 countries, Shan et al. (2021) for Turkey, and Ke et al. (2022) for China have concluded that green technology enhances the quality of ecological footprint.

The attainment of environmental sustainability within an economy is predicated on the enforcement of environmental regulations. Thus, several previous studies have explored the dynamic impact of environmental regulations on environmental sustainability. For instance, Dogan et al. (2022) found that environmental tax reduces carbon emissions and increase environmental sustainability for G7 countries. Similarly, other studies found that environmental tax hinders the environmental degradation ([10], [27], [28], [29]). Moreover, research on the connection between renewable energy consumption and the environment has exploded in recent years. Sahoo and Sethi (2021) examined the dynamic impact of renewable energy consumption on ecological footprint for developing countries and found that clean energy increases ecological footprint efficiency. Recent studies obtained similar findings for other countries ([1], [8], [14], [31], [32], [33]).

3. Data and method

This study aims at examining the impact of green technology innovation, environmental taxes, renewable energy consumption, economic growth, trade openness and urban population on the ecological footprint-growth-environmental nexus of G7 countries for the period 1994-2018. A detailed description of the above

variables is given in Table 1.

Table 1: Description of variables

Variables	Description	Sources
EFP	Ecological footprint (global hectares per person)	GFN
GTI	Green technology innovation (No. of patents related to environmental technologies on total patents - %)	OECD
ET	Environmental taxes (% of GDP)	OECD
REN	Renewable energy consumption (% of total final energy consumption)	WDI
GDP	Gross Domestic Product (constant 2015 US$) per capita	WDI
TO	Ratio of exports plus imports over GDP (%)	WDI
UP	Urban population (% of total population)	WDI

All the variables are expressed in their logarithmic forms to avoid the issue of heteroscedasticity and to ensure the robust vector findings. The empirical model we use in this study is specified as follows:

$$lnEFP_{it} = \beta_o + \beta_1 lnGTI_{i,t} + \beta_2 lnET_{i,t} + \beta_3 lnREN_{i,t} + \beta_4 lnGDP_{i,t} + \beta_5 lnGDP_{it}^2 + \beta_6 lnTO_{i,t} + \beta_7 lnUP_{i,t} + \varepsilon_{it} \quad (1)$$

where EFP, GTI, ET, REN, GDP, GDP^2, TO and UP denote the ecological footprint, green technology innovation, environmental taxes, renewable energy consumption, per capita GDP, the square term of per capita GDP, trade openness and urban population, respectively. To examine the impact of the explanatory variables on the ecological footprint in their normal log equation at the selected quantile levels we performed the Panel Quantile regression (PQR) approach. This approach provides the heterogeneous results as compared to the long-run mean estimates such as (FMOLS, DOLS, and FE-LS) which only provides the mean estimators. However, in the real world the data does not fulfil the normality assumption. So, these long-run mean estimates may produce the inconsistent outcomes. The following is the equation of PQR:

$$Q\tau(lnEFP) = \vartheta\tau + \delta_{1\tau} lnGTI_{i,t} + \delta_{2\tau} lnET_{i,t} + \delta_{3\tau} lnREN_{i,t} + \delta_{4\tau} lnGDP_{i,t} + \delta_{5\tau} lnGDP_{it}^2 + \delta_{6\tau} lnTO_{i,t} + \delta_{7\tau} lnUP_{i,t} + \varepsilon_{it} \quad (2)$$

The locus idea τ is based on the explicative factors. $Q\tau$ parallels to the τth distributional stage regression evaluation which can be obtained by applying the method in Eq. 3:

$$Q_\tau = \arg\min \sum_{k=1}^{q} \sum_{t=1}^{T} \sum_{i=1}^{N} (|y_{it} - \alpha_i - x'_{it} Q_\tau| w_{it}) \quad (3)$$

where q, T, N and w_{it} denote the number of quantiles, years, cross sections and weight of the i-th country in the i-th year, respectively.

4. Empirical results

Table 2 lists the results obtained by testing for slope heterogeneity. The findings indicate that both the parameters $\tilde{\Delta}$ and $\tilde{\Delta}$ adjusted are significant, thus providing evidence that slope coefficients are heterogenous in the considered panel. Table 3 presents the results of the cross-sectional dependence analysis obtained by means of Breusch and Pagan LM test [5], Pesaran scaled LM test [17] and Pesaran CD test [16]. They provide evidence against the null hypothesis of no cross-sectional dependence. We utilize the 2nd-generation unit root test, which is more powerful in dealing with slope heterogeneity and panel cross-section dependence. The results show that GTI is significant at level, while the other variables become stationary at the first difference (Table 4). Hence, the stationarity of all variables allows us to examine the long-run elasticities of the variables under analysis. Further, the results of the cointegration test, listed in Table 5, led us to offer the most appropriate assessment techniques, such as quantile regression (QR), augmented mean group (AMG), fully modified ordinary least square (FMOLS), dynamic ordinary least square (DOLS) and fixed effect ordinary least square (FE-OLS).

Table 6 presents the results obtained by applying AMG, FMOLS, DOLS and FE-OLS methods to examine the long-run impact of the considered regressors on ecological footprint. For all the estimation techniques applied, the results confirm the existence of an inverted U-shape curve for the G7 countries (the relationship between economic growth and pollution is positive, while the relationship between the square term of per capita GDP and pollution is negative). Moreover, regarding the trade openness, we observe a positive significant relationship with environmental degradation. On the contrary, green technology innovation, environmental taxes and renewable energy show a negative relationship with pollution. The results obtained by applying the quantile regression method are shown in Table 7. They indicate that green technology innovation and environmental taxes reduce the level of ecological footprint for all quantiles, suggesting that any increase in these variables promotes the ecological sustainability in G7 economies. These results are in line with previous literature ([9], [11], [15]. Regarding renewable energy consumption, even if the relationship is not significant at the early stages (Q10 and Q30), it negatively affects the environmental degradation at the later stages. This implies that the increase of the use of renewable energy would mitigate the environmental deterioration in the G7 countries. These findings are also in line with the results of previous research ([1], [33]). In addition, the results show that economic growth positively influences the pollution for all quantiles. This imply that higher income in the G7 economies is an important factor of the regions' economic degeneration. Besides, the square term of per capita GDP shows a negative and significant relationship with the ecological footprint across all quantiles. This indicates an inverse U-shaped relationship

between these variables and confirms also in this case the EKC hypothesis, as suggested by other studies ([6], [26]), given that the coefficients of GDP and GDP^2 are statistically significant with positive and negative signs, respectively. Finally, trade openness shows a positive and significant effect on the ecological footprint (except for Q10), thus increasing environmental degradation in the G7 economies.

5. Conclusion

This study addresses the ecological sustainability in the G7 economies (Canada, France, Germany, Italy, Japan, United Kingdom, USA) by using a combination of second-generation empirical methodologies. Within the framework of EKC hypothesis, we examined the environmental impact of green technology innovation, environmental taxes and renewable energy consumption on the ecological footprint for the period 1994-2018. The results reveal that green innovation, environmental taxes, renewable energy consumption and urban population are the most impacting factors of ecological sustainability within the G7 countries. Moreover, both income levels and trade openness significantly harm the environmental quality.

The empirical findings provide some important policy implications for the ecological sustainability in the G7 countries. First of all, they indicate that policy makers should encourage investments in green innovation and renewable energy industries. G7 authorities must plan more carefully the implementation of fiscal incentives for green energy investment while putting more effort into ensuring favourable conditions for clean energy investors. These actions will significantly boost the actualization of crucial goals for the development of renewable energy usage and targets for a sustainable environment via a lower carbon emission for G7 economies. This will not only motivate new investments in clean energy, but it will also encourage existing investors in non-renewable energy sources, such as coal and fossil fuel sources, to gradually shift their attention toward green energy investments.

Doubly Robust DID for National Parks evaluation: "just" environmental benefits, or socioeconomics impacts as well?

Riccardo D'Alberto[a], Francesco Pagliacci[b], and Matteo Zavalloni[c]

Abstract

National Parks (NPs) and protected areas are supposed to preserve the environment and prevent the loss of biodiversity. However, having substantially incremented worldwide, they now also include many areas that are important for economic development. Also, the literature on the subject has expanded, but targeting mainly the environmental benefits. This work investigates both the environmental and socioeconomic impacts of the Italian NPs of the 90s, by applying at the municipality level a Doubly Robust Difference-In-Differences estimator combined with Propensity Score Matching. The results suggest a positive effect on the environment on both the municipalities in NPs and the neighbouring ones, both in the short (2001) and medium run (2011). There are also socioeconomic effects in terms of the increase of incoming work-commuters and the number of workers employed in the tourism sector establishments.

Keywords: difference-in-differences, protected areas, socioeconomic impacts, spillover effects

1. Introduction

Being the backbone of the conservation policy, protected areas (PAs) are supposed to preserve the environment and prevent the loss of biodiversity. To date, PAs have substantially incremented worldwide, being this incrementation supported by both scholars and institutions [28,29]. The literature on PAs has increased and expanded as well, not only by targeting the (expected) environmental benefits but, also, by looking for potential socioeconomic benefits that the establishment of, e.g., a National Park (NP) can bring to local communities. The state of the art in the subject presents several works focusing on the Global South [3,9,10,19,25], finding a win-win situation in terms of both poverty and negative environmental externalities alleviation. Concerning high-income countries, the focus was mainly on the US [5,11,30], while the European PAs were seldom considered [7,26], with a specific focus on tourism and management [18,20], or by adopting a merely qualitative approach [21].

This research aims at reducing the gap by analysing the Italian NPs of the 90s, assessing both their environmental and socioeconomic impacts. The novelty of the works is threefold. First, it applies an innovative methodology, i.e., the Doubly Robust Difference-In-Differences (DR DID). Second, it considers two different post-treatment periods (compared to the single post-treatment instant usually considered [5,9,10]). Third, the analysis (carried out at the municipality level) targets both the municipalities covered by the NPs and the "neighbouring" municipalities, i.e., those not covered by NPs, but contiguous to the covered municipalities, where potential spillover effects could have been generated.

2. Methods

When a NP is established, it is not possible to observe what would have happened in that territory if the area had not been protected. Hence, the assessment of the NP impact represents a challenge of the "observational studies" framework, where a counterfactual estimation approach is applied to mimic the experimental design. Indeed, a sample of "untreated" municipalities (not included in a NP) is selected

to form the "counterfactual group" that must be compared with the "treated" one (the municipalities in NPs). The selection is made according to the similarity between the untreated and treated municipalities in terms of the relevant characteristics that are observable [4,9,10]. These help in identifying the most similar observations to be "matched". This sub-sample of matched municipalities is then considered for the estimation of the average treatment effect on the treated (ATT) with the new DR DID estimator [24].

The similarity between treated and counterfactual municipalities is based on a set of covariates, i.e., all the relevant, observable characteristics that are 1) statistically significant in terms of treatment adoption, 2) observed *before* the treatment, or not directly associated with it, 3) predictive of the outcome(s) but not influencing the treatment status. The covariates selection must undergo the "ignorability condition" [22], or the assumption of "selection on observable" [12].

The matching procedure selected for the extraction of the sub-sample on which to estimate the ATT must guarantee the optimal balancing of the covariates and the highest level of reduction of the differences originally observed between the treated and untreated units [14,15]. The same rationale is applied to the analysis of the potential geographical spillover effects.

Let t be the time ($t = 0$ is the baseline year; $t = 1$ is the follow-up year). Let Y_{mt} be the outcome of interest for the m-th municipality at time t. Whereas the m-th municipality hosts a NP before time t (i.e., it is treated), $P_{mt} = 1$. Otherwise, $P_{mt} = 0$. Easing the notation, $P_m = P_{m1}$. Following [23], let $Y_{mt}(0)$ be the outcome of municipality m at time t if it is not part of a NP, while $Y_{mt}(1)$ indicates the outcome of the same municipality if the NP has been established. The outcome will be $Y_{mt} = P_{\mathrm{m}} Y_{mt}(1) + (1 - P_m) Y_{mt}(0)$. Let X_m be the observed set of covariates. Assume that:

A1. $\{Y_{m0}, Y_{m1}, P_m, X_m\}$, for $m = 1, \ldots, n$, observations are independent and identically distributed (i.i.d.). The parameter of interest is $\tau = E[Y_{m1}(1) - Y_{m1}(0) | P_m = 1]$. The ATT can be rewritten as $\tau = E[P_m = 1] - E[P_m = 1] = E[P_m = 1] - E[P_m = 1]$.

A2. $E[P_m = 1, X_m] = E[P_m = 0, X_m]$, meaning that the average conditional outcome of the municipalities within a NP and the municipalities out of a NP would have been the same if the NP were not established (the "parallel trend assumption").

A3. For some $\xi > 0$, $P(P_m = 1) > \xi$ and $P(P_m = 1 | X_i) \leq 1 - \xi$, meaning that there is at least a small portion of the municipalities that are included in a NP and, for every value of the covariates, there is at least a small probability for the municipality not being part of a NP (the "overlap condition").

From these assumptions it follows $E[P_m = 1] = E[P_m = 1, X_m] + E[P_m = 0, X_m] - E[P_m = 0, X_m | P_m = 1] = E[P_m = 1] + E[P_m = 0, X_m] - E[P_m = 0, X_m | P_m = 1]$. For estimating the ATT, [1] proposed to use $\tau = \frac{1}{E[P]} E[\frac{P - ps(X)}{1 - ps(X)} (Y_1 - Y_0)]$, where $ps(X) = P(P = 1 | X)$ (the propensity score). Consequently, the estimator for the ATT is $\hat{\tau}^{ps} = \frac{1}{E_n[P]} - E_n \left[\frac{P - \hat{\pi}(X)}{1 - \hat{\pi}(X)} (Y_1 - Y_0)\right]$, with $\hat{\pi}(x)$ being the estimator for the true but unknown $ps(x)$.

The DR DID estimator combines the consistency property of the ordinary DID model by [13] and the properties of the $\hat{\pi}(\bullet)$ estimator for $ps(x)$ proposed by [1]. The result is an estimator that shows robustness even if either the ordinary DID model or the model for the propensity score are misspecified. Consequently, let it be that $\Delta Y = Y_1 - Y_0$ and let it be that $\mu^{ps}_{p,\Delta}(X) = \mu^{ps}_{p,1}(X) - \mu^{ps}_{p,0}(X)$, where $\mu^{ps}_{p,t}(x)$ is the model for the true but unknown outcome regression $\gamma^{ps}_{p,t}(x) = E[Y_t | P = p, X = x]$ with $p, t = 0,1$, where the true, but unknown, $\gamma_{p,t}(x) = E[Y_t | P = p, X = x]$. The DR DID estimator for the ATT results to be $\hat{\tau}^{DRDID} = E\left[\left(w^{ps}_1(P) - w^{ps}_0(P, X, \pi)\right)\left(\Delta Y - \mu^{ps}_{0,\Delta}(X)\right)\right]$, where, for a generic function g, we have that $w^{ps}_1(P) = \frac{P}{E(P)}$ and $w^{ps}_0(P, X; g) = \frac{g(X)(1-P)}{1-g(X)} / E\left[\frac{g(X)(1-P)}{1-g(X)}\right]$.

3. Data

The NPs under consideration here are 8, depicted in Figure 1. They are classified as:

- "northern NPs", for a total number of 39 involved municipalities, including the Parco Nazionale delle Dolomiti Bellunesi (1990), the Parco Nazionale della Val Grande (1992), the Parco Nazionale delle Foreste Casentinesi, Monte Falterona e Campigna (1993);
- "central NPs", with 98 municipalities covered, including the Parco Nazionale dei Monti Sibillini (1993), the Parco Nazionale del Gran Sasso e Monti della Laga (1995), the Parco Nazionale della Maiella (1995);

- "southern NPs", with 68 municipalities covered, including the Parco Nazionale del Pollino (1993) and the Parco Nazionale del Vesuvio (1995).

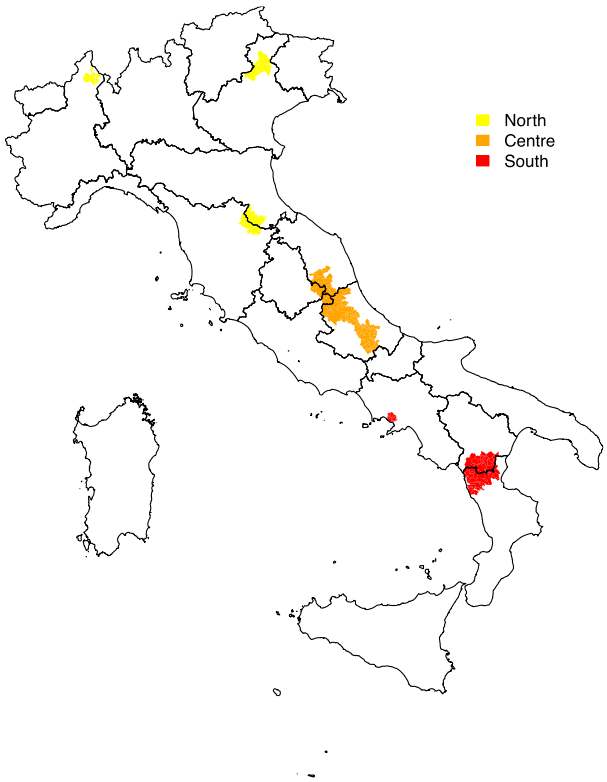

Figure 1: National Parks considered.

The 8 NPs (out of 25 Italian NPs [16]) were all established in the 1990s and include 205 municipalities, for a total surface of 11,148.22 km^2 (3.69% of the country area) and 947,703 inhabitants (1.67% of the Italian population). We use data on the geographical characteristics of the municipalities, the 1991, 2001, and 2011 *Census of Population and Housing*, and *Census of Industry, Services and Non-profit Institutions*, the 1990, 2000, and 2010 *Census of Agriculture* [17], the CORINE Land Cover source [6], while other data have been elaborated by the authors based on Istat data.

Two sets of variables are used: 1) the matching variables (covariates), for pairing the "treated" and the "untreated" municipalities; 2) the outcome variables on which the NPs impact is estimated.

7,423 municipalities not included in any of the NPs represent the potential counterfactual units, selected by matching the 205 municipalities in the NPs of interest by means of the altitude above sea level (in meters), the distance from the coast (in km), the area of the municipality (in km^2), the number of local establishment (firms or section of firms that operate within the municipality area) at year 1981, the number of workers employed in local establishments at year 1981, the population density (inhabitants/km^2) at year 1981, the percentage of urbanized land at year 1990.

The impact of the NPs is assessed from the baseline year 1991 to the follow-up years 2001 and 2011, on the following outcome variables: population density, number of local establishments, number of workers employed in these local establishments, number of local establishments in the tourism sector, number of workers employed by local establishments in the tourism sector, incoming, outgoing, and within-municipalities work-commuters, percentage of forested land.

4. Results

For the sake of brevity, we do not depict the balancing results of the best matching approach that is selected (among the 13 approaches tested) for the ATT estimation, i.e., the one producing the highest level of balance between the observable characteristics of the treated and the untreated municipalities: the Bayesian additive regression tree propensity score matching. It performs well in terms of the Standardized Mean Difference (SMD), the variance ratio, the mean and maximum of the empirical cumulative density function (eCDF). Following [2,8,27], the optimality of balance is assessed by considering that

SMD values < 0.1 indicate "perfect balance", values between 0.1 and 0.2 indicate "good balance", while SMD > 0.2 hints at concerns about covariates imbalance. For the northern NPs, 6 out of 8 matching variables are perfectly balanced, while the others present a good level of balance. About the central NPs, 5 matching variables are perfectly balanced, while 3 are well balanced. Finally, considering the southern NPs, 6 matching variables present perfect balance, 1 present good balance, while the distance from the coast has a SMD value slightly higher than 0.2. Considering the neighboring municipalities and the analysis of the spillover effects, the matching strategy performs well for the northern group, perfectly balancing 6 out of 8 matching variables, while the others present a good level of balance. About the central NPs, 6 matching variables are perfectly balanced, 1 is well balanced, while 1 (altitude above sea level) is unbalanced. Regarding the southern NPs, 4 matching variables present perfect balance, while 4 are well balanced.

4.1 Municipalities in NPs

Table 1 depicts the ATT estimation on the municipalities in NPs.

Table 1: Estimation of the Average Treatment Effect on the Treated (ATT)

5. Discussion

The evidence from the data at hand suggests that there is a positive impact on the percentage of forested land in the municipalities in a NP, existing specific time dynamics in the effects. In the medium run, the impact is larger than in the short run. The results are more nuanced considering the socioeconomic impacts. It is observed a positive effect on the number of workers employed in the tourism sector establishments in central NPs in the medium run, while there is an increase in the number of incoming work-commuters in the northern NPs both in the short and medium run, and in central NPs limited to the short run. The scrutiny of the role of geographical spillovers highlights socioeconomic leakages to the surrounding municipalities, e.g., in terms of the positive impact on the number of workers employed in local establishments in neighbouring municipalities of the northern NPs (both in the short and medium run), as well as in the number of incoming work-commuters (in the short run) in the neighbouring municipalities of the northern NPs. The spillover effects are supposed to be stronger in environmental terms, with central and southern NPs affected by an increase in the percentage of forested land. Further analyses could be devoted to the investigation of such spillovers by adopting a robust spatial model. The main policy implication is that the data at hand support the idea that NPs benefit not only the environment, but they can support the socioeconomic development of local communities as well. This does not apply limitedly to Global South countries but to high-income countries as well.

Abstract

The Carbon Footprint (CFP) is one of the most common indicators to quantify environmental pollution and it is based on household consumption. In this paper, we estimate the per capita CFP of the Italian regions and we compare CFP with the CO_2 absorbed by forest per inhabitant. The idea that is enough to plant more and more trees to obtain carbon neutrality, i.e. emitted CO_2 equal to the intake one, is debunked.

Keywords: Carbon footprint, climate change, $CO2_{eq}$, forest inventory, HBS

1. Introduction

Nowadays the problem of climate change is quite evident. Since 1972 (10) researchers have tried to find possible solutions to the challenge of carbon emission reduction. Two of the most recent international meeting on this topic are the 2015 conference about Sustainable Development Goals (14) and the 2021 United Nations Climate Change Conference (12). In particular, the impact of human activities on greenhouse gas emissions is usually studied and measured by the Carbon Footprint (now on CFP). For a complete review of the literature of the CFP measure see (6). An important aim in the field of CFP measure is to obtain carbon neutrality within 2100, but how can it be done? This work aims to contributes to this debate debunking the very widespread idea that to plant trees is enough to reduce the CO_2. To achieve this result we estimate the CFP from the household expenditure and we compare it with the absorbed CO_2 by the forest.

In order to obtain the CFP estimation matrices relationship based on Input-Output Tables (IoT) and consumption data are usually adopted. Two of the most known approaches are presented in (13) and (7). (13) starting from Swiss data, define the CFP as a sum of three components and use national IoTs. (7) substitute the IoTs with the EXIOBASE dataset that has the same structure of the IoTs, but it is appositely created to estimate the CFP by (15) and it is suitable for more than 41 countries. Both approaches, in our view, could be improved. Indeed, the EXIOBASE dataset has been developed in 2014 and not updated data could bring to unreliable estimates. On the other hand, the method developed by (13) need to have all the involved datasets expressed with the same classification. This request cannot be satisfied by data produced under the guidelines of EUROSTAT that use different classifications for firm production and household consumption. In order to solve this problem, we define a strategy that uses a matrix bridging the two classifications. Using the estimated CFP and the intake carbon dioxide by forests, we verify the idea that to plant several trees could have a central role in the achievement of carbon neutrality. The difference between the two dimensions, that is the gap between per capita emitted and absorbed carbon dioxide, is huge and, mostly, heterogeneous among regions. This suggests that forests will not be able to completely absorb carbon dioxide and that regional estimates (7) can help to design equitable carbon place-based policies leading to engage local actors (9).

2. Data

The estimation of the household CFP based on household consumption data requires information coming from the following datasets:

- Household Budget Survey (HBS) data, reporting household expenditure and published by the Italian Statistical Institute (ISTAT). In this survey data are classified following the Classification of Individual Consumption by Purpose (COICOP).
- National Accounting Matrix, including Environmental Accounts (NAMEA) and reporting the emission intensities. NAMEA is an air emissions report calculated starting from the national emission inventory annually produced by Istituto Superiore per la Ricerca e la Protezione Ambientale (Ispra). In this dataset, air pollutants are reported in CO_2 equivalent. The aggregation level used is NACE Rev. 2 for the economic activities and the Classification of Products by Activity (CPA) for products.
- Input-Output table (IoT), published by ISTAT, reporting matrix of supply and use for each economic sector. The classification used for economic activities and for products is the same as of NAMEA.

3. The carbon footprint estimation

Here we present the strategy to obtain the measure of CFP. Let i ($i = 1, \ldots, n$) indicate the sampled units in the region j ($j = 1, \ldots, J$), m the number of COICOP in the HBS and ν the number of CPA. Following (13), the CFP_{ij} is defined as:

$$CFP_{ij} = IND_{ij} + DIR_{ij} + EEI_{ij} \tag{1}$$

where IND, DIR and EEI indicates respectively indirect emissions, direct emissions and embodied emissions in import. Indirect emission are the emissions induced by final consumption of domestic, imported goods and services. The measure of IND_{ij} is based on a matrix relationship that involves HBS and IoT. Unfortunately these two informative sets are not directly comparable due to the different classification. This problem is present in each country (also Italy) that follows the European Classification. In order to achieve comparability, we use the conversion matrix (**cf**) obtained by (3) and (4) for each European country, and available in the supplementary material of (4). This matrix, obtained through the count-seed RAS approach, allows us to bridge data on consumption categories (COICOP in HBS) and on final use categories (CPA in IoTs) and then to re-define formulas proposed in (13). At the best of our knowledge, this strategy has never been used to derive IND_{ij} in the estimation of CFP. The new formulation is:

$$IND_{ij} = \underbrace{\begin{bmatrix} e_1 \\ \vdots \\ e_\nu \end{bmatrix}^T}_{\text{e}} \times \underbrace{\left[\underbrace{\begin{bmatrix} 1 \dots 0 \\ \vdots \ddots \vdots \\ 0 \dots 1 \end{bmatrix}}_{I_\nu} - \underbrace{\begin{bmatrix} z_{1,1} \dots z_{1,\nu} \\ \vdots \ddots \vdots \\ z_{\nu,1} \dots z_{\nu,\nu} \end{bmatrix} \times \begin{bmatrix} \frac{1}{v_1} \dots 0 \\ \vdots \ddots \vdots \\ 0 \dots \frac{1}{v_\nu} \end{bmatrix}}_{\text{coefficient matrix (z×v)}} \right]^{-1}}_{(I-A)^{-1}}$$

$$\times \underbrace{\left[\underbrace{\left[\underbrace{\begin{bmatrix} cf_{1,1} \dots cf_{1,m} \\ \vdots \ddots \vdots \\ cf_{\nu,1} \dots cf_{\nu,m} \end{bmatrix}}_{\text{conversion factor (cf)}} \times \underbrace{\begin{bmatrix} c_{1i} \\ \vdots \\ c_{mi} \end{bmatrix}}_{\text{consumption (c)}} \right]^T}_{\substack{\text{converted} \\ \text{household} \\ \text{consumption}}} \times \underbrace{\begin{bmatrix} y_{1,1} \dots y_{1,\nu} \\ \vdots \ddots \vdots \\ y_{\nu,1} \dots y_{\nu,\nu} \end{bmatrix}}_{\text{final use (y)}} \right]^T}_{\text{Y}} \tag{2}$$

where **e** is the vector of emission intensities derived from the NAMEA air emission inventory, (**I**-**A**)$^{-1}$ denotes the Leontief's inverse matrix, and **Y** is the final demand matrix based on a vector of household expenditure across final use categories. (**I**-**A**)$^{-1}$ involves the product of matrix **z**, which represents the transaction between activities, and matrix **v**, which has on the principal diagonal the inverse of the total output. The final demand matrix **Y** involves the conversion matrix **cf**, the household expenditure and the final use matrix **y** . The other two components, DIR and EEI, of eq. 1 don't need to be re-defined and we use the formulation of (13). Direct emissions, which are associated with household consumption of fuels for transportation and housing, are measured as follows:

$$DIR_{ij} = \frac{cc_{ij}}{\sum_{i=1}^{n} cc_{i|j}} \times DHE \frac{n_j}{N_j} \tag{3}$$

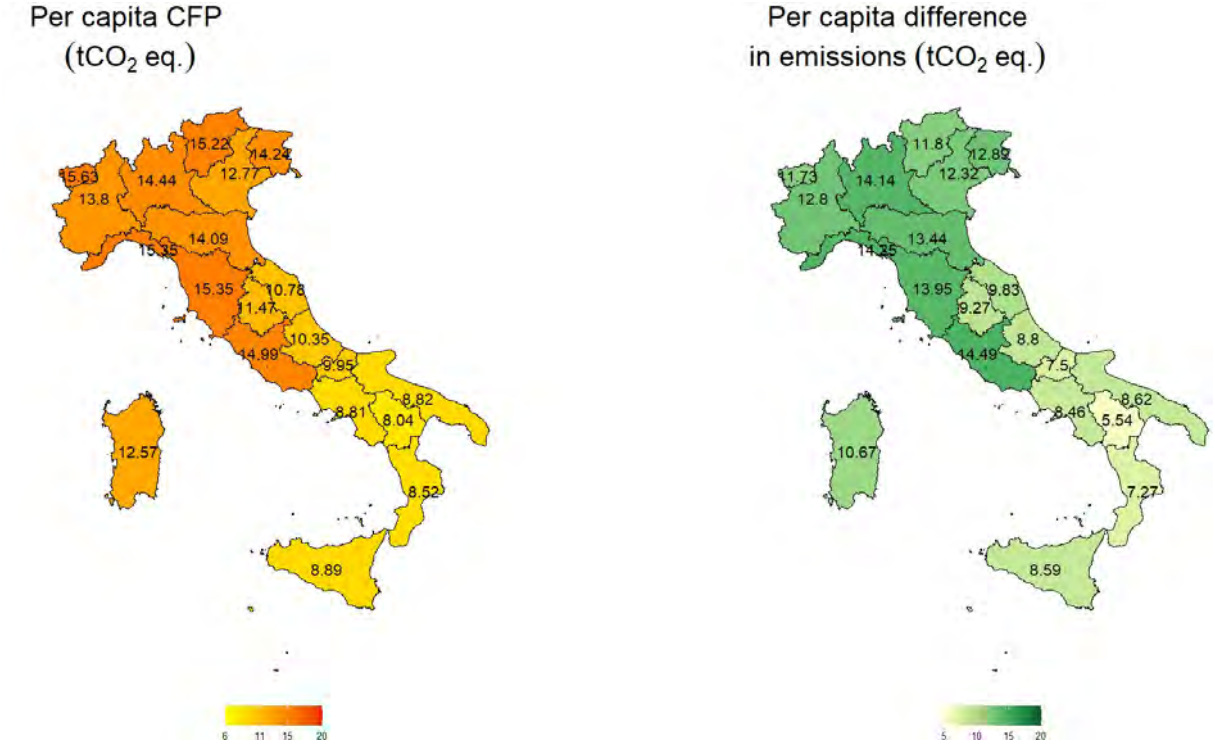
where cc_{ij} is the expenditure on combustible of the family i in region j, $\sum_{i=1}^{n} cc_{ij}$ is the total expenditure on combustibles for all the families living in the same region and DHE is the total volume of direct household emissions from the NAMEA emissions inventory, scaled accordingly to the number of households surveyed in the HBS.

The embodied emissions in import of the household *i* in the region *j* are defined as:

$$EEI_{ij} = \underbrace{\begin{bmatrix} e_1^{EU} \\ \vdots \\ e_\nu^{EU} \end{bmatrix}^T}_{e^{UE}} \times \underbrace{\left[\begin{bmatrix} Im_1 \dots 0 \\ \vdots \ddots \vdots \\ 0 \dots Im_\nu \end{bmatrix} \times \begin{bmatrix} \frac{1}{x_1} \dots 0 \\ \vdots \ddots \vdots \\ 0 \dots \frac{1}{x_\nu} \end{bmatrix} \right]}_{\text{import coefficient (Im×x)}} \times \underbrace{[I - A_s]^{-1}}_{\substack{\text{Leontief's inverse} \\ \text{of supply}}} \times Y \tag{4}$$

where $\mathbf{e}^{UE}$ is the vector of emission intensities derived from the NAMEA air emission inventory of EU countries, (**I**-$\mathbf{A}_s$)$^{-1}$ denotes the Leontief's inverse matrix this time respect the supply IoT matrices instead of total output, and **Y** is the final demand matrix based on a vector of household expenditure across final use as before. The import coefficient matrix is obtained by multiplying imports (**Im**) and matrix (**x**). This last matrix has on the principal diagonal the inverse of the total supply. To conclude, all tables are re-scaled in order to obtain results in tonnes of equivalent CO_2 (tCO_2eq.).

Figure 1: Choropleth maps of average CFP and difference between emitted and absorbed CO_2



4. Results

In this section, we will briefly summarize the main results. First of all, as proof of the goodness of the proposed strategy to measure IND_{ij}, it is important to note that the results obtained and those of (7) for 2016, with a completely different approach, present a clearly comparable path. Results on this comparison are available on requests. As expected, per-capita CFP (Fig. 1) is higher in Northern and Central Italy than it is in the South. The region with the highest per-capita CFP is Aosta Valley (15.63 tCO_2 eq.), while Basilicata shows the lowest level (8.04 tCO_2 eq.). With data published from the last Italian national forest inventory is possible to estimate how much CO_2 is intake regionally every year. To do this we use the forest area per inhabitant (per capita km^2) estimated by the inventory and the results published by (5) which asserts that the amount of CO_2 taken up by forests is around 500 tonnes per square kilometre per year. Subtracting the amount of caught-up CO_2 to the produced one (CFP) we obtain the gap between emitted and absorbed carbon dioxide. Basilicata remain the region with the lowest values while Lazio becomes the one with the highest. As expected, Aosta Valley reduces to only 11.73 tCO_2 eq. the per capita difference in emission. Other two notable regions are Umbria and Apulia. The first one, known to be the green lung of Italy, thanks to trees markedly reduce the per capita emission going from 11.47 to 9.27 tCO_2 eq.. Apulia, on the other hand, is the region with the least decrease in CO_2 emissions (-0.2 tCO_2 eq.). Is evident that forests are unable to absorb the carbon dioxide produced by consumption. In reality, they will never be, as to be able to do so they should have an extension equal to about double that of Italy. These results, although extreme, are in line with those obtained by (2) for UK.

5. Concluding remarks

We present a new method to compute the per capita CFP from consumption expenditure data and we compare them with the quantity of CO_2 absorbed by the Italian forests. Estimates, obtained at regional level, clearly show that trees are not sufficient to reduce the quantity of CO_2 and mostly that they cannot be, in the future, the only solution for the ambitious and primary goal of 0 emissions in

2100. Obviously, the contribution of trees in reducing CO_2 emissions is beyond question, but, as noted by (8), forest carbon sequestration should only be viewed as a component of a mitigation strategy and not as the solution. Then, the question we all need to answer is: which can be the way to achieve the objectives set with the Sustainable Development Goals? Answer to this question is not easy. Regions are different in terms of territorial conformation and of presence of both pollutants and forests. We obtain results showing the heterogeneity among regions of the difference between carbon dioxide absorbed and produced. This highlight the necessity of place-based policies that encourage regions to adopt peculiar tools suitable at the local level. The definition of a regional policy would not mean creating differences but rather aiming at the different strengths that each region has in order to remove their critical points in the path of CFP reduction.

Small scale analysis of energy vulnerability in the municipality of Palermo

Giuliana La Mantia[a]

[a]First Address of Institute; giuliana.lamantia@unipa.it

Abstract

The current increase in energy prices has raised concerns about the repercussions on households, particularly the most vulnerable ones. This paper aims to provide a preliminary analysis of energy poverty in the municipality of Palermo. Based on the evidence from the most recent literature, we select a set of vulnerability indicators, also taking into account data availability. We then perform a principal component analysis to reduce the dataset into a few components and map them to the urban context under study. The analysis identifies two distinct vulnerability profiles concentrated in the historic centre and the Filippo-Neri, Roccella and Brancaccio-Ciaculli neighbourhoods.

Keywords: energy vulnerability, energy justice, principal component analysis

1. Introduction

Domestic energy deprivation or Energy Poverty (EP) concerns the accessibility and affordability of energy goods and services. A household is energy poor if is unable to access adequate levels of energy services to ensure the satisfaction of its essential needs (3). Over the past decade, the literature on EP has grown significantly, with different methodologies for measuring and monitoring it emerging. A strand of literature has focused on the spatial distribution of EP and its interaction with structural deprivation and inequality at various geographic scales (4). While national assessments have helped frame the scale of the issue and enable cross-country comparisons, small-scale studies have revealed significant disparities between groups and locations that country-level analysis cannot capture (8). This report aims to contribute to the literature on local EP analysis by conducting a preliminary study of the municipality of Palermo.

2. The new theoretical framework of Energy Poverty

The notion of Energy Poverty was first studied in the UK where it was recognized as an issue of energy affordability, mainly in terms of heating costs. The leading causes of energy poverty were identified as a combination of the triad: low income, high energy prices, and inefficient housing (1; 6). The literature has expanded over the past decade and has embedded energy poverty in new theoretical frameworks that consider the particularities of specific groups and contexts and their interaction with other structural inequalities (2; 9; 12).

The Energy Vulnerability framework attempts to provide a more comprehensive and nuanced analysis of energy poverty, highlighting different dimensions of the concept and identifying spatial patterns. Vulnerable groups include the elderly, disabled, and families with young children which spend more time

at home, and their particular needs require more energy consumption to achieve comfortable temperatures (7). Households in the private rental sector also face significant challenges, including high housing and energy costs, and difficulty negotiating efficiency improvements with landlords. On the other hand, students, precarious workers, residents of informal settlements and ethnic minorities are more likely to be unable to afford adequate energy services (2; 9). Generally speaking, researchers identified six risk factors that increase the risk of fuel poverty among households: access to energy services, affordability, level of energy efficiency, special needs of households and lack of public recognition of the issue (3). These factors interact with each other and interplay with other structural inequalities, such as job insecurity and housing market conditions. Energy poverty can be also viewed as the result of broader dynamics of injustice, as it involves unequal access to energy services, which are necessary for the satisfaction of basic needs (13).
The evidence shows that the driving forces of energy poverty are locally contingent and that there are clear geographical patterns of energy poverty at different scales (4; 12). Bouzarovski and Thomson (5) investigated the links between sociodemographic and housing vulnerabilities to energy poverty, and wider patterns of urban social inequality. The authors analyze how forms of energy injustice can arise from inequalities in the distribution of urban amenities combined with socioeconomic disparities to create distinctive geographies of segregation. Building on this literature, the report examines the factors that increase the risk of energy vulnerability of households in the city of Palermo, in order to contribute to the understanding of spatial patterns of energy poverty in the urban context.

2.1 Data and aims

Studies with higher spatial resolution can provide more specific information on energy poverty, leading to better identification of energy vulnerability for different contexts and groups.
Nevertheless, small-scale analyses must consider the limited availability of data at such a granular level. At the Italian level, population and housing census data is the most spatially detailed source of information. The National Institute of Statistics (ISTAT) publishes the spatial basis system associated with the data collected with the 2011 Census, which provides aggregated information on the socio-demographic characteristics of the population and on the status of dwellings.

This analysis focuses on the municipality of Palermo, specifically our observation units are 43 census areas, identified by ISTAT. The areas are census sections aggregated with respect to demographic and social characteristics. Two sets of census variables were selected based on vulnerability factors identified in the literature and data availability. The first group includes demographic and socioeconomic characteristics of the population, such as the percentage of elderly people and children, the number of foreigners per thousand Italian residents, and the percentage of families experiencing economic deprivation (where no member receives income from work or pension). It also includes information on the type of tenure (owned, rented, or other) of the families' homes. The second group includes information about the residential buildings themselves, such as their state of preservation, construction period, and size (number of floors).
We point out two significant constraints in the analysis. Firstly, the data was gathered approximately ten years ago during the last census. Secondly, expenditure and energy consumption data are unavailable, and thus *proxies* such as employment and specialization levels and building conditions are utilized.
In the next stage of the analysis, we will examine the municipal area to see if a pattern of vulnerability to energy poverty can be identified. The aim of the analysis is twofold: first, we want to reduce the multivariate dimension of our dataset into a few components. Then we map the result of the analysis in order to investigate if exists a spatial pattern of vulnerability to energy poverty and how interplays with structural urban inequality. In the next section, we provide some descriptive analysis and then move on to the principal component analysis.

Table 1: Descriptive statistics.*Source*: Census data, 2011.

Sociodemographic variables	Italy	Sicily	Palermo
People above 75 years	10.4	9.4	8.9
Children under six years	5.6	5.7	5.9
Unemploymente rate	**11.4**	**21.8**	**24.4**
Low-skilled employment	16.2	20.7	18.9
Young people outside the labour market and training	**12.3**	**19.4**	**21.2**
Foreigners	67.8	25	21.6
Large household	1.6	1.8	2.2
Economic deprivation	**2.7**	**5.9**	**7.2**
Homeowner	70.5	69.8	60.9
Renters	21.2	16.6	29
Other occupation title	10	14.9	11
State of preservation			
Buildings in good state of preservation	83.3	72.9	72.3
Buildings in a mediocre state of preservation	**15**	**23.8**	**24.5**
Buildings in a poor state of preservation	**1.7**	**3.3**	**3.2** [a]
Construction period			
Buildings built before 1946	**23.5**	**19.5**	**29.6**
Buildings built between 1946 and 1960	17.8	14.5	20
Buildings built between 1961 and 1980	35.1	38.9	35.5
Buildings after 1981	23.6	27.2	14.9
Floors number			
Buildings with one floor	14.2	26	13.8
Buildings with two floors	37.9	34.5	28.1
Buildings with three floors	21.4	19.6	18.2
Buildings with four or more floors	26.5	19.8	39.9
Census size			
Total residents	59.433.744	5.002.904	657.561
Total households	24.611.766	1.963.577	246.227
Total number of dwelling*	24.135.177	1.940.472	244.053
Total number of residential buildings	12.187.698	1.431.419	46.293

* Refers to dwellings occupied by residents

3. Descriptive analysis

Data from the 2011 Census (Table 1) indicates that the municipality of Palermo has higher rates of social and material deprivation compared to both national and regional averages. Specifically, the unemployment rate in Palermo (24.4%) is more than twice the national average of 11.4%. Additionally, 21.2% of the city's young population is neither employed nor pursuing further formation, a figure that exceeds the national average by 9 percentage point. The percentage of residential buildings in Palermo built before 1946 (30%) is 42% higher than the national average of 21.4% and almost double that of Sicily (16%). Moreover, the share of buildings in a poor state of preservation is 3.2%, a value that is in line with the regional average of 3.3% but double the national average of 1.7%.
To sum up, the data show that the municipality of Palermo is characterised by a higher proportion of old residential buildings in a poor state of preservation than the national average, and the vulnerability indicators have a higher value than both the national and regional level.

4. Principal Component analysis

Principal component analysis (PCA) allows us to reduce a multivariate data set into a few principal components. Starting from a set of correlated variables, the analysis generates new variables, linear combinations of the original ones. The new components are uncorrelated, so each component reflects distinct statistical dimensions in the data. The contribution of each variable to the formation of the components, known as the *loadings*, is quantified by the correlation between the principal component and the variable. The loading values can be either positive or negative, signifying the direction and strength of the relationship between the variables and the component. We conduct a PCA after standardising our set of variables to have zero means and unit variances, which ensures that the analysis is not affected by variable scales and that all variables are equally important. The first two components explain the 60% of the total variance. Fig. 1 shows the loading values between each variable and the first two components. The positive and negative values of the variables allow us to identify different profiles and the maps (Fig. 2 and Fig. 3) show us the new coordinates for the observations.

The first principal component explains 39% of the total variance and is positively correlated with various vulnerability indicators, including low education, unemployment, and economic deprivation. It is also associated with sociodemographic characteristics related to energy poverty risks, such as large families, young children, and renters, as well as modestly sized and poorly maintained residential buildings. Conversely, the component is negatively associated with owner-occupied homes, elderly people, and well-preserved, medium to large-sized buildings.
Fig. 2 shows the observation score, the higher the score, the greater the variance explained by the first component in those areas. The first component's positive contributions effectively account for the variance in Filippo-Neri, Centro Storico, Roccella, and Brancaccio-Ciaculli neighbourhoods, whereas its negative contributions accurately reflect Resuttana, Villa Sperlinga, and Malaspina-Palagonia.
The second component accounts for 22% of the total variance. It is negatively associated with foreigners, low-skilled workers, elderly persons and households living in rented or other property titles. This component is also negatively related to medium-sized and old residential buildings in poor condition and is mainly found in the historic centre and surrounding areas. On the other hand, the second component is positively correlated with small and newly built residential buildings in good condition (Fig. 3).

The analysis indicates the presence of two profiles of vulnerability, based on indicators positively associated with the first component and those negatively correlated with the second component. The first component is strongly linked to social and economic hardships, indicating low income and limited ability to invest in energy-saving measures. The presence of large families and children is also associated with this component, as families with children spend more time at home and have a higher energy consumption.
The first component well represents the variation of the Filippo Neri neighbourhood, a peripheral area of the city that has been the subject of several studies for its urban development that have made it one of the most segregated areas of the city (10). The historic centre is characterized by the second vulnerability

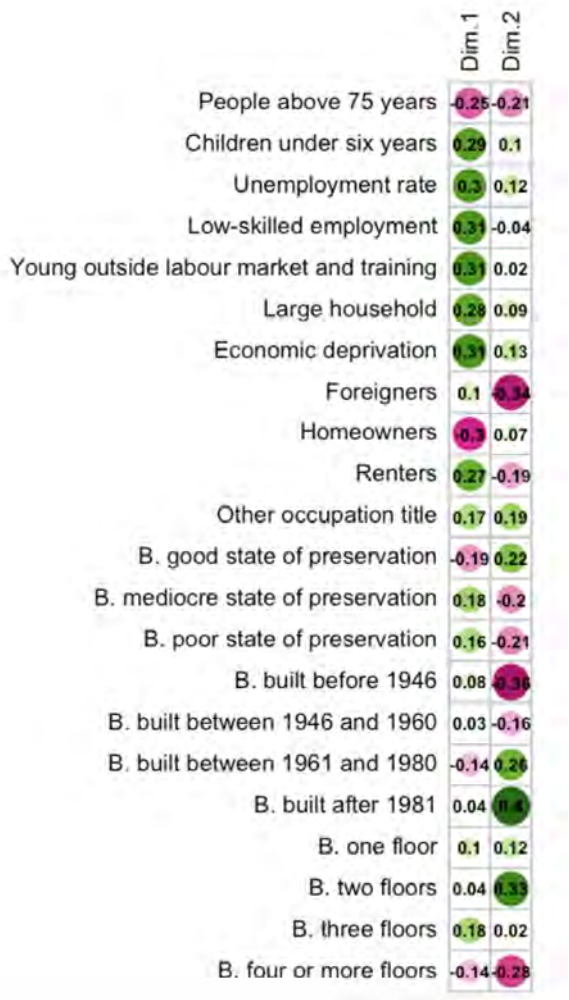

Figure 1: Loading values of the first two components.

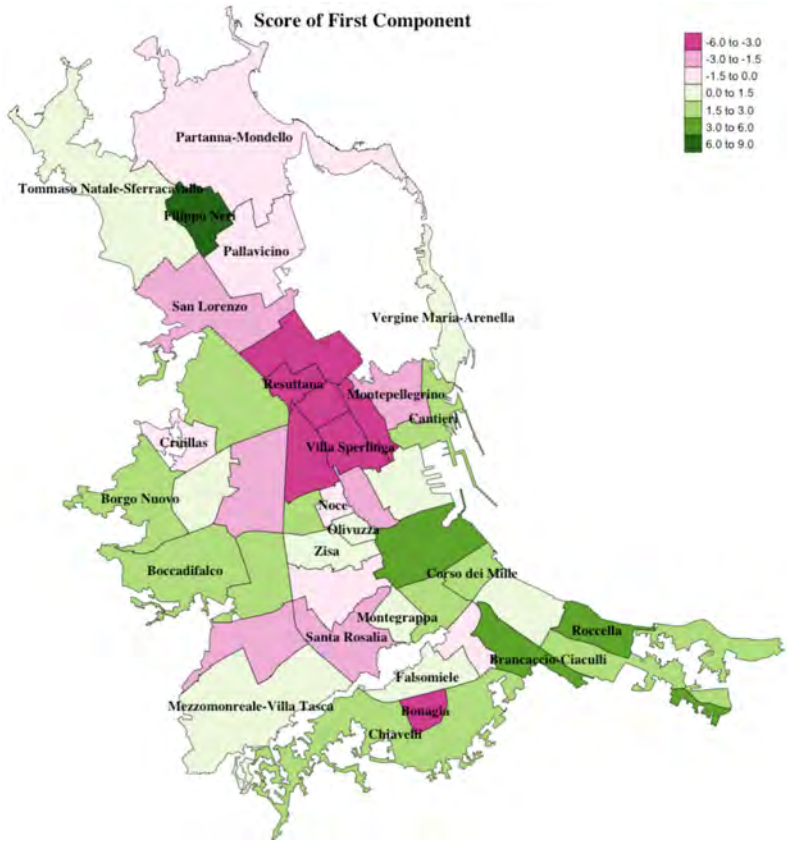

Figure 2: Score of the First Component.

profile identified, in which other types of vulnerability coexist such as the presence of foreigners and the elderly and old and badly preserved real estate. This area in recent years has been interested in several urban redevelopment projects that have changed the urban and social configuration, necessitating a more in-depth and up-to-date analysis (11).

5. Conclusion

In conclusion, this report contributes to the local PE analysis literature by conducting a preliminary study of the municipality of Palermo. The analysis revealed two profiles of vulnerability and shows their spatial distribution in the urban context. There are important limitations to this analysis. The available data comes from the 2011 Census, so we are aware that they need an update. The analysis uses only data aggregated by geographical area, therefore it is of the area-target type. Essential information such as spending and energy consumption data is not available, but proxies such as education level, building state and construction period are used. The plan for further analysis is to combine different data sources to get more accurate information.

Abstract

In epidemiological database studies, the true value of the outcome of interest is unknown, and it is measured with error through indicators implemented by appropriate algorithms. Differential misclassification of sensitivity of the study outcome across exposure groups may severely bias measures of association, in both directions. In this work, we introduce a bootstrap test for differential sensitivity and we conduct a simulation study to explore the properties of the method under multiple scenarios.

Keywords: bootstrap test, measurement error, validity indices

1. Background

In epidemiology, when the outcome is measured with error, it is common practice to choose a very specific indicator (no false positives) and to rely on the assumption that sensitivity (SE) is non-differential across exposure strata. Unfortunately, estimating the sensitivity across exposure strata is usually impossible, and the assumption of non-differentiality is not tested (4). In safety studies, when an outcome is a suspected adverse effect of exposure, it is realistic to expect that exposed subjects may have their diagnoses recorded with diagnostic codes having higher precision. Differential sensitivity of the study outcome across exposure groups may severely bias measures of association in both directions.

2. Non-differentiality test

Several different indicators can potentially point to one single event (3). We exploited the interrelationships between validation indices of multiple indicators (1) of the same event to build a test for non-differentiality. The formulas are based on the observed prevalence of all indicators and their intersections, and on the values of their PPV. More details are included in Appendix. Brenner and Gefeller (2) showed that it is possible to adjust the risk ratio observed by an indicator A as long as its PPV is available across exposure strata and the sensitivity is non-differential, namely equal across exposure strata. Therefore, to implement the adjustment, it is essential to test the hypothesis $H_0 : SE_A^e = SE_A^{\bar{e}}$, which can be written as

$$H_0 : \frac{SE_A^e}{SE_A^{\bar{e}}} - 1 = 0 \tag{1}$$

To carry out the test, we exploit an auxiliary indicator B. Under the assumption of non-differentiality of the sensitvity of the union $SE_{A\cup B}$, the hypothesis (1) is equivalent to:

$$H_0 : \frac{P_A^e PPV_A^e (P_A^{\bar{e}} PPV_A^{\bar{e}} + P_B^{\bar{e}} PPV_B^{\bar{e}} - P_{A\cap B}^{\bar{e}} PPV_{A\cap B}^{\bar{e}})}{P_A^{\bar{e}} PPV_A^{\bar{e}} (P_A^e PPV_A^e + P_B^e PPV_B^e - P_{A\cap B}^e PPV_{A\cap B}^e)} - 1 = 0 \tag{2}$$

The test statistic is calculated by replacing the values of PPV in equation (2) with their estimates obtained from validation studies. The validation sample can be extracted by a stratified sampling across exposure groups and within each exposure group stratified by indicator (in our simulation study: 50% of the sample from $A = 1$ and 50% from $B = 1$, for the exposed group, and the same for the non-exposed group). The statistical test is carried out with the bootstrap method.

3. Simulation study

To evaluate the performance of the proposed non-differentiality test, we developed a simulation study. We generated one binary vector representing the true outcome of interest Y and one representing the exposure group E. Different scenarios were explored, letting $\pi^{\bar{e}}$ ($Y^{\bar{e}}/N^{\bar{e}}$) vary between 1%, 5% and 10% and varying the relative risk, RR, between 1.2 and 2. The proportion of exposed was fixed at 5% in every simulation. Then, two different indicators of Y, A and B, were generated, misclassified with specific error rates for each exposure group. $SE_{A\cup B}$ was fixed to 0.8 in both exposure groups, in order to comply with the assumption of non-differentiality of $SE_{A\cup B}$. In each scenario, we defined the value of SE_A and of the specificities, SP, while the other validity indices were derived. The sensitivity of A in the unexposed group was set at 0.50, while the sensitivity in the exposed group varied between 0.3 and 0.7. Thus, the sensitivity ratio ranged from 0.6 to 1.4. Only a non-intersection scenario was studied, in which no subject tested positive for both indicators. $SE_{A\cap B}$ was set to 0 and $SP_{A\cap B}$ was set to 1. So, the formula (2) become:

$$H_0 : \frac{P_A^e PPV_A^e (P_A^{\bar{e}} PPV_A^{\bar{e}} + P_B^{\bar{e}} PPV_B^{\bar{e}})}{P_A^{\bar{e}} PPV_A^{\bar{e}} (P_A^e PPV_A^e + P_B^e PPV_B^e)} - 1 = 0 \tag{3}$$

Similar scenarios are plausible, as shown in a case study concerning angioedema disease (5). The specificity was set at $1 - \frac{\pi^{\bar{e}}}{10}$ for A and $1 - \pi^{\bar{e}}$ for B in both exposure groups, and we assumed that $P(A = 1|Y = 0, E = e)$ is independent from $P(B = 1|Y = 0, E = e)$, so $1 - SP_{A\cap B} = 1 - SP_A \times 1 - SP_B$. Once the data had been generated, the validation and the test were performed 1000 times for each scenario using three different sample sizes (200, 400 and 600, of which 50% from A and 50% from B) and the proportion of times the test leads to rejecting the null hypothesis, P_{rej}, was calculated.

3.1 Results

The PPVs of indicators ranged between 78% to 95%, for A, and between 11% to 33% for B, depending on the scenario. When the sample size was equal to 200 or 400, the power of the test was greater than 80% only in the extreme values of the sensitivity ratio (0.6 and 1.4), irrespective of risk ratio and true prevalence. For a sample size of 600, the power of the test was greater than 80% and for the sensitivity ratio equal to 0.8 and 1.2, but only if the risk ratio was equal to 2 or the prevalence was greater than 0.01. Figure 1 shows how the proportion of times in which the null hypothesis is rejected (P_{rej}) varies according to the true sensitivity ratio, for the scenario in which $RR = 2$, and $\pi^{\bar{e}} = 0.05$.

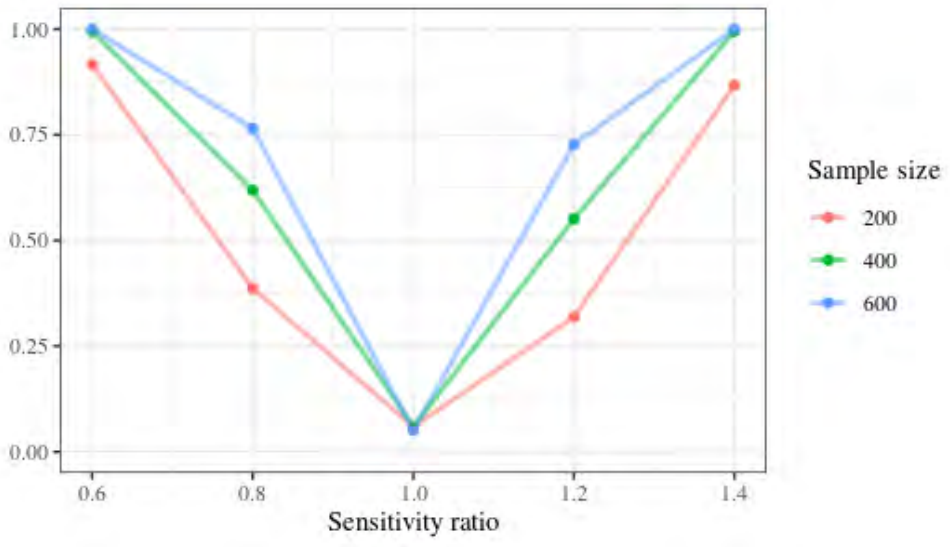

Figure 1: Proportion of times in which the null hypothesis is rejected, P_{rej}. In scenarios where the sensitivity ratio is different from 1, P_{rej} corresponds to the power of the test.

Acknowledgments This work has received support from the EU/EFPIA Innovative Medicines Initiative Joint Undertaking ConcePTION grant n. 821520.

Appendix

Prevalence can be defined as $\pi = \frac{TP+FN}{N}$, where N represents the numerosity of the study population. It can therefore be rewritten as a function of observed prevalence ($P = \frac{TP+FP}{N}$), positive predictive value (PPV), and sensitivity (SE):

$$\begin{aligned} \pi &= \frac{TP+FN}{N} \\ &= \frac{TP+FN}{N} \times \frac{TP+FP}{TP} \times \frac{TP}{TP+FP} \\ &= \frac{TP+FP}{N} \times \frac{TP+FN}{TP} \times \frac{TP}{TP+FP} \\ &= P \times \frac{1}{SE} \times PPV \end{aligned} \tag{4}$$

therefore:

$$SE = \frac{P \times PPV}{\pi} \tag{5}$$

$$\pi = \frac{P \times PPV}{SE} \tag{6}$$

In order to perform the non-differentiality test, the null hypothesis $H_0 : SE_A^E = SE_A^{\bar{E}}$ can be rewritten as:

$$\frac{SE_A^E}{SE_A^{\bar{E}}} - 1 = 0 \tag{7}$$

and using equation (5):

$$SE_A = \frac{P_A \times PPV_A}{\pi} \tag{8}$$

then, using equation (6):

$$SE_A = \frac{P_A \times PPV_A}{\frac{P_A \times PPV_A}{SE_{AUB}} + \frac{P_B \times PPV_B}{SE_{AUB}} - \frac{P_{A\cap B} \times PPV_{A\cap B}}{SE_{AUB}}} \tag{9}$$

thus, the test statistic can be rewritten as:

$$t = \frac{\frac{P_A^E \times PPV_A^E}{P_A^E \times PPV_A^E + P_B^E \times PPV_B^E - P_{A\cap B}^E \times PPV_{A\cap B}^E}}{\frac{P_A^{\bar{E}} \times PPV_A^{\bar{E}}}{P_A^{\bar{E}} \times PPV_A^{\bar{E}} + P_B^{\bar{E}} \times PPV_B^{\bar{E}} - P_{A\cap B}^{\bar{E}} \times PPV_{A\cap B}^{\bar{E}}}} \times \frac{SE_{AUB}^E}{SE_{AUB}^{\bar{E}}} - 1 \tag{10}$$

finally, if $SE_{AUB}^E = SE_{AUB}^{\bar{E}}$:

$$t = \frac{P_A^E PPV_A^E (P_A^{\bar{E}} PPV_A^{\bar{E}} + P_B^{\bar{E}} PPV_B^{\bar{E}} - P_{A\cap B}^{\bar{E}} PPV_{A\cap B}^{\bar{E}})}{P_A^{\bar{E}} PPV_A^{\bar{E}} (P_A^E PPV_A^E + P_B^E PPV_B^E - P_{A\cap B}^E PPV_{A\cap B}^E)} - 1 \tag{11}$$

Is the COVID-19 ‘color code’ of Italian regions subjected to political manipulation?

Giovanni Busetta [a] and Fabio Fiorillo [b]

Abstract

While the first wave of the COVID-19 pandemic saw the Italian government adopt a strategy of strict containment measures (lockdown) to stop the spread of the virus, the second one saw it apply a regional division into colored zones with differentiated restrictions, depending on the specific local pandemic risk. The aim of this paper is to analyze whether in addition to health reasons, some political motivations, such as the will of increasing mobility inflows and outflows, could affect pandemic restrictions based on regions’ colors. The idea underlying the paper is that, if no political reasons affect the decision of applying restrictions, the probability for a certain region to obtain a particular color shall depend only on factors concerning public health and included by law as factors influencing the color of the region. By applying a probit model to a regional panel, some clues of political manipulation emerge.

Keywords: Regional classification of pandemic risk, airport passengers’ flows, political manipulation.

1. Introduction

Looking at the Coronavirus Source Data by Our World in Data, Italy was among the countries with the highest mortality rate, with 1226.6 deaths per million of inhabitants (DpM). Notwithstanding the widespread average diffusion of COVID-19 in the country, Italian regions experienced very different levels of contagion, especially during the first wave of pandemic, and thus different mortality rates (De Leo and Araújo 2021). Indeed, the pandemic has affected Italian regions differently because the capacity of the various regional hospital systems is also very different.

Citizens and regional governments did not want to further worsen the economic impact of pandemic. Hence, as of the end of November 2020, central government relaxed lockdown measures, defining a regional classification of pandemic risk. Such a classification was based on parameters related to the diffusion of the virus and the capacity of the hospital system to accept new patients. Based on the results achieved on these parameters, each Italian region was identified by a color which determined the level of restriction to mobility (De Leo and Araújo 2021).

The aim of this paper is to analyze whether the wish for increased people mobility could affect the changes in the color-based risk classification of the regions, in addition to health reasons defined by law. The idea underlying the paper is that, if no political reasons affect the decision of applying

restrictions, the likelihood of a certain region to obtain a particular color should depend only upon the factors influencing the color of the region by law. Restrictions depend on the levels reached by three main health indicators in the region. These indicators are the ratio of hospitalized over positive people (HOSP), COVID-19 occupancy of beds (INTENS) in intensive care units (hereafter ICUs) and the reproduction number (hereafter RT).

Our idea is in line with the results of other studies (Tassinari et al. 2021), in which the authors found a significant link between the cooperative pressure exerted by business organizations against the containment measures and the reduction of the measures themselves. This result undoubtedly indicates a significant role of the 'business world' in shaping the responses to the pandemic by regional authorities. The reason underlying the inclusion of these three parameters as identifiers of the regional COVID-19 danger is awareness of the fact that mortality is not the only problem to face.

On the one side, the pandemic crisis challenged the sustainability of health care system. The risk of the ICU in Italy collapsing was the main concern in facing the pandemic. The presence and the number of such wards is particularly relevant because COVID-19 often induces infected people not to breathe on their own. On the other side, the economic consequences of COVID-19 have been huge. In response to the pandemic crisis, governments have called for policies with unprecedented restrictions on mobility and activities (OECD, 2020a, 2020b). These policies, which are characterized by enormous, short, and long-term economic and social costs, have generated the worst economic crisis since the Second World War. The considerations of Hebert and Curry (2022) may explain why central government changed its strategy after the first wave of pandemic passed and vaccines started to be distributed among population. Indeed, to maintain the levels of contagions sufficiently low for the pandemic not to explode, central government abandoned the strict lockdown approach and defined a 'color based' risk classification to be applied to regions.

Even though the pandemic shock simultaneously affects all countries (Caragliu, 2022), thereby decreasing the trust of citizens, it is worth to note that the mortality rate (De Leo and Araújo 2021), the economic impact and the long run effect of such shock has been uneven among regions, as investigated by Caragliu and Capello (2021). Indeed, the incidence of the virus is affected by differences in socio-economic variables (González-Val and Sanz-Gracia, 2022). As the mortality rate was uneven distributed and the pressure to reduce the economic effect was strong, central government accepted to apply differential rules to regions depending on three indicators particularly relevant in influencing spread and diffusion of the pandemic. The Italian government adopted three sets of restrictions (yellow for low levels of restriction, orange for intermediate levels and red for high levels of restrictions) to be imposed on a regional basis.

It is likely that, in a multi-governmental system, the incentive of central and regional government's incentives could not be aligned. Regional government may have stronger incentives to reduce restrictions to make the economy restart. Following Hebert and Curry (2022) weak lockdown policies are often correlated to minimal levels of tourism, stable population, and high vaccination rates. As Koyama (2021) states, policymakers face incentive and information problems, therefore we may formulate the following hypotheses.

Hypothesis 1. Regional governments have some incentive of exploiting their information advantages so as to manipulate regional health indicators and display a better color risk code and have lower restrictions.

The main contribution of our paper is to test such hypothesis by verifying the assumption of independence of regional restrictions (colors) during COVID-19 pandemic from political reasons. Our null hypothesis is the independence of worsening regional color risk code due to the political need of promoting the economy through avoiding restrictions. We used the number of passengers that have passed through regional airports one month before as a proxy of such a need. Indeed, the greatest the number of passengers passing through regional airports, the highest the costs of mobility restrictions for the entire regional economy. If the null hypothesis is true, the only parameters explaining the

probability of worsening the color risk code will be the three parameters used by government, the percentage of people positive to COVID-19 in the region, the color of the region a week before and regional dummies as control variables. The information of such parameters should provide all the information required to determine whether the risk of contagion would increase, and thus the future restrictions to be applied in the region. Eventually, the number of passengers could have an effect in increasing the spread of virus, worsening the risk code. On the contrary, the null hypothesis is rejected in case the impact of the number of passengers a month before significantly reduce the probability of the color code worsening. We interpret such results as a clue that political motivation matters in exploiting all the possible informative advantages when regions provide data for risk codification.

2. Data and methods

We used a balanced panel which contains daily data covering the period from 23 November 2020 to 18 January 2022. Such period was divided in two sub periods: the first one covers the time before the introduction of the green pass (from 23 November 2020 to 5 August 2021), while the second one does cover the period after it was introduced (from 6 August 2021 to 18 January 2022).

Since we used daily, weekly, and monthly data, first we presented a specific description for each variable (Table 1). In Table 2, descriptive statistics for all the time spans and the two sub periods are presented.

Table 1: variables description

Variable	Description	Periodicity	Source
worsening	Dependent variable. Dummy equal to 1 if the color risk code worsens with respect to the code of a week before	Daily	Authors' elaboration on Italian Ministry of Health's decrees
orange	Dummy equal to 1 if the color risk code is red, intermediate restrictions	Daily	Authors' elaboration on Italian Ministry of Health's decrees
yellow	Dummy equal to 1 if the color risk code is yellow, low restrictions	Daily	Authors' elaboration on Italian Ministry of Health's decrees
white	Dummy equal to 1 if the color risk code is yellow, no restrictions	Daily	Authors' elaboration on Italian Ministry of Health's decrees
RT	Effective reproduction number	Weekly	Health Ministry, ISS
INTENS	% of occupied beds in ICUs	Weekly	Health Ministry, ISS
HOSP	Ratio of hospitalized over positive people	Weekly	Health Ministry, ISS
positive_PC	Share of positive to the COVID-19 on regional population	Daily	Health Ministry and Gimbe foundation
K_passengers	Thousands of passengers	Monthly	Assaeroporti
GP	Dummy equal to 1 after the introduction of the green pass, 6 August 2021.	Daily	Authors'elaboration on Italian Ministry of Health's decrees

If the three indicators (RT, HOSP, INTENS) of a week before, exhibit bad values, the color risk code is worsened. This is the reason why we used weekly data for such indicators. On the contrary, the worsening of the risk code is measured daily, since for specific periods (Christmas and Easter days) the regional color risk code was not applied, and the color was set to orange and red for all the regions regardless of the indicators. The source (Assaeroporti: Italian Airport Association) provides the monthly number of passengers of all Italian airport, which we aggregated on regional basis. Having monthly data permits us to consider the effect of previous inflows on color code. Such data may depend on both regional and airport location, morever it should be influenced by the pandemic restrictions. To avoid endogeneity problems, we considered data on passengers lagged by one month and all other variables lagged by a week. Table 2 presents descriptive statistics.

Table 2: descriptive statistics, from 23 November 2020 to 18 January 2022

Variable	Obs	Mean	Std. Dev.	Min	Max
worsening	8.855	0.0902315	0.2865293	0	1
red	8.855	0.079616	0.2707131	0	1
orange	8.855	0.1586675	0.3653863	0	1
yellow	8.855	0.2866177	0.4522069	0	1
white	8.855	0.4750988	0.4994077	0	1
RT	8.855	1.00349	0.3027737	0	2.44
INTENS	8.841	0.1614184	0.1492893	0	0.67
HOSP	8.841	0.1939815	0.1658585	0	0.8
positive_PC	8.855	0.0058458	0.0070748	7.77E-05	0.0728643
K_passengers	8.855	286.1524	530.7765	0	2942368
GP	8.855	0.3928854	0.4884193	0	1

We estimated the probability of worsening the color risk code using a linear probability model, a probit and a logit estimation. The use of three different models provides a robustness check. For comparisons, we present only the marginal effect[1].

2. Results

Table 3 presents our results. The sign of the parameters relative to the three indicators and to the share of individuals positive to COVID-19 shows a positive coefficient as expected. Moreover, the null hypothesis of independence of the worsening of the color risk code from the number of passengers a month before is rejected with a negative sign. Indeed, the probability of the restrictive color of the region worsening decreases with the number of passengers a month before in all the performed analyses. This result must necessarily imply either that an increase in the passengers landed in the region reduces the probability of being infected, which is epidemiological very unlikely, or that political reasons influenced the decision of not applying stronger restrictions to a particular region.

2. Concluding remarks

Results of the analysis show that the increase in the restrictions applied to the regions during COVID-19 pandemic is explained not only by health indicators, but also by economic variables such as people mobility. The relation between this mobility in the previous month and the probability of worsening of the color risk code is not positive as can be expected from epidemiological considerations. On the contrary, it is negative and significant. This result led us to think of some kind of political manipulation, as restrictions applied to regions may impact on inflows and outflows of people, and thus on the general economic development of the region in that period.

Hence, our results provide some strong clues of manipulation mechanisms at work. We suspect that regions would delay the transmission of information not to worsen their color risk code. This way, regions gained an additional week with few restrictions on mobility. Such behavior is not punishable since a delay in transmitting information can depend on many legitimate causes . Even if our suspicion seems likely, further investigation should be conducted to describe the manipulation mechanism in detail.

Modelling multilevel ordinal response under endogeneity: application to DTC patients' outcome.

Silvia D'Elia[a]

[a] Sapienza Università di Roma, silvia.delia@uniroma1.it

Abstract

Ordinal data are widely used in medicine as they help to summarise health states or responses to treatment. Cumulative link models are useful because they explicitly consider the order in response's categories, and they allow to model the probability of observing a value that does not exceed a specific category. In this contribution, two situations that often arise in real data analysis will be investigated: i) data with hierarchical structure; ii) presence of endogenous covariates. We describe this framework by discussing the application to the response to treatment at 3 years in patients with differentiated thyroid cancer (DTC) diagnosis. The application aims to evaluate potential predictors for the response at 3 years considering both repeated measurements from the same patient, and data from several clinical centres. The analysis of the response over time is of interest as it evaluates whether the improvement can be attributed to the time that allows to obtain clearer eco images. Consequently, it could lead to a reduction in the use of radioactive iodine therapy, which is essential both to limit the side effects it produces on patients and to reduce the production of waste that are difficult to dispose of.

Keywords: Ordinal data, Cumulative link models, Multilevel structure, Endogenous covariates.

1. Introduction

Ordinal data are widely used in health and social science, where ordinal scales are used to measure response to a treatment or summarise the severity of a disease. Ordinal data are characterized by the fact that they can assume values in a discrete set of ordered categories with no assumption on distance between adjacent categories. Cumulative link models are a powerful models' class since they allow to treat the observations as categorical and explicitly consider the order in response's categories.

The structure of this paper follows. In section 2 we review basic regression models for ordinal data with a focus on random effects and endogenous covariates. In section 3 we introduce the relevant application; the results are briefly described in section 4.

2. Regression models for ordinal data

Let us start considering a response variable Y_i which is measured on an ordinal scale taking values in the ordered set $\{1, \dots, J\}$. Cumulative link models are widely used to analyse ordinal response variable as they allow to model the cumulative probability $\gamma_{ij} = P(Y_i \leq j)$[1] as

$$\gamma_{ij} = h(\eta_{ij}), \qquad \eta_{ij} = \theta_j - \boldsymbol{x}_i'\boldsymbol{\beta} \quad i = 1, \dots, n \ , j = 1, \dots, J-1 \tag{1}$$

When we adopt a so-called underlying latent variable framework, the response function h in equation (1), is usually a cumulative distribution function of an unobserved, continuous, latent variable. This choice allows to explicitly consider the order in response categories, by using category-specific thresholds θ_j and a common parameter vector $\boldsymbol{\beta}$. In the following we will assume that the underlying latent

variable is Gaussian and, therefore, adopt the Gaussian cdf as the response function, leading to the ordinal probit model. To be more specific, the observed categorical variable Y_i is obtained by discretizing a latent continuous variable Y_i^* according to the following scheme:

$$Y_i = j \leftrightarrow \theta_{j-1} < Y_i^* \leq \theta_j \tag{2}$$

where $-\infty = \theta_1 \leq \theta_2 \leq \cdots \leq \theta_J = +\infty$ are non-decreasing category-specific thresholds on the continuous scale, when latent variable falls in the *j*-th interval the observed variable is equal to *j* [2]. The latent continuous variable Y_i^* is described via a standard regression model where error terms are independent and identically distributed Gaussian random variables:

$$Y_i^* = \boldsymbol{x}_i'\boldsymbol{\beta} + \varepsilon_i, \qquad \varepsilon_i \sim N(0,1) \tag{3}$$

Given the previous hypotheses, the probability of Y_i not exceeding the *j*-th category can be written as in equation (4). Therefore, fixed a category specific threshold θ_j, a positive value of β coefficient means that the probability of not exceeding the *j*-th category decreasing.

$$P(Y_i \leq j) = P(Y_i^* \leq \theta_j) = P(\boldsymbol{x}_i'\boldsymbol{\beta} + \varepsilon_i \leq \theta_j) = P(\varepsilon_i \leq \theta_j - \boldsymbol{x}_i'\boldsymbol{\beta}) = \Phi(\theta_j - \boldsymbol{x}_i'\boldsymbol{\beta}) \tag{4}$$

The probability associated with a specific category *j* can in fact be written as the difference between two consecutive values of the cumulative distribution function of a standard normal random variable.

$$P(Y_i = j) = \Phi(\theta_j - \boldsymbol{x}_i'\beta) - \Phi(\theta_{j-1} - \boldsymbol{x}_i'\beta), \qquad j = 1, \dots, J \tag{5}$$

For the last category probability, the following equality holds:

$$P(Y_i = J) = P(Y_i^* \leq \theta_J) - P(Y_i^* \leq \theta_{J-1}) = 1 - \Phi(\theta_{J-1} - \boldsymbol{x}_i'\beta) \tag{6}$$

The likelihood function, given the sample, is defined, according to Wooldridge (2010) [3], as

$$L(\theta, \beta) = \prod_{i=1}^{n}\prod_{j=1}^{J} P(Y_i = j)^{Y_{ij}} \tag{7}$$

The parameters can be estimated by maximizing the corresponding log – likelihood function that can be written as follow:

$$l(\theta, \beta) = \sum_{i=1}^{n}\left\{1[Y_i = 1]\log[\Phi(\theta_1 - \boldsymbol{x}_i'\beta)] + \sum_{j=2}^{J-1} 1[Y_i = j]\log[\Phi(\theta_j - \boldsymbol{x}_i'\beta) - \Phi(\theta_{j-1} - \boldsymbol{x}_i'\beta)] + 1[Y_i = J]\log[1 - \Phi(\theta_{J-1} - \boldsymbol{x}_i'\beta)]\right\} \tag{8}$$

2.1 Random effects in ordinal regression models

When data has a hierarchical structure, it is possible to consider the information within the model specification. A random effects ordinal model may be proposed for the analysis of clustered ordinal data to account for potential dependence of responses recorded from the same higher-level unit.

In this case, the model in equation (3) could be modified to account for unobserved, time-constant, features of the higher-level units by considering the model below.

$$\begin{aligned} &\gamma_{ijk} = h(\eta_{ijk}), \quad \eta_{ijk} = \theta_j - \boldsymbol{x}_i'\boldsymbol{\beta} - \alpha_k \\ &\alpha_k \sim N(0, \sigma_\alpha^2),\ \varepsilon_i \sim N(0,1), \qquad \alpha_k \perp \varepsilon_i \\ &i = 1, \dots, n;\ j = 1, \dots, J;\ k = 1, \dots, K. \end{aligned} \tag{9}$$

We must consider that random effects account for unobserved, time-constant, features of the higher-level units. As they may be correlated with observed covariates, according to Nehuaus and Kalbfleish (1998) [4] and Neuhaus and McCulloch (2006) [5], we need consider also higher-level specific averages, obtaining the following model structure:

$$\begin{gathered}\gamma_{ijk} = h(\eta_{ijk}), \qquad \eta_{ijk} = \theta_j - \boldsymbol{x}_i'\boldsymbol{\beta} - \bar{x}_k'\boldsymbol{\gamma} - \alpha_k, \\ \alpha_k \sim N(0, \sigma_\alpha^2),\ \varepsilon_i \sim N(0,1), \qquad \alpha_k \perp \varepsilon_i \\ i = 1, \dots, n, j = 1, \dots, J, k = 1, \dots, K\end{gathered} \tag{10}$$

For sake of simplicity, we did not consider a random effects approach, but we used the linear predictor above and employed a robust estimator for the standard errors of model parameters.

2.2 Endogenous variables in ordinal regression models

A complication in the model is given by potential endogenous covariates. The model in equation (3) restricts all the covariates to be independent of unobserved heterogeneity and error terms. Some observed covariates may be endogenous in the sense that they are correlated with the error terms. It is possible to formulate the model for the response variable Y_i^* considering exogenous covariates and an ordinal covariate w_i.

$$Y_i^* = \boldsymbol{x}_i'\beta_1 + w_i\beta_{e1} + \varepsilon_i \tag{11}$$

The probability in equation (4) can be written as:

$$\begin{gathered}P(Y_i \le j) = P\left(Y_i^* \le \theta_j\right) = P\left(\boldsymbol{x}_i'\beta + w_i\beta_{e1} + \varepsilon_i \le \theta_j\right) = \\ = P\left(\varepsilon_i \le \theta_j - \boldsymbol{x}_i'\beta - w_i\beta_{e1}\right) = \Phi(\theta_j - \boldsymbol{x}_i'\beta - w_i\beta_{e1})\end{gathered} \tag{12}$$

The endogenous covariate w_i in the model (11) is assumed to be correlated with the error term ε_i as, for example, both response and the observed covariates are produced by a (partially) common data generation process. In order to account for such data generation process, a model for the endogenous covariate taking values in the ordered set $\{1, \dots, G\}$. is fitted as follow:

$$w_i^* = \boldsymbol{z}_i'\alpha + \eta_i \tag{13}$$

The errors η_i have a standard normal distribution.

Given the assumption in formula (2), the cumulative probability for the observed endogenous variable is:

$$P(w_i \le g) = P\left(w_i^* \le \theta_g\right) = P\left(\boldsymbol{z}_i'\alpha + \eta_i \le \theta_g\right) = P\left(\eta_i \le \theta_g - \boldsymbol{z}_i'\alpha\right) = \Phi\left(\theta_g - \boldsymbol{z}_i'\alpha\right) \tag{14}$$

To account for the dependence between the errors in equation (11) e (13) we assume that they are bivariate Gaussian random variables:

$$\begin{pmatrix}\varepsilon_i \\ \eta_i\end{pmatrix} \sim MVN(0, \Sigma), \qquad \Sigma = \begin{pmatrix}1 & \rho_{\varepsilon,\eta} \\ \rho_{\varepsilon,\eta} & 1\end{pmatrix} \tag{15}$$

The likelihood function, according to Winship and Mare (1984) [6], can be written as:

$$L(\theta, \beta, \Sigma) = \prod_{i=1}^{n}\prod_{j=1}^{J}\prod_{g=1}^{G} P(Y_i = j, w_i = g)^{d_{ijg}} \tag{16}$$

where d_{ijg} is an indicator for $Y_i = j$ and $w_i = g$. The corresponding conditional probabilities can be written as follow:

$$P(Y_i = j|\boldsymbol{x}_i, \boldsymbol{z}_i, w_i) = \frac{\Phi(\theta_j - \boldsymbol{x}_i'\beta - w_i\beta_{e1}) - \Phi(\theta_{j-1} - \boldsymbol{x}_i'\beta - w_i\beta_{e1})}{\Phi(\theta_g - \boldsymbol{z}_i'\alpha) - \Phi(\theta_{g-1} - \boldsymbol{z}_i'\alpha)} \quad (17)$$

3. Application: Italian Thyroid Cancer Observatory

We used the approach described so far to analyse data from the Italian Thyroid Cancer Observatory (ITCO). ITCO, founded in 2013, is a database that collects data about patients with diagnosis of thyroid cancer, treated in different clinical centres in Italy. The thyroid cancer is associated with a high survival rate with mortality less than 1x100.000. The concern for this pathology is due to the considerable prevalence of disease relapse. For this reason, long-term management through follow-up protocols is necessary. ITCO has the aim to evaluate the response to treatment over time, enrolling patients from 54 clinical centres and following each of them periodically after the initial surgical treatment.

The analysis of the response to treatment over time is important to evaluate if there are conditions that define a change in the patient's clinical status among those recorded at each follow-up, such as the residual tumoral tissue, or at baseline such as neck dissection, initial treatment, or assessment of the risk level. The analysis includes only patients that did not undergo further treatments as this allows to check whether changes in the response is associated to information available at baseline or at each follow up. Alternatively, changes may be just due to time passing by that allow to obtain clearer and more definite eco imaging.

The response to treatment is measured on an ordinal scale based on information obtained during the follow up. When compared to other staging systems, that include only primary characteristic of the tumour, the response to treatment we analysed is a dynamic one; it is based on clinical advice, thyroglobulin levels and eco imaging. Given such information, the status of the disease is classified into 4 classes in non-decreasing order of desirability as excellent (ER, no evidence of disease), indeterminate (IND), biochemical incomplete (BIR) and structural incomplete (SIR, evidence of disease).

4. Real world analysis of the response to treatment at 3 years.

Table 1: Distribution of the response at 3 years by response at 12 months

Response		*3 years*				
		SIR	BIR	IND	ER	TOTAL
12 months	SIR	16 (34%)	6 (12.8%)	14 (29.8%)	11 (23.4%)	47
	BIR	10 (8.4%)	37 (31.1%)	51 (42.9%)	21 (17.6%)	119
	IND	18 (1.9%)	33 (3.6%)	434 (46.7%)	444 (47.8%)	929
	ER	2 (0.2%)	17 (1.5%)	202 (18%)	904 (80.4%)	1125

Table 1 shows transitions between the response at two, pre-specified, different timepoints 12 months and 3 years since initial treatment. It is possible to observe some changes with direction from the lower categories (SIR, BIR, IND) at 12 months towards the higher ER category at 3 years. On the main diagonal there are percentage of patients that do not register changes in their disease status after (approximately) 24 months. The percentage are calculated over row totals.

The response to treatment can assume 4 values $j = \{SIR, BIR, IND, ER\}$. According to the literature [7], the response to treatment at 12 months (rtt_{12m}) is analysed conditionally to three covariates, that represent different patient's baseline information: level of risk as defined by the American Thyroid Association (z_1), the type of initial treatment (z_2), and the possible neck dissection (z_3). We defined the following ordered probit model:

$$P(rtt_{12m_i} \leq g) = P(rtt^*_{12m_i} \leq \theta_g) = P(z_{1i}\alpha_1 + z_{2i}\alpha_2 + z_{3i}\alpha_3 + \eta_i \leq \theta_g) = \\ = P(\eta_i \leq \theta_{gj} - z_{1i}\alpha_1 - z_{2i}\alpha_2 - z_{3i}\alpha_3) = \Phi(\theta_g - z_{1i}\alpha_1 - z_{2i}\alpha_2 - z_{3i}\alpha_3) \quad (18)$$

Then, we model the response to treatment at 3 years (rtt_{3y}) conditional on the response at 12 months and residual tumoral tissue. Obviously, responses to treatment observed at different times cannot be considered independent since they come from the same data generation process.

$$P\left(rtt_{3y_i} \le j\right) = P\left(rtt^*_{3Y_i} \le \theta_j\right) = P\left(x_i\beta + w_{1i}\beta_{e1} + w_{2i}\beta_{e2} + w_{3i}\beta_{e3} + \varepsilon_i \le \theta_j\right) = \\ = P\left(\varepsilon_i \le \theta_j - x_i\beta - w_{1i}\beta_{e1} - w_{2i}\beta_{e2} - w_{3i}\beta_{e3}\right) = \\ = \Phi(\theta_j - x_i\beta - w_{1i}\beta_{e1} - w_{2i}\beta_{e2} - w_{3i}\beta_{e3}) \tag{19}$$

Here, the response to treatment at 3 years rtt_{3y} is analysed conditional on a potential exogenous predictor, the residual suspicious tissue in thyroid bed (x), and the endogenous covariate rtt_{12m} . The latter is ordinal and, when we come to the regression model it is represented by a series of binary variables, one for each level minus one $(\boldsymbol{w_i})$.

Considering the response at 12 months as endogenous in the model for the response at 3 years, it is important to evaluate the relation between these two variables and estimate the correlation $\rho_{\varepsilon,\eta}$ between the errors in models (17) and (18).

To properly consider the effects of covariates on response, given that patients are nested in clinical centres, we inserted in both equations the centre-specific mean value of each covariate, as in equation (10). To account for similarities within the same centre, we used a robust estimator for the standard errors of model coefficients.

Acknowledgments

The drafting of the paper was possible thanks to the contribution of ITCO, Italian Thyroid Cancer Observatory, the research group of the Prof. Cosimo Durante and all the clinical centre that collaborate on the project.

Abstract

The prevalence of heart failure (HF) is increasing globally and its treatment is mainly based on drug therapy. However, non-adherence to therapies is widespread in patients with heart failure and is often associated with worse health conditions and an increase in hospital admissions. This study focuses on developing an innovative method, the state-sequence analysis (SSA), for profiling HF patients based on different drug-utilisation patterns and then investigating if and how the information is extracted by combining clustering algorithms to this technique affects patients' overall survival. This information can be used by people in charge of the healthcare government to properly asses different patterns of care and then plan tailored patient care supporting the proper resource allocation within the National Health Service.

Keywords: Heart failure, State-sequence analysis, Administrative database, Clustering

1. Introduction

Heart failure (HF) is currently the most common cardiovascular reason for hospitalisation among individuals over the age of 60. The prevalence of heart failure is increasing globally due to the increasing incidence of the ageing population (8), and the primary goals of its treatments are the reduction in mortality, the prevention of recurrent hospitalisation and improvement in the clinical status and functional capacity (5). The data suggest that non-adherence to drugs is associated with worse patient health conditions and an increase in hospital admissions. According to numerous studies, non-adherence is very common in patients with HF and the corresponding estimated rates range from 10% to 93%, making therapy non-adherence a severe medical problem on a global scale (12). For this reason, we focus on the therapeutic pathways administered to HF patients using an innovative method, at the expense of more traditional ones, to have a deeper description capable of evaluating the temporal order of drug prescription to extract drug-utilisation patterns and their association with health outcomes. The most widely administered therapies to HF patients are Angiotensin-Converting Enzyme Inhibitors (ACE-I). ACE-Is are the first class of drugs shown to reduce mortality and morbidity in HF patients and are recommended in all patients unless contraindicated or not tolerated. In this latter case, Angiotensin-Receptor Blockers (ARBs) are administered. ACE-I and ARB drugs will be grouped into a single drug class, namely

Renin-Angiotensin System (RAS) (6). In addition, Beta-Blocking agents (BB) combined with ACE-I have been shown to reduce mortality and morbidity in patients. Anti-Aldosterone agents (AA) are recommended, in addition to an ACE-I and a BB, to reduce mortality and the risk of HF hospitalisation (10). Moreover, diuretics (DIU) are recommended to reduce the signs and symptoms of congestion, which is one of the main predictors of HF. Finally, antithrombotic agents (AAG) are advised for patients with atrial fibrillation, which increases the risk of thromboembolic events (2). The aim of this work is to develop a suitable methodological framework for the representation of therapies prescription history in HF patients, with the final purpose of obtaining workable mathematical objects to be used in prognostic models. We apply such methods to an administrative database of hospitalised HF patients in the Lombardy region (RL) from 2006 to 2012. Administrative databases allow access to a large amount of heterogeneous data collected systematically. These data are rich in quantity and precision of information but poor in clinical content, as financial reasons drive their collection (11). The availability of many variables defined on a large number of patients makes the population similar to the "real-world" one, allowing the study of low-incidence phenomena and patients for an extended follow-up period. It is possible to extract information about drugs and comorbidities through algorithms based on national systems: the Anatomical Therapeutic Chemical (ATC) drug classification system and the International Classification of Diseases (ICD-9-CM). The information provided by this database allows us to estimate a proxy of the real drug-utilisation starting from drug purchases.

2. Cohort selection

The data used in this study is taken from the Healthcare Utilisation Databases of Lombardy, a Region of Italy with approximately 16% of its population (more than 10 million residents) (7). This database describes patients hospitalised for HF using information about hospitalisations and pharmaceutical purchases. For each patient, the follow-up begins with the discharge from the first HF hospitalisation and ends with his death or exit from the study. Then, we extracted the pharmacological class of each drug purchase using the ATC system. Next, using the ICD-9-CM system, each hospitalisation diagnosis encoded by the Clinical Classification Software was converted into comorbidity. This procedure provides the information necessary to compute the Multisource Comorbidity Score (MCS), which describes the patient's overall clinical condition (1). We decide to use this score in our analysis since it is the first that combines hospital diagnosis and drug prescriptions to provide a tool capable of measuring the severity of the clinical condition and it has demonstrated good performance in predicting mortality.

The last step of this pre-processing is the choice of the patients' cohort. As the goal is to study mortality one year after the reference date through drug-based patterns, all patients with censoring data that fall within this period or without pharmaceutical purchases were excluded. In addition, the analysis is focused on the three commonly administered drugs, in this context, RAS, BB and AA. Consequently, only patients who provided at least one purchase of these three drugs were taken into consideration in the first year of follow-up. The final sample is made up of 35,842 patients.

3. Methodologies

The analysis is developed as follows. First, SSA was applied to study patients' behaviour in terms of proper drug assumption and capture informative patterns that may affect patients' prognosis through sequence clustering. Then, sequence analysis is integrated into the predictive models through the clustering result to evaluate the association between drug patterns and health-related outcomes.

3.1 State-sequence analysis

State-sequence analysis was born to understand how events in ordered sequences can be related to the outcome of the observation. It is a well-defined technique in sociology that assesses how the chronological order of events in subgroups can lead to different social behaviours (9).

The main objective of sequence methods is to extract simplified, workable information from longitudinal data. Combined with cluster analysis, this method allows us to identify sequence descriptors that can be used in predictive models. In general, it is possible to divide the SSA into three main steps:

1. Identification sequences' states
2. Measuring sequence dissimilarity
3. Clustering sequences

State-sequences are characterised by two properties: an *alphabet* which is the list of all possible states or events, and a *time axis*, which assigns to each state a time stamp (3). Sequences are mathematical objects that contain elaborated information coming from the original data. An essential part of this study is the analysis of these objects, which may be conducted using visual tools and extracting statistics that characterise the sequences, like entropy or turbulence.

After analysing the sequences, it is necessary to define a metric to measure their dissimilarity. The sequences can be represented by different aspects that are not independent of each other, but the similarity of two sequences can be measured over one or many of these dimensions. So, comparing sequences is a significant issue of SSA, which may result in different partitions according to the metric adopted. We use a commonly used method called Optimal Matching distance. This edit-based metric generates edit distances that are the minimal cost, in terms of insertions, deletions and substitutions, for transforming one sequence into another. The insertion/deletion of an element, which generates a one-position shift of all the elements on its right, has the cost set to a default value of 1. At the same time, the substitution cost of one element by another derives from the observed transition rates between states. The parameterisation of the operations costs makes this measure flexible and allows for finding a trade-off between sequentiality and contemporaneity of the states (4). Once the dissimilarity matrix is computed, a cluster analysis can be performed to construct partitions of the sequences into distinct groups. Two clustering algorithms are applied to our work: hierarchical clustering and partitioning around medoids (PAM). In order to evaluate the partition obtained, we use three different metrics to assess their capability:

- Point Biserial Correlation (PBC) which measures the partition's capacity to reproduce the distance matrix
- Hubert's C (HC) index which measures the gap between the partition obtained with the best partition that could have been obtained with this number of groups and this distance matrix
- Average Silhouette Width (ASW) which measures the coherence of observation assignments to a given group

We obtain the final clustering by applying hierarchical clustering to the whole set of sequences and choosing the best number of clusters maximising the PBC and ASW and minimising the HC. Then we initialise the PAM algorithm with the best result of the hierarchical clustering. Finally, we choose the partition which gives the best quality metrics and a significant interpretation of the clusters.

4. Results

4.1 State-sequence construction

Using SSA, we study RAS, BB, AA, DIU and AAG drug classes prescribed during the first year after the first hospital discharge of each patient. This period allows us to observe patients' behaviour long enough to characterise them but at the same time not excessively long to limit the effect of the immortal bias. To construct the sequences, we keep all the purchases made during the first year of observation with the condition that if the drug coverage expires after the year, we truncate the coverage days to the final day of observation. Then we eliminate all the purchase overlaps, which occur when the purchase date of a drug happens during the coverage period of a previous purchase of the same type of drug. Patient purchases are grouped by pharmaceutical class and studied separately; in this way, each patient is associated with a sequence for each of the five drug classes taken at least once in the first year of observation. Sequences are composed of 52 elements, each of which represents a week of observation. Each state is assigned

zero if the drug prescription does not cover the patient for at least four out of seven days of the specific week and one otherwise.

For the RAS, BB and AA therapies, we introduce an additional phase that enables us to analyse the simultaneous intake of these drugs. For each patient starting from the three single sequences of RAS, BB and AA, we build a sequence that combines their states, forming an alphabet of eight elements. The states that make up the alphabet represent which of the three drugs are taken by the patient in any week. At this point, we have a combined-sequence of RAS & BB & AA for each patient and two separate sequences indicating the intake of DIU e AAG only for those patients who assume them.

4.2 State-sequence analysis

The analysis of the combined-sequences RAS & BB & AA performed through visual tools and statistical measures show that over the first two months, the proportion of patients who do not take any therapy decreased in favour of a rise in the RAS assumption. A small fraction of patients takes AA and BB separately, showing roughly the same proportion across the observation period. BB and AA are rarely taken by people who do not already take RAS. Looking at the transition rates, the probability of remaining in states which represent no treatments or monotherapy is elevated. However, BB and AA states are more unstable since the probability of stopping these therapies when accompanied by RAS is relatively high. Generally, it is more likely for a patient to leave a therapy than to start or add a new one.

The diuretics and antithrombotic sequences show similar behaviour. In the first weeks, the proportion of patients taking them increases by about 20%, then stabilises. This proportion remains almost constant in the weeks of observation, counting about 60% of the patients who take the therapy.

4.3 State-sequence clustering

Following the clustering procedure, we obtain for the combined-sequence RAS & BB & AA an eight-cluster partition from the hierarchical clustering. This partition captures the main behavioural patterns of the patients assuming the three classes of drugs, as shown in 1. Clusters 1, 2 and 3 denote patients with constant therapy patterns for most of the observation period. In particular, cluster 1 identifies patients who are non-adopters of therapies, cluster 2 the combined intake of RAS and BB therapies and cluster 3 RAS as monotherapy. Clusters 4, 5 and 6 identify those patients who, on average, take monotherapy for half of the observation period and no therapy for the remaining weeks. Finally, clusters 7 and 8 identify heterogeneous behaviours about the three pharmacological classes.

A two-cluster partition from the PAM method is obtained for the DIU and AAG sequence. This grouping recognises patients as *low-adopters* and *adopters* of these two drugs. The choice of such a small partition is supported by the quality metrics and the interpretation we can make. Compared to the combined-sequences, these sequences represent more simplistic patterns since they only have two states. We underline that this innovative procedure provides insights into how diuretics or antithrombotic agents are prescribed over time, not only recording the flag of having or not the prescription.

4.4 Including SSA-based representation into predictive models

To each patient, is associate the information about the three sequences clustering to examine, through the use of the Cox regression model, whether and to what extent this information adds value in predicting the overall survival of patients. We add to the model some explanatory variables, such as age, gender, the multisource comorbidity score, and the total number of procedures the patient has undergone.

Looking at the p-values of the stratified log-rank tests, we can state that the difference in survival between all the groups is significant. In particular, being diuretics adopters decreases the chances of survival by 40% (CI, [35% - 46%]); this could be explained by the fact that those who take diuretics are in a severe clinical condition. On the contrary, being antithrombotic adopters increases the survival probability of 11% (CI, [8% - 14%]), which identifies this drug as a protective factor.

Looking at the cluster of the combined-sequence of RAS & BB & AA, we can state that all the therapies increase the probability of survival since the Hazard Ratios are all significantly less than one.

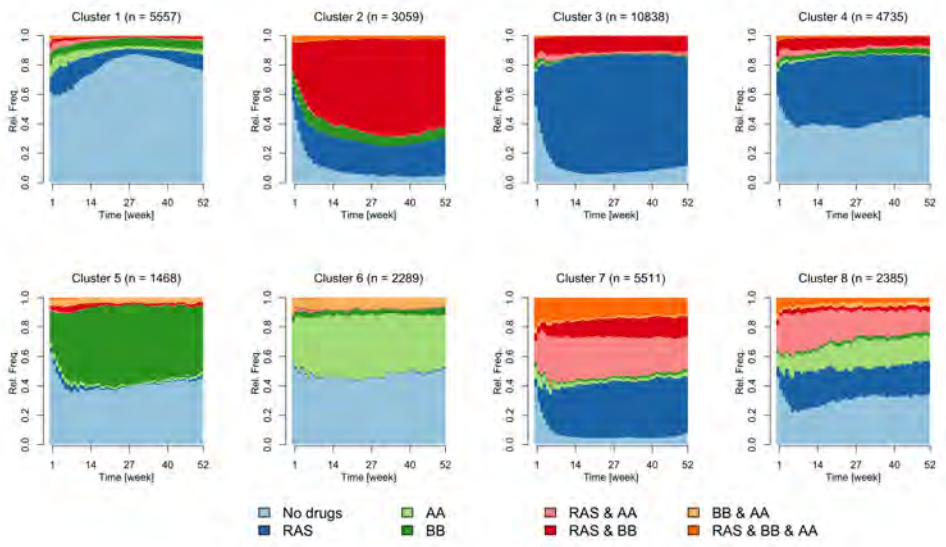

Figure 1: Sequence distribution plot by cluster of the combined-sequence of RAS & BB & AA.

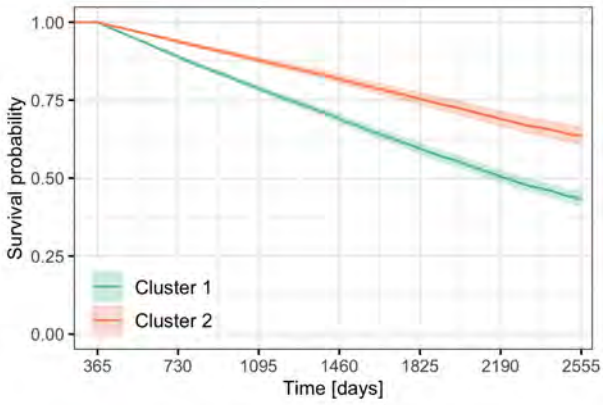

Figure 2: Survival probability plot for male patients aged 75 with 15 days of hospital stay, low category of MCS, without undergoing procedures, which are low-adopters of DIU and AAG and that belongs to clusters 1 and 2 of the combined-sequence of RAS & BB & AA.

In particular, patients belonging to cluster 2 have the highest survival probability, which is 46% (CI, [40% - 51%]) higher than the reference cluster, as shown in the KM survival curves in 2. So, we can infer that despite the diagnosis severity being unknown, taking drugs for an extended period after the first hospitalisation seems essential to improve the prognosis of HF.

5. Discussion and conclusions

The state-sequence analysis allows the description of drug-utilisation patterns for each patient through a mathematical object, which provides tools for assessing and associating the primary endpoint of interest. Compared to commonly used baseline measures, which omit some time-dependent information, this technique yields more realistic and valuable results since it considers the entire evolution of each patient's clinical path. In particular, it allows observing which weeks and how long the patient is covered by the therapies after the first hospitalisation. In addition, it allows the analysis of the polytherapy taken by the patient using a single patient descriptor (the sequence). The SSA, therefore, allows a change of perspective in the analysis of the prescriptions, moving from a transversal and syntactical approach to

a holistic one that exploits the information available through the application of statistical tools, slightly more complex than traditional methods. One of the limitations, deriving from the use of administrative databases, is the lack of detailed and contextual clinical information that would have supported the predictive models.

This work represents an important step in evaluating HF patients' drug-based path and paves the way for future developments. Latent Markov Models can be applied to study hidden patterns in this data to investigate the evolution of an individual characteristic which is not directly observable. Future expansions regard the application of these techniques to the so-called multichannel sequence analysis, i.e., the case where multiple sources of information are described through SSA, allowing us to describe individual trajectories on several dimensions simultaneously.

In conclusion, SSA has provided impressive results in studying drug-utilisation patterns of heart failure patients. However, more specific and updated data can lead to even more effective results that can support healthcare specialists in evaluating the pathways provided to patients and the National Health Service in allocating the most appropriate resources.

Abstract

In phase II clinical trials, two-stage designs allowing early stopping for lack of efficacy are frequently used. We present a Bayesian two-stage design that ensures high posterior probabilities that the response rate of the experimental drug exceeds a desirable level, when the decision is to proceed with treatment evaluation. Moreover, the design exploits the distinction between *analysis* and *design* prior distributions, to control the predictive probability of Type I and II errors, while minimizing the expected sample size under the null hypothesis.

Keywords: analysis and design priors, Bayesian approach, error rates, two-stage design

1. Introduction

Single-arm two-stage designs are frequently used in phase II clinical trials with binary endpoints. The aim is to stop the study early for futility if the response rate of the experimental drug is not sufficiently high. According to the original scheme suggested by Simon (1989), at the first stage n_1 patients are enrolled and if $s_1 \leq r_1$, the trial terminates for lack of efficacy, where s_1 denotes the observed number of responders. Otherwise, the trial continues to the second stage and n_2 additional patients are treated. Then, if the observed number of responders s out of the total sample $n = n_1 + n_2$ is not grater than r, the trial stops and the treatment is declared not effective. Otherwise, it is recommended for a more rigorous evaluation in a phase III trial.

The most popular two-stage designs are the optimal and the minimax designs developed by Simon (1989) under a frequentist framework, with many extensions and modifications presented in the literature. Several Bayesian two-stage designs have been also proposed (see, among others, Tan and Machin, 2002; Sambucini, 2008; Dong et al., 2012; Matano and Sambucini, 2016). In a recent work, Shi and Yin (2018) proposed a Bayesian enhancement two-stage (BET) design, that (i) guarantees a high posterior probability of the response rate exceeding the target of interest, when the observed number of responders reaches the minimum required level to continue with the experimentation and (ii) controls the length of the HPD interval for the response rate. In line with Shi and Yin (2018), we propose a Bayesian two-stage design that satisfies condition (i) and also yields the minimum expected sample size under the null hypothesis, while controlling the probability of Type I and Type II errors at a certain prespecified levels. To compute the error probabilities, we use a predictive approach by exploiting different kinds of prior distributions, which play different roles in the design of the trial. More specifically, we introduce an *analysis prior distribution* to express pre-experimental information and to construct posterior distributions. On the other hand, we elicit two different *design prior distributions* to represent suitable design scenarios to evaluate the Type I and Type II error rates.

The outline of the article is as follows. In Section 2, we formalize the Bayesian problem. In Section 3, the procedure to obtain the predictive probabilities of errors is described and the Bayesian strategy to find the optimal design is illustrated. Some numerical results are given in Sections 4 and, finally, Section 5 contains a brief discussion.

2. Preliminaries

Let θ be the unknown response rate of the experimental treatment and assume that the interest is focused on testing $H_0 : \theta \leq \theta^*$ vs $H_1 : \theta > \theta^*$. Thus, the treatment is considered sufficiently promising if θ exceeds the target value θ^*. Moreover, let us denote by S_1 and S the total number of responders at the end of the first and the second stage, respectively.

We introduce a beta prior density, $\pi^A(\theta) = \text{Beta}(\theta; \alpha^A, \beta^A)$, and use it to obtain the posterior distributions of θ at the end of both the stages. $\pi^A(\theta)$ is called the *analysis prior distribution*, because it is used to represent pre-experimental knowledge available at the analysis stage, that can be for instance gathered by previous studies or derived from expert opinions. We have that $S_1|\theta \sim \text{Bin}(n_1, \theta)$ and, from standard conjugate analysis, the first stage posterior distribution of θ is $\text{Beta}(\theta; \alpha^A + s_1, \beta^A + n_1 - s_1)$. Since S includes the number of successes of the first stage, the posterior distribution for θ at the end of the second stage should be conditional on the event $S_1 > r_1$. However, it is possible to show that this condition does not affect the second stage posterior distribution (see Sambucini, 2008), that results to be $\text{Beta}(\theta; \alpha^A + s, \beta^A + n - s)$.

In each stage, we assume that the trial terminates if the posterior probability assigned to the alternative hypothesis is not sufficiently high. More specifically, at the end of the first stage the trial proceeds to the second one if

$$Pr(\theta > \theta^* | S_1 = s_1, n_1) > \lambda_1, \tag{1}$$

and, similarly, at the end of the second stage we claim the experimental treatment promising if

$$Pr(\theta > \theta^* | S = s, n) > \lambda_2, \tag{2}$$

where λ_1 and λ_2 are two desired probability thresholds, typically fixed so that $\lambda_2 > \lambda_1$.

3. The proposed two-stage design

For fixed values of n_1 and n, the posterior probabilities in (1) and (2) are increasing functions of s_1 and s, respectively. We use an algorithm that searches the optimal design by varying n from $n^{min} = 10$ to $n^{max} = 100$. For each value of n, we consider n_1 in the range from $n_1^{min} = \max\{5, \frac{n}{3}\}$ to $n_1^{max} = n-1$. This choice for n_1^{min} aims at avoiding that the sample size of the first stage may be relatively small compared to the total sample size. For each couple of n and n_1, the two-stage boundaries are selected as

$$r_1 = \min\left\{s_1 \in \{0, ..., n_1\} : \; Pr(\theta > \theta^* | S_1 = s_1, n_1) > \lambda_1\right\} - 1 \tag{3}$$

$$r = \min\left\{s \in \{r_1 + 1, ..., n\} : \; Pr(\theta > \theta^* | S = s, n) > \lambda_2\right\} - 1 \tag{4}$$

In this way, we obtain a set of designs (n_1, r_1, n, r) such that in each stage the posterior probability assigned to the alternative hypothesis is larger than the threshold of interest, when the observed number of responders exceeds the corresponding boundary, r_1 or r. Among these designs, we select the one that satisfies error probability constraints at the end of the second stage and minimizes the expected sample size under H_0.

3.1 Error probability computation

We consider the standard two types of errors that can occur in hypothesis testing: rejecting the null hypothesis when it is actually true (Type I) and failing to reject the null hypothesis, when the alternative is

true (Type II). When studying the operating characteristic of two-stage designs under a frequentist framework, the probabilities of these errors are evaluated by specifying a single value for θ, suitably selected under H_0 or H_1 according to the type of error we are interested in. By adopting a Bayesian approach, we instead introduce two different prior distributions that model uncertainty on the single values of the parameter specified in the classical framework and add flexibility to the procedure. In the statistical literature, these priors are typically called *design prior distributions*, because they are used at the design stage of the study to describe a scenario of interest and to derive the prior predictive distributions of the data (see, Wang and Gelfand, 2002; Sahu and Smith, 2006; Brutti et al., 2008; Sambucini, 2008). This allows to obtain the probability model that generates the data, under the assumption that θ is highly likely to be in a certain subset of the parameter space.

More specifically, to compute the Type I error rate, we need to realize the conjecture that H_0 is true. Thus, we introduce a beta design prior distribution for θ, $\pi^D_{H_0}(\theta) = \text{Beta}(\theta; \alpha^D_{H_0}, \beta^D_{H_0})$, which has mode θ^D_0 smaller than θ^* and assigns negligible probability to values of the parameter under the alternative hypothesis. By marginalizing the sampling distribution of the data over $\pi^D_{H_0}(\theta)$, we obtain the prior predictive distribution of S_1 and $S - S_1$, that are

$$m^D_{H_0}(s_1) = \text{Bin-Beta}(s_1;\, n, \alpha^D_{H_0}, \beta^D_{H_0}), \quad \forall\, s_1 = 0, ..., n_1,$$

$$m^D_{H_0}(s - s_1) = \text{Bin-Beta}(s - s_1;\, n - n_1, \alpha^D_{H_0}, \beta^D_{H_0}), \quad \forall\, s - s_1 = 0, ..., n - n_1.$$

Here, Bin-Beta$(\cdot\,;\, m, a, b)$ denotes the probability mass function of a Binomial-Beta distribution with parameters m, a and b. Therefore, given the four values (n_1, r_1, n, r), the predictive probability of a Type I error is provided by

$$Pr(\text{Type I error}) = \sum_{i=r_1+1}^{n_1} \sum_{j=r+1}^{n} \text{Bin-Beta}(i;\, n_1, \alpha^D_{H_0}, \beta^D_{H_0}) \text{Bin-Beta}(j - i;\, n - n_1, \alpha^D_{H_0}, \beta^D_{H_0}).$$

When the focus is on the Type II error, we elicit a beta design prior distribution for θ, $\pi^D_{H_1}(\theta) = \text{Beta}(\theta; \alpha^D_{H_1}, \beta^D_{H_1})$, used to realize the assumption that the alternative hypothesis is true. Its prior mode is $\theta^D_1 > \theta^*$ and the prior probability assigned to values of the θ under the null hypothesis is negligible. Analogously to the previuos case, $\pi^D_{H_1}(\theta)$ is exploited to obtain the prior predictive distribution of S_1 and $S - S_1$, that are still Binomial-Beta. Therefore, the predictive probability of a Type II error is given by

$$Pr(\text{Type II error}) = 1 - \sum_{i=r_1+1}^{n_1} \sum_{j=r+1}^{n} \text{Bin-Beta}(i;\, n_1, \alpha^D_{H_1}, \beta^D_{H_1}) \text{Bin-Beta}(j - i;\, n - n_1, \alpha^D_{H_1}, \beta^D_{H_1}).$$

3.2 Optimal design strategy

As described before, the first step of the proposed strategy to find the optimal design consists in considering all the possible couples of n and n_1 and identifying the corresponding boundaries r_1 and r by exploiting the conditions (3) and (4) about the posterior probabilities that the alternative hypothesis is true. Among the set of (n_1, r_1, n, r) identified using this procedure, we select the one that

1. satisfies the error constraints $Pr(\text{Type I error}) < \alpha$ and $Pr(\text{Type II error}) < \beta$, where α and β are desired levels for the error rates;
2. minimizes the expected sample size under H_0, $E(N|H_0) = n_1 + (n - n_1)(1 - PET(H_0))$, where $PET(H_0)$ is the *probability of early termination*, that is computed for θ equal to the mode of the design prior $\pi^D_{H_0}(\theta)$ and is given by

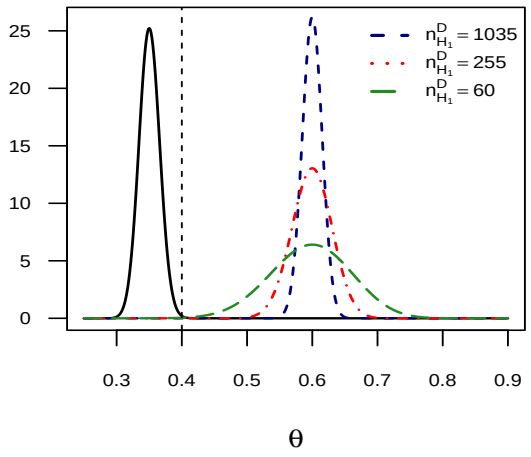
$$PET(H_0) = \sum_{i=0}^{r_1} \binom{n_1}{i} (\theta^D_0)^i (1 - \theta^D_0)^{n_1 - i}.$$

4. Numerical results

In this Section, we report some numerical results to illustrate the main features of the proposed design. We set $\theta^* = 0.4$ and consider a non-informative analysis prior distribution, $\pi^A(\theta) = \text{Beta}(\theta; 1, 1)$. To elicit the design prior distributions, we resort to a typical way of proceeding by expressing the hyperparameters in terms of prior mode and prior sample size. For instance, the hyperparameters of the design prior $\pi^D_{H_1}(\theta)$ can be fixed as

$$\alpha^D_{H_1} = n^D_{H_1}\theta^D_1 + 1 \qquad \text{and} \qquad \beta^D_{H_1} = n^D_{H_1}(1 - \theta^D_1) + 1,$$

where the prior sample size $n^D_{H_1}$ regulates the concentration of the prior around its mode. In particular, we set $\theta^D_1 = 0.6$ and select $n^D_{H_1}$ so that it is equal to 0.99 the prior probability assigned to the intervals $[0.55, 0.65]$, $[0.5, 0.7]$ and $[0.4, 0.8]$. Consequently, we obtain three design priors with $n^D_{H_1}$ equal to 1035, 255 and 60, respectively, that assign negligible probability to values of θ smaller than θ^*. These distributions are represented in Figure 1 along with the design prior $\pi^D_{H_0}(\theta)$. This latter density has mode $\theta^D_0 = 0.35$ and is based on a prior sample size, $n^D_{H_0}$, equal to 909. On the right of the graph, a small Table shows the optimal designs that correspond to the diffrent design priors $\pi^D_{H_1}(\theta)$. As expected, the corresponding optimal sample sizes increase when $n^D_{H_1}$ decreases, as a consequence of the greater dispersion of the design distribution.



θ^*	$n^D_{H_1}$	r_1/n_1	r/n
0.4	1035	7/16	16/33
	255	7/16	19/40
	60	9/20	23/49

Figure 1: Design prior distributions $\pi^D_{H_0}(\theta)$ and $\pi^D_{H_1}(\theta)$ for different values $n^D_{H_1}$, when $\theta^* = 0.4$. The Table shows the corresponding optimal designs when $\pi^A(\theta) = \text{Beta}(\theta; 1, 1)$ and $(\alpha, \beta) = (0.05, 0.2)$

In Table 1, we report the optimal designs for different values of θ^* and (α, β), when $\theta^D_0 = \theta^* - 0.05$, $\theta^D_1 = \theta^* + 0.2$, $\alpha^A = \beta^A = 1$, $\lambda_1 = 0.8$ and $\lambda_2 = 0.9$. The prior sample sizes of the design priors, $n^D_{H_0}$ and $n^D_{H_1}$, are selected as the minimum values so that the probabilities assigned to H_0 and H_1, respectively, are equal to 0.999. The corresponding probabilities of early termination and the expected sample sizes are also reported. Regardless of θ^*, the optimal sample sizes obtained when $\alpha = \beta = 0.1$ in both the stages are greater than the ones obtained with $\alpha = 0.05$ and $\beta = 0.1$. Furthermore, in the first case the probabilities of early termination are higher, resulting in expected sample sizes closer to n_1. As for the analysis prior distributions, we expect that their impact varies according to the degree of skepticism expressed towards the treatment efficacy.

Table 1: Optimal proposed two-stage design for different values of θ^*, α and β, when $\theta_0^D = \theta^* - 0.05$, $\theta_1^D = \theta^* + 0.2$, $\alpha^A = \beta^A = 1$, $\lambda_1 = 0.8$ and $\lambda_2 = 0.9$

θ^*	(α, β)	r_1/n_1	r/n	$EN(H_0)$	$PET(H_0)$
0.2	(0.1, 0.1)	6/27	12/48	27.070	0.901
	(0.05, 0.2)	3/14	7/27	15.094	0.853
0.3	(0.1, 0.1)	11/33	25/70	36.652	0.901
	(0.05, 0.2)	6/18	14/38	20.780	0.861
0.4	(0.1, 0.1)	18/41	27/58	42.509	0.911
	(0.05, 0.2)	9/20	27/58	24.628	0.878
0.5	(0.1, 0.1)	22/40	40/71	42.377	0.923
	(0.05, 0.2)	11/20	27/47	23.531	0.869

5. Discussion

The most popular and commonly used two-stage designs have been developed by Simon (1989) under a frequentist framework. From a Bayesian perspective, Shi and Yin (2018) showed that, given promising results according to Simon's designs, the posterior probabilities that the response rate reaches the desirable target level are very low. Thus, this Author proposed a Bayesian two-stage design that ensures high posterior probabilities of the response rate exceeding the target of interest, when the observed results suggest to proceed with treatment investigation.

In this paper, we present a Bayesian two-stage design based on the same condition used by Shi and Yin (2018) and that in addition minimizes the expected sample size under null hypothesis, while controlling the Type I and Type II error rates at fixed desired levels. To offer a more flexible evaluation of the errors probabilities, we adopt a predictive approach by using design prior distributions to specify design expectations and to realize the assumption that θ belongs to a specific subset of the parameter space. These prior densities are employed to obtain the prior predictive distribution of the data, used to compute the error probabilities. A different prior distribution is used to represent prior information and to compute the posterior distribution of the parameter.

Abstract

The objective of this paper is to investigate the information and to detect the presence of misinformation on Twitter posts circulating in relation to migration events happened in 2020 at the Greek-Turkish border and in 2021 at the Polish-Belarusian border. Data were retrieved through API by using keywords referring to the two border events. The study was carried out by applying text mining and sentiment analysis techniques on tweets and retweets related to these two events, and by conducting a qualitative analysis on specific subsets of tweets. Our results show that in both borders' crises migration is perceived as an emergency issue, migration-related narratives mainly refer to "war", "attacks", "tension", "invasion" and the emotions expressed are mostly negative. In addition, in outbreaking crisis, the identification of misinformation in social media is extremely challenging, because of the rapid circulation of rumours related to facts that are rather difficult to ascertain.

Key words: misinformation, twitter, migration, Europe, border

1. Migration events at the Greece-Turkey and Poland-Belarus borders

This study focuses on the analysis of information spreading on social media during specific migration-related events in Europe and it is part of the work conducted within the H2020 Perceptions project[1]. The study focuses on a relevant topic related to migration phenomenon, i.e., the spread of misinformation and rumours that can have a great impact on the lives of migrants and influence the ideas circulating among migrants themselves and the inhabitants of receiving countries.

We focus on two borders' crises. The first one is the border between Greece and Turkey. This border has been the scene of several humanitarian crises involving migrants in recent years. One of the last events originated in late February 2020, when the Turkish president declared the opening of the border for migrants directed to Europe. During spring 2020 videos, pictures, and news on migrants at the Greek-Turkish border started to circulate. The two sides involved, Greece and Turkey, began to make accusations against each other regarding the treatment of migrants and the circulation of misinformation. The Greek and Turkish governments themselves have actively participated in this exchange of accusations, also by using social media. In this context, not only hardly verifiable news began to be spread, but real news was possibly being pointed as fake news or made confusing for political purposes.

Beyond specific ad hoc created fake news then, there was an underlying misinformation and confusion about real events. Misinformation also arose regarding the size of the phenomenon, with the Turkish side tending to overestimate the number of migrants who left Turkish territory. In addition to distorted news, real fake news was artfully created.

The second border's crisis that we analyse is the one on Poland-Border border in 2021. It was triggered by the tensions' escalation in Belarus–European Union (EU) relations started in August 2020, following the Belarusian presidential election, the repression of mass-protests in the country, and other events such as the hijacking of the Ryanair Flight 4978 for the arrest of Belarusian journalist Roman Protasevich. As a response, United States Treasury Department, and the EU imposed sanctions to President Aleksander Lukashenko and to exponents of Belarusian administration and economy. In May 2021, President Aleksander Lukashenko warned the EU of the possibility for Belarus to stop patrolling

[1] The project PERCEPTIONS is funded by the European Commission H2020 Research & Innovation Action under Grant Agreement No 833870. It aims to identify and understand narratives, images, and perceptions of the EU outside Europe, and to study ways, channels and actors through which narratives are distributed.

the EU border, threatening EU to provoke a migrant's crises in response to sanctions. From that moment, Frontex reports thousands of border crossing attempts from Belarus into EU, with the growing apprehension of Polish and European authorities and public opinion as well as the rising tension in the whole region, involving Russia, Latvia, Lithuania and Ukraine. The president of Belarus has been publicly accused by European authorities of offering tourists' visas and flights to migrants from Iraq and Syria. While thousands of migrants were stuck on the Belarus side of the border, tensions between Belarusian government and EU increased also in contents posted on Twitter. Both sides were accusing the other to use migrants as a destabilizing weapon, neglecting international protection's procedures and keeping migrants in life danger.

Both the contexts under study involved two EU border countries (Poland and Greece) facing migrant's events perceived as crises, under the guidance on the EU in a controversy with third countries (Belarus and Turkey). Both crises have echoed widely in the mainstream media, prompted discussions and news circulations (accurate or distorted) in social media. The spread of misinformation on social media has undoubtedly exacerbated the tension in crisis phases and could have also misled migrants and potential migrants' idea about the migration issue in Europe.

2. Research design, data and method

Focusing on misinformation this concept has numerous, and sometimes contradictory, definitions (Treen et al. 2020, p. 3). According to the Oxford English Dictionary 2018, misinformation is defined as "wrong or misleading information". In many cases, misinformation is used as a synonym of false facts, rumours (e.g., Donato et al, 2022). Slightly different is the concept of disinformation, defined in literature as a "deliberately false information". This differentiation has been embraced by many authors (e.g. Stahl 2006, Alonso et al. 2021, Treen et al. 2020), while others, such as Ruokolainen & Widén (2020), do not rigidly classify the terms misinformation and disinformation. In the framework of this analysis, we decided to adopt the umbrella concept of *misinformation*, as ambivalent, distorted or falsified information (Zhou and Zhang 2007), without distinction as to intention or source of origin of
the information. Rumours and fake news are thus equally included in this concept.

The objective of the work is to investigate the information and misinformation circulating in Twitter during specific geopolitical crisis related to migration flows at the abovementioned border areas, by examining tweets and retweets retrieved using targeted keywords.

In particular, the first research question of the study is: (RQ1) what words are most frequently expressed in Twitter environment during migration-related events at border areas and what sentiments do they communicate about the discussion taking place in social media? Our aim is to examine the nature of discourse developed on Twitter around these issues. We hypothesize that the words used, and the sentiment expressed, may indicate the presence of certain topics related to specific actors of these migration events.

The second research question is: (RQ2) is it possible to identify misinformation in Twitter contents about migration-related events at the borders? We hypothesize that tweets posted during the uprising of these kind of crises are a huge, heterogeneous and fragmented corpus of text and they can be hardly analysed as whole. Therefore, a qualitative approach on subsets of tweets containing selected keywords could be more informative for the analysis of patterns in narratives and misinformation about specific topics.

The data used for the analysis were downloaded using the Academic Research Twitter API, by searching for the hashtags #GreeceTurkeyBorder and #PolandBorder and #BelarusBorder. Our analysis is restricted to the content in English language, since English messages are more likely to cross national borders and spread all over the world.

For these three complete datasets, we applied text mining and sentiment analysis techniques to analyse the words used and to understand what kind of sentiment they express.

Using the *TM* package in R, we have built a term-document matrix that describes the frequency of single terms that occur in the corpus of documents. To perform the analysis, we cleaned the text data by applying a series of filters and we only selected semantically significant terms. We analysed the association between words through a correlation analysis, a statistical technique that can demonstrate whether, and how strongly, pairs of words could be related, helping to map the discourses around these words.

We investigated the most recurrent words related to the migrant situation at the borders to evaluate the prevalence of specific topics in tweets' contents.

We then conducted a sentiment analysis to understand what sentiments and emotions the tweets expressed, by using the *syuzhet* R package. We used the NRC Emotion Lexicon, developed by Saif and Turney (2010), that assigns words to 8 different types of emotions (Naldi 2019; Widyaningrum et al. 2019). The 8 emotions are anger, fear, sadness, disgust (negative ones) and anticipation, trust, surprise, and joy (positive ones). For each tweet the method counts the number of words associated with each category (Naldi 2019, Widyaningrum et al. 2019), providing a cumulative score representing the sentiments for the whole corpus of text.

We then created various subsets of specific tweets (excluding retweets). First, we selected tweets containing the words "misinformation", "disinformation", and "fake". On these we conducted a manual qualitative analysis, trying to understand which news items were categorized as misinformation by the users in social media. Then, we created targeted subsets of tweets, by searching for selected keywords related to specific topics that generated a major flow of information during the two events. We manually analyzed the contents to understand what kind of information was conveyed and in what ways, in order to identify biased or inaccurate information.

3. Section Heading

The analysis produced some interesting results, useful in understanding what kind of discourse emerges during critical situations concerning the migration phenomenon, and what role misinformation can play. Although these results derive from contents posted on Twitter only in English and related to specific geographic contexts, they can be representative of general discourses spread via social media related to migration phenomena.

We found common patterns among the contents concerning the situations on the Greek-Turkish and Polish-Belarusian borders. In both cases, the words circulating in social media about these migration-related events refer to wars, attacks, tension, crises, invasion. In addition to terminology related to the theme of conflict, the use of words connected with the most vulnerable groups, such as children and women, is also frequent. In both cases, the perception of migration as an emergency issue emerges. The feelings and emotions expressed by the words contained in these tweets are mostly negative. The messages and information existing in social media regarding these issues are therefore dominated by negative elements, mainly related to anger and fear (RQ1).

The qualitative analysis carried out on more specific subsets of data made it possible to integrate and deepen the results emerged from the text mining analysis and to understand whether misinformation could be identified in tweets concerning specific topics. Regarding the different topics related to critical situations at the borders, confused discourses emerged, with polarized messages and viewpoints, in which it is very difficult to distinguish between misinformation and accurate information (RQ2). This is true both in the context of events on the Greek-Turkish and on the Polish-Belarusian borders.

Opposing views emerged regarding migrants. On the one hand, they are depicted as victims of a cynical policy in a game for power assets, on the other hand, they are often identified as an invasion force and a source of violent crime. As emerged by the analysis of words' associations in the entire datasets, and confirmed by the qualitative analysis of specific subsets, refugees and asylum seekers, as being subject to a more careful regulation and therefore more entitled to enter Europe, presented a slightly different representation, more empathetic and supportive in comparison to generic migrants. Around migrants' arrival to Europe, their crossing the borders, even on social media (as happens in the public debate), a war on numbers has been fought. Also on this issue, social media acts as an echo chamber of the confusion existing in society regarding the real numbers of migratory flows.

In the analysed tweets, Europe as a political entity is often defined as a weak, silent, role-playing spectator in crisis involving migrants. In this context, both the idea of Europe as a political entity completely helpless and disinterested in migratory events for political ends, and the idea of Europe as an entity that is victim of the events and under attacks, emerges. Discourses that can be based on real facts are therefore mixed with preconceived ideas that do not sink into real information.

In some tweets concerning situations on both borders, Europe is also considered weak in countering the spread of misinformation.

Names of politicians frequently appear in circulating social media discourse. Social media seem to function as echo chambers for politicians' declarations, and this implies a fundamental role that they should play in providing correct and non-distorted information. The reconstruction of what happened on the Greek-Turkish and Polish-Belarusian borders showed that some public actors have been found to push misinformation, by accident or not, spreading confusion, fear, anger, or prejudice.

In social media, we found discourses and accusations very similar to those that emerged and were disseminated in the mainstream media during the days of the two crises. On some specific episodes mentioned in tweets, we found different interpretations regarding the protagonists and the parties involved, demonstrating the various narratives that can circulate and the confusion that can arise about what is true and what is fake. How difficult is identifying misinformation from real information was evidenced not only by the presence of various points of view, but also by the lack of reliable reference points. Indeed, the information circulating in social media in relation to the migration-related events at the borders are often "black box information", without mentioning any verifiable source, often found to be supported by misleading or manipulative images and videos, providing inaccurate messages or marked by simplistic or sensationalist slogans.

Our findings underlined the difficulty in identifying misinformation from real news in social media. The coexistence of so many points of view, often unsupported by reliable data and sources, is an indication of a tendency to provide inaccurate information in social media. Indirectly, this leads to the idea that misinformation, now understood in a very broad sense, can influence the lives of migrants and potential migrants and the perceptions of migrants travelling to Europe, but also of Europeans themselves.

Certainly, the results that emerged from these analyses cannot be considered as definitive. The issue of misinformation can be investigated with further methods and by drawing on further data. Still, these findings are an important indication of how information is developing and circulating on social media, shedding further light on the theme of narratives and discourses, their construction and dissemination, and their potential role on people lives.

Graduates' interregional migration in times of crisis: the Italian case

Thaís García-Pereiro[a], Ivano Dileo[b] and Anna Paterno[a]

Abstract

The economic crisis has affected migration of young adults while experiencing increasing entering and remaining in the labour market. In Italy the share of graduates working in a different territory than those of graduation increased during this period. Previous studies mostly focused on regular business-cycles highlighting the relationship between employment and leaving the place of origin, but studies considering the impact of the Great Recession on interregional migration of graduates is still missing. To fill this gap, the main purpose of this paper is to analyze the effect of economic conditions on graduates' interregional migration, and whether and how these effects change over time in Italy. Our dataset merged two micro-waves of survey data with macrolevel variables, from which we estimated multilevel models for binary responses. Our results shown that the positive effect of regional Youth Unemployment Rates on graduates' likelihood of interregional migration was stronger for those obtaining their degree in 2011 compared to those who graduated in 2007.

Keywords: interregional mobility, economic crisis, graduates, multilevel models, Italy.

1. Introduction

Research has paid attention to migration patterns of high-skilled individuals founding that interregional movements are more likely to be acted by skilled individuals (Greenwood 1975, Faggian and McCann 2006, 2009, Miguélez and Moreno 2013). Also, the highly-educated are highly-mobile, not only internationally but also internally (Faggian et al. 2017).

Interregional migration of graduates strongly depends on individual factors such as gender (Faggian, McCann and Sheppard 2007), age (Busch and Weigert 2010, Marinelli 2013), geographical origin (Iammarino and Marinelli 2015) as well as on context variables (Florida 2002, Boschma and Fritsch 2009, Nifo and Vecchione 2014, Crescenzi et al. 2017). Interregional migration has been changing so fast recently because of the interfering of uncertain job expectations and socioeconomic challenges (Faggian et al. 2017).

The recession has especially affected migration of the younger age groups, who have experienced high unemployment and difficulties entering the labour market (Bonifazi and Heinz, 2017). In fact, during the crisis, graduates working in a different territory than those of graduation increased (Almalaurea, 2005; 2010; 2012; 2017).

Previous studies mostly focused on regular business cycles highlighting the relationship between the likelihood of being employed after graduation and/or the likelihood of moving out the place of origin (Di Pietro 2005, Dalmazio and De Blasio 2011, Marinelli 2013, Dotti et al. 2013, Etzo 2013) but studies considering the impact that the Great Economic Recession has had on interregional migration of graduates is still missing.

The main purpose of this paper is to analyse the effect of economic conditions on graduates' interregional migration at both micro (individual) and macro (context) levels, and whether and how these effects change over time (pre and during the great recession) in Italy.

2. Brief state of the art and hypotheses

At the microlevel, research has demonstrated that employment reduces the propensity toward migration since territorial movements often imply losing an already achieved position in the labor market (Card et al. 2004, Busch and Weigert 2010).

Even though the interregional migration process is a phenomenon mostly related to individual choices, literature has demonstrated that the characteristics of regions of origin and destination also play an important role in explaining the mobility of graduates.

Most research showed that not only individual unemployment, but also structural unemployment is positively associated with out-migration, which is consistent with a push-pull model of migration (Sjastaas 1962, Harris and Todaro 1970).

Evidence focused on interregional migration during recession periods is still limited, and the existent evidence is mixed. On one hand, Davies et al. (2001) find that the relationship between unemployment and interstate migration is stronger during years with a high mean unemployment. Nifo and Vecchione (2014) follow this line showing that as unemployment in the province of origin increases, the probability of migration increases. On the other, some scholars stressed that the disadvantage of migration during the Great Recession for graduates might be more severe (Doherty 2009, Frey 2009), this way increasing obstacles and uncertainty from migratory decisions (postponement).

The direction and magnitude of these relationships in the context of the Great Recession are unclear, but Davies et al. (2001) and Nifo and Vecchione (2014), demonstrated that origin-specific economic characteristics, measured by Youth Unemployment Rates (YUR) of the region of origin, might be especially important for interregional migration.

Following the existing literature and according to available data, we formulate three research hypotheses:

RH1: we expect to find higher likelihoods of performing interregional migration among graduates who were non-employed after graduation, if compared to those who were already employed.

RH2: we suppose graduates' unemployment to be even more important in times of economic recession.

RH3: we suppose that Youth Unemployment Rates will positively influence graduates' interregional migration and, given the impact that the Great Recession might has had on mobility across regions, we hypothesize a change on this influence over time, being Youth Unemployment Rates more important for interregional migration of graduates appertaining to the 2011 cohort (interviewed in 2015) respect to those of the 2007 cohort (interviewed in 2011).

3. Data and methods

Individual level microdata were drawn from the last two waves of the survey "Indagine sull'Inserimento Professionale dei Laureati" conducted by the Italian National Statistical Institute (ISTAT) in 2011 and 2015, respectively. Contextual economic macrolevel data, on yearly basis, were drawn from ISTAT regional indicators.

As we analyze interregional migration in Italy during the period between obtaining the degree and the time of surveys (2007-2011 and 2011-2015), we have harmonized and clean survey microdata on both cohorts of graduates into one micro-dataset and merged this information to macro-data on macroeconomic indicators[1] of the region in which the interviewed was living before moving into another region logically matched to each one, nesting graduates in regions (20). Our final sample consisted of 53,880 graduates of the 2007 and 50,106 graduates of the 2011 cohorts.

Our dependent variable measures interregional mobility of graduates in Italy considering graduates who performed interregional migration after graduation vs those who do not moved. The main set of independent variables comprises, a measure indicating if the graduate was unemployed after graduation

[1] Using the mean values of the indicator (Billiet et al. 2014) relative to the five years that preceded graduation for each wave of the survey (between 2002-2006 for graduates interviewed in 2011, graduated in 2007; and 2006-2010 for those interviewed in 2015, graduated in 2011).

as proxy to its own economic conditions before deciding to move to another region, graduates' gender and the survey year (corresponding to a specific cohort of graduates). At the macro/contextual level, our variables of interest were the Youth Unemployment Rates of the region where graduates were living before moving to a different region after obtaining their degree. Model estimations also controls for a set of variables that the literature on graduates' mobility has previously identified as important determinants[2].

Empirical analyses were divided into three stages. On the first, after the null model, the first model includes graduate's unemployment after graduation, to test for graduate's own economic situation; and survey year, to test for changes in graduates' interregional migration over time; and all control variables considered. In the second stage, we added our context variable (Youth Unemployment Rates) to explore its influence on graduates' likelihood of performing interregional migration. Finally, we explore time effects of the economic conditions throughout interactions to a) test if the effect of the employment situation on interregional migration depends on survey year (first-level interaction) and b) test changes over time of the effect of the context on graduates' mobility (cross-level interaction). We have clustered robust standard errors by regions.

4. Selected results

The estimates from models of our empirical strategy are showed in Table 1. Estimates of Model 1 show the effect (OR) of individual-level variables on graduates' likelihood of performing interregional migration. Strong significant effects are found for these variables. First, after graduation, unemployed graduates have a 14% higher likelihood of leaving the region where living while attending university than those that were employed. Second, the odds of having performed interregional migration were 38% higher for graduates appertaining to the latest cohort (2011) respect to the previous one (2007).

The second stage is dedicated to test the effects of the Youth Unemployment Rates as contextual predictor on interregional migration. As expected, Youth Unemployment Rates positively influence graduates' interregional migration (Model 3 in Table 1 OR = 1.03, $p<0.001$). Interestingly, the variance of the random effect at the region level diminishes significantly from M1 (0.11) to M2 (0.06), indicating that the inclusion of Youth Unemployment Rates reduces differences on interregional migration across regions in Italy.

The first-level interaction (third stage of empirical analyses) shows that the association of being unemployment after graduation with interregional migration is consistent over time and across cohorts. This means that unemployed graduates were more likely to leave the region in which were living while attending university than those who were employed.

Regarding the final stage, the cross-level interaction shows that graduates' interregional migration has changed during a period of economic recession. The positive effect of regional Youth Unemployment Rates on graduates' likelihood of interregional migration was stronger for those obtaining their degree in 2007 compared to those who graduated in 2011. Thus, the trigger effect of Youth Unemployment Rates on interregional mobility increased over time, being a key factor to understand why graduates moved after graduation during the economic recession.

Table 1: Estimates of a series of binary multilevel regression models for graduates' interregional migration as function variables of interest (micro-macro levels, Odds Ratio).

5. Brief discussion of main findings

This article was aimed at studying the influence of individual and structural economic conditions on graduates' interregional migration while exploring whether and how these effects change over time (pre and during the great recession).

At the micro-level, results show that interregional migration of graduates in Italy is strongly influenced by their individual economic conditions after graduation. Confirming our RH1, likelihoods of interregional migration are higher among non-employed graduates. Regarding changes over time, the role of graduates' unemployment becomes even more important among graduates obtaining their degree in 2011 than among those appertaining to the previous cohort (2007). Thus, as expected (RH2), being unemployed increases interregional migration of graduates in times of economic recession.

Macro-level relations confirm our RH3, since coming from a region with high levels of Youth Unemployment Rates increases the likelihood of changing region of residence after graduation. Its positive effect on interregional migration is stronger over time, as observed for micro-level relations, being more important among graduates obtaining their degree in 2011 than among those of the previous cohort (2007). This points out to the Great Recession as a sort of "trigger event" of graduates' decision to move, increasing their interregional migration likelihood in Italy.

Intentions to stay: The experiences of return migrants in Albania

Maria Carella[a], Thaís García-Pereiro[a], Roberta Pace[a] and Anna Paterno[a]

[a] Università degli Studi di Bari Aldo Moro; C.A. t.garcia.pereiro@uniba.it

Abstract

The economic crisis intensified both the magnitude and complexity of return migration dynamics, increasing migrants' likelihood of returning to their country of origin mainly as a consequence of unemployment and the worsening of their economic conditions. Despite the importance gained recently, little research has been focused on the relationship between economic consitions and return migration due to the lack of data on the subject. This paper is aimed at contributing to the existent literature on the subject by analysing the case of Albanian migrants who returned between 2009-2013. Data drawn from the 2013 Albanian Survey on Return Migration and Reintegration is used to estimate logistic regression models to predict the intentions to stay in the country of origin after returning. These analyses help us to better understand how return trajectories arise and develop according to the characteristics of returnees, those of their initial migratory project and the situations experienced during and after migration.

Keywords: return migration, Albania, migratory intentions, migratory projects, economic conditions.

1. Introduction

Return migration is one of the most complex and multifaceted phenomena concerning migratory biographies. The decision behind the return to the country of origin may depend on push factors that have motivated leaving the country of destination (economic circumstances, family or health-related issues) and on pull factors, that may attract migrants back.

The economic crisis started in 2007 intensified both the magnitude and complexity of return migration dynamics. As demonstrated in previous studies (Castles and Vezzoli 2009, Papademetriou and Terrazas 2009, García-Pereiro 2019) the crisis increased migrants' likelihood of returning to their country of origin mainly because of unemployment and worsening economic conditions. Unfortunately, due to the lack of data on the subject and its reduced visibility, little research has been focused on shedding some lights on this relationship.

This paper is aimed at contributing to the existent literature on the subject by analysing the case of Albanian returnees between 2009-2013 to disentangle the decision-making process that have led migrants to return in times of crises. In particular, we analyse returnees' intentions to stay in Albania after returning. We study the effect of variables related to the initial migratory project and situations lived before leaving Albania (before migration) and whether and how its influence change after taking into account situations lived by returnees both in the host country and right after their return.

2. Theoretical background and state of the art (in brief)

Theoretical approaches regarding international migration have differently interpreted migrant's return to the country of origin. One set of theories have read return as a positive and successful event which has been part or become part of the migratory project. This is the case of the New Economics of Labour Migration (Stark and Bloom 1985, Taylor 1999, Constant and Massey 2002), Transnationalism (Portes et al. 1999) and return preparation (Cassarino 2004). Other theories, instead, have deemed return as a negative event, signing the failure of the migratory project. Behind this second set is the Neoclassical Theory for which return is the result of the failure of the migratory project (Sjaastad 1962, Todaro 1969, Constant and Massey 2002).

With reference to migration intentions, there is little research that has been focused on whether and how migration intentions change and evolve according to the experiences lived during the development of the migratory project in different territories (country of origin, country of destinations, etc.). Although, we consider that some findings might be somehow interesting to our subject of study. The papers of Balaz et al. (2004) and Khoo et al. (2008) highlight migrants' adaptation experiences in destination places as one of the main drivers behind migration intentions. For Alberts and Hazen (2005) and Lu et al. (2009), these intentions might be strongly dependent on changes in social and personal factors (such as family structure) and mediated by family financial situation. It was also highlighted that migrants living abroad can experienced serious difficulties in accomplishing economic-related migration goals as a result of unemployment, which has been directly related to an increased in the likelihood of remigration (Pecoraro 2012). Instead, being employed or self-employed in the country of destination reduces this likelihood (de Haas and Fokkema 2011, Paparusso and Ambrosetti 2017).

In this paper, deepening the determinants of the emigration and return projects, we analyze the likelihood of being intended to stay in Albania permanently after returning to test whether and how the influence of the initial migratory project changes and if experiences lived in the host country and after return affect such relation. Based on the above-mentioned literature, we are able to build the following research hypotheses:

H1: the return to Albania is a result of the success of the migration project because it is linked to the intention to improve family, individual and working conditions, that, at the time of departure were worse than those at the time of return.

H2: the return to Albania is a result of the failure of the migration project due to the worsening of family, individual working conditions; in this case, the migration experience has not accomplished intentions regarding the improvement of these conditions. H1 and H2 are mutually exclusive competing hypotheses.

H3: the intention to remain in Albania after returning is a result of the modification of the migratory project, due to the experiences and changes that have occurred during this experience.

3. Data and methods

Data are drawn from the Survey on Return Migration and Reintegration in Albania conducted by INSTAT and IOM in 2013. This survey has a nationally representative sample size of 1,878 individuals aged 18 years and over who returned to Albania between 2009 and 2013. According to the survey, returnees are those individuals who returned to Albania (permanently or temporarily), after living in another country for at least one year. The dataset includes some information about three stages of migration, asking about situations and conditions experienced before leaving Albania (before migrating), those experienced abroad (while living in the host country) and also post-return (after returning).

We use binary logistic regression models to predict the intentions to permanently stay (intended to stay vs other intention) in the country of origin after returning, which might help us understanding the decision-making process taking place after the return considering as important determinants both main return motivations and initial migratory intentions.

We examine the effects of several predictors that are expected to be associated with the reasons behind these intentions, while controlling for other variables. Model estimations are aimed at getting a deeper understanding of the intention to stay in Albania after returning that, taking part at a well ahead stage of the migratory experience, allowed us to add variables regarding not only the initial migratory project but also experiences lived while settled abroad (financial situation) and after the return (financial situation, having returned with family members). These analyses are aimed at testing H1 vs H2. In order to test for H3, further steps include information regarding experiences lived in the host countries that

were not economic in nature (such as: changes in the marital status and children ever had, having pursued studies or having integration difficulties while living abroad).

Model estimations control for returnees' characteristics (gender, age at migration, marital status, number of dependent family members and educational attainment before migration), year of return, NUTS2 where living before departure, last country of emigration, and length of stay.

In future steps, our attention will be focused on developing robustness checks in which we plan to further disaggregate the intention using multinomial regression models with 3 categories (permanently, temporally, do not know) to disentangle the effect of those whose intentions were not certain. We are also working on the construction of a typology of returnees based on the combination of their initial and final migratory intentions.

4. Summarizing results

Table 1 displays the results regarding the intention to stay permanently in Albania after return considering situations experienced by migrants before migrating, during their stay abroad, and after returning. As expected, each step of the migratory experience plays a well differentiated role on returnees' intentions to permanently stay in Albania. The initial migratory project (Table 1, M1) seems to lose relevance after considering experiences lived in the host country (Table 1, M2). In this stage of the migratory project, having experienced a not good-very bad financial situation, changes in family structure and having encountered integration difficulties are of particular importance while controlling for the initial characteristics of the migratory project. In fact, all these covariates exert a positive influence on returnees' likelihood of intending to permanently stay in Albania after having returned.

Although, the effects of two covariates referred to the initial stage (before migrating) remain unchanged: having had prior migration experiences (in terms of international migration) and having planned to migrate alone (without friends or family members).

It is interesting to note that the effects of the covariates illustrating situations experienced by returnees while living in the host country diminished after introducing situations experienced after return. The positive likelihood of being intended to stay in Albania decreases the most when considering non-economic situations (integration difficulties or changes in the family structure). This is not the case of returnees who pursued their studies abroad. The influence of economic conditions, measured thru the financial situation, increases when passing from M2 to M3 (Table 1). Returnees who experienced a not good-very bad financial situation were 19% more likely to be intended to permanently stay when considering situations experienced before migrating and while living abroad (M2), and this likelihood increased to 29% after adding situations experienced after return (M3).

For staying intentions, remains even more important the effect of variables related to situations experienced by return migrants after returning to Albania (Table 1, M3). However, there are some differences between economic and non-economic determinants that deserve to be highlighted. About economic conditions experienced after having return, we found that the likelihood of being intended to stay of return migrants whose financial situation remained unchanged or decrease upon returning (if compared to the situation experienced in the host country) was 17% lower than the one declared by those whose financial situation improved. Then emerges the need to consider the impact that non-economic situations have on their own intentions to stay. Results show that returnees that were back to Albania without their family members were 48% less likely to be intended to stay if compared to those who returned together whit their family.

Table 1: Results from binary logistic regression on the likelihood of being intended to stay in Albania permanently after returning in M1: base model, M2: base model + situations lived abroad, and M3: base model + situations lived after the return (Odds Ratio).

5. Concluding remarks

The central purpose of this article was to study the intentions to permanently stay in Albania after returning of return migrants while considering the initial characteristics of their migratory projects and the economic and non-economic situations experienced both in the host country and right after their return.

Following theories on return migration, we hypostasized that returning to Albania may be interpreted or as a result of the success (H1) or as a result of the failure (H2) of the migration project. These are competing hypotheses that were built comparing situations experienced by return migrants before migration, while living abroad and after returning. In the first case, the success is proxied through the improvement of individual or family economic conditions. In the second, the migratory experience has not significantly improved such conditions. Here, findings pointed to the confirmation of H2 giving that the influence economic conditions remained of crucial relevance and positive intentions to stay are strongly dependent on returnees having experienced a poor financial situation while living in the host country.

Going further, our third hypothesis (H3) was aimed at recognizing how relevant non-economic conditions are in shaping future intentions to stay rather than to leave the country again. We found support for it, calling the attention to the intrinsic dynamic nature of the migratory project which is constantly evolving over time and across space. The most important role on post-return migratory intentions is played by experiences and changes that have occurred during this experience, which are non-economic in nature.

Return migration to home country: a systematic literature review with text mining and topic modelling

Cecilia Fortunato[a], Andrea Iacobucci[b], and Elena Ambrosetti[a]

[a] Sapienza University of Rome; cecilia.fortunato@uniroma1.it, elena.ambrosetti@uniroma1.it

[b] Regione Emilia-Romagna; iacobucciandrea@gmail.com

Abstract

A crucial (and less developed) part of migration studies is the exploration of migrant's further mobility and the intention of return to home country at some point in life. Knowing who, why and when returns matters for both the host and the home country. Very few studies have focused on return in a wider perspective, adopting a comparative approach. The present study aims at providing a systematic review of peer-reviewed literature indexed in Scopus database, to understand how return has been dealt with by researchers. The main objectives are: collecting and synthetizing previous studies; comparing approaches, conceptualizations of return, methods and variable of interest. A bibliometric analysis on metadata and content analysis based on text mining and topic modelling techniques has been conducted on a sample of approximately 3,000 publications. With our contribution, we expect to implement a baseline for theoretical development and empirical research, presenting an overview on the evolution of trend topics, with regional and temporal patterns of research focus and identifying knowledge gaps in literature.

Key words: return migration, remigration, home country, systematic literature review, topic modelling

1. Introduction

Migration studies have developed rapidly in recent decades, in terms of size, methods used, interdisciplinarity, heterogeneity of theoretical frameworks and internationalization of research groups (Pisarevskaya et al., 2020; Vargas-Silva, 2012; Bonifazi and Strozza, 2006; King and Skeldon, 2010; Massey et al., 1993).

Migration flows and many aspects of the migration cycle have been widely discussed in the literature, relating to a growing diversity of migratory categories (from refugees and forced migrants to economic or climate migrants) and specific case-studies at national and global level (Abel, 2018; Castels and Miller,2014).

Researchers have concentrated their efforts in analyzing why people decide to migrate. But a crucial (and poorly developed) part of migration knowledge is the exploration of migrant's further mobility over the life course. A fundamental theoretical and practical question should be: what are future plans and prospects of migrants? What factors influence their decision for permanent stay in host country, for onward migration to a third destination, or for the return to home country, at some point in life? Awareness on the whole migratory cycle is scarce. Yet, knowing who, why and when returns, estimating future migration scenarios and forecasting returns, matters for both the host and the home country. And this aspect could be even more relevant in times of crisis, as shown by the COVID-19 pandemic, when millions of migrants have been returned to their countries of origin, we don't know if permanently, and large numbers of migrants have found themselves "stranded abroad and in need of assistance" (Le Coz and Newland, 2021).

Modern fluid societies, characterized by the globalization of movements, communications, technologies and information, make the ground extremely rough for analysis, because of the volatility of events, the heterogeneity in biographies and experiences and the increasing transnationalism of migrants. Return decision making is a complex process (Carling and Pettersen, 2014; Waldorf, 1995): it is influenced by a variety of

factors related to conditions both in origin and destination countries and motivated by needs at individual, household and social level (Krasniqi and Williams, 2018; Paparusso and Ambrosetti, 2017). Migrants' characteristics and situational conditions affect return probabilities and reintegration prospects of returnees. Furthermore, return to home country is particularly difficult to measure because of the lack of reliable and consistent register data and large-scale survey data, as it often goes spontaneous and unrecorded.

We know from literature and international reports that 1/4 of total migratory events are estimated to be returns; up to 50% of immigrants leave the host country within 5 years (return home or secondary emigration) and return migrant's selection tends to be the reverse of the initial selection process for migration (Azose and Raftery 2019; Abel 2018; OECD, 2017; Åkesson and Baaz, 2015).

However, very few studies have focused on return in a wider perspective, adopting a comprehensive and comparative approach (see Cassarino, 2015; Mohamed and Abdul-Talib, 2020)

2. Main objectives and Research Questions

Knowledge production within the field of migration is accelerating at a tremendous speed, while risking at the same time to remain over-specialized, fragmented and inconsistent (Pisarevskaya, 2020; Snyder, 2019; Denyer and Tranfield, 2009; Kitchenham, 2004; Tranfield, et al., 2003; Webster and Watson, 2002,).

The present study aimed at providing a theoretical basis necessary for the further analysis of factors driving intentions and realizations of migrant's homeland return, and the relationship between initial migration drivers and return intentions. Mapping academic landscape is an important step in addressing new research questions, proposing new conceptual framework, facilitating theory development and identifying knowledge gaps and topics that need further research.

The systematic review of peer-reviewed literature indexed on citation databases is a powerful tool for understanding how return has been dealt with by researchers. What has been studied so far may shed light on what has been relevant in time, assuming that fundamental research questions arise with the development of societies and follow the evolution of phenomena under study (Snyder, 2019).

The main objective of this study was collecting and synthetizing previous studies, comparing approaches, conceptualizations of return, methods and variable of interest, integrating findings and perspectives, testing return theories against international migration theories and comparing the assumptions on which they rest. We aimed at providing a detailed overview of the existing literature through a comprehensive search in publication's repositories, using relevant keywords.

The following questions guided our study:

RQ1: How the studies on return migration developed from 1960 to 2020?

RQ2: How has return been conceptualized in terms of topical focus?

RQ3: What theoretical framework and motivational factors have been taken into account?

RQ4: Is the evolution of "return theories" following the evolution of "migration theories"?

3. Data and Method

Bibliometric analysis and content analysis based on text mining and topic modelling algorithm have been applied to publications, gathered from Sci-Verse Scopus.

The first step was building a valid search query (combinations of key terms and logical operators) that would retrieve (in title, author's keywords or abstract) as many documents as possible with minimum irrelevant results. When possible, we gathered publication and metadata via API, alternatively, we gathered data with search-by-string method (Belter, 2020; Aria and Cuccurullo, 2017-2018). We applied a massive data cleaning procedure to exclude out of scope articles and to clean text with lemmatization and tokenization techniques. For data analysis, we selected specific packages of the statistical software R: dplyr, ldatuning, topicmodels, rscopus, bibliometrix.

The descriptive analysis of the collection and the bibliometric analysis of meta-data aimed at discovering the temporal and spatial distribution of publications, evaluating the impact of a publication in the scientific community, identifying important theoretical contributions and mapping the evolution in international research cooperation networks.

The content analysis of title-keywords-abstract with text mining and topic modelling techniques identified topics or topic clusters that figure centrally in the specific textual landscape. We aimed at

discovering patterns and regularities within the corpus of texts, elaborating classification and categorization of topics, evaluating correlations among topics and following the evolution of trend topics. For text analysis we use the TF-IDF technique (term frequency-inverse document frequency), assessing how relevant a word is to a document in a collection of documents, on the base of how many times the word occurs in the document; and the inverse document frequency of the word across a set of documents. We considered the absolute frequency of a term in the whole corpus of text (frequency) as well as the numbers of documents containing the specific token (count).

For topic modelling, Latent Dirichlet Allocation model has been selected (Farren, 2019). LDA model is a Bayesian probabilistic model of latent topics from the contents of abstracts, based on the assumptions that each document in a corpus discusses multiple topics in differing proportions. A topic can be considered as a collection of words ordered by their probability of occurrence. The topic structure in the corpus of words is hidden and this method seeks to provide an ideal number of topics (k), a matrix with per-topic word probabilities and a matrix with per-document topic proportions. As a result, it was possible to summarize and label the topic in topic clusters and their probability of occurrence. Two metrics have been defined to summarize topic distribution across documents and classify articles: the topic presence, showing the number of document in which the topic is present, equal to 1 if the gamma score of LDA model is above the per topic average of gamma (and 0 otherwise); and the topic dominance, showing the number of document in which the topic is prevailing over other topics, selecting the topic with maximum gamma score for each document.

4. Main results

Our final sample included almost 3.000 documents published in English between 1960 and 2020 by more than 1.400 publishers.

The great majority of the publications focusing on return were articles published in specialized journals (2469) and only the 12.9% of them were published in open access. The first publishers, in terms of number of publications and citation obtained were migration's specialized scientific journals such as International Migration and the Journal of Ethnic and Migration Studies; the only regional journal among the top publishers was the Asian and Pacific Migration Journal. Among the top 15 publishers, two were journals specialized on refugees and forced migration, a fundamental component of the migration phenomenon (Journal of Refugee Studies and the Refugee Survey Quarterly).

Our results from the descriptive and bibliometric analysis of meta-data showed that first return migration studies can be traced back to the beginning of the 1960s, with an exponential growth of scientific production on the topic starting from the late seventies. However, a proper corpus of studies took shape only in the 1980s, with the politization of international migration movement and the growing importance of the discourse on (economic) development in origin countries, both in academia and in the institutional and public debate (Cassarino, 2015). The great acceleration of the topic's relevance started at the beginning of the new millennium, with researchers looking at the effects of the global economic crises on millions of migrants living in recessing high industrialized countries. Indeed, 60% of total studies have been published between 2010 and 2020.

Looking at the spatial distribution of publications, we highlighted the dominant role of receiving countries involved in the "knowledge production" on return. The 50% of total documents have been published in only 5 countries, namely United States, United Kingdom, Canada, Germany and Australia.

We than analysed the textual landscape presented in publications retrieved, mining the text of title, abstract and keywords. In the overall corpus of text, most frequent tokens present a variegated nature, including all the topical aspects of different migration theories. Among the top frequent tokens, a major role can be attributed to economic, push and pull factors and labour migration theories, followed by systemic and macrolevel theories and transnationalism and social network theories.

We then analysed most frequent tokens divided in three subperiods (1960-1980, 1981-2000 and 2001-2020), showing a shift in scientific focus over the last 40 years, with economic and labor market associated keywords leaving room for more subjective aspects of migration.

The first period considered (1960-1980) has been dominated by the economic paradigm. In this perspective, the return has been considered as the "logical outcome of a calculated strategy" (Cassarino, 2015), underlining the importance of wage differentials, accumulations of savings and, more important, remittances as explanatory factors of the return decision. In the second period considered (1981-2000),

words related to the economic perspective are still relevant, but a growing attention has been paid to the macro-level influence and constraints on return migration, especially related to the increasing number of conflicts and humanitarian crises around the world during the '90s. In that period, experts and researchers from different discipline implemented a series of new empirical tools ("model") to study migration trends, and most of them started to take into account meso-level factors (group and community) behind migration and return, such as the new role of family in migration strategies and the increasing number of women among international migrants. In the beginning of the new millennium (2001-2020), the phenomenon of return gained another level of interest as well as complexity of analytical frameworks. The increasing globalization of information, facilitated by communication and transportation, the cyclical economic crisis and the higher mobility of high skilled workers, led the researcher to focus on social capital and transnational practices. Many studies still point out that economic factors play a crucial role in homeland return's decision, but there is a slight cultural shift in the economic paradigm as the focus has turned into a matter of "aspirations" for an upward-mobility. As it was predictable, in the last twenty years the discourse on return has been dominated by an increasing attention on the refugee return to post-conflict areas, and it is worth mentioning the growing importance of gender perspective in research landscape.

Topic models applied to our textual data with the LDA algorithm provided the 17 topics that best describe our data. Each topic is defined by a string of words that are semantically connected, according to LDA model. We analysed 10 selected words among the top 30 words defining the topic and assigned a label to each topic. We than analysed relevance of each topic in the whole corpus.

In the overall period, the dominant topic focuses on cultural, ethnic and identity issues, defined by words related to diasporic communities and the difficult compromise between the need of preserving the own cultural identity and the need of getting integrated in the host society. The second dominant topic is the classical economic paradigm anticipated by the top frequent words, concerning skills, labour market opportunities and wage differentials, highlighting the rational benefit-cost perspective upon the possibility of return based on migrants' selection, skills, education, wage and returnees' prospects once back to their origin country (for temporary or permanent return). The third dominant topic is the topic on refugee and post-conflict return. From our results, lower attention has been paid to the topic of circular mobility in conflict areas, a topic mainly defined by a set of words related to specific territory and repeated border crossing between two "national states". Also, the topic of European migration flows, mainly related to internal temporary movement in Europe has attracted a lower interest compared to other topics.

Dividing the whole period in the above mentioned three subperiods, we presented our results starting with topics that have gained importance in researchers' works in the last 60 years. The most relevant topic in 2000-2020 concerns "Cultural, ethnic and political identity", marginal in the first period (dominant in only 3% of documents) but gaining importance in the last twenty years of the last century and dominant in almost the 16% of total document published in the last period considered. The second topic in terms of relevance in the last period (2001- 2020) is related to "Refugee and post-conflict return", experiencing a constant increase in relevance and dominant in the 13% of publications of recent years. As already reported, the topic of "Skills, labour market opportunities and wage differentials" has been relevant in the whole scientific production on return migration, but at the same pace of the growing importance of the neoclassical economic paradigm proposed by Todaro in 1969, it reached the maximum interest in the eighties, being dominant in the 15% of total publications of the period. It can be considered one of the most important topical focus also in the last 20 years, being dominant in the 13% of scientific publications. As anticipated by the top tokens cited in publications in the last period considered, the topic on "Gender, family and vulnerabilities" has gained growing importance in research already in the central period, following an increasing female migration flow, primarily from former Soviet Union Republics, and becoming crucial with the increasing process of family reunifications in "mature" host countries and the aging process and the subsequent higher need of caregivers in high income countries. The topic defined by words expressing a wider "Systemic approach and multiple focus", is dominant in a growing number of publications in the whole period considered, maintaining however a stable proportion of 10% of publications in which the topic is dominant in the three different periods considered.

As for topic that have experienced a vigorous decline in the interest received from the scientific community, we first mention the topic on "South-North migration, Africa and demographic imbalances", which appears to be the most discussed between 1960 and 1980, dominant in almost the 28% of researches published in that period. In recent decades, instead, the topic has been the focal point only in

the 3% of publications. Such decline in relevance could be partially explained by the persistent lack of consistent data in African countries, discouraging researchers always seeking for large-scale data to conduct robust quantitative analysis. Another reason could be the growing complexity of migration phenomena, the consequent questioning of the "South-North" migration model and the growing attention referred to emergent "South-South" mobility patterns. The topic identified as "Rural-urban mobility" and mainly referring to the context of rural Asian countries, has also experienced a sustained and constant decline, being dominant in 15% of publications in the sixties and only in the 7% in the beginning of the millennium. Same destiny has the topic on "Economic-differential and cost-opportunities assessment", with declining dominance from 10% to 4% of total publications in the whole period. This lower interest in a topic defined by words that are key points of the New Economics of Labour Migration approach (NELM), can be interpreted as an overcome of the classical view of return migration as the logical outcome of a "calculated strategy" in favour of a greater attention toward new paradigms focused on identity and cultural issues, transnational practices and social network effects on return's decision-making process. An expected result is the decline of interest in the topic related to "EU migration flows and temporary/permanent stay", dominant in only 1% of recent publications. The first 10 selected words suggested a focus on mobility occurred in the last half of nineteenth century, presenting very different characteristics from nowadays migration patterns in terms of migrants' selection, education and skills, information and opportunities, migration policies and mobility in Europe, social networks and family settlement. However, understanding what happened to guest workers migrated to European countries in that period could be of great importance to understand present patterns of aspirations to return.

The topic of "Education/qualification opportunities and high skilled mobility", attracted a small interest in the eighties, probably because of the average higher proportion of unskilled migrants, but regained importance in last 20 years. The same trend is shown for the topic of "Eastern to Northern Europe migration", probably related to old migration pattern, not highly representative of current situation. And also, the decline in relevance of the topic on "Optimal strategies, return/ onward mobility" can be explained with an overcome of the neoclassical and the NELM paradigms.

Lastly, marginal topics in our dataset, meaning dominant in less than 3% of the publications from the first to the last period are "Circular mobility in conflict areas", "Southern Asia-Pacific labor migration", "Socialization, linguistic skills and integration", (Higher education mobility and opportunities".

5. Conclusions and further development

Topic modelling provides an affordable way to classify scientific papers and discover hidden characteristics of documents in a corpus of text. However, natural language processing still needs expert's supervision and interpretation and, in some cases, the full interpretability of topics can be challenging. Also, the way of indexing publications with meta-data and keywords, the query selected for data retrieving, filters applied in data cleaning process and the authors' classification procedure are, intuitively, of fundamental importance for systematic review results.

We found consistent results with what has been highlighted by the scientific literature in the field and the evolution of international migration theories, keeping in mind that ongoing processes of social transformation will perpetually create the need for theoretical innovation (de Haas 2021).

Our results clearly show the dominance of receiving countries in the knowledge's production of return migration, stressing the need of sending countries perspectives on return prospects of reintegration and effective returnees.

Moreover, the number of topics identified and the evolution of their relevance in time, suggests an over-fragmentation of the field and the need for a more comprehensive, wider social-scientific perspective, supported by an historical-comparative approach, which is completely absent in our dataset of publications.

The aspiration-capability framework and the conceptualization of return capability within the interaction between structural constraint (macro and meso-level factors) and agency are "great absents" in the scientific field.

With the increasing role of both emigration and immigration states in controlling and managing migration and return, as suggested by literature (de Haas et al. 2019, Hollifield et al. 2014, Waldinger 2015, Cassarino 2004) we suggest the relevance of the focus on how changing political contexts influence the possibility of return and reintegration experiences of returnees.

Our results also suggested that lower attention has been paid so far to the development of concept of

return in terms of intrinsic aspirations (subjective: identity, perceptions, networks and ties), instrumental aspirations (objective: costs/opportunities, policies and external factors) and effective capabilities, as mainly stressed by Carling and others (Carling, 2002; Carling and Petersen, 2014; Carling and Schewel, 2018; de Haas, 2014).

We finally reported the need of more attention on emerging migration patterns, such as the possibility of return for climate and environmental refugees, as well as the relevant question on what the age and gender composition of migrants' population can tell us about their probability of return, a topic that can be further investigated with the exploitation of decomposition and microsimulations techniques.

The allocation of time within native and foreign couples living in Italy

Giovanni Busetta[a], Maria Gabriella Campolo[a], and Antonino Di Pino Incognito[a]

[a]Department of Economics, University of Messina, Via Dei Verdi 75, 98122 Messina; gbusetta@unime.it, mgcampolo@unime.it,dipino@unime.it

Abstract

The empirical analysis of the intra-household allocation of time suggests that female labour market participation in Italy is lower than in other European countries. Conversely, the contribution in terms of domestic work and childcare by Italian men is very low. Studies found that the gender gap in time allocation strongly depends on the traditional social norms, and on the cultural background of the subjects. The aim of this paper is to investigate if people resident in Italy but born in other countries, suffer from the same decision-making process of Italian families, involving a gendered division of roles in the intra-household allocation of time. Using the Italian Time Use survey 2013, a Seemingly Unrelated Regression Estimation model of paid and unpaid work, leisure and personal care, is estimated to compare couples in which both partners have Italian nationality with couples in which at least one partner is an immigrant.

Key words: allocation of time, households, natives and immigrants, SURE

1. Introduction

The empirical analysis of the intra-household allocation of time has had a remarkable growth in re-cent years with the increase of interdisciplinary studies that affect the economic, demographic, social and statistical area. Studying the use of time and, therefore, different ways of allocation of time, we analyse a plurality of phenomena which are interconnected with each other. National and international literature suggests that Italy is characterized by a low rate of female participation in the labour market compared to most of the European countries (Mangiavacchi and Rapallini, 2012), especially considering the subsample of mothers with young children (Anxo et. al, 2011).

Several studies have confirmed that the birth of a child revolutionizes the allocation of time with-in the family, with an increase of the time dedicated to paid work by fathers and a decrease in that of mothers who, at the same time, increase in domestic and childcare activities (Anxo et al., 2011; Bloemen et al., 2010; Campolo and Di Pino, 2012; Campolo et al., 2016; Del Boca and Vuri, 2007).

Failure or difficult to access to the labour market, as well as the difficult reintegration after the childbirth, makes the women economically disadvantaged and most vulnerable to poverty. Only 30% of them, in fact, continue to work after the childbirth (Del Boca and Rosina, 2009). In addition, the unequal distribution of domestic work and the division of gender roles begins in the family of origin, and it passes on from generation to generation (Del Boca et al., 2012). Intra-household allocation of time is usually affected not only by the bargaining power of the partners, but also by social contexts and norms, cultural and family background. For this reason, one could wonder whether immigrants residents in Italy suffer either from gender roles imposed by Italian families, or from the ones of their country of origin.

The aim of this work is to analyse whether factors characterizing the intra-household division of labour of Italian couples (i.e., couple in which both partners are Italians), are the same explaining the reasons underlying gender differentiations within foreign couples (i.e. couples in which both partners are foreigners), or mixed couples (i.e. only one partner is Italian). Deeply, we want to understand whether standard theoretical models predicting immigrant wives' housework time are comparable with to the one operating in native-born and mixed couples, as immigrants usually tend to show more traditional gendered division of labour (Blau et al. 2020)

Throughout the specification of a Seemingly Unrelated Regression Estimation Model (SURE), we jointly estimated the time spent by men and women in different kinds of activities. To do so, we used data coming from the last survey of ISTAT "Use of Time 2013". To do so, we distinguished data in two subsamples: one formed only by Italian couples and the other formed only by foreign-born or mixed couples. The results obtained from an analysis of time use may be supportive not only of the development and support of policies for family/work conciliation, removing obstacles that makes women and foreign-born economically disadvantaged, but also of policies to encourage other kind of activities as leisure time. As shown by Hamermesh and Trejo (2013), the leisure time, in fact, includes both socializing activities, carried out in company and non-socializing activities. To this regard, a (provisional) result obtained from our analysis shows how the female partners of foreign and mixed couples reduce the frequency of contacts with friends to devote more time to housework.

In particular, the socializing activities allow a social integration of the immigrant into the social mainstream of the country in which he lives (Depalo et al., 2007). To incentive foreigners to spend their time socializing could be a way to make them less alone and less exposed to the risk of poverty in a foreign country, as "the allocation and efficiency of non-working time may now be more important to economic welfare than that of working time" (Becker, 1965).

2. Data and methods

The study sample was drawn from the 2013 Use of Time Survey carried out by Istat with the time diary method. The diary method is an important instrument that allows to investigate how people organize their days and the relationship between the different timing of the same family's members with an extremely high level of accuracy.

The sample is formed by 12727 Italian couples and 1183 foreign couples in working age.

The aim of this analysis is to compare how Italians and foreigners manage their daily lives and examine whether there are significant differences. Unfortunately, we cannot focus the analysis on the country of origin, because in the Use of Time survey, the only information that can identify ethnic origin is the nationality (Italian or foreign). From the answer to this question, we can identify couples in which both partners are Italians (IC = Italian Couples), both or only one of them is foreigner (FC = Foreign Couples). We performed our analysis not only at the individual level but also at familiar one, as our final goal is the joint estimation of the time spent by the partners in paid and unpaid work, personal care and leisure, considering the latter both as aggregating and not aggregating activity.

The different activities have been grouped into the five following sectors: 1) Paid work (including main and secondary work, break, job search); 2) unpaid work (including housework; family care: washing, cooking, cleaning, gardening, pet care, shopping, care and support to adults in the family, repairs; and child care: physical care, help with homework, play and accompaniment); 3) Personal care (sleeping, eating, or other activities; 4) Media Leisure (TV, radio, reading books and magazines); 5) Non Media Leisure. About this last activity, according to the distinction suggested by Robinson and Godbey (1997), it includes both informal leisure activities which allow an exchange of feelings and opinions (socializing, conversations, sports, and hobbies), and formal activities that allow, however, a cultural development of the individual (voluntary work, aid to other families, social participation and religious, adult education, cultural events).

To estimate simultaneously the time spent from both partners in these five groups of activities, a SURE model of ten simultaneous equations (five for each partner) was implemented. Our assumption is that the time spent on each activity by the subject, and specified as a dependent variable, depends also on the time spent by his/her partner. Therefore, the specification of the system of equations SURE (Campolo, 2012; Campolo et al., 2016; Zellner, 1962), is based on the assumption that de-pendent variables are jointly related and depend on common factors usually not observable. The joint correlation

between dependent variables can be formalized by modeling the error terms of the five model equations for men and women, considering separately Italian and foreign couples (ε_W, ε_D, ε_P, ε_{NM}, ε_M).

In particular, at the first stage of our model, we estimated the five equations using a Tobit model, which allows us to estimate dependent variables also in case of censoring. At the second stage, we used the residuals terms of the five regressions iteratively to estimate the cross-correlation between errors of the individual equations, considering also that we simultaneously estimate both activities performed by the same subjects, and also those carried out by partner. The estimated cross-correlations between residuals of the ten equations (5 equations for men and 5 for women), will be used as correction terms for the dependent variables. We used the same procedure separately for Italians couples and foreign and mixed couples (where one or both partners are foreigners).

The demographic explanatory variables used to explain different ways of allocating time among men and women in Italian and foreign couples, include: the age of the subject (Age); if the subjects in the couples are married or cohabiting (Married: 1= yes; 0=otherwise); where he/she lives (South or Islands: 1=Yes; 0=otherwise); the level of education expressed in years of schooling; the working status (1=no work as reference; 2=part time; 3=full time); an index concerning the housing space (House Index) calculated as the ratio between the number of rooms and the number of components. Moreover, to evaluate the relationship with neighbors and the territorial context, we considered two dummy variables, indicating the level of integration with the surrounding environment and the opportunity for the individual to weave the networks of relationships outside the family: a dummy variable about the frequency of contacts with friends (Friends = 1 if subject meet his/her friends during free time at least once a week, and 0 otherwise), and a dummy variable about the level of trust in others (Trust: 1=most people are trustworthy;0=otherwise). A dummy variable about the level of stress (Stress=1 if the subject feel always or often stressed, 0 otherwise), the general level of life satisfaction (Satisfaction: score 0-10); a categorical variable about the satisfaction of the economic situation (Economics: 1 = not at all as reference; 2= little; 3= quite; 4= much).

3. Results

Our econometric model specification allows us to jointly estimate five different activities concerning the use of time, considering men and women in couple (married or cohabiting). Moreover, in a comparative perspective, we have estimated the same model separately for Italian and mixed couples (where at least one of two partner is foreigner). The unobservable correlations within the ten equations (five for each partner) are then simultaneously estimated for both types of couples.

By comparing coefficients, it is possible to identify a first significant difference in the distribution of time within Italians (Tab. 1) and foreign or mixed couples (Tab. 2).

Results on individual's age show a negative and significant effect only for women both for paid and unpaid work, while it does not show any statistical significance for men. The time devoted to personal care also decreases for women with ages, while the same does not happen for men.

As predictable, having both a part and a full-time job, increases the time spent in paid work and decrease the one spent in personal care and media and non-media leisure both for men and women. Less predictable, it increases also the time spent in unpaid work both for men and women. Being stressed increases the time spent in paid work for men and in paid and unpaid work for women, while it does not affect the time spent in unpaid work for men. Finally, life satisfaction is negatively correlated to paid and unpaid hours of work and positive correlated to media leisure both for men and women. Years of schooling reduces the number of hours spent both in paid and unpaid work for both men and women, reduces the time spent in personal care for men and increases the time spent in media leisure for women (Table 1).

We are not able to exclude the possibility of an inverse causality between stress and use of time and life satisfaction and use of time, because this result risks being affected by endogeneity problems.

Concerning foreigners and mixed couples (Table 2), similar results are obtained for the relationship between, part- and full-time job, and the time spent in paid and unpaid work both for men and women.

An opposite result is shown instead in terms of the relationship between ages of individuals and time spent in paid work, which used to be significant in the previous case only for women and is instead only significant for men in the present case. It means that foreigners men or men living in mixed couples tend to decrease the hours spent in paid work becoming older while the same does not happen for women in the same situation. No relationship appears mixed or foreign couples on respect to stress and life satisfaction. Different from the previous analysis, having friends decreases in this case the

amount of paid and unpaid hours of work for women. Years of schooling increases the number of hours spent in unpaid work for men and decreases the number of hours spent in paid work for women.

4. Conclusions

National statistics available confirm that in most cases foreigners come to Italy for work reasons and tend to settle in areas that offer more job opportunities. Notwithstanding our estimates confirm this trend, foreign women appear to be less active both at home and outside if they live in the Centre and North just like Italian ones. On the contrary, their male partners are less active only in paid work in the same situation, both in cases of Italian couples than foreign or mixed. Analysing Italian couples, however, the contraction of media and non-media leisure time is often determined by stress for men, while for women is determined by stress only the contraction of non-media leisure. Considering foreign and mixed the same does not happen for both media and non-media leisure neither for men nor for women.

Consider now the effect of the education level. While education plays an important role in the distribution of women's time in Italian couple (negative for paid and unpaid work both for men and women, negative for personal care for men and positive for media leisure time for women), for women in foreign couple or mixed, however, the greater the educational level the less time is devoted to non-media leisure, while a positive and significant correlation appears with unpaid work and non-media leisure for men, and with media leisure for women. An inverse relationship, for men and women in mixed couples, is observed in estimating relationship between unpaid work and frequency of contacts with friends. The opposite occurs, in-stead, for natives.

Abstract

The fertility differential of foreign women in Italy has decreased considerably over the years and it is expected to decrease even more over time but, despite this, the role of foreign children in slowing the decline in births remains crucial.

This study aims to further the debate on the fertility of migrants, providing an estimate of the fertility rates among foreign nationals at the provincial level over the past two decades. We intend to analyse the evolution over time and space of the contribution to fertility by foreign female citizens, investigating the determinants of their fertility behaviour and identifying differences and similarities with Italian female citizens.

Keywords: Migrants' Fertility, Italy, Foreign woman, Fertility, Employment level.

1. Introduction

Although fertility gaps within the same territory are frequent in many countries (Frejka, Sobotka 2008), there are few analyses exploring the subnational level in Europe and especially in Italy (Vitali, Billari 2017; Campisi et al. 2020).

Italy is constituted by very heterogeneous territories in terms of geographic, socioeconomic and demographic characteristics (Reynaud et al., 2020) and fertility levels differ considerably both at the level of rural or urban territories and by geographical distribution (Zambon et al. 2020).

Despite the extensive research in the field of migrant fertility examining the relationship between migration and family and reproductive dynamics (Landale 1997; Toulemon, Mazuy 2004; Cooke 2008; Milewski 2010), to our knowledge, there is no analysis to date that explores the subnational level with regard to the fertility of foreign female citizens.

The contribution of this paper is precisely to fill this gap in the literature.

We aim to estimate the age-specific and total fertility rates of foreign women in Italy, disaggregated by citizenship (for the five main citizenships), at a provincial level.

2. Fertility of foreign women in Italy

On 1st January 2022, more than 50% of the foreign female population resident in Italy came from Romania, Albania, Morocco, China and Ukraine. These five groups are characterised by different levels of maturity in the migration cycle. Foreign female residents are on average a younger population than the Italian female one and have contributed to slowing the decline in births, due to a significant presence at fertile age, a younger average age at childbirth and a fertility rate almost close to replacement level.

The share of foreign children in the Italian birth rate remains crucial. Due to the composition of the presence, it is not surprising that the highest number of foreign children recorded in the national registry is Romanian (14,248 born in 2020), followed by Moroccan (9,991) and Albanian (8,082). These citizenships represent about 40% of births to foreign mothers residing in Italy. As regards other citizenships, a non-negligible contribution comes from other African communities (in particular Egyptian and Tunisian nationals) and several Asian communities (in particular from India, Bangladesh, China and Pakistan).

As for Italian nationals, the fertility of foreigners shows territorial differences: the fertility rate is 2 children per woman in the North, 1.65 in the Centre and 1.86 in the South. (ISTAT, 2020)

Although the gap with the fertility rate of Italian women (1.17 in 2020) remains considerable, the reduction experienced by foreign female citizens in the last ten years has been sharper (-18% for the TFR of foreign women and -12% for the TFR of Italian women since 2010).

Numerous studies underline how the convergence of Italian and foreign women's reproductive behaviour is determined by social, political, cultural and employment conditions in the host society (Alba, Nee 1997; Carter 2000). In this context, several works stress the importance of the growing propensity of foreign women to work, mostly in the family service sectors with great variability linked to nationality and migratory background (Gabrielli et al. 2007; Lübke 2015; Sobotka 2008).

3. Data and methods

This research is conducted as part of a curricular internship at ISTAT, carried out in the context of the EMOS (European Master in Official Statistics Workshop) programme, on "Estimating the fertility of the cohorts of women resident in Italy by citizenship in the years 2002-2020", within the framework of the doctorate in the School of Statistical Sciences, Demography curriculum, at La Sapienza University of Rome. Starting from the ISTAT births database, which contains data on all women who have had at least onechild registered in the registry office since 1999, total and age-specific fertility rates were constructed for Italians and foreigners and for the five main citizenships in Italy (Romanians, Albanians, Moroccans, Chinese, Ukrainians). These indicators were then validated to provincial detail.

4. Preliminary results

Figure 1 displays age-specific fertility rates for the total, Italian and foreign female population at national level and by macro-areas. Foreign nationals realize their fertility behaviour earlier than Italians and with higher rates but, compared to 2010, in 2020 they experienced a greater reduction in number of births and a stronger postponement. The underlying area between the age specific rate of the total population and that of the Italian population reveals that the contribution of foreign female citizens, both in 2010 and 2020, is lower in the South than in the rest of Italy. This depends on several factors: the lower fertility rate experienced by foreign nationals in the South compared to North and Centre, their older age structure (explained by looking at the prevailing nationalities in the different macro-areas) and also on the fact that in the south, as we have already pointed, there are precisely fewer foreigners present and therefore their contribution is lower when calculating the rate of the total population.

The provincial detail of the total fertility rate (figure 2) reveals how despite a certain heterogeneity between the geographic areas, there is a clear homogeneity between the various levels of fertility of Italian provinces in the different macro-areas.

The provinces reporting a high total fertility rate for foreigners are mainly in the North, with the exception of some Sicilian provinces. The lowest rates are instead concentrated in the Centre, in some provinces of the South and in Sardinia.

Although the fertility of foreigners follows the trend of that of Italians, the data indicate a fertility differential present in almost all the provinces of the North and the Centre but limited in the South.

The five communities examined, although they have all experienced widespread fertility declines, differ in their levels of fertility in their countries of origin. In 2020 TFR ranges from 1.2 in Ukraine to 2.4 in Morocco. Except for the latter case, while remaining higher than that of Italian nationals, the TFRin the countries of origin lies below the replacement level.

One of the factors explaining the low fertility rate of foreign women in Italy is their origin mainly fromlow fertility countries.

Concerning Romanian migrants, we found that they have a lower fertility rate than non-migrant women,confirming previous research (Mussino, Cantalini, 2022).

One of the most original results that emerged from our study is the higher fertility of Albanian and Moroccan citizens in Italy compared to both those who remained in the country of origin (table 1) and to native Italians (figure 3). The analysis of the socio-economic characteristics, labour market integration and attitudes of these communities allowed us to hypothesise explanations for this result.

5. Conclusion and further developments

This preliminary work introduced the relevant literature on migrants' fertility, presented a syntheticpicture of the foreign presence on Italian territory and of the characteristics of the different nationalities, and illustrated a selection of the descriptive results obtained.

The paper will be implemented with linear regression models to analyse the relationship between fertility behaviour and socio-economic and contextual factors, as well as to identify differencesbetween Italian provinces.

ESG, sustainability and stock market risk

Michele Costa[a]

[a]Department of Economics, University of Bologna; michele.costa@unibo.it

Abstract

In this paper we aim to investigate the relationship between ESG score and assets characteristics, focusing on volatility. We classify stocks on the basis of high/low ESG score and we evaluate ESG effects by measuring the distance between the 2 group distributions. The analysis of stocks in the STOXX 600 Index from 2017 to 2021 suggests that companies with higher ESG outperform companies with lower ESG, also allowing to highlight COVID related effects.

Keywords: Sustainable finance, ESG, Stock market risk, Volatility

1. Introduction

Environmental, Social and Governance (ESG) score represents the most widespread and used indicator to evaluate the sustainability dimension of a company and it is the key factor to assess the sustainability impact of an investment in a company. Over the last years we are facing a significant shift in capital markets perception toward corporate sustainability, which has fueled a growing empirical and theoretical literature.

In this paper we aim at investigating the relationship between the ESG score and the risk of a stock, with the purpose to contribute to the debaate on the relevance and the effectiveness of ESG indicators and to explore and assess the role of ESG.

The relationship between ESG and assets characteristics is multi-faceted and not straightforward (1; 2; 4; 5). On one hand, companies with high ESG could have stronger risk mangement practices, which could contribute to a lower volatility, on the other hand, ESG score represents only one element of the overall risk profile, which certainly depends on a variety of factors. There are also different ESG metrics and their effect on asset characteristics may not be uniform.

We add inequality decomposition methods to the tools used to evaluate the effects of ESG scores, so as to combine distribution-based assessments with traditional assessments based on synthetic indicators such as averages. An analysis of the companies included in the STOXX Europe 600 Index points to a link between higher ESG and lower volatility, with, however, companies with high ESG mostly affected by effects related to the COVID19 pandemic.

2. Methodology

We address che relationship between ESG score and asset characteristics as a classification problem. Given n assets, in order to classify them into 2 groups, we introduce a $n \times 1$ vector Z

$$Z = \begin{cases} z_1 & \text{with } z_1 = 1 \text{ if } ESG < p_1 \\ z_2 & \text{with } z_2 = 0 \text{ if } ESG \geq p_2 \end{cases} \tag{1}$$

where, for $p_1 = p_2$, e.g. when using the median of ESG score, all n assets are considered, while for $p_1 \neq p_2$, e.g. when the ESG quartiles are considered, it is possible to refer to a part of the assets only.

With the aim to evaluate the relevance of ESG score and its effects on volatility, we thus define two groups of assets on the basis of a high / low ESG score level, thus tracing the assessment of ESG-related effects to the comparison between two distributions.

Our traditional starting point is given by the synthetic evaluation provided by the difference between the group means. Our purpose is to add to the information derived from the group means, the information provided by the comparison of the group distributions.

We compare the volatility distribution of groups High and Low: when the two distributions perfectly overlap, the ESG score does not affect the assets returns, while, for decreasing overlapping levels, the influence of ESG score on asset volatility increases. When groups High and Low do not overlap, the influence of ESG score reaches its maximum and assets are perfectly classified on the basis of their ESG score.

In order to evaluate the distance between the distributions of groups High and Low, as well as to take into account their overlapping, we resort to the decomposition of an inequality indicator, thus allowing to effectively compare different groups.

We refer to one of the most used and widespread inequality measures, the Gini index, for which many different decompositions have been proposed. Among the many contributions we use the Dagum's Gini index decomposition (3), which allows to explicitly take into account the overlap between groups.

For the case of n assets disaggregated into 2 groups of size n_1 and n_2, with $n_1 + n_2 = n$, the Gini index can be expressed as

$$G = \frac{1}{2n^2\bar{y}} \sum_{j=1}^{2} \sum_{h=1}^{2} \sum_{i=1}^{n_j} \sum_{r=1}^{n_h} |y_{ji} - y_{hr}| \tag{2}$$

where Y is the assets characteristic being investigated, in our case volatility, $\bar{y}$ is its arithmetic mean, y_{ji} is its value in the i-th asset of the j-th group and, accordingly, y_{hr} is its value in the r-th asset of the h-th group. For the case $j \neq h$, let us define

$$(y_{ji} - y_{hr})^+ = max\{(y_{ji} - y_{hr}), 0\}$$

and

$$(y_{ji} - y_{hr})^- = max\{-(y_{ji} - y_{hr}), 0\}$$

such as

$$|y_{ji} - y_{hr}| = (y_{ji} - y_{hr})^+ + (y_{ji} - y_{hr})^-.$$

It is therefore possible to derive the expressions for the inequality between groups G_b and for the overlapping component G_o as

$$G_b = \frac{1}{2n^2\bar{y}} \left(\sum_{i=1}^{n_1} \sum_{r=1}^{n_2} (y_{1i} - y_{2r})^+ + \sum_{i=1}^{n_2} \sum_{r=1}^{n_1} (y_{2i} - y_{1r})^+ \right) \tag{3}$$

and

$$G_o = \frac{1}{2n^2\bar{y}} \left(\sum_{i=1}^{n_1} \sum_{r=1}^{n_2} (y_{1i} - y_{2r})^- + \sum_{i=1}^{n_2} \sum_{r=1}^{n_1} (y_{2i} - y_{1r})^- \right). \tag{4}$$

Inequality between G_b and overlapping component G_o allow to evaluate the contribution to total inequality attributable to the differences between the groups, that is, in our case, to the effect of ESG score.

The role of the two components is quite different. On one hand, an high (low) G_b indicates a relevant (slight) ESG effect, as total inequality is (is not) strongly influenced by inequality between. On the other hand, as pointed out above, an high (low) G_o suggests a slight (relevant) ESG effect, since complete overlapping corresponds to the absence of ESG effect, while $G_0 = 0$ (High and Low groups are perfectly separated) indicates a total stratification.

On the basis of the different meaning of G_b and G_o it is possible to derive an indicator of the relevance of ESG as $I_G = (Gb - G_o)/G$. A further indicator of ESG effects can be obtained by calculating the ratio between the means of the standard deviations in the two groups: $I_{\bar{\sigma}} = (\bar{\sigma}_L - \bar{\sigma}_H)/\bar{\sigma}_H$. When the two indicators show a similar trend, the information provided by the means is supported by the indications derived by the group distributions. In the opposite case, when I_G differs from $I_{\bar{\sigma}}$, the group means are not fully informative and it is important to also exploit information from group distributions.

Our method is extremely flexible and can be adopted to investigate different assets characteristics more than volatility. We can generalize our analysis, moving from the $n \times 1$ vector Z to a $n \times k$ matrix Z, where k is the number of characteristics analyzed and each column of Z is a $0, 1$ vector classifying the n asstes into two groups with respect a specific characteristic. Further possible generalizations concern employing more than two groups and weighing the different characteristics differently, always remaining within the same framework.

3. Data and results

We investigate the relationship between ESG and volatility of the stocks included in the STOXX Europe 600 Index, measured by means of the standard deviation of their returns. We employ monthly data ranging from 2017 to 2021, thus allowing us to also evaluate the presence of effects related to the COVID19 pandemic. Among the different ESG metrics available, we refer to Refinitiv methodology, fully aware that the use of a different metric could influence the results. An interesting future development could involve the joint use of multiple ESG indicators and the comparison of the deriving stock classifications, so as to analyze their effects on results. In order to classify the n assets into 2 groups we use both the median of ESG score with $p_1 = p_2$, and the case p_1 equal to the first quartile and p_2 equal to the third quartile.

Table 1 illustrates the results related to the two groups obtained by classifying the assets on the basis of the median of their ESG score (the results for the first and last quartile are quite similar). First we report the mean of the standard deviations of the assets in the two groups. We can observe how, from 2017 to 2021, the average of the standard deviations increases, with a peak in 2020 in correspondence with the COVID. The values of volatility in the group with lower ESG are steadily higher.

We assess the relevance of our results by developing a bootstrap procedure resampling assets from the original list according to an i.i.d. sampling with replacement. Table 1 includes the mean and the standard deviation of 10000 replicates of the bootstrap. The bootstrap mean is always equal or very close to the observed values; this element, together with the low values of the standard deviation, strongly supports our results.

The second part of Table 1 shows the ratios G_b/G and G_o/G which, by evaluating the weight of inequality between groups and of overlapping component on total inequality, allow us to obtain further information on the role of ESG scores. From 2017 to 2021 the relevance of G_b increases slightly, with the exception of the negative peak of 2020, suggesting a stronger ESG effect and a deep impact of COVID pandemic. The overlapping component also indcates, by decreasing, a stronger ESG effect, still except in 2020. Also for G_b and G_o the bootstrap results support our findings: the means of 10000 bootstrap replicates are always equal or very close to the observed values, with an almost negligible standard deviation.

The last part of Table 1 shows indicators $I_{\bar{\sigma}}$ and I_G which agree in suggesting an increase in the ESG effect over the last 5 years, together with detecting a strong impact of COVID pandemic. An interesting element arising from the comparison between $I_{\bar{\sigma}}$ and I_G highlights the dynamic after the pandemic: from 2020 to 2021, I_G shows a stronger recovery and, with respect to 2019, I_G indicates a more pronounced ESG effect, while $I_{\bar{\sigma}}$ suggests a slight decline.

Table 1: Mean of the observed standard deviations of the assets in group with High / Low ESG score; observed ratios G_b/G and G_o/G; mean and standard deviation of 10000 bootstrap replicates

	I_G	0.08	0.13	0.10	0.04	0.12	0.17	0.06

4. Conclusions

The analysis between ESG score and assets characteristics can be addressed in the framework of classification and can greatly benefit from using inequality decompositioni methods, able to also take into account the overlapping between group distributions. On the basis of these methods it is possible to exploit the information related to the entire distribution of the groups and not rely only on the group means.

We analyze the stocks included in the STOXX Europe 600 Index and refer to Refinitiv ESG score from 2017 to 2021. Our findinds support ESG as a positive driver of assets returns, with a relationship between higher ESG score and lower volatility. Covid pandemic strongly affected ESG effect, which was greatly weakeened in 2020, while a strong recovery can already be observed in 2021. The size of the recovery is stronger on the basis of I_G, that is when evaluating the entire group distributions.

The extreme flexibility of our proposal makes it possible to add other asset characteristics to the analysis, also considering them jointly, with numerous further developments, such as the possibility of more than two groups, capable of providing promising results and effectively including sustainability issues in stock market risk evaluation.

Abstract

In shifting towards a more sustainable food system, agri-food companies increasingly integrate sustainability into their innovation decisions and practices. However, their success depends on consumers' willingness to pay (WTP) for more sustainable food products and actual purchases. Key to this are government policies and companies' marketing and pricing strategies, for which understanding the interaction of factors driving food choices is essential. We use conditional logit in this work because the objective of the Discrete choice experiments (DCE) is to relate choice to the attribute levels used to define each profile in the choice task.

Keywords: Sustainability, Discrete choice experiment, Food, Consumers

1. Introduction

In shifting towards a more sustainable food system, agri-food companies increasingly integrate sustainability into their innovation decisions and practices. However, their success depends on consumers' willingness to pay (WTP) for more sustainable food products when they buy [1]. Abundant literature suggests that consumers pay significant attention to and declare WTP for sustainability-related attributes of packaged food products, such as eco-labels, fair trade, health and other claims and visual attributes, but these may not be the main drivers of consumer choices [2], [3]. There is a value-action gap (also called the attitude-behavior gap) that the complex interactions between different purchase priorities and perceptions may explain [3], [4]. To close this gap, government policies and companies' marketing and pricing strategies are critical, for which understanding the interaction of factors driving choices is essential.

In this study we used a Discrete choice experiments (DCE) that is a quantitative technique for eliciting preferences that can be used in the absence of revealed preference data. The method involves asking individuals to state their preference over hypothetical alternative scenarios, goods or services. Each alternative is described by several attributes and the responses are used to determine whether preferences are significantly influenced by the attributes and also their relative importance. DCEs have become a method increasingly used in food research to uncover trade-offs when choosing alternatives, particularly when exploring credence attributes, such as those related to sustainability [5].

2. Motivation

The paper makes an original contribution to the field of sustainable food systems by examining the factors that influence consumers' choices and willingness to pay for more sustainable food products. We argue that for agri-food companies to successfully integrate sustainability into their innovation decisions and practices, it is important to understand how consumers' choices are influenced by government policies and marketing and pricing strategies.

To achieve this, the paper uses a Discrete Choice Experiment (DCE) and conditional logit analysis to assess consumers' preferences and WTP for different attributes of sustainable food products. The results of the study provide insights into the relative importance of various attributes, such as eco-labels, product origin, and production methods, in driving consumers' choices.

The paper's original contribution lies in its use of DCE and conditional logit analysis to understand the factors that influence consumer choices and WTP for sustainable food products. This approach allows for a more nuanced analysis of the complex interactions between various attributes and their impact on consumers' choices. The results of the study can inform the development of effective marketing and pricing strategies for sustainable food products that are more likely to appeal to consumers. In addition, the original contribution comes from a unique, multi-national and representative database, providing important insights and empirical findings on how to bridge the gap between consumers valuing sustainable food and being willing to pay for it.

In summary, we analyzed the factors that influence consumers' choices and WTP for more sustainable food products. The study's results can inform the development of effective marketing and pricing strategies that promote sustainable food choices and contribute to the shift towards a more sustainable food system.

3. Methods

The analysis of DCE data typically involves regression models that have a dichotomous or polychotomous categorical dependent variable, such as a probit, logit, or multinominal logit specification. In its simplest form, the observed sources of utility can be defined as a linear expression in which each attribute is weighted by a unique parameter to account for that attribute's marginal utility. It is usual to specify the regression model in terms of differences in attribute levels between the choices being analyzed:

$$\Delta Y = \beta_0 + \beta_1(X_{1i} - X_{1j}) + \beta_2(X_{2i} - X_{2j}) + \cdots + \beta_k(X_{ki} - X_{kj}) + (\varepsilon_i - \varepsilon_j)$$

Moreover, as respondents are asked to consider multiple choice pairs, it cannot be assumed that the error terms are independent and panel data estimation techniques are required. The estimated parameters represent the marginal utility associated with a change in the attribute level in moving from one alternative to the other.

This work will assist researchers in evaluating and selecting among alternative approaches to conducting statistical analysis of DCE data.
We first present a DCE example and a simple method for using the resulting data.
In this study, we use a survey of more than 20 000 individuals evenly split across ten European countries to explore whether purchase motives are reflected in food choice decisions. Consumers undertook a Discrete Choice Experiment with packaging elements as varying attributes in six food products (instant coffee, crisps, baby food, fish fingers, chocolate and yoghurt) and an online experiment where they identified packaging elements that led them to believe products were different concerning sustainability aspects (i.e. environmental sustainability and healthiness) among others. Then consumers identified the three most important motives when purchasing food. In the analysis, we combine these three information sources for the same individual to see whether consumers declaring sustainability is the most important factor when buying food attach higher utility to packaging elements informing them of significant differences in sustainability between products (i.e. packaging elements conveying product sustainability).
For this, the experiment presented product pairs as front-of-pack pictures of hypothetical branded product versions. They differed across eight potential design elements, including claim or logo-type attributes (taste, quality, origin, recipe) which can be either present or absent, and package design variants (product description, background colour, picture and positioning of the picture) which can take one of two options. The purchase decision (DCE) choice set followed an efficient design, resulting in 12 choice situations. As each choice card had two options, this yielded 24 different images per product. The 12 choice cards were blocked into six groups of two, and each individual saw a group for each of the five products. The choice set for eliciting perceived product differences (i.e. environmental sustainability and healthiness) was created manually to capture choice pairs with variations in the number of elements differing between options in the choice cards. In both experiments, the choice set block and order of products were randomised across individuals.

3.1 Conditional Logit

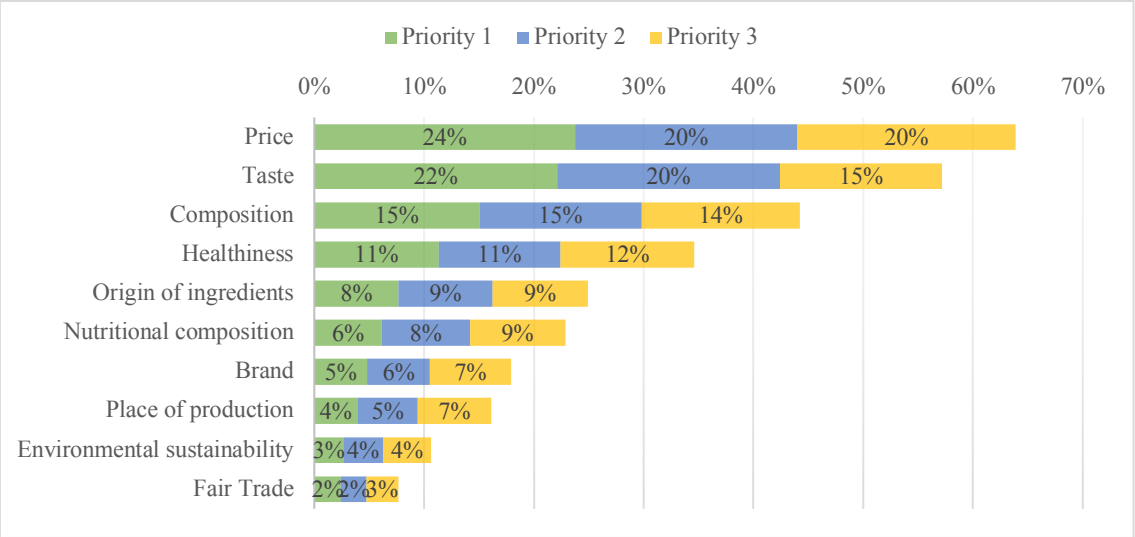
Choice data from a two-alternative, forced-choice DCE as described in several examples are most often analyzed using a limited dependent-variable model because the left-hand-side variable in the regression is typically a 1 for the alternative that was chosen in a given choice task or a 0 for the alternative that was not chosen in that choice task. The basic limited dependent-variable method used to analyze data generated by this type of experiment is conditional logit. Conditional logit relates the probability of choice among two or more alternatives to the characteristics of the attribute levels defining those alternatives. In a DCE, the elements describing the alternatives are the attribute levels used to define each profile in the choice task. Conditional logit was shown by [7] to be consistent with random utility theory. The novelty in McFadden's use of the logit model is that he applied this model to choice behavior that was consistent with economic theory and derived a regression model that relates choices to the characteristics of the alternatives available to decision makers. McFadden used the term "conditional logit" to describe this innovation.
McFadden originally applied this framework to observed transportation choices. His work laid the foundation for what is now known as conjoint analysis [8] involving hypothetical or stated choices. Using random utility theory, the utility associated with an alternative or profile is assumed to be a function of observed characteristics (attribute levels) and unobserved characteristics of the alternative. This theoretic framework also assumes that each individual, when faced with a choice between two or more alternatives, will choose the alternative that maximizes his or her utility.
We use conditional logit in this work because the objective of the DCE is to relate choice to the attribute levels used to define each profile in the choice task. The conditional logit model can be executed by using the function clogit() that is included in the survival package. Frequently,

in order to consider the effects of individual characteristics on the valuation of attributes, the interaction between individual characteristics and attribute variables are included in the model.

4. Results

The results in Figure 1 show that, consistent with other surveys, consumers prioritise price (64%) and taste (57%) over sustainability concerns when purchasing food. Regarding sustainability dimensions, health (34%) is more important than the environment (11%) when shopping for food.

Table 1. Declared top three consumers' food purchase motivations.



We run logistic regressions for the two dichotomous variables capturing whether consumers perceive differences in product environmental sustainability and healthiness [6]. Our independent variables capture whether there is a difference in each of the design elements. We also include controls for product, country and socio-demographics.

Table 2 Effects of variations in packaging attributes on consumers believing product versions differ in sustainability-related product characteristics.

	Front-of-pack elements							
Product characteristics	**Recipe claim**	**Colour**	**Image position**	**Origin of ingredients**	**Taste claim**	**Quality logo**	**Image**	**Product description**
Healthiness	-0.073	-0.18***	0.042	0.068**	0.034	0.051	0.038	0.016
Sustainability	-0.088	-0.055	-0.069**	0.25***	0.095	-0.090*	0.14*	-0.073*

Robust standard errors in parentheses clustered at the level of respondent ID
*** p<0.01, ** p<0.05, * p<0.1
Note: A positive (negative) and significant coefficient means that consumers perceive the attribute signals (does not signal) the specific product characteristic. A non-significant coefficient means that the attribute does not affect the perception of the specific product characteristic. We retain the information from those coefficients significant at $p < 0.05$
Source: Solano-Hermosilla et al. (2023)

The DCE results show that consumers' purchasing behaviour aligns with their stated motives, as they are willing to pay more for attributes that signal their motivations and less for those that do not. However, interaction with the importance of prices partly masks this for environmental

sustainability but not healthiness. It partly explains the lack of correspondence between declared motives and actual choices.

The study results are expected to help policymakers and agri-food companies design labelling and marketing and communication strategies, as well as possible interventions to affect what consumers value and moderate the relationship between what they value, perceive and buy based on consumer responses and decisions. Further research can explore heterogeneity of results across products and

and human-centric design principles in their AI development strategies. New business models will also emerge, such as AI-as-a-service, which will enable companies to access AI technologies without the need for significant upfront investments in infrastructure and expertise. Ultimately, the future of AI is likely to be characterized by both exciting advancements and new challenges, and it will be essential for businesses and society as a whole to navigate this evolving landscape carefully.

The use of new artificial intelligence and machine learning models such as ChatGPT, a prototype chatbot for natural language processing, has implications for sustainability [13]. ChatGPT uses advanced machine learning algorithms to generate responses that are similar to human responses. While AI can help corporate sustainability professionals in various ways, such as data analysis and processing large amounts of data, there are also concerns about the carbon footprint of running ChatGPT2. However, ChatGPT can also help forward-thinking brands enhance their sustainability efforts by improving supply chains and gathering ESG and sustainability data [11]. Overall, using AI and machine learning models like ChatGPT can have both positive and negative impacts on sustainability, and it is essential to consider these implications when implementing such technologies.

The text in the paper was created using a tool developed by OpenAI based on the GPT-3 model, which generates text and code embeddings. The authors then revised the text using a text-similarity approach and verified its features using a human-in-the-loop approach. GPT-3 embeddings can be used for text similarity, semantic search, classification, and clustering. However, some argue that large language models like GPT-3 do not generate the best semantic textual insights [4].

Abstract

This research paper was created to tackle the issue of sustainability by exploiting new artificial intelligence and machine learning models such as ChatGPT, a prototype chatbot for natural language processing which, thanks to advanced machine learning algorithms, can generate responses that are completely similar to human responses. The texts in this paper were created by the tool developed by OpenAI based on the GPT-3 (Generative Pre-trained Transformer 3) model and subsequently revised by the authors who, using a text-similarity approach, duly verified their features using a human-in-the-loop (HITL).

Key words: ChatGPT, HITL, text-similarity, UN 2030 Agenda, Sustainable Development

1. Introduction

In recent years, artificial intelligence has undergone a rapid evolution that has led to a greater capacity for processing and reproducing natural language. This has been made possible by the use of increasingly complex deep learning models, such as recurrent neural networks (RNNs) and training systems on large amounts of text.

A concrete example of these state-of-the-art systems is OpenAI's GPT-3 and Google's BERT, which can understand and produce text with remarkable accuracy. The Generative Pre-trained Transformer architecture is the basis of ChatGPT, a prototype chatbot that allows users to discuss with the AI by making suggestions based on OpenAI's language model [5].

This development has led to a greater ability for computers to understand natural language and has opened the way to many new applications and opportunities in the fields of communication, machine translation and virtual assistance. This paper aims to showcase the potential of scientific text creation using ChatGPT from the perspective of HITL, which, as we mentioned earlier, is a prototype humanoid chatbot developed on the GPT-3 model which is nothing more than an artificial intelligence model trained on a corpus of more than 45 terabytes of text and which uses a recurrent neural network that enables it to understand and use a wide range of languages and to generate sophisticated text indistinguishable from that produced by a human [3]. The public datasets used as training data for the GPT-3 model include:

- Common Crawl, a vast archive of web data collected periodically by the Internet Archive that includes

websites, blogs and other online content;
- WebText2, a dataset of online conversations collected from sources such as Reddit, Twitter and other social media;
- Books1 and Books2, which are datasets of books and novels;
- Wikipedia, the famous online encyclopaedia that provides information about the real world.

To understand the potential of ChatGPT, we, therefore, asked the chatbot to describe itself, obtaining the following answer: "ChatGPT is a language model developed by OpenAI that uses artificial intelligence technology to answer user questions and generate text. ChatGPT is based on the GPT-3 (Generative Pre-trained Transformer 3) model and uses a recurrent neural network to understand natural language and generate coherent, understandable answers [6]. The model has been trained on large amounts of text and conversation data, making it capable of answering multiple questions and understanding multiple contexts. ChatGPT has been used in many applications, including chatbots, virtual assistants and machine translation systems, and is becoming increasingly common as a solution to help companies interact with their customers in a more efficient and personalised manner." To find out whether the information found online on ChatGPT was true and correct, we, therefore, asked the chatbot to describe what datasets it had been trained on, finally obtaining the following answer: "I have been trained on a large dataset, which includes a large amount of text from multiple sources, including newspaper articles, novels, online conversations, websites and more. The model was trained on a corpus of over 45 terabytes of text, enabling it to understand and utilise a wide range of languages and generate coherent, understandable text. Among the datasets used to train me are Common Crawl, WebText2, Books1, Books2 and Wikipedia. Common Crawl is a vast archive of web data collected periodically by the Internet Archive, which includes websites, blogs and other online content. This dataset is important because it provides an authentic, real-time representation of conversations and information on the Internet. WebText2 is a dataset of online conversations collected from sources such as Reddit, Twitter and other social media. This dataset provides a deep understanding of the informal language used in online conversations and the context in which certain words and phrases are used. Books1 and Books2 are datasets of books and novels. These datasets are important because they provide a representation of formal language and narrative contexts. These datasets were used to train the model and provide ChatGPT with an in-depth understanding of formal language and narrative contexts. Finally, Wikipedia is a famous online encyclopaedia that provides information about the real world. This dataset is important because it provides an understanding of the language used to describe events, places, people and more. Together, these datasets provide ChatGPT with a broad and deep understanding of natural language and context. With this vast database, ChatGPT can answer a wide range of questions and generate coherent and comprehensible text. This makes ChatGPT one of the most advanced AI (artificial intelligence) models in the world, capable of providing reliable information and helping companies interact with their customers in a more efficient and personalised way." The aim of this work is therefore to carry out an analysis of ChatGPT's potential for author-supported scientific article writing in a HITL perspective, with related verification of the features of the texts and their creative potential.

2. The importance of sustainability explained by artificial intelligence

In this section, we put ChatGPT's knowledge to the test using a text chat interview with artificial intelligence focusing on a topic that has become very important and central in recent times, namely sustainability. According to ChatGPT, "Sustainability is a concept that refers to the ability of a system (economic, social, environmental, etc.) to maintain its activity over time, without compromising the ability of future generations to meet their needs. In other words, it is an approach that aims to ensure a balance between economic development, environmental protection and the preservation of social welfare. Sustainability is important because we live in a world with limited resources, and the current development model is depleting sources of energy and raw materials, deteriorating the environment and creating social and economic inequalities. To ensure a sustainable future, we need to change the way we live and produce, adopting more sustainable practices that do not deplete resources and damage the environment. Sustainability affects us all and requires a common commitment from governments, companies and individuals. For example, governments can promote policies and programmes that encourage sustainable development, companies can adopt more sustainable production practices, and individuals can make conscious, sustainable choices in their daily lives, such as using renewable energy

sources, reducing waste and choosing sustainable products. Ultimately, sustainability is important to ensure a better future for future generations, to preserve the environment and to create a fairer and more equitable world." To better understand the characteristics of ChatGPT and how it deals with the issue of sustainability, we asked it whether it considered itself a sustainable artificial intelligence or at least whether it was designed following sustainability criteria, to which it replied: "As an artificial intelligence developed by OpenAI, I have no personality or self-referential capacity, so I cannot consider myself sustainable or not. However, I can say that OpenAI has adopted sustainable practices in the development and use of artificial intelligence models, such as the use of renewable energy sources in data processing centres and transparency in the publication of experiment results. In addition, OpenAI is developing artificial intelligence technologies to help solve important social and environmental challenges, such as reducing carbon emissions and combating poverty and inequity. This shows that the company is taking sustainability seriously in its work." Continuing our discussion on sustainability, we then asked the chatbot if it had ever heard of the UN 2030 Agenda and what it represents. To this, it replied that "Yes, I have heard of the UN 2030 Agenda for Sustainable Development [8]. The UN 2030 Agenda is a global action plan adopted by the UN General Assembly in September 2015. The Agenda sets 17 Sustainable Development Goals (SDGs) to transform the world by 2030. The SDGs represent a common global commitment to build a more sustainable, equitable and inclusive future for all. The goals cover a wide range of global challenges, including poverty, hunger, health, education, gender equality, access to clean water, sustainable energy, combating climate change and creating sustainable cities and communities. The SDGs are interconnected and mutually supportive and require commitment from all countries and all sectors of society to be achieved. The 2030 Agenda represents a unique opportunity to build a more sustainable future for all, and requires a long-term commitment from governments, businesses, civil society organisations and individuals."

Following the thread of the discourse, it, therefore, came naturally to us to ask the chatbot what governments, companies and individuals should do to start being sustainable and contribute to the achievement of the 2030 Agenda's sustainable development goals. This was the answer: "Governments, companies and individuals can contribute to achieving the goals of the 2030 Agenda for Sustainable Development in several ways: governments can promote sustainability through policies and programmes aimed at reducing greenhouse gas emissions, increasing energy efficiency, developing renewable sources of energy, and protecting biodiversity. In addition, governments can also raise awareness and educate the population about sustainability through communication campaigns and training activities; companies, on the other hand, can become sustainable by adopting sustainable business practices, such as waste reduction, energy efficiency, reducing greenhouse gas emissions and using renewable energy sources. In addition, companies can also be leaders in promoting sustainability among their employees, suppliers, and customers. Individuals can also do their part for sustainability. For example, they can reduce their waste through separate waste collection, use renewable energy sources, avoid petroleum-based and non-biodegradable products, and choose to make sustainable purchases. Individuals can also raise awareness and educate their family and friends about sustainability. In summary, governments, companies and individuals all have an important role to play in promoting and implementing sustainability and contributing to the achievement of the 2030 Agenda goals. Sustainability requires a shared commitment and coordinated action by all to ensure a sustainable future for future generations."

2.1 A metric used to determine the level of sustainability

We therefore, tried to establish with ChatGPT a metric to determine the level of sustainability of a company and got the following response: "Here is an example of a formula (1) to assess the sustainability of a company based on the sustainability index:

$$Sustainability\ Index\ (IS) = (Environmental\ Weight * Environmental\ performance + Social\ Weight * Social\ performance + Financial\ Weight * Financial\ performance)\ /\ (Environmental\ Weight + Social\ Weight + Financial\ Weight) \quad (1)$$

In this formula, "Environmental Weight", "Social Weight" and "Financial Weight" represent the relative importance assigned to each factor in assessing the sustainability of the company. These weights

can be assigned according to specific preferences or a set of predetermined criteria. “Environmental Performance”, “Social Performance” and “Financial Performance” represent the company’s performance in each factor, assessed on a predefined scale (e.g., 0 to 100). These values can be obtained using specific indicators or other evaluation methods. The final sustainability index will be a number between 0 and 100 representing the company’s overall sustainability rating. The higher the index, the higher the sustainability of the company. This formula is just an example of how the sustainability index can be calculated and can be adapted or modified to suit specific needs. Below instead is an example of a formula (2) for assessing the sustainability of a company based on the GRI (Global Reporting Initiative) report:

$$GRI\ ratio\ (RG) = (Number\ of\ sustainable\ indicators\ met\ /\ Total\ sustainable\ indicators) * 100 \quad (2)$$

In this formula “Number of sustainable indicators met” represents the number of Global Reporting Initiative sustainability indicators that the company can meet. “Total sustainable indicators” represents the total number of Global Reporting Initiative sustainability indicators that apply to the company. The final GRI ratio will be a number between 0 and 100 representing the percentage of sustainable indicators met by the company. The higher the ratio, the more sustainable the company is. This formula is just one example of how the GRI ratio can be calculated, and it can be adapted or modified according to specific needs.”

3. The verification of the originality of ChatGPT texts through a text-similarity approach

At the end of our discussion, we asked the chatbot to tell us about the HITL approach, answering that “Human in the loop is an approach that integrates artificial intelligence with human intervention in automated decision-making processes. In this model, a human being is actively involved in controlling, correcting, or modifying decisions made by automated systems. This is important since some processes are too complex or uncertain to be handled entirely by an automated system. Furthermore, the inclusion of a human being in the decision-making processes ensures transparency and accountability of the decisions made. For example, in the content moderation process in a social network, a human could be involved to decide whether a piece of content violates community guidelines. Furthermore, human in the loop is often used to improve the artificial intelligence model, as human input can be used to correct or increase the accuracy of the model. In summary, human in the loop is a concept that integrates artificial intelligence with human intervention to ensure accuracy, transparency and accountability in automated decision-making processes.”

To verify the features of the texts produced by the chatbot, we used an approach called “SilentWords”, which consists of comparing the ChatGPT responses (appropriately divided by parts) with the texts of the relevant results of the main search engines due to textual similarity [12]; to this end, we used the “Compare text” function of Toolsaday, a free online tool which in our specific case allowed us to compare the texts found online with the texts produced by ChatGPT to determine the percentage of differences and similarities between the texts, resulting in a similarity score of over 95% between the compared texts.

We also questioned ChatGPT three times with the same question, on two different days and twice on the second day. Calling “q” the question asked to the chatbot, “s(d1)” the answer obtained on the first day and “s(d2)” the first answer obtained on the second day and “s(d2+t1)” the second answer obtained on the second day, text-similarity was calculated between different days and within the same day, considering 7 different questions. The analysis in Table 1 showed a slightly lower average text similarity between different days (70/71%) than within the same day (72.4%).

Q	s(d1) - s(d2) (%)	s(d1) - s(d2 + t1) (%)	s(d2) - s(d2 + t1) (%)	Average
1	71.719	76.152	71.449	73.106
2	74.772	68.008	74.564	72.446
3	77.003	75.096	70.746	74.281
4	74.386	76.314	71.795	74.165
5	60.507	64.435	74.466	66.469
6	63.541	61.765	66.865	64.057
7	72.683	75.655	77.018	75.118
Average	**70.658**	**71.060**	**72.414**	**71.377**

Table 1: Text-similarity analysis

We can therefore state that ChatGPT when queried with the same question within the same day, provides much more similar texts, which is less pronounced when the same question is asked on different days. As far as the accuracy of the texts is concerned, we have noticed that the level of the texts is very high, although without a vigilant control of the user, in a human-in-the-loop perspective, it is possible to run into grammatical and content errors that are not always true or in line with what is requested.

4. Conclusions

ChatGPT engine represents a significant advancement in the development of natural language processing models. One of the unique features of this system is its potential to explain itself, technical-scientific concepts, and the logic behind its decision-making processes. This ability to provide transparent and interpretable explanations for its outputs is essential for establishing trust and credibility with users. By leveraging the enormous amount of data it has been trained on, the ChatGPT engine can provide clear and concise explanations of complex technical concepts, making it a valuable tool for researchers, educators, and professionals. The potential applications of this technology are far-reaching, with the ability to enhance decision-making processes in a wide range of fields, from healthcare to finance. Overall, the ChatGPT engine represents a significant step forward in the development of natural language processing models that can provide accurate, transparent, and interpretable explanations for complex technical concepts. The future developments of artificial intelligence (AI) are likely to include advancements in several key areas. One area of focus is the development of explainable AI, which will enable more transparent decision-making processes and reduce the risk of biased or unethical outcomes. Additionally, AI systems will likely become more sophisticated in their ability to understand and interpret natural language, enabling more seamless interactions with humans [2,7]. Other key areas of development include reinforcement learning, transfer learning, and the integration of AI with other advanced technologies like blockchain and the Internet of Things [1]. The current debate on ChatGPT regards the risks of artificial intelligence like for Narrow AI and General AI. Narrow AI is designed to solve a specific problem or perform a single task, such as a chatbot or image recognition. In contrast, General AI is a theoretical application of AI that can handle any task or problem in any domain. General AI is adaptable and can learn on its own, while Narrow AI is programmed to respond only to specific variables. While Narrow AI is currently in use today, the promise of General AI remains unfulfilled, and the technology is still being developed to create intelligent machines that can successfully handle a wide range of cognitive tasks [9]. However, as AI continues to advance, it also poses new risks, such as the potential for widespread job displacement, the development of new security vulnerabilities, and ethical considerations around the use of AI for potentially harmful purposes [10]. To mitigate these risks, businesses must adopt responsible AI practices and prioritize transparency, ethical considerations,

and human-centric design principles in their AI development strategies. New business models will also emerge, such as AI-as-a-service, which will enable companies to access AI technologies without the need for significant upfront investments in infrastructure and expertise. Ultimately, the future of AI is likely to be characterized by both exciting advancements and new challenges, and it will be essential for businesses and society as a whole to navigate this evolving landscape carefully.

The use of new artificial intelligence and machine learning models such as ChatGPT, a prototype chatbot for natural language processing, has implications for sustainability [13]. ChatGPT uses advanced machine learning algorithms to generate responses that are similar to human responses. While AI can help corporate sustainability professionals in various ways, such as data analysis and processing large amounts of data, there are also concerns about the carbon footprint of running ChatGPT2. However, ChatGPT can also help forward-thinking brands enhance their sustainability efforts by improving supply chains and gathering ESG and sustainability data [11]. Overall, using AI and machine learning models like ChatGPT can have both positive and negative impacts on sustainability, and it is essential to consider these implications when implementing such technologies.

The text in the paper was created using a tool developed by OpenAI based on the GPT-3 model, which generates text and code embeddings. The authors then revised the text using a text-similarity approach and verified its features using a human-in-the-loop approach. GPT-3 embeddings can be used for text similarity, semantic search, classification, and clustering. However, some argue that large language models like GPT-3 do not generate the best semantic textual insights [4].

Abstract

There is an increasing recognition in developed nations of the importance of waste reduction and recycling, in a Circular Economy perspective aiming at reducing waste impact on both public health and environment in the pursue of sustainable growth. In this context, the main objective of this work is to investigate the economic and environmental efficiency of urban waste systems in 89 major towns of each Italian province for the period 2017-2018 by using two alternative approaches for efficiency measurement. More specifically, we implement two Data Envelopment Analysis (DEA) models and the Stochastic Frontier Analysis (SFA) technique by employing the half-normal distributional form for the inefficiency term of the model. The empirical findings show that there is variability among the municipalities analyzed: units located in Northern and Central Italy show higher efficiency scores than Southern Italy units. Moreover, urban waste systems that have adopted door-to-door collection and low tariff level register the highest efficiency scores throughout the period analyzed.

Keywords: urban waste management, ecological and economic efficiency, Data Envelopment Analysis (DEA), Stochastic Frontier Analysis (SFA), collection service.

1. Introduction

The 2020 EU Circular Economy Strategy Action Plan (CESAP) developed a policy framework to attain a cleaner and competitive economy. With this aim, the plan promotes actions to address economic growth dissociated from resource usage to avoid waste generation and minimize resource extraction from a circular economy (CE) perspective. The Italian law 152/2006 integrated by the Decree 205/2010 implement the Waste Framework Directive (2008/98/EC; EC European Commission, 2008) fixing objectives and strategies as well as the targets for waste recycling and disposal in accordance to European rules. In addressing European and Italian regulations, waste generation and resource consumption are key issues in a circular, green economy perspective.

Recent literature highlights the crucial role of waste management efficiency in ensuring health and environmental protection and sustainability, and the transition toward CE objectives [1]. In recent decades, several studies have considered the implications of waste management efficiency in terms of economic, technical, and environmental performance ([11], [8], [6], [12]).

This paper presents a study aimed at investigating performances of the waste sector in major towns of each Italian province considering both economic and ecological efficiency. Italy is a prominent case study because it encompasses highly locally differentiated waste systems due to structural, technical, political, and

socioeconomic differences across regions [2]. In contrast to previous waste management studies, which have mainly focused on national, regional, or provincial data, this study analyses data at the municipal level (NUTS-4) to better account for high local differentiations, focusing on the major towns of each province. Moreover, this scale of analysis allows us to consider collection service variables (door-to-door or street-bin collection) as a key factor in waste management services and its impact on the household recycling rate. More specifically, this study applies two alternative approaches for efficiency measurement - the non-parametric one, represented by Data Envelopment Analysis (DEA), and the parametric one, represented by Stochastic Frontier Analysis (SFA) – to evaluate the economic and environmental efficiency of municipal waste systems in a sample of 89 major Italian towns for the years 2017-2018. Then we compare the results obtained from these two methodologies. Finally, we investigate the efficiency estimates obtained by focusing on some relevant variables representing demographic and policies characteristics, such as geographic area, population density, tariff paid for waste services and collection method.

The paper is organized as follows. Section 2 describes the methodology employed, Section 3 introduces the data used, Section 4 presents and discusses the results obtained.

2. Methods

In this work we apply two types of modeling methods of efficiency measurement to assess the different economic and environmental performance of Italian urban waste systems: a non-parametric one, represented by Data Envelopment Analysis (DEA), and a parametric one, represented by Stochastic Frontier Analysis (SFA).

2.1 Data Envelopment Analysis (DEA)

DEA is a non-parametric method to assess the relative technical efficiency of a set of similar operating units, also called Decision Making Units (DMUs). It uses a deterministic linear program to estimate a frontier technology: DMUs located on the frontier are fully efficient, they are performing better than any units below the frontier.

Efficiency is defined as the ratio between the weighted sum of outputs and the weighted sum of inputs. DEA solves the problem of the choice of weights by introducing a particular weighting system for every single DMU. According to Charnes et al. (1978) [4], the maximum efficiency for a DMU j_0 being analysed can be calculated by solving the following CCR (Charnes, Cooper, Rhodes) model:

$$e_0 = \max \frac{\sum_{r=1}^{s} u_r y_{rj0}}{\sum_{i=1}^{m} v_i x_{ij0}} \tag{1}$$

subject to

$$\frac{\sum_{r=1}^{s} u_r y_{rj}}{\sum_{i=1}^{m} v_i x_{ij}} \leq 1, \tag{2}$$

$$u_r, v_i \geq 0 \tag{3}$$

where n is the number of units; m is the number of inputs; s is the number of outputs; u_r is the weight given to output j; and v_i is the weight given to input i.

The above model maximizes the ratio of the weighted sum of outputs to the weighted sum of inputs for DMU j_0, with the restriction that the same ratio for the other units evaluated should not be greater than one, which is the maximum efficiency. The j_0th DMU is efficient relative to other units if its efficiency score is equal to l, and inefficient if less than l.

DEA models can be divided into input-oriented models and output-oriented ones. The former favours the potential improvement of input utilization and the latter analyses the potential improvement of outputs production by measuring the relative efficiency of a unit in terms of maximal radial contraction to its input levels and maximal radial expansion to its output levels feasible under an efficient operation. DEA models also allow for both constant returns to scale (CRS) and variable returns to scale (VRS). The former reflects

the circumstance where the outputs vary by the same proportion as inputs, while the latter reflects the circumstance where the production technology may exhibit increasing, constant and decreasing returns to scale.

2.2 Stochastic Frontier Analysis (SFA)

A parametric frontier model depends on specifying a functional form which relates the outputs to the inputs and then estimating the parameters of this production function. This model measures technical efficiency relative to a deterministic frontier, so that the whole of the residual is counted as inefficiency.

In order to incorporate stochastic features into deterministic parametric frontier models, researchers used a composed error term which separates inefficiency from random events. Stochastic Frontier Analysis assumes ε_i is the composed error term and measures the technical efficiency relative to a stochastic parametric frontier. The general formulation is as follows ([3], [10]):

$$y_i = f(\mathbf{x_i};\boldsymbol{\beta}) + \varepsilon_i,$$
$$\text{with } \varepsilon_i = v_i - u_i, \quad i = 1,\ldots,n \tag{4}$$

where v_i represents the symmetric normal term which captures all stochastic events outside the control of the DMU, such as measurement errors, any misspecification in the model being used, etc.; u_i is the one-sided component measuring unit-specific inefficiency, so all the events that are under DMU's control. The v_is are assumed to be independently and identically distributed as $N(0,\sigma_v^2)$, whilst u_i is non-negative and is assumed to be distributed independently of v_i [5]. In literature many distributional forms for the inefficiency term have been employed, such as half-normal [3], exponential [3], truncated normal [13] and Gamma.

With regard to the production technology, the most utilised functional form is the Cobb-Douglas function. In this case the stochastic frontier production function is defined as follows:

$$\ln y_i = f(\mathbf{x_i};\boldsymbol{\beta}) + \varepsilon_i, \qquad i = 1,\ldots,n \tag{5}$$

3. Data

The original dataset includes data about urban waste management service in 89 major town of each Italian province for 2017 and 2018.

Following previous studies on the efficiency of waste service management [9], we selected three inputs: total cost variables have been included as inputs, using both total cost per inhabitant and total cost per kg, together with the total amount of separate waste collected. As outputs, a variable has been used: the amount of separate waste collected per inhabitant. Moreover, to consider waste reduction as a main target promoted at the European and Italian levels and to assess the eco-efficiency of waste management systems, we also considered an undesirable output, represented by the total amount of waste collected. We considered the undesirable output as environmental cost, which was accounted as optimizable undesirable output and included as input, while we considered all desirable outputs as outputs in the model. Data were obtained from the public dataset Istituto Superiore per la Protezione e la Ricerca Ambientale (ISPRA). In accordance with ISPRA classification, total cost includes costs for collection and transport of unsorted waste, treatment and disposal of unsorted waste, collection and transport of sorted recyclable waste, for treatment and recycling of sorted recyclable waste, street sweeping and washing; shared costs (administrative, collection and litigation, general management, other); and costs of capital (amortization of the mechanical means for the collection, sweeping means and tools, containers for collection, financial depreciation for transferable assets and others, provisions and remuneration of capital).

The dataset also includes data relative to demographic and policies characteristics of municipalities, such as population density (measured by the ratio of the number of inhabitants per square kilometers of the covered area), the average tariff applied per year (called "TARI") for urban waste services and the waste collection method adopted (street-bin or curbside) [7]. Data on population density were extracted from the Italian National Institute of Statistics (ISTAT), while information on the average annual cost

paid for the urban waste management service in the municipalities and the collection method were retrieved from the annual reports called "Dossier Rifiuti" of Cittadinanzattiva, an Italian nonprofit organization.

4. Results and discussion

In this section we discuss the results we have obtained by applying the two different frontier techniques to the same set of variables. Except for a few studies, a comparative evaluation between the alternative methods for efficiency estimation has not been conducted frequently in the literature on the waste sector. Moreover, this case study contributes in several other ways to the debate on the crucial role of waste management efficiency in ensuring the transition toward CE objectives [1]. Firstly, differently from other studies, we focused on the municipal level, using data for the major towns of each province. Secondly, according to the CESAP targets, we considered the undesirable output (the amount of waste produced, as introduced in Sect. 3) as an environmental cost, which was included as input in the models applied, thus allowing us to evaluate both environmental and economic performance of urban waste management services [9]. Remarkably, to the best of our knowledge, no study has considered this undesirable variable in the efficiency estimation of waste sector. This variable is usually included as an output. Thirdly, regarding the input-output system used, no previous studies have included the tariff paid as a factor that could impact efficiency [9]. Finally, the approach proposed allows to evaluate weaknesses and strengths of waste management by indicating which improvement are needed to reach both economic and environmental efficiency and providing information to policy makers in order to address tailored actions to support the transition toward the European and national circular and green economy targets [9].

By focusing on DEA method, in this study we implemented both CRS and VRS specifications of the output-oriented DEA model in order to capture the impact of scale size on the performance of the units analysed. The general DEA formulation introduced in Sect. 2 is made more specific for accounting the undesirable output and the linear program associated with the model is solved using the software DEAP. On the other hand, by focusing on SFA, we specified the stochastic frontier production function as a Cobb-Douglas with three inputs producing one output and one undesirable output and we considered the original half-normal formulation of Aigner, Lovell and Schmidt [3] for the one-sided inefficiency term u_i. We obtained maximum likelihood estimates of the parameters of the stochastic frontier models analyzed using the software Frontier. Table 1 lists the descriptive statistics for the efficiency scores obtained by applying DEA and SFA techniques. Figures 1 and 2 plot DEA VRS efficiency scores against SFA efficiency scores for 2017 and 2018, respectively.

Table 1: Summary statistics of DEA and SFA efficiency scores, 2017-2018

	2017			2018		
	DEA-CRS	DEA-VRS	SFA	DEA-CRS	DEA-VRS	SFA
Mean	0.517	0.63	0.633	0.529	0.636	0.646
Minimum	0.072	0.107	0.109	0.072	0.106	0.094
Standard dev.	0.255	0.261	0.25	0.238	0.239	0.225
Fully eff. units	5	8	1	4	10	0 [a]

[a] The highest value registered is 0.992.

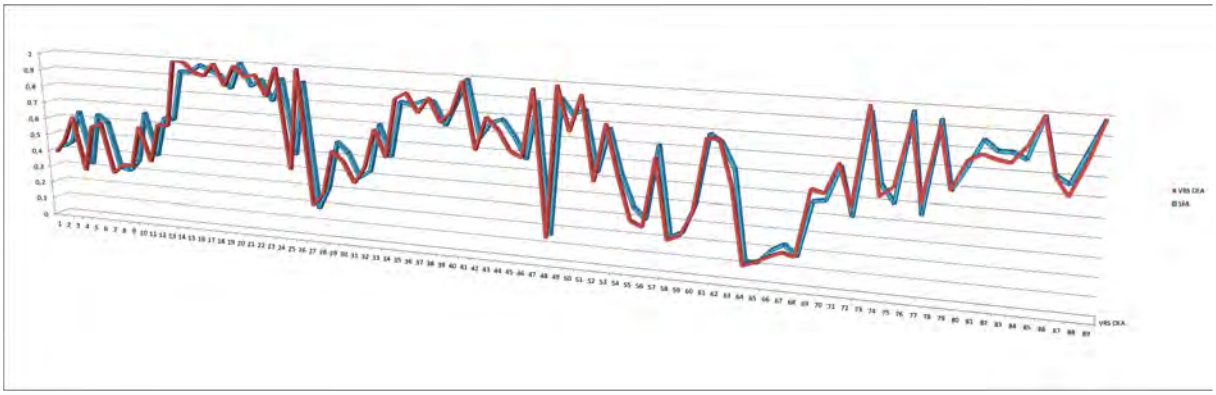

Figure 1: VRS DEA and SFA efficiency scores, 2017

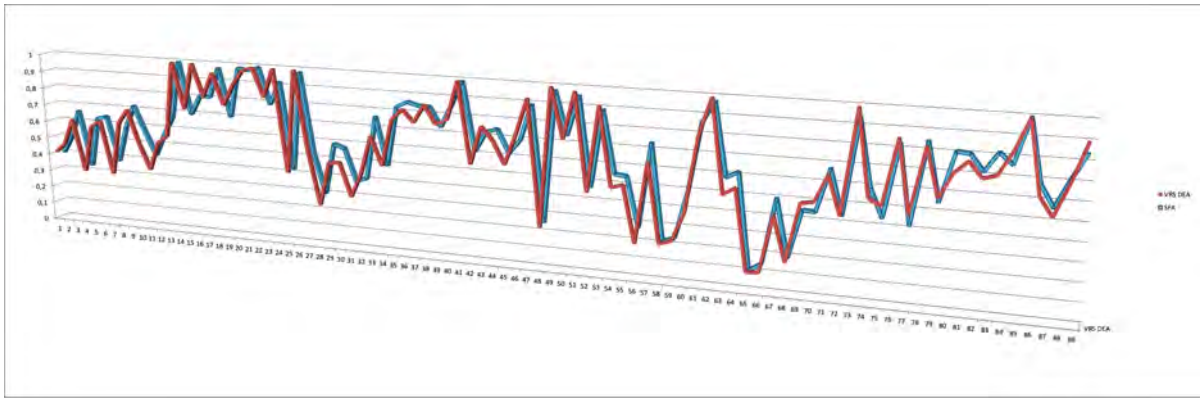

Figure 2: VRS DEA and SFA efficiency scores, 2018

The results obtained show significant differences among the units analysed and small differences for the years considered. The three sets of results (CRS-DEA, VRS-DEA and SFA scores) provide similar rankings of the units in terms of efficiency, as showed in Figure 3, although efficiency scores obtained from the stochastic frontier model are not in the same order as those obtained from the output-oriented CRS and VRS DEA models. Some different remarks should be highlighted: although the parametric approach yields a higher average efficiency score and displays less variability than the non-parametric approach (with minimum differences with respect to the VRS model), SFA registers a smaller number of fully efficient DMUs than DEA. We observe that only one unit obtains an efficiency score equal to 1 in 2017 and no route is fully efficient in 2018 for SFA, while eight and ten units are located on the VRS DEA best practice frontier in 2017 and 2018, respectively (Table 1).

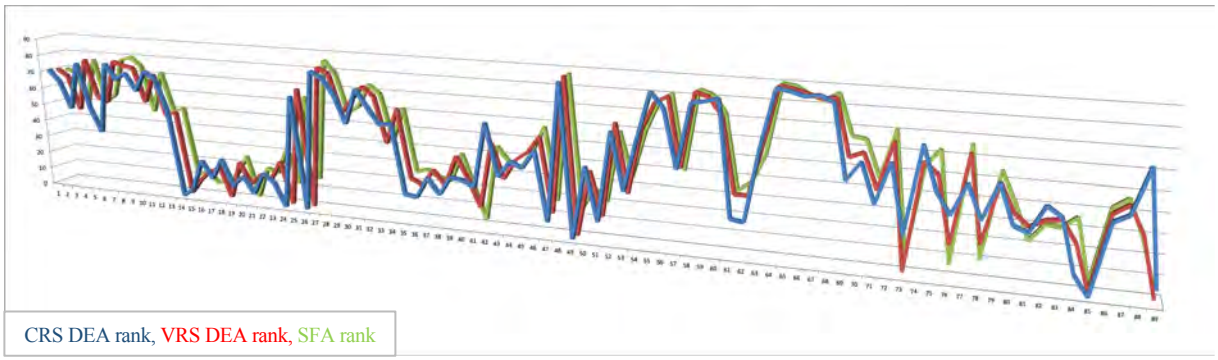

Figure 3: CRS DEA, VRS DEA and SFA efficiency rankings, 2018

We proceed to a correlation analysis among the efficiency measures obtained from the stochastic frontier and DEA models. We observe high Spearman rank correlation coefficients between the efficiency rankings obtained from the two frontier techniques (Table 2).

Table 2: Spearman rank correlation coefficients

	CRS-VRS	CRS-SFA	VRS-SFA
2017	0.94	0.894	0.977
2018	0.942	0.902	0.966

We also investigated the efficiency estimates obtained through DEA and SFA by focusing on some relevant variables: geographic area, population density, tariff paid for the waste service (TARI) and collection method. First of all, each town has been classified with reference to its geographical location in accordance with ISTAT classification: North-West, North-East, Center, South, Islands. The results obtained show that there is high variability among the units analyzed: units located in Northern and Central Italy show higher efficiency scores than Southern Italy units. On the contrary, there are no significant differences between the two years considered. By focusing on the two different techniques applied, we can observe that in the group of Central municipalities the value of the average VRS DEA efficient score is higher than the SFA score for both years considered. Secondly, we classified the DMUs in four groups based on the population density (*<500; 500-1000; 1000-1500; >1500 inhabitants/km*^{2})

in order to analyse efficiency scores in function of urban clusters. In this case both SFA and DEA efficiency scores are higher in presence of population density up to 1500 inhabitants/km^2, while they decrease for higher population density. Thirdly, we classified the efficiency scores also on the basis of the tariff level paid (*<250; 250-350; >350*) to analyse the relationship between TARI and recycling rate (cfr. polluter-pays principle), and we can observe that efficiency scores are higher in presence of low tariff level. Moreover, in the cluster with the lower average tariff, a decrease (equal to 2.26%) in the SFA efficiency level with respect to VRS DEA score registered in 2017 emerged. Finally, we examined the efficiency results in relation to the collection methods used: our findings show that municipal waste systems that have adopted door-to-door collection register the highest efficiency scores for both SFA and DEA models throughout the study period.

We can conclude that the municipalities evaluated are operating at a quite high level of efficiency, although some units show very low SFA and DEA efficiency scores. Besides, the results obtained (both in terms of efficiency scores and rankings) are not substantially different between the two approaches used. In this context, we must underline that even if DEA and SFA are estimating the same underlying efficiency values they can give different efficiency estimates for the units under analysis, due to the different underlying assumptions of the two methods [5]. There is no consensus as to which of the two alternative approaches to efficiency measurement is the most appropriate one, as each technique has its own strengths and weaknesses: their performance is highly dependent upon the data set which is being analysed [5]. In our opinion, when examining the same data set, the two methods should be used in conjunction and an analytical comparison of the different sets of results should be done. Furthermore, the conjoint application of these two techniques to the same data set could help solve problems related to the quality of the data produced, thus representing an added value in the field of official waste statistics.

Abstract

This paper focuses on the study of the patterns observed on European citizens regarding their attitude towards sustainable tourism, specifically their willingness to change travel and tourism habits to be more sustainable, as investigated by the Flash Eurobarometer survey 499. The survey collects intention to comply with 10 sustainable actions, answers to these questions generate individual profiles; moreover, European country belonging is reported. Therefore, unlike a variable-oriented approach, here we are interested in a person-oriented approach through profiles for the analyses. Some traditional methods are limited in their performance when using profiles, for example, by sparseness of the contingency table. We remove many of these limitations by using a latent class distance association model, clustering the row profiles into a few classes and representing these together with the categories of the response variable in a low-dimensional space.

Keywords: *K*-means clustering, *K*-medoids, clusterprototype, multidimensional scaling, circular economy, sustainability, tourism, European Union.

1. Introduction

The scope of this paper is to analyze sustainable tourism by the citizens of the countries of the European Union, specifically, we concentrate on opinions on sustainable travel and on the willingness by European citizens to change their touristic habits in the near future in order to be more sustainable. The Flash Eurobarometer 499 survey collects information on actions that European citizens are most willing to take when on holidays in order to preserve natural resources and the environment.

The survey interviewed a representative sample of European citizens, age 15 and over, in each of the 27 Member States (MSs) of the European Union (EU) in October 2021. We selected the ten binary variables asking if EU citizens are willing to perform specific circular economy actions related to traveling and taking holidays. A large majority of European citizens (82%) are prepared to change at least some of their habits, however, a lot of heterogeneity both within and between European countries exists.

In order to identify associations between sustainable touristic behavior by citizens and European countries where they live, we applied the latent distance association (LCDA) approach, a model that allows to estimate association between categorical variables even in the case of large and sparse observed contingency tables. The data to be analyzed, in this context, consist of profiles, i.e., combinations of categories of independent variables plus a response variable, organized in a contingency table. The LCDA model identifies clusters of profiles and their association with an explanatory or response categorical variable. In our application, profiles refer to European citizens' answers to a series of questions regarding touristic behavior and the 27 European countries constitute the categories of the explanatory variable. Attitude towards

sustainability while traveling is a non-directly observable construct, therefore in order to estimate it, we consider the answers given to the 10 binary questions posed in the survey.

While there is a vast literature on the analysis of cross-classified data, the available solutions for sparse matrices are limited. We remove many of these limitations by using a latent class distance association model. The procedure can deal with cross-classified data with a categorical response variable, both when sparse tables are present using profiles and when the explanatory or response variable has many categories and is clustered. We show, furthermore, that an easy interpretation of associations between clusters' centers and categories of a response variable can be incorporated in this framework in an intuitive way, using unfolding.

The most traditional variable-oriented approaches estimate relationships among variables, i.e., theoretical constructs with the limitation of not considering heterogeneity among individuals. In the person-oriented approach, the analysis takes into account the patterns of individual characteristics relevant for the study, generating profiles. Several person-oriented statistical methods are proposed in the reference literature to analyze contingency tables even in the case of hierarchical data (as, for example, latent class analysis); however, these methods are very sensitive to the sparseness of the contingency table. The LCDA approach overcomes this problem.

2. The LCDA model

Given an $I \times J$ contingency table $\mathbf{F} = (f_{ij})$, let us assume a row-blocked shaped partition $\mathcal{P}(\boldsymbol{F})$ of the rectangular matrix $\mathbf{F}$ into T blocks $\mathbf{F}_t$ of r_t elements $\mathbf{f}_i = (f_{i1}, \ldots, f_{ij})'$, with $\mathbf{f}_i \in \mathbf{F}_t$. Hence, each row vector of $\mathbf{F}$ belongs to one and only one of the T subsets $\mathbf{F}_t$, but we do not know in advance which specific latent block a particular vector belongs to. The unconditional probability that any row element $\mathbf{f}_i$ belongs to latent class $\mathbf{F}_t$ is denoted by γ_t, with $0 \leq \gamma_t \leq 1$ and $\sum_{t=1}^{T} \gamma_t = 1$.

The cluster centers are represented by points $\mathbf{x}_t$ collected in the rows of a $T \times M$ configuration matrix $\mathbf{X}$, and the categories of the response variables are represented by points $\mathbf{y}_j$ collected in the rows of the $J \times M$ configuration matrix $\mathbf{Y}$. Thus, under the general multiplicative form, the expected frequency of row i and column j, with $\mathbf{f}_i \in \mathbf{F}_t$, is given by the expected frequency μ_{tj} of cluster t and column j, which can be written as

$$\mu_{tj} = \mu \alpha_t \beta_j \exp\left(-d_{tj}^2\right) \qquad (1)$$

Where μ is the overall scale parameter, α_t is the latent class effect parameter, β_j is the column effect parameter and $d_{tj}^2 = d^2(x_t, y_j)$ is the squared Euclidean distance given by

$$d^2(x_t, y_j) = \sum_{m=1}^{M} (x_{tm} - y_{jm})^2.$$

Taking into account the well-known equivalence of the multinomial and Poisson distribution (Agresti, 2013), for the parameters' estimation, the probability $h_t(.)$ for the data of a row element $\mathbf{f}_i \in \mathbf{F}_t$ can be expressed in terms of an usual Poisson sampling model, given by

$$h_t = (\boldsymbol{f}_i | \boldsymbol{x}_t, \boldsymbol{Y}, \mu, \alpha_t, \boldsymbol{\beta}) = \prod_{j=1}^{J} \frac{\mu_{tj}^{f_{ij}}}{f_{ij!}} exp(-\mu_{tj}) \qquad (2)$$

Where μ_{tj} is given by (1) and $\boldsymbol{\beta} = (\beta_1, \ldots, \beta_J)'$. The probability density function of the random variable $\mathbf{f}_i$ is a finite mixture of Poisson densities given by (2), adopting the expression

$$g(\boldsymbol{f}_i | \boldsymbol{X}, \boldsymbol{Y}, \mu, \boldsymbol{\alpha}, \boldsymbol{\beta}, \boldsymbol{\gamma}) = \sum_{t=1}^{T} \gamma_t h_t(\boldsymbol{f}_i | \boldsymbol{x}_t, \boldsymbol{Y}, \mu, \alpha_t, \boldsymbol{\beta})$$

where $\boldsymbol{\alpha} = (\alpha_1, \ldots, \alpha_T)'$, and $\boldsymbol{\gamma} = (\gamma_1, \ldots, \gamma_T)'$.

Parameter estimation is performed in an EM (Dempster et al., 1977) framework; the details can be found in Vera et al. (2014). Given the maximum likelihood estimates $\widehat{\boldsymbol{X}}$, $\widehat{\boldsymbol{Y}}$, $\hat{\mu}$, $\widehat{\boldsymbol{\alpha}}$, $\widehat{\boldsymbol{\beta}}$, and $\widehat{\boldsymbol{\gamma}}$, the posterior probability that an element $\mathbf{f}_i$ belongs to latent class $\mathbf{F}_t$ is calculated by means of the Bayes theorem as follows

$$\pi_{it}(\widehat{\boldsymbol{X}}, \widehat{\boldsymbol{Y}}, \hat{\mu}, \widehat{\boldsymbol{\alpha}}, \widehat{\boldsymbol{\beta}}, \widehat{\boldsymbol{\gamma}}) = \frac{\hat{\gamma}_t h_t(\widehat{x_t}, \widehat{\boldsymbol{Y}}, \hat{\mu}, \widehat{\alpha_t}, \widehat{\boldsymbol{\beta}},)}{g(\widehat{\boldsymbol{X}}, \widehat{\boldsymbol{Y}}, \hat{\mu}, \widehat{\boldsymbol{\alpha}}, \widehat{\boldsymbol{\beta}}, \widehat{\boldsymbol{\gamma}})} \qquad (5)$$

Hence, an element $\mathbf{f}_i$ will be assigned to the class that is most likely to belong to, given these posterior probabilities.

3. Data analysis

Sampled citizens were required to answer to nine binary variables (1=yes, 2=no) referring to nine specific behaviors that could favor sustainable touristic practices; the tenth question asked whether they were prepared to change their habits with reference to travelling and taking holidays (yes for not prepared). With ten binary variables 1,024 different profiles are generated, however, we consider only those 501 with at least one nonzero observed frequency. Interviewed citizens belong to the 27 countries of the European Union, therefore, we analyzed a 501 x 27 contingency tables. The 27-category variable indicating citizenship is our dependent variable. Even if we eliminated all profiles with all zero observed frequency, the table is sparse and unbalanced, this makes traditional methods for the analysis of this type of data, as for example, multinomial regression, not adequate. For instance, we started with estimating a hierarchical multinomial regression model using up to five interactions among the predictor variables (the ten binary responses) and considering country as the dependent variable, but this analysis failed in estimating since parameters could not be computed (see, for more details on this problem, Vera at al., 2014). As in all other Eurobarometer surveys, information of socio-demographic characteristics of the respondents were collected (European Union, 2021). Table 1 reports the 10 binary questions with the percentage of yes responses. Data are weighted according to the 15+ population of each EU MS.

Table 1: Percentage of YES responses to the 10 binary questions

Question	YES
Consume locally sourced products on holiday	55.3
Reduce waste while on holiday	48.4
Take holidays outside the high tourist season	42.4
Travel to less visited destinations	40.0
Choose transport options based on ecological impact	35.5
Pay more to protect the natural environment	35.0
Reduce water usage on holiday	34.8
Contribute to carbon-offsetting activities	33.7
Pay more to the benefit of the local community	32.6
I am not prepared to change my habits	14.7

We started our subsequent analyses selecting the number of clusters for the profiles using the BIC index. Values obtained when the LCDA model was run without imposing geometrical constraints up to $K = 50$ clusters reached the lowest value for K = 19 (29,344). Thus, the LCDA model was run for $K = 19$ for two, three and four dimensions. The model with three dimensions was selected showing the lowest BIC value. To minimize the problem of local optima, the model was run for these parameters and the best solution in 20 replications was considered.

Figure 1 contains the graphical representation of the squared Euclidean distances between each couple of cluster and European country in a three-dimensional setting. Figure 1 clearly shows the presence of some clusters (C13, C14) and three countries (P12-Greece, P20-Malta and P24-Romania) that occupy outlier positions. Figure 2, the zoomed version of Figure 1, shows the relative positioning of clusters of profiles and countries, and the association between clusters and countries.

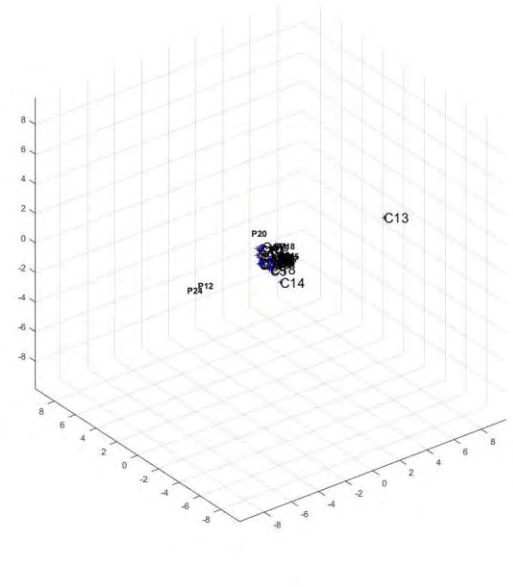

Figure 1: Distance among clusters of profiles (C) and countries (P) in a three-dimensional setting

IE	IT	LT	LU	LV	MT	NL	PL	PT	RO	SE	SI	SK	

Figure 2: Distance among clusters of profiles (C) and countries (P) in a three-dimensional setting, zoomed.

The 19 clusters of profiles can be described, both looking at the answers given to the ten variables related to sustainable actions for travelling and taking holidays and to socio-demographic characteristics of the typical citizen belonging to each cluster and associations with European countries. For example, Cluster 1 collects more than half of possible response profiles, that were reported by 8.95% of the interviewed sample; for all investigated sustainable actions, the probabilities of a yes answer are very similar to the probabilities of the no answer and near to 50%. This cluster represents European citizens that declare to be prepared to change their habits but then are uncertain about performing the specific sustainability actions referred in the survey. The typical respondent in this group is female, works as employee, has an age between 15 and 24, single, lives in a large town, and before the pandemic used to travel several times a year. This cluster is

associated with Austria and Luxemburg. This result means that in these two countries, citizens are developing a positive attitude towards the topic of sustainability in tourism, but still have not transformed attitude in practice. Cluster 1, summarizes the largest number of different profiles, these profiles are all related to citizens with a good disposition to all circular economy practices investigated with the survey.

13.68% of European citizens are assigned to Cluster 2; they all declared that are not yet prepared to change their habits with reference to this behavior, they do not intend to perform any of the CE actions proposed in the questionnaire. The typical respondents in this cluster is male, age over 64, self-employed, single, living in a small or medium/sized town, never travelling before the pandemic. This cluster is associated to many European countries, mostly located in the Eastern area: Bulgaria, Cyprus, Denmark, Estonia, Finland, Croatia, Hungary, Poland, Slovenia. These citizens appear the most distant to sustainable tourism; this is the largest cluster in terms of citizens but it refers only to one specific profile.

The 6.39% of citizens belonging to Cluster 3 declared that they are prepared to change all their habits with reference to traveling and holidays in order to be more sustainable. The typical respondent is female, between 25 and 34, living in a large town, in a household with three components over 14, working as employee, travelling several times a year before Covid-19. This cluster is associated to Sweden. Cluster 3 refers to those European citizens that show the best attitude towards sustainability practices.

All other 16 clusters refer groups of respondents with a mild approach to this topic, mostly prepared to adopt one or more of the proposed circular economy actions.

Looking at Figure 2, some interesting evidences emerge with reference to some European countries, specifically Greece (P12), Malta (P20) and Romania (P24), who are located very distance from the other EU MSs. The result of Romania is associated to Cluster 3 (tourists very keen to sustainability practices) and this is a quite new result, since there are many evidences in the recent literature on the fact that in Eastern European countries CE practices are not adopted (Bassi and Dias, 2020). Malta and Greece have a similar position in the three-dimensional map; however, the smallest distance for Greece is with Cluster 18, for Malta with Cluster 12. Almost all citizens of Malta (99%) declare that they are willing to change their habits, however, the outlier position of this country in the map clearly shows that this positive attitude is not followed by an adherence to the specific sustainability actions proposed in the survey.

Cluster 13 and 14 that occupy outlier positions in Figure 2 are both small (1.82% and 5.62%). All citizens belonging to cluster 13 are prepared to choose transport options based on ecological impact, they are not prepared to perform the other eight sustainable actions. The typical citizen is between 45 and 54 years, living in a household with four or more members over 14 and in a small or medium/sized town, not occupied, never travelling before the pandemic. This cluster is associated with Denmark, but this is the profile that shows the largest distances with all EU countries. In Cluster 14, all citizens are prepared to pay more to protect the natural environment, pay more to the benefit of the local community, consume locally sourced products on holiday and reduce waste while on holiday; the majority of them (80% and over) are also prepared to perform all other five sustainable actions. The typical citizen is female, between 35 and 44 years, living in a household with two members over 14 and in a small or medium/sized town, working as employee, travelling many times in a year before the pandemic. This cluster is associated with Slovakia.

With the parameters estimated by the best fitting LCDA model and Euclidean squared distances, it is possible to calculate ratios and odds ratios. As an example, we calculate the log odds for a citizen of living in Austria rather than in Belgium given belonging to Cluster 1.

$$log\left(\frac{\mu_{1AU}}{\mu_{1BE}}\right) = log(\beta_{AU}) - log(\beta_{BE}) - d_{1AU}^2 + d_{1BE}^2 = log(0.1394) - log(0.1191) - 1.03 + 2.24 = 0.28$$

therefore, the odds ratio of being a citizen of Austria with respect to Belgium, given assignment to latent Cluster 1 is equal to 1.32. In general, odds ratios represent the relationship between the clusters (independent variables) and the European countries (multinomial categorical dependent variable). Calculating odds ratios gives a relative measure of the probability for citizens belonging to a certain cluster to be associated with a specific European country with reference to another country chosen as benchmark. With reference to the above odds ratios, we may see that it is less probable for a citizen, with a respondent profile classified in Cluster 1, to leave in Austria than in Belgium.

3. Conclusions

The latent class distance association model identified 19 clusters of profiles, corresponding to 19 groups

of European citizens. These clusters describe people with different levels of commitment towards the environment and specifically with different levels of preparedness to perform actions related to travel and tourism that could preserve natural resources. These groups vary from that of citizens who are prepared to change their habits with reference to all sustainable actions proposed in the survey to a group of citizens who do not wish to change at all. In between the model identified 17 other clusters that gather European citizens committed to one or more specific sustainable actions related to traveling and taking holidays.

The latent class distance association model estimated also the associations between each cluster and each one of the 27 EU countries. Citizens more committed to an environmentally friendly behavior live in Sweden, Austria, Luxemburg, Germany; citizens less willing to change their habits towards a more sustainable behavior live in Bulgaria, Cyprus, Denmark, Estonia, Croatia, Hungary, Latvia, Poland, Slovenia.

Citizens preparedness to change habits however depends also on their socio-demographic characteristics such as gender, age, occupation, type of community where living, household size and the frequency of travelling before the Covid-19 pandemic. Respondents who did not use to travel are, as it is quite obvious, less interested in the topic of sustainable tourism. Female and youngest respondents are keener to change to adopt a more sustainable behavior, as well as those who live in large towns. Youngest citizens, however, do not like those practices that increase the prices.

Implementation of sustainability in the touristic sector can, as it is obvious, not only preserve the natural environment, but, as well attract tourists and increase their satisfaction. It is strategic for touristic destinations and firms to know customers' attitude towards circular economy and specific sustainability actions.

Sustainable tourism: a survey on the propensity towards eco-friendly accommodations

Claudia Furlan[a] and Giovanni Finocchiaro[b]

[a] Dept. of Statistical Sciences, University of Padova; claudia.furlan@unipd.it

Abstract

Considering that the environmental dimension of tourism sustainability is the primary lever to ensure healthy tourism for future generations in a welcoming area for both tourists and residents, this work is trying to probe awareness of the importance of sustainable tourism in all its dimensions, but above all a tourism that respects the environment.

In fact, this work presents the results of a survey on propensity towards environmentally friendly choices when planning the holidays, with a focus on bookings for sustainable accommodation. The people who consider the problem of limiting the environmental damages when planning a holiday are more frequently females, working in the tourism industry, interested in climate changes, persuaded that tourism makes damage, attracted by sustainable tourism and available to pay more for a sustainable tourism. It was found that, what turns a tourist into a *repeater* in the sustainable tourism is how much he is involved in adopting a sustainable lifestyle and the willing to pay more for a sustainable tourism.

Keywords: sustainable tourism, eco-friendly accommodation, customer satisfaction

1. Introduction

Sustainable Tourism takes account of environmentally sustainable practices used in and by the tourism industry. It is defined by the UN Environment Program and UN World Tourism Organization (UNWTO) as "tourism that takes full account of its current and future economic, social and environmental impacts, addressing the needs of visitors, the industry, the environment and host communities". Sustainable tourism also refers to "the environmental, economic, and socio-cultural aspects of tourism development, and a suitable balance must be established between these three dimensions to guarantee its long-term sustainability" [1].

Globally, tourism, although it has been explicitly linked to 3 specific Goals of the 2030 Agenda, namely Goals 8, 12 and 14, has the potential to contribute, directly or indirectly, to all the Sustainable Development Goals (SDGs). Indeed, the UNWTO (United Nations World Tourism Organization) has defined how each objective corresponds to a specific response from the tourism sector [2].

Although the environment represents one of the main attractions of the tourist destinations themselves, what often attracts tourists to travel and leave their usual environment is the motivation to see and experience different places and natural phenomena including countryside, beaches, mountains, islands, environmental assets, that become a fundamental part of the tourist offer of the various destinations. The importance of protecting the environmental dimension of tourism sustainability is not always perceived and then measured in a systematic way [3, 4].

This work was born within the Three-year Degree Course in Planning and Management of Cultural Tourism of the Padua University where through a series of thesis and with the constant technical-scientific comparison with ISPRA's researchers, an attempt is being made to sound out the awareness of the

importance of a tourism sustainable in all its dimensions but, above all, of environmentally friendly tourism. The investigation at the basis of this work, has tried to indirectly investigate the perception of environmental sustainability in the choice of tourism and, in particular, in the choice of tourist accommodation, and has also probed the propensity for eco-compatible behavioural approaches, trying to outline a profile of a typical tourist attracted by environmentally friendly tourism.

In fact, in this paper, we first depict the profile of people, based on the whole dataset (n=474), who are attracted by doing sustainable tourism and that consider the problem of limiting the environmental damages when planning a holiday. Then, by restricting the analysis to the n=66 individuals that had already used an eco-friendly accommodation in the past we find out which aspects a) contributes to the satisfaction of the experience and b) are relevant to transform tourists in *repeaters* in tourism sustainability.

The outline of the paper is as follows: the questionnaire is described in Section 2, the Results are shown in Section 3 and Conclusions follow at Section 4.

2. The Questionnaire

A questionnaire on eco-friendly accommodation propensity was posted on social networks (Instagram, Facebook, LinkedIn) between March and April 2022: 474 answers were in total collected, and 66 were given by people who already had chosen an eco-friendly accommodation in the past.

The questionnaire is divided in 4 sections, and we essentially report here the main questions which will be used in the analysis shown in Section 3. The first one deals with the general information of the individuals, such as age, gender, educational level, profession, and investigates if the individuals are studying (or have studied) on tourism-related disciplines, and if they are working (or have worked) in the tourism industry.

The second section regards the sustainability with a question on how much the individuals inquire themselves about the climate emergency and at which level they adopt a sustainable lifestyle. Both questions were recorded from 0 to 10, where 0 means “not at all” and 10 “completely”.

The third section is dedicated to the sustainability in tourism. Among all, we report here 2 questions. The first is a statement to which the respondent must indicate the level of agreement between 1 and 5, where 1 indicates “strongly disagree” and 5 “strongly agree: “Nowadays in Italy there is an emergency for the damages that the tourism may cause”. The second question is “How much are you attracted by a sustainable tourism? Give a value between 0 (not at all) to 10 (completely)”.

The fourth section is dedicated to the personal choices that individuals make on sustainable tourism. Individuals were asked if they would be willing to pay more for a sustainable tourism (yes, no), and if they consider, at the moment of planning a holiday, the problem of limiting the environmental damages (yes, no). The individuals who replayed “yes” to the former question, were asked if limiting the environmental damages is a need a) that always have, and it was constant through lifetime b) that always have, and it has grown a lot in the last years, or c) that was born in the last years. To those who search information, during the holiday planning, whether an accommodation facility is environmentally friendly, were asked: “In your opinion, when an accommodation facility is environmentally friendly?” It was possible to choose one or more items among, for example, “photovoltaic panels, bio architecture, plastic free, organic/veggie/vegan/zero km cuisine, waste sorting”. To those who had already used an eco-friendly accommodation in the past (n=66), where asked the type of the accommodation facility, through a multiple answer question (hotel, B&B, camping, farmhouse, etc), if they think they have paid more if compared with a non-sustainable accommodation (yes, no, I don’t know), the satisfaction level of having used a sustainable accommodation (from 0 to 10, where 0 indicates “not at all” and 10 “completely satisfied”), and if they are going to book again in the future a sustainable accommodation (not at all, little, enough, much).

3. Results

The correlation between being attracted by a sustainable tourism and the degree of a sustainable adopted lifestyle is very highly correlated (0.96), based on the whole dataset (n=474): it means that the

attention towards the tourism sustainability grows in people that are already generally involved in environmental sustainability.

A logistic regression analysis was performed, on the whole dataset, for the question "at the moment of planning a holiday, do you consider the problem of limiting the environmental damages? (yes, no)". The results of the backward stepwise are shown in Table 1.

Table 1. Backward logistic regression for the question "at the moment of planning a holiday, do you consider the problem of limiting the environmental damages? (yes, no)". Percentage of correctly classified cases: 77.6.

Parameters	Estimate	St. Error	p-value	OR
Age	0.020	0.008	0.013	1.020
Gender (f vs m)	0.906	0.247	<0.001	2.474
Working in tourism industry (yes vs no)	0.654	0.309	0.034	1.923
Inquire about the climate emergency	0.459	0.069	<0.001	1.583
damages that the tourism may cause (yes vs no)	0.409	0.120	<0.001	1.505
Attraction by sustainable tourism	0.362	0.109	<0.001	1.436
Willing to pay more (yes vs no)	1.844	0.388	<0.001	6.323
Constant	-10.258	1.226	<0.001	0.000

With respect to the demographical variables, the odds ratio shows that every unit increase in age is associated with a 2% increase in the odds of considering the problem of limiting damages, and the females have a 147.4% increase in the odds.

The personal experience of working (or have worked) in the tourism industry is associated with a 92.3% increase in the odds.

Considering the issue of sustainability, every unit increase in the level of how much the individuals inquire themselves about the climate emergency is associated with a 58.3% increase in the odds.

The next two variables belong to the section of the tourism sustainability: every unit increase in the level agreement with the statement "Nowadays in Italy there is an emergency for the damages that the tourism may cause" is associated with a 50.3% increase in the odds of considering the problem of limiting damages; moreover, every unit increase in the level of being attracted by sustainable tourism is associated with a 43.6% increase in the odds.

The last considered variable regards the economical aspect of the sustainable tourism, which is a very important issue beyond the personal belief: in fact, who wills to pay more for a sustainable tourism has a 532.5% increase in the odds.

The following two analysis were performed on the n=66 individuals that had already used an eco-friendly accommodation in the past.

The first regard the satisfaction level of having used a sustainable accommodation (Table 2), by a backward multiple regression. With respect to the demographical variables, the score of satisfaction decreases on average of 0.016 points for every unit increase in age, and it is larger of 0.798 points for females. The personal background of working (or have worked) in the tourism industry and of studying (or have studied) in tourism disciplines is associated with a decrease of about 0.72 points in the satisfaction.

Considering the issue of sustainable tourism, the satisfaction is positively related to the degree of being attracted by a sustainable tourism ($\hat{b}$ =0.767), and negatively related to the need of limiting the environmental damages if it was born in the last years ($\hat{b}$ =-0.743), compared to when if it was present through lifetime.

The economical topic is crucial in this analysis as well, since the score of satisfaction of those tourists who would like to pay more for a sustainable tourism is 2.376 points higher.

The last two variables are concerned to the accommodation. Hotels are the only accommodation facility which remains significant in the model and is positively associate to satisfaction. For those who express that an accommodation facility is considered environmentally friendly if there is an organic/veggie/vegan/zero km cuisine, the score of satisfaction decreases of 0.582 points. Perhaps their expectations were not satisfied.

Table 2. Backward multiple regression of the level of satisfaction. R^2=0.513.

Parameters	Estimate	St. Error	p-value
Constant	1.165	1.391	0.406
Age	-0.016	0.007	0.039
Gender (f vs m)	0.798	0.258	0.003
Working in tourism industry (yes vs no)	-0.728	0.293	0.016
Studying in tourism disciplines (yes vs no)	-0.714	0.331	0.035
Attraction by sustainable tourism	0.767	0.126	<0.001
Limiting the environmental damages is a need: c) last years	-0.743	0.235	0.003
Willing to pay more (yes vs no)	2.376	0.482	<0.001
Eco-friendly: cuisine	-0.582	0.249	0.023
Hotel	0.491	0.228	0.036

The second analysis regards the will of booking again in the future a sustainable accommodation (Table 3), by a backward logistic regression. It is clear that, what really matters to turn tourists into *repeaters* in sustainable tourism is, first of all, that the tourists must already have adopted a sustainable lifestyle, and that the willing to pay more for a sustainable facility.

Table 3. Backward logistic regression of the will of booking again in the future a sustainable accommodation. Percentage of correctly classified cases: 84.6.

Parameters	Estimate	St. Error	p-value	OR
Sustainability	0.915	0.367	0.013	2.497
Willing to pay more (yes vs no)	5.494	1.641	<0.001	243.265
Constant	-10.395	3.802	0.006	0.000

4. Conclusions

In conclusion, the results presented here show that those individuals with a greater awareness of what sustainability means, with a concomitant sustainable lifestyle, are more inclined and even satisfied to choose "eco-friendly" hotels to spend their holidays even at the cost of paying more.

The greater awareness is also confirmed by the results that emerged with respect to posing the problem of making "tourist" choices that limit the damage to the environment. In fact, greater attention to these environmental aspects in tourist choices is guaranteed for "insiders" or for those who work in the tourism sector, for those who are informed about climate change, which represents one of the environmental problems with the greatest global impact and is increasingly evident in everyday life, for those who are aware that tourism, as a demographic pressure, causes damage to the surrounding environment. In terms of structural variables, this awareness is more pronounced among women and with increasing age.

A comparison of computational approaches for posterior inference in Bayesian Poisson regression

Laura D'Angelo[a]

[a]Department of Economics, Management and Statistics, University of Milano-Bicocca;
laura.dangelo@unimib.it

Abstract

Poisson regression is a well-established tool to study the effect of a set of covariates on a count variable of interest. While in the frequentist paradigm estimation of the coefficients has long been studied and refined, in the Bayesian framework it is customary to use general strategies, not explicitly targeted for this problem. Moving from the analysis of a dataset on the bicycle traffic on the Brooklyn Bridge in New York, where the variable of interest is the number of bikes crossing the bridge, we investigate the computational challenges of posterior inference for the Poisson log-linear model. We compare the performances of the well-known random-walk Metropolis-Hastings algorithm with those of the recently introduced algorithm of [2] implemented in the R package "bpr".

Keywords: Count data; Log-linear model; Metropolis-Hastings

1. Introduction

Regression models stand at the core of the analysis of multivariate data sets and of the study of the relationship between several variables. The simplicity of their formulation, combined with the straightforward interpretation of the results, have contributed to their enduring success. When the variable of interest consists of counts, a typical choice is certainly Poisson regression, where the mean parameter of the distribution is linked with the explanatory variables via a logarithmic link function. In the frequentist framework, computation of the maximum likelihood estimates of the regression coefficients via iteratively reweighted least squares algorithm is a well-established procedure. In the Bayesian context, however, since the posterior distribution is not available in closed form, it is customary to approximate it using, for example, some type of Markov chain Monte Carlo method. For this reason, researchers have focused on improving computation for specific classes of models for count data: for example, count-valued time series [5] or hierarchical models [6].

In general, to perform Bayesian inference for Poisson log-linear models, there are mainly two viable options. The first is to rely on libraries such as Jags [3] or Stan [11], which are extremely flexible but require learning their particular programming language; the second is to implement a general algorithm as, for example, a Metropolis-Hastings (MH) [7] algorithm with a suitable proposal density (e.g., a random-walk, or an independent sampler). More recently, [2] developed a Metropolis-Hastings algorithm based on a proposal density which is an approximation of the posterior distribution, and hence leads to superior performances in terms of efficiency and mixing of the chains compared to general proposals. In their work, [2] compared the efficiency of their approach with that of the Hamiltonian Monte-Carlo algorithm [9] implemented using Stan, and they showed that their method held superior performances in scenarios with a moderate number of covariates.

Moving from the analysis of a real dataset of the number of bikes crossings a bridge in New York [10], we delve into the challenges of posterior inference in the context of Bayesian Poisson regression. The dataset we considered is part of a large public data repository provided by the city of New York aimed at studying the road traffic of different types of vehicles to improve transportation planning. In particular, we considered the data collected in 2017 on the Brooklyn Bridge. Each observation corresponds to the daily number of bicycles that crossed the bridge in the period that goes from April to October. Moreover, for each day it is also recorded the maximum and minimum temperature, and the rain intensity, when present. To improve the analysis, we also introduced two additional dummy variables: one that indicates if the day was a weekday or weekend, and a dichotomized version of the precipitation variable (hence indicating only the presence or absence of rain). The dataset hence contains 214 observations of 11 covariates, plus the number of crossings. The bikes count ranges between 151 and 4960; Figure 1 shows its distribution in the two groups identified by the new dummy variables "weekend" and "rain". The number of bicycles crossing the bridge varies greatly depending on the conditions, thus justifying the need to analyze the traffic more thoroughly to improve the management of the city mobility. Regarding the specification of the prior distributions, we selected independent Gaussian priors centered at zero for all the coefficients, since we did not have specific indications or prior knowledge.

The purpose of this paper is twofold: investigating the computational challenges of estimating the parameters of the regression model under consideration, and deriving inferential results on the specific dataset. In Sec. 2, we compare the efficiency of the algorithm of [2] as implemented in the R package `bpr` [1] with that of a MH algorithm with uniform random walk proposals; then, in Sec. 3, we illustrate how the output of the simulation can be used to perform inference on the dataset we considered.

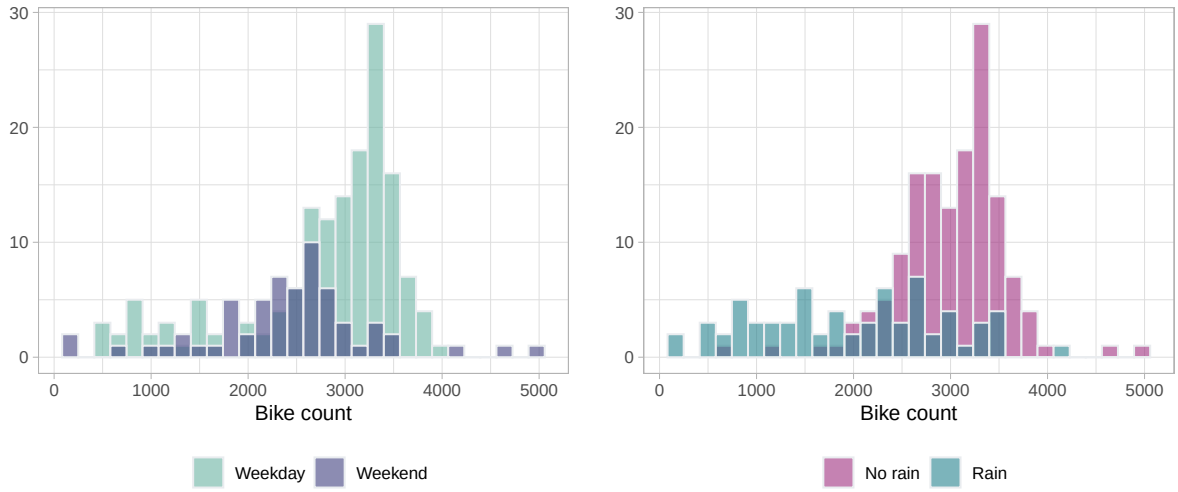

Figure 1: Distribution of the bikes count during weekends/weekdays (left panel), and in days with rain/no rain (right panel).

2. Comparison of posterior sampling algorithms

The Metropolis-Hastings algorithm is a well-known Markov chain Monte Carlo method to simulate a sample from a generic target distribution that is known only up to a normalizing constant. The reasons for its success are clear, as it provides a general and extremely simple strategy to approximate any density, and it is especially useful when the number of dimensions is high and other approaches would be too complex or inaccurate. Briefly, the algorithm works as follows: a tentative sample is proposed from a known density, and the sample is accepted or rejected according to a probability that will allow the chains to have as stationary distribution the target density. In addition to the original formulation, other variants have been proposed to improve particular aspects, for example, the ease of finding a suitable proposal density and the consequent efficiency. For this application, as comparison with the algorithm

of [2], we used a modification of the MH that is more suited for high dimensional settings: in our case the parameter lives in a 12-dimensional space, hence finding an adequate proposal density can be tricky. In particular, we implemented the so-called "component-wise" random walk, where one variable at a time is updated, rather than performing a single full-dimensional update [8]. If, on the one hand, this approach allows defining distributions that ensure an adequate acceptance rate also in high-dimensions; on the other hand, it means selecting 12 tuning parameters (in this case, the "length" of the step), which can be burdensome. This is one of the advantages of the algorithm proposed by [2]: being based on an approximation of the posterior distribution of the coefficients of Poisson regression models, the only tuning parameter is the "distance" of the approximation from the target, hence requiring minimal tuning.

Each algorithm was run for 10000 iterations with 5000 of them discarded as burn-in. The convergence of the chains was assessed by graphical inspection of the trace plots; the tuning parameters were selected by running the algorithms several times on a grid of values to optimize the resulting acceptance rate and effective sample size. Both algorithms are written in C++ language exploiting the Rcpp package [4], and they were executed on a Linux machine running R 4.2.2.

As a metric to compare the results we used the time necessary to generate one independent sample (to take into account the autocorrelation of the chains). It can be computed as the total computation time over the effective sample size. Figure 2 shows the logarithm of the time (in seconds) per independent sample for the two algorithms, for each variable (the logarithmic transformation was used only for graphical purposes). Values larger than 0 means that more than 1 second was necessary to simulate one independent sample. The plot clearly shows the superior performances of the approach of [2], even if the random-walk MH allowed for a "variable-wise" tuning.

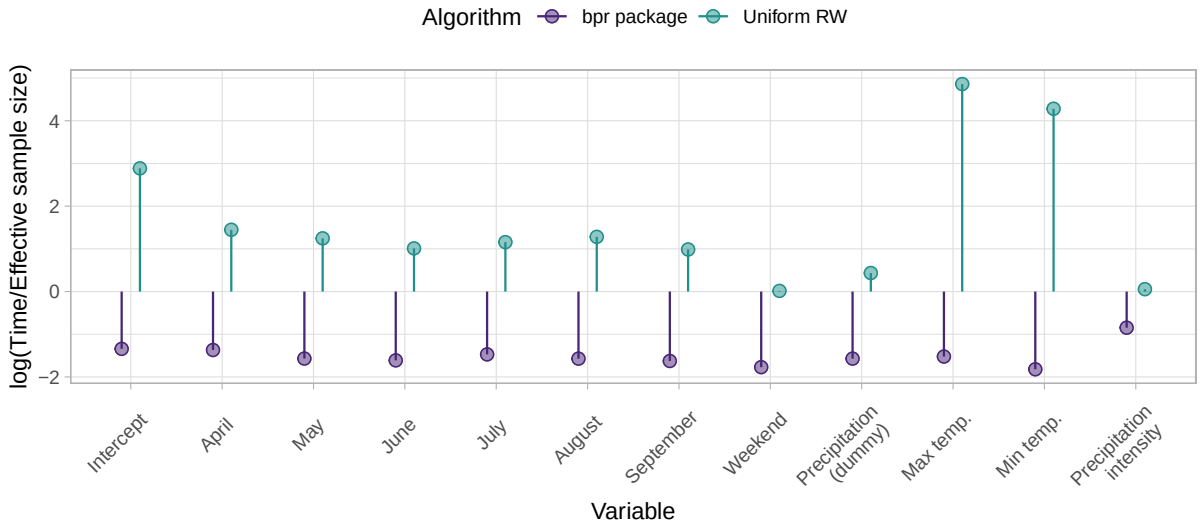

Figure 2: Logarithm of the time per independent sample for the two algorithms, for each variable.

3. Bikes count data analysis

To perform posterior inference on the considered dataset we used the output of the *bpr* R package since the chains have a larger effective sample (thus they convey more information). Table 1 summarizes the estimated coefficients: for each variable, it shows the posterior estimate of the median, mean and standard deviation, and the lower and upper bound of the 95% highest-posterior-density (HPD) interval. The only coefficient for which the credible interval contains 0 is the dummy variable associated with the month of May: hence the effect of this month is the same as the reference month, which is October (we introduced the intercept and removed the associated dummy). All other variables have instead a

Table 1: Summary of the estimated regression coefficients: median, mean and standard deviation; lower and upper bound of the 95% HPD interval.

	Intercept	April	May	June	July	August	September
Median	7.5365	-0.1013	-0.0011	0.0483	0.0146	0.1167	0.0414
Mean	7.5364	-0.1010	-0.0008	0.0480	0.0144	0.1168	0.0416
Std. dev.	0.0073	0.0052	0.0050	0.0052	0.0057	0.0056	0.0051
HPD lower	7.5226	-0.1117	-0.0093	0.0380	0.0037	0.1058	0.0321
HPD upper	7.5506	-0.0918	0.0104	0.0573	0.0246	0.1279	0.0516

	Weekend (dummy)	Precipitation (dummy)	Max temperature	Min temperature	Precipitation intensity
Median	-0.1165	-0.1304	0.0399	-0.0291	-0.6441
Mean	-0.1166	-0.1304	0.0400	-0.0291	-0.6442
Std. dev.	0.0028	0.0035	0.0005	0.0007	0.0073
HPD lower	-0.1219	-0.1368	0.0389	-0.0304	-0.6564
HPD upper	-0.1109	-0.1235	0.0410	-0.0278	-0.6292

non-null effect on the mean number of bikes. Looking at the bottom table it is possible to notice how, as expected, the variables associated with a worsening of the atmospheric conditions (presence and intensity of rain, lowering temperature) have a negative effect, with the strongest being the presence of rain. More interesting is the coefficient of the day of the week: the traffic of bikes is more intense during weekdays, hence it is possible that many of the cyclists moving between Brooklyn and Manhattan use their bikes to go to work rather than for pleasure.

To ease the interpretation of the coefficients associated with the months, in Figure 3 it is shown the distribution of the parameters. From the plot it is immediate to see what months are associated with an increased number of bikes: as expected, spring and summer have a positive effect with respect to October. Surprisingly, April has a strong negative effect: however, if we further analyze the characteristics of that particular month, it is possible to see that it was much colder than all other months, even than October. Hence the coefficient of the temperature could not fully capture the exceptional cold of that period compared to the rest of spring and summer.

Although the dataset we considered is quite simple, with only a few recorded meteorological variables, the results are still interesting in showing a clear pattern of the bike traffic moving between Brooklyn and Manhattan. This kind of analysis could turn extremely useful for city planning to improve mobility and safety of the people, for example, by reducing or increasing the space reserved for bicycles according to the period of the year.

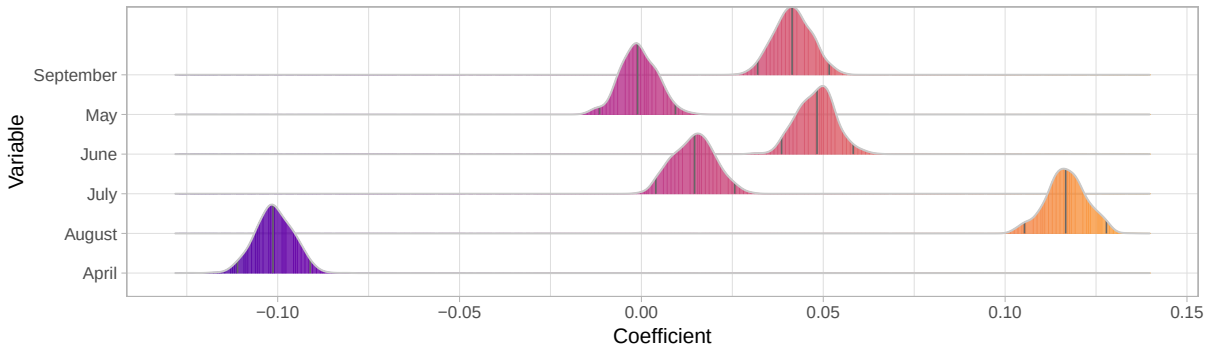

Figure 3: Posterior distribution of the coefficients associated with the month variables. The vertical dark lines corresponds to the lower bound of the HPD interval, median, and upper bound of the HPD interval.

Abstract

Poisson regression models for count responses are routinely used in statistical practice. However, some difficulties may arise when there is limited information within the data: the maximum likelihood estimate may not exist or it could be highly biased. We address this issue by considering a suitable penalty for the likelihood function. Such a penalization term has a clear Bayesian interpretation and important connections with the reduced-bias approach of Firth (1993) [5]. We show that the associated penalized estimates may be obtained by maximizing a genuine likelihood in which pseudo-counts are used in place of the original data. Compared to the method of [5], our approach speeds up computations by a significant margin, as it leverages well-established algorithms for Poisson models. This is achieved while maintaining comparable inferential performance, as illustrated through an application to real data.

Keywords: Bias-reduction, Conjugate priors, Penalized generalized linear models, Poisson regression.

1. Introduction

Generalized linear models [18] (GLM) are classical tools for the modeling of the relationship between a response variable and a set of predictors. A canonical overview is the book by [16]. Despite their popularity, GLMs have some well-known limitations. One aspect of potential concern is the presence of bias in the maximum likelihood estimates, which, beyond the Gaussian case, may impact the inferential conclusions. To address this issue, a variety of methods have been proposed in the literature, including the bias-reduction technique of [5] and subsequent developments; see for example [12; 13; 14; 15; 10; 9; 2]. Unfortunately, albeit theoretically appealing, most of these methods may face computational bottlenecks.

In a recent paper, [19] presents a fast alternative to Firth's method in the logistic regression case, which is based on a penalized likelihood function. The key idea relies on the notion of conjugate priors for exponential family models, due to Diaconis and Ylvisaker (1979) [4] and well experienced by several authors; see, for example, [1; 7; 8]. Indeed, [19] penalizes the likelihood by the conjugate prior defined in [4; 1], showing that, under suitably specified parameters, the results can be seen as an approximation of Firth's method [5]. Such an approach is a milestone in the bias-reduction literature, being routinely employed in applied studies thanks to various software implementations [e.g., 11].

Actually, most works on bias reduction for GLM regard Binomial responses. Indeed, binary regression is widely used in several fields but is also more vulnerable to issues, such as data *separability*,

which leads to infinite MLE. Even if this issue is mostly recurrent in logistic regression, it also occurs in other models, such as the Poisson regression. Hence, we will borrow ideas from [19] to present a bias-reduction method for Poisson regression models that brings computational advantages. Similar to this approach, we penalize the likelihood with the Diaconis-Ylvisaker (DY) conjugate prior, obtaining a convenient formulation. The resulting posterior law is a genuine likelihood function in which *pseudo-counts* are employed rather than the original response variables. In particular, each pseudo-count is a linear combination of the original data and the parameters of the DY prior.

The demand for bias-reduction methodologies in Poisson models descends from their broad range of applications. Indeed, the Poisson regression is an essential tool in applied research, see for further details [6; 17]. Moreover, the growing complexity of the contexts in which these models are employed justifies the necessity of faster alternatives.

In this manuscript, we will focus on count response data. More precisely, we assume that the response variables $Y_1, \ldots, Y_n$ are such that

$$Y_i \overset{\text{ind}}{\sim} \text{Pois}(\lambda_i), \qquad g(\lambda_i) = \boldsymbol{x}_i^\intercal \boldsymbol{\beta} = \beta_1 x_{i1} + \cdots + \beta_p x_{ip}, \tag{1}$$

independently for $i = 1, \ldots, n$. The vector $\boldsymbol{x}_i = (x_{i1}, \ldots, x_{ip})^\intercal$ contains the covariate information of the ith observation, whereas the p-dimensional vector $\boldsymbol{\beta} = (\beta_1, \ldots, \beta_p)^\intercal$ corresponds to the regression coefficients. The function $g(\cdot)$ is the *link function*, which in this paper is assumed to be $g(\cdot) = \log(\cdot)$, that is, the so-called canonical link for Poisson models [16].

2. Diaconis and Ylvisaker conjugate priors

Let $\boldsymbol{y} = (y_1, \ldots, y_n)^\intercal$ be realizations of independent Poisson random variables with means $\lambda_1, \ldots, \lambda_n$, as in (1). Thus, the likelihood function assumes the following form

$$\mathscr{L}(\boldsymbol{\beta}; \boldsymbol{y}) \propto \exp\left[\sum_{i=1}^{n} \{y_i \boldsymbol{x}_i^\intercal \boldsymbol{\beta} - \exp(\boldsymbol{x}_i^\intercal \boldsymbol{\beta})\}\right]. \tag{2}$$

Following [1; 19], we consider the DY conjugate prior for the regression coefficients $\boldsymbol{\beta}$, with density proportional to

$$\pi(\boldsymbol{\beta}) \propto \exp\left[\tau \sum_{i=1}^{n} \{\psi_i \boldsymbol{x}_i^\intercal \boldsymbol{\beta} - \exp(\boldsymbol{x}_i^\intercal \boldsymbol{\beta})\}\right], \tag{3}$$

where $\tau > 0$ and $\boldsymbol{\psi} = (\psi_1, \ldots, \psi_n)^\intercal$ are prior hyperparameters such that $\psi_i > 0$, for $i = 1, \ldots, n$. The hyperparameters τ and $\boldsymbol{\psi}$ can be interpreted as scale and location parameters, respectively. Specifically, τ controls the variability and the strength of the prior belief on $\boldsymbol{\psi}$, with larger values for $\tau > 0$ representing strong prior information and smaller τ less confidence in $\pi(\boldsymbol{\beta})$. Instead, $\boldsymbol{\psi}$ is the mode of the prior distribution, thus defining a location parameter for $\pi(\boldsymbol{\beta})$.

The posterior distribution can be obtained combining prior information (3) with the likelihood function (2) as $\pi(\boldsymbol{\beta} \mid \boldsymbol{y}) \propto \pi(\boldsymbol{\beta}) \mathscr{L}(\boldsymbol{\beta}; \boldsymbol{y})$, leading to

$$\pi(\boldsymbol{\beta} \mid \boldsymbol{y}) \propto \exp\left[(\tau + 1)\left\{\sum_{i=i}^{n} \left(\frac{\tau\psi_i + y_i}{\tau + 1}\right) \boldsymbol{x}_i^\intercal \boldsymbol{\beta} - \exp(\boldsymbol{x}_i^\intercal \boldsymbol{\beta})\right\}\right]. \tag{4}$$

In equation (4), it is easy to see that the posterior is in the same family of the prior, leading to a posterior distribution which is again in the DY family with updated parameters. In addition, the results in [1] guarantee that (4) has a finite normalizing constant, and therefore can be regarded as a proper posterior distribution. The prior parameters $\boldsymbol{\psi}$ are updated, obtaining the pseudo-counts $\tilde{y}_i = (y_i + \tau\psi_i)/(\tau + 1)$ for $i = 1, \ldots, n$. We will later tune the prior hyperparameters for bias reduction purposes. Similarly to [19] the penalized likelihood is equivalent to the original one minus a constant term depending only on the hyperparameter τ, that is

$$\pi(\boldsymbol{\beta} \mid \boldsymbol{y}) \propto \exp\{(\tau + 1)\ell(\boldsymbol{\beta}; \tilde{\boldsymbol{y}})\}, \tag{5}$$

where $\ell(\boldsymbol{\beta}; \tilde{\boldsymbol{y}})$ is the log-likelihood and $\tilde{\boldsymbol{y}} = (\tilde{y}_1, \ldots, \tilde{y}_n)^\intercal$. From (5), it follows that the maximum a posteriori (MAP) of $\pi(\boldsymbol{\beta} \mid \boldsymbol{y})$ corresponds to the MLE obtained from $\ell(\boldsymbol{\beta}; \tilde{\boldsymbol{y}})$. This result allows us to rely on standard algorithms for Poisson regression, obtaining important computational benefits.

3. Penalized score equations

We now introduce the score function, defined as the vector of derivatives $U(\boldsymbol{\beta}) = \partial \ell(\boldsymbol{\beta}) / \partial \boldsymbol{\beta}$. Maximum likelihood estimates are obtained as the solution of the system of *score equations* $U_r(\boldsymbol{\beta}) = 0$, for $r = 1, \ldots, p$. A penalization for the likelihood leads to penalized score equations, so that

$$U_r(\boldsymbol{\beta}) = \sum_{i=1}^{n} (y_i - \mu_i) x_{ir} \ , \quad U_{r,\text{DY}}(\boldsymbol{\beta}) = C(\tau) \sum_{i=1}^{n} (\tilde{y}_i - \mu_i) x_{ir} \ , \quad U_{r,\text{FI}}(\boldsymbol{\beta}) = \sum_{i=1}^{n} (y_i^* - \mu_i) x_{ir}, \quad (6)$$

with $r = 1, \ldots, p$ and $\mu_i = \exp(\boldsymbol{x}_i^\intercal \boldsymbol{\beta})$, where $U_r(\boldsymbol{\beta})$ is the score equation for the original model, $U_{r,\text{DY}}(\boldsymbol{\beta})$ relies on the score equation of our penalized model with $C(\tau) = (\tau + 1)$, and $U_{r,\text{FI}}(\boldsymbol{\beta})$ is the score equations obtained with [5]. In particular, Firth's pseudo-counts correspond to $y_i^* = y_i + h_{ii}/2$ for $i = 1, \ldots, n$, where $h_{11}, \ldots, h_{nn}$ represent the diagonal elements of the *leverage matrix* $H(\boldsymbol{\beta}) = W(\boldsymbol{\beta})^{1/2} X (X^\intercal W(\boldsymbol{\beta}) X)^{-1} X^\intercal W(\boldsymbol{\beta})^{1/2}$, with $W(\boldsymbol{\beta}) = \text{diag}(\lambda_1, \ldots, \lambda_n)$.

The score equations in (6) are similar and involve different pseudo-observations. Our approach and the one by [5] provide a penalized system of score equations depending on a different set of pseudo-counts, respectively defined as

$$y_i^* = y_i + \frac{h_{ii}}{2} \ , \quad \tilde{y}_i = \frac{y_i + \tau \psi_i}{\tau + 1} \ , \quad i = 1, \ldots, n. \quad (7)$$

Firth's pseudo-counts $\boldsymbol{y}^* = (y_1^*, \ldots, y_n^*)^\intercal$ depend on the diagonal elements of $H(\boldsymbol{\beta})$, while $\tilde{\boldsymbol{y}}$ depends only on the prior hyperparameters τ and $\boldsymbol{\psi}$. We search for the values τ and $\boldsymbol{\psi}$ that introduce as much similarity as possible between $\tilde{\boldsymbol{y}}$ and $\boldsymbol{y}^*$. Indeed, it is well-known that [5] removes the first-order term of the asymptotic bias.

Henceforth, we exploit the concept of *quadratic balance approximation*, discussed in [3]. This is a computational expedient that avoids the computational drawbacks due to the computation of $H(\boldsymbol{\beta})$ at each iteration of the optimization procedure. It can be shown that $H(\boldsymbol{\beta})$ is a projection matrix with a suitable algebraic property: if the design matrix has full rank, the trace of $H(\boldsymbol{\beta})$ is equal to its rank, which is p. Thus, one could approximate each h_{ii} for $i = 1, \ldots, n$ with their mean, obtained as the ratio between the trace of $H(\boldsymbol{\beta})$ and the dimension of its diagonal n, that is p/n. We call this procedure *mean approximation*, in order to discern it from the concept discussed in [3].

The mean approximation is the tool that allows us to reach the similarity between the pseudo-counts. We set the hyperparameters that define $\tilde{\boldsymbol{y}}$ with the purpose of emulating the pseudo-observations $\boldsymbol{y}^*$. In particular, we can substitute the terms h_{ii} with p/n. To mimic this idea under the DY penalty, we allow $\tau = \tau(\alpha)$ and each $\psi_i = \psi_i(\alpha)$ to depend on a fixed constant $\alpha > 0$, chosen so that $\tau(\alpha)\psi_i(\alpha) = p/(2n)$, obtaining

$$\tilde{y}_i(\alpha) = \frac{y_i + \tau(\alpha)\psi_i(\alpha)}{\tau(\alpha) + 1} = \frac{y_i + p/(2n)}{\tau(\alpha) + 1}, \qquad i = 1, \ldots, n. \quad (8)$$

For example, one could set $\tau(\alpha) = p/(\alpha n)$ and $\psi_i(\alpha) = \alpha/2$ for $i = 1, \ldots, n$. The pseudo-counts in (8) do not correspond exactly with the mean approximation of Firth's pseudo-counts, which would be $y_i + p/(2n)$. However, note that the mean approximation of the pseudo-counts can be seen as the result of an improper prior, occurring when the precision $\tau(\alpha) \to 0$. The pseudo-counts $\tilde{\boldsymbol{y}}$ defined in (8) have two important implications: as desired, we recover a quantity that resembles the mean approximation of $\boldsymbol{y}^*$. Secondly, we have an increasing coincidence between $U_{\text{DY}}(\boldsymbol{\beta})$ and $U_{\text{FI}}(\boldsymbol{\beta})$, as the following study suggests.

4. Illustration

We follow the structure of the *birthweight* example presented in [15] and [19], considering the *infert* data. The data regard $n = 248$ women in a case-control study, in which the number of spontaneous aborts is considered as a count outcome. The models consider a regression of the response variable on an intercept and six covariates, leading to $p = 7$. In this example, maximum likelihood estimates $\hat{\boldsymbol{\beta}} = (\hat{\beta}_1, \ldots, \hat{\beta}_7)^\intercal$ of the regression coefficients $\boldsymbol{\beta}$ exists finite. In this illustration, we simulate 10000 datasets from a Poisson regression model with parameter $\hat{\boldsymbol{\beta}}$ obtained as MLE from the original data. This allows us to evaluate estimators' behavior for all the models presented in Section 3. Moreover, we compare their performances in terms of bias and root mean squared error (RMSE). Results are presented in Table 1.

		β_1	β_2	β_3	β_4	β_5	β_6	β_7
BIAS	$\hat{\boldsymbol{\beta}}_{\text{MLE}}$	-0.20	0.21	0.21	0	0.00	-0.01	0.00
	$\hat{\boldsymbol{\beta}}_{\text{DY}}$	-0.09	0.09	0.09	0	-0.01	0.02	-0.02
	$\hat{\boldsymbol{\beta}}_{\text{FI}}$	0.00	0.00	0.00	0	0.00	0.00	0.00
RMSE	$\hat{\boldsymbol{\beta}}_{\text{MLE}}$	1.57	1.49	1.49	0.02	0.07	0.16	0.17
	$\hat{\boldsymbol{\beta}}_{\text{DY}}$	0.78	0.60	0.60	0.02	0.07	0.15	0.17
	$\hat{\boldsymbol{\beta}}_{\text{FI}}$	0.73	0.53	0.53	0.02	0.07	0.16	0.17

Table 1: Simulation study results on the regression coefficients estimates obtained for spontaneous abort counts problem from the three models considered.

The estimator $\hat{\boldsymbol{\beta}}_{\text{MLE}}$ performs significantly worse than all the reduced-bias methodologies in terms of bias and RMSE. Moreover, we observe a striking empirical similarity in terms of bias between the performance of the proposed penalized estimator $\hat{\boldsymbol{\beta}}_{\text{DY}}$ and the one of [5]. This finding is in line with the considerations discussed in Section 2. As a matter of fact, the proposed penalized estimator $\hat{\boldsymbol{\beta}}_{\text{DY}}$ has only a slightly worse RMSE compared to $\hat{\boldsymbol{\beta}}_{\text{FI}}$.

In addition, we investigate the computational timing of the estimation process for both our and [5] model, relying on a native R implementation and considering 100 replications.

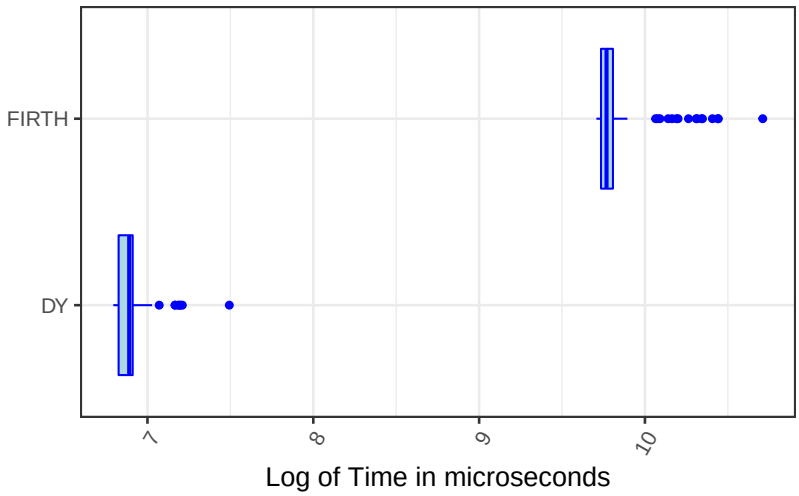

Figure 1: Timing boxplot of the estimation processes for the DY penalized and the Firth's models.

Results are presented in Figure 1, where it is evident that the proposed approach outperforms the competitor. In particular, our model estimation process takes approximately 19 times less than the com-

pared one. This is a further indication that the proposed contribution avoids the computational drawbacks of the milestones in bias-reduction techniques, while retaining comparable performance.

Abstract

In this paper, we propose a Bayesian nonparametric level-dependent mixture model for clustering. To achieve this, we employ a vector of species sampling models with shared atoms and level-specific weights. This results in multiple random probability measures with a common support, which we use to perform both inter-level and within-level clustering of the data. This approach enables us to take into account both heterogeneity and common patterns shared across levels in our clustering analysis. Specifically, we study the properties of the group-dependent clustering structure induced by our hierarchical mixture model. We develop both a marginal and a conditional Gibbs sampler to perform Bayesian inference. We evaluate the model's ability to recover the original clustering of the data and assess its goodness of fit through simulated data.

Keywords: Bayesian analysis, clustering, partial exchangeability, density estimation

1. Introduction

In several statistical settings there is the need to model multilevel data, allowing for sharing of information across the levels. In the Bayesian framework, this is achieved by hierarchical modeling, where the joint distribution of level-specific parameters accounts for such dependence. For instance, in Bayesian nonparametrics, the seminal work by (11) considered a mixture model within each level, say j, where the level-specific parameter is the mixing measure P_j whose joint law is defined by an extra layer of hierarchy, yielding to the hierarchical Dirichlet process. This approach has been extended to the class of Normalized Random Measures with Independent Increments (NRMI) (10) by (6) and (1) and to species sampling models by (3).

In this work, we propose a hierarchical model where the level-specific mixing distribution belongs to the class of almost surely finite dimensional distributions introduced by (2). The following are defined such that they have level-specific weights but shared atoms, i.e they share the same support. The idea of using a common support for the mixing measures reminds the recent works by (4), (8) and (7) with the difference that both previous works build the dependent prior following a nested approach while we focus on the hierarchical construction. By following this approach, we attain both a level-specific and a global clustering of the observations. Specifically, for each individual i and each level j, we independently sample a latent parameter $\boldsymbol{\theta}_{ji}$ from P_j, which is almost surely discrete. This results in ties within each level, thus producing a level-specific clustering. Furthermore, since the P_j's share the same support, we expect also ties between levels, providing a global clustering.

The paper proceeds as follow, in Section 2. we define the vector of species sampling models and derive the proposed model. Then in Section 3. we shade light on the clustering mechanism induced by the model and in Section 4. we provide a simulation study to assess the ability of recovering the true partitioning of the data as well as to perform density estimation.

2. Model

Consider d levels of observations, $\boldsymbol{y}_j = \left(y_{j1}, \ldots, y_{jn_j}\right)$ for $j = 1, \ldots, d$ that we assume to be partially exchangeable. This means that the level membership introduces heterogeneity across subgroups of the population. Traditional modeling approaches such as pooling all observations or performing d level independent analysis fall short in capturing both the differences across levels or the relationships between the observations, which relate to the same phenomenon and therefore may share common patters. To balance these opposing situations, we aim to build a statistical model that accounts for heterogeneity while also allowing for borrowing of strength across units.

For example, referring to Figure 1, we model students within each school to be exchangeable but we do not allow for exchangeability between schools acknowledging that their performances may be influenced by their school membership. At the same time, it would also be advantageous to share information across schools.

Let y_{ji} be the observed variable for level j, and individual i, $i = 1, \ldots, n_j$. We assume that the data in each level j come from a finite mixture of M components, that is

$$y_{j1}, \ldots, y_{jn_j} \overset{\text{iid}}{\sim} \int_{\Theta} f(y_{ji}|\boldsymbol{\theta}_j) P_j(d\boldsymbol{\theta}_j), \quad \text{for each } j = 1, \ldots, d, \tag{1}$$

where $f(y_{ji} \mid \boldsymbol{\theta}_j)$ is the parametric density kernel over the sampling space, $\boldsymbol{\theta}_j \in \Theta \subset \mathbb{R}^l$ for each $j = 1, \ldots, d$ and $P_1, \ldots, P_d$ are the mixing measures. In the present work, we focus on finite dependent random probability measures having support Θ defined as follows,

$$P_j(\cdot) = \sum_{m=1}^{M} \frac{S_{jm}}{T_j} \delta_{\tau_m}(\cdot), \tag{2}$$

having denoted by δ_{τ_m} the delta-Dirac mass at τ_m, and $T_j = \sum_{m=1}^{M} S_{jm}$ is the total mass. Here $(\tau_1, \ldots, \tau_M)$ are common random atoms across the d random probability measures, which are assumed independent and identically distributed with common distribution P_0 i.e, a diffuse probability measure on $\mathbb{R}^l$. The unnormalized weights $(S_{j1}, \ldots, S_{jM})$ are i.i.d. from gamma$(\gamma_j, 1)$, where γ_j is a parameter specific for level $j \in \{1, \ldots, d\}$. The induced prior on the normalized mixture weights $(\pi_{j1}, \ldots, \pi_{jM})$ is

$$(\pi_{j1}, \ldots, \pi_{jM}) = \left(\frac{S_{j1}}{T_j}, \ldots, \frac{S_{jM}}{T_j}\right) \sim \text{Dir}_M(\gamma_j, \ldots, \gamma_j), \quad \text{for each } j = 1 \ldots, d,$$

where $\text{Dir}_M(\gamma_j, \ldots, \gamma_j)$ denotes the M-dimensional symmetric Dirichlet distribution with parameter γ_j. Finally, M is supposed to be a positive integer-valued random variable with distribution $q_M(\cdot)$ on $\{1, 2, 3, \ldots\}$.

Summing up, the model can be formulated in the following hierarchical form,

$$\begin{aligned}
y_{j1}, \ldots, y_{jn_j} \mid \boldsymbol{w}, \boldsymbol{\tau}, M &\overset{\text{iid}}{\sim} \sum_{m=1}^{M} w_{jm} f(y_{ji} \mid \boldsymbol{\tau}_m), && \text{for } j = 1, \ldots, d \\
\tau_1, \ldots, \tau_M \mid M &\overset{\text{iid}}{\sim} P_0\,(d\theta) && \\
S_{j1}, \ldots, S_{jM} \mid \gamma_j, M &\overset{\text{iid}}{\sim} \text{gamma}\left(\gamma_j, 1\right), && \text{for } j = 1, \ldots, d \\
\gamma_1, \ldots, \gamma_M \mid M &\overset{\text{iid}}{\sim} \text{gamma}\,(a_1, b_1) && \\
M &\sim q_M(M). &&
\end{aligned} \tag{3}$$

In this work we focus on the particular case where the kernel $f(y \mid \boldsymbol{\theta})$ represents the density of a univariate normal distribution with parameter $\boldsymbol{\theta} = (\mu, \sigma^2)$, hence $l = 2$ and $\Theta = \mathbb{R} \times \mathbb{R}^+$. We choose $P_0(\boldsymbol{\theta})$ as the density of a conjugate normal inverse gamma prior with parameters μ_0, κ_0, ν_0 and σ_0^2. Finally, we set $q_M(\cdot)$ to be the p.m.f. of a 1−shifted Poisson distribution with parameter Λ. To allow further flexibility, we also place a gamma(a_2, b_2) prior on Λ.

3. Model Based Clustering

The hierarchical model in (3) allows to define a level-dependent clustering based on the latent variables $\boldsymbol{\theta}_{ji}$. First, we introduce latent allocation variables c_{ji} such that $c_{ji} = m$ if $\boldsymbol{\theta}_{ji} = \tau_m$. Then, we denote $\mathscr{M}^{(a)}$ the set of couples (j, m) such that exists an index i for which $c_{ij} = m$ and we define the number of allocated components as

$$K = \left| \left\{ m \in \{1, \dots, M\} \ : \ \text{there exists one couple}(j, m) \in \mathscr{M}^{(a)}, j = 1, \dots, d \right\} \right|,$$

where the $|\cdot|$ operator indicates the cardinality of the set. We denote $\mathscr{M}^{(na)}$ the complement of $\mathscr{M}^{(a)}$. Hence, for every pair (j, m), we define $n_{jm} = |\{(j, i) : \ c_{ji} = m\}|$. Note that

$$(j, m) \in \mathscr{M}^{(na)} \Rightarrow n_{jm} = 0$$

$$(j, m) \in \mathscr{M}^{(a)} \Rightarrow n_{jm} \geq 0.$$

Finally, let $c_1^*, \dots, c_K^*$ be the allocated columns, that is, the indexes within $\{1, \dots, M\}$ such that $(j, c_k^*) \in \mathscr{M}^{(a)}$. For each level j, we define the partition $\rho_j = \{C_{j1}, \dots, C_{jK}\}$, where $C_{jk} = \{(j, i) : \ (j, c_{ki}^*) \in \mathscr{M}^{(a)}\}$ and $k = 1, ..., K$. In other words, C_{jk} is the set of data points of level j belonging to the k-th cluster. By construction, $n_{jk} = |C_{jk}|$. A distinctive feature of our setting, is that some C_{jk} can be an empty sets. Nevertheless, if $C_{jk} = \emptyset$ appears in ρ_j, it means that there is at least another group $\tilde{j}$ such that $C_{\tilde{j}k}$ is not empty. In other words, $n_{jk} \geq 0$ but they must satisfy the following constrains

$$\sum_{j=1}^{d} n_{jk} > 0, \text{ and } \sum_{k=1}^{K} n_{jk} = n_j,$$

for $k = 1, ..., K$ and $j = 1, \dots, d$ respectively.

Figure 1 provides a visual representation of the clustering. In this example, we measure data for each student in each of the $d = 3$ schools (levels). To account for heterogeneity between schools, students are assumed to be partially exchangeable, i.e they are exchangeable within each school but not across different schools. Each color represent a cluster, hence $K = 2$. The same color in different schools shows how clusters with the same interpretation can be found in different schools.

4. Simulation Study

In this section we aim to assess the performance of our model in terms of ability of recovering the original clustering of the observations as well as to evaluate its goodness of fit. In particular, to evaluate the clustering we monitor the estimated number of clusters as well as the popular Rand Index (RI). Additionally, we perform density estimation and visually inspect the results to gain further insights, see Figure 2.

We generated data from $d = 3$ distinct levels of 200, 100, 100 observations, respectively. The global number of clusters K is 4 with means $-20, -10, 0, 15$ and standard deviations $2, 1, 2.5, 3$. Data in the first level are generated from a mixture of all four clusters with weights equal to $2/10, 3/10, 1/10, 4/10$. This is the only level where all 4 clusters are present, the second level does not include the cluster with mean equal to -10 while the third level does not include neither the one centered in -20 nor the one

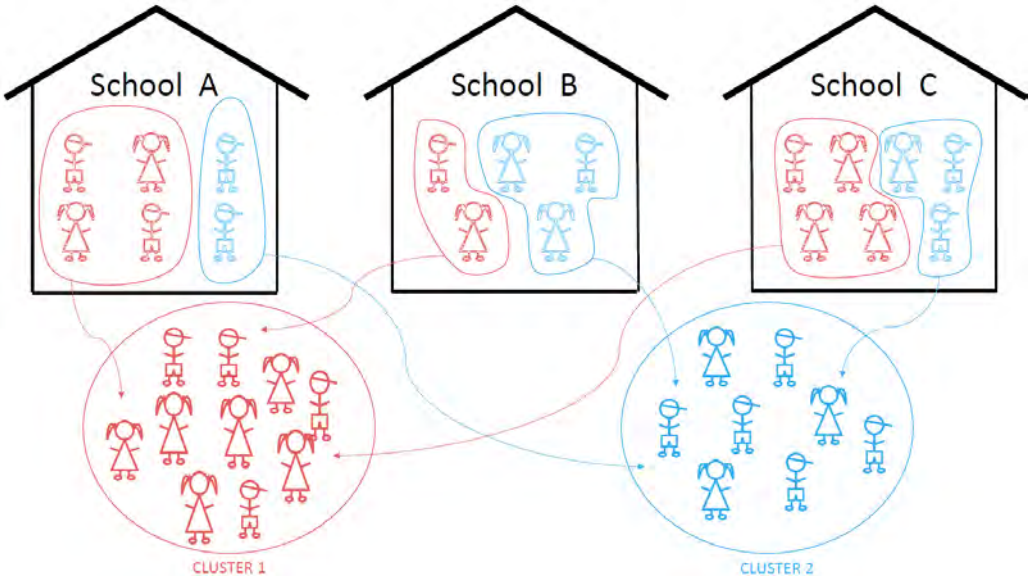

Figure 1: Visualization of local and global clustering. Each color represents a cluster

centered in 0. The mixture weights are equal to $3/10, 3/10, 4/10$ and $2/10, 8/10$, respectively. Given such framework, we generated 50 independent different datasets.

We follow a default non informative choice for both the process and P_0 hyperparameters. The first ones are $a_1 = 1$, $b_1 = 1$, $a_2 = 10$, $b_2 = 2$ while the second ones are $(\mu_0, \kappa_0, \nu_0, \sigma_0^2) = (0, 0.1, 10, 1)$. In all simulations, we started the MCMC with the empty partitions, i.e each data point is a cluster by its own. To perform posterior inference, we developed a marginal posterior sampler. Once the posterior sample has been collected, a point estimate for the partition by minimizing the expected posterior loss. Different choices can be made for the loss function, in this work we resort to the variation of information loss function (9) which is preferred to the Binder loss function (5) as tends to avoid clusters of size 1.

Throughout the 50 repetitions, the true partition has almost always been recovered correctly. The mean RI value is 0.985 with very little standard deviation (0.084). The estimated number of cluster has always been the correct one, that is 4, but only one time. Finally, Figure 2 shows the estimated density where the solid red line is the true density that generated the data while the solid blue line is the density estimated by our model, with the corresponding 2.5% and 97.5% credibility bands. In particular, we highlight how in the second level, our estimated density presents a small peak in $x = -10$ even though there are no points in that area. The peak is so small that it does not really influence the result, nevertheless it is a perfect example of the borrowing of information across the levels that is allowed by our hierarchical model.

Going forward, our efforts will be directed towards both theoretical and practical advancements. We intend to delve deeper into the distributional properties of the proposed model, focusing specifically on the distribution of the number of clusters induced by the prior. Additionally, we plan to apply the model to real-world environmental data to demonstrate its practicality.

Abstract

Evaluation of reliability of a production process is a crucial step in sustainability assessment. In this article we consider the sample size determination problem when time-to-failure is modeled by a Rayleigh distribution. Following a hybrid Bayesian-frequentist approach, the selection of the number of units is based on the so-called probability of success (PoS) of the experiment, that is the expected value of the power function with respect to a design prior distribution for the mean failure time. This method works properly only if PoS is a representative summary of the distribution of the power function induced by the design prior. Therefore we derive and analyze the density of the power function for one-sided tests on the Rayleigh parameter, using conjugate design priors. Numerical examples are discussed.

Keywords: Bayesian analysis, power function, probability of success, Rayleigh model, sample size determination.

1. Introduction

Sustainability is of great importance in the development of new technologies. However the life cycle of a product and the failure probability of its components strongly influence its overall environmental impact. Thus, evaluation of sustainability in the production process should be accompanied by the assessment of reliability since the earliest steps of design and production. In this paper we consider the Rayleigh distribution, often used to model time-to-failure in reliability analysis (see for instance (1)). We focus on sample size determination, one of the first issues to be addressed in experimental design, usually based on the power of a statistical test, that is a function of the unknown parameter of a model. Following the Bayesian approach to experimental design, instead of relying on a single design value we specify a design prior distribution that models possible uncertainty on the true value of the parameter of interest Θ, here considered as a random variable. As a consequence, the power function is a random variable as well: its distribution is typically summarized by taking its expectation that is the so-called probability of success (PoS) of the experiment (2; 3; 4): the larger its value, the higher the chances of observing data supporting reliability. The limitations of PoS as a suitable summary of the random power function have been pointed out in (5) with reference to tests on the location parameter of the normal model. The Authors propose to study the whole distribution instead of considering only its expected value. In this paper we follow this idea with application to the scale parameter of a Rayleigh model. Specifically, we derive the closed-form expressions for the cumulative distribution function (cdf) and probability density function (pdf) of the power function, induced by a conjugate prior on Θ.

2. Methodology

Let $\boldsymbol{X_n} = (X_1, \ldots, X_n)$ be a random sample from a Rayleigh distribution where $\theta \in \mathbb{R}^+$ is the scale parameter of interest. The density function is

$$f_X(x|\theta) = \frac{x}{\theta^2} \exp\left\{-\frac{x^2}{2\theta^2}\right\}, \quad x \geq 0, \quad \theta > 0. \tag{1}$$

It is easy to check that $T(\boldsymbol{x_n}) = \sum_{i=1}^n x_i^2$ is a sufficient complete statistic and that

$$W(\boldsymbol{X_n}, \theta) = \frac{T(\boldsymbol{X_n})}{\theta^2} \sim \chi^2_{2n} \tag{2}$$

is a pivotal quantity for θ. Without loss of generality we consider the one-sided test $H_0 : \theta \geq \theta_0$ vs $H_1 : \theta < \theta_0$. The size-α uniformly most powerful test rejects the null hypothesis if $W(\boldsymbol{X_n}, \theta_0) \leq q(\alpha)$, where $q(\alpha)$ is the α-level quantile of the χ^2_{2n} distribution. The power function is then

$$\begin{aligned} \beta_n(\theta) &= \mathbb{P}\left[W(\boldsymbol{X_n}, \theta_0) \leq q(\alpha) \,\middle|\, \theta\right] \\ &= \mathbb{P}\left[W(\boldsymbol{X_n}, \theta) \leq \left(\frac{\theta_0}{\theta}\right)^2 q(\alpha)\right] \\ &= \mathbb{F}\left[\left(\frac{\theta_0}{\theta}\right)^2 q(\alpha)\right] \end{aligned} \tag{3}$$

where $\mathbb{P}(\cdot)$ and $\mathbb{F}(\cdot)$ are the probability measure and the cdf of the χ^2_{2n} random variable. According to the Bayesian approach to experimental design (3), we assign a design distribution to Θ and we denote by $\mathbb{P}_\Theta(\cdot)$, $\mathbb{F}_\Theta(\cdot)$, $f_\Theta(\cdot)$, $\mathbb{E}_\Theta(\cdot)$ the corresponding probability measure, cdf, pdf and expected value. Specifically, we consider a conjugate square root inverse gamma as design prior (see (1)), i.e. $\Theta \sim \text{SqInvGa}(a, b)$, whose prior mode is $\tilde{\theta} = \sqrt{2b/(2a+1)}$ and prior sample size (that controls the precision of the distribution) is $n_d = 2a+1$. Following (5), we now consider the random variable $\beta_n(\Theta)$ with cdf

$$\begin{aligned} G(y) &= \mathbb{P}_\Theta\left[\beta_n(\Theta) \leq y\right] \\ &= \mathbb{P}_\Theta\left(\mathbb{F}\left[\left(\frac{\theta_0}{\theta}\right)^2 q(\alpha)\right] \leq y\right) = \\ &= \mathbb{P}_\Theta\left[\left(\frac{\theta_0}{\theta}\right)^2 q(\alpha) \leq q(y)\right] = \\ &= 1 - \mathbb{F}_\Theta\left[\theta_0 \left(\frac{q(\alpha)}{q(y)}\right)^{1/2}\right]. \end{aligned} \tag{4}$$

Then, by deriving $G(y)$ with respect to y we obtain the density function of $\beta_n(\Theta)$

$$g(y) = K \cdot \left[\theta_0^2 q(\alpha)\right]^{-a} \left[q(y)\right]^{a-n} \exp\left\{-\frac{q(y)}{2}\left[\frac{b}{q(\alpha)\theta_0^2} - 1\right]\right\}. \tag{5}$$

where $K = b^a \left[\Gamma(a)\Gamma(n)2^n\right]^{-1}$. PoS is then defined as

$$e_n = \mathbb{E}_\Theta[\beta_n(\Theta)] = \int_{\mathbb{R}^+} \beta_n(\theta) f_\Theta(\theta) d\theta = \int_0^1 y \cdot g(y) dy. \tag{6}$$

A closed-form expression for (6) is not available for this model, but application of Monte Carlo is straightforward to obtain numerical approximation of values of e_n, for each given n. As shown in the examples of Section 3, exploration of the features of $g(y)$ induced by the choice of f_Θ is useful to check

whether PoS is a representative summary of $g(y)$. In this case, assuming that e_n is an increasing function of n, PoS can be used for sample size determination: we select the minimum sample size such that e_n is above a suitable threshold $\lambda \in (0, 1)$, i.e.

$$n^{\star}_{\text{PoS}} = \min\{n \in \mathbb{N} : e_n > \lambda\}. \tag{7}$$

In the following, for comparison, we refer to the standard criterion for optimal sample size based on the power function, i.e.

$$n^{\star}_{\text{pow}} = \min\{n \in \mathbb{N} : \beta_n(\theta_d) > \lambda\}. \tag{8}$$

3. Example

In this section we consider the sample size problem for a reliability experiment on a new technology system, whose components are assumed to have a lifetime cycle well described by a Rayleigh distribution of unknown parameter θ, measured on a given time scale. Suppose that we want to test $H_0 : \theta \geq \theta_0 = 15$ vs $H_1 : \theta < \theta_0 = 15$. First of all, for a given sample size $n = 20$, we study the impact of the design parameters on the density of the power function. In Figure 1, first row, the prior sample size is smaller than the actual sample size (e.g. $n_d = 10$), whereas in the second row the design prior gets more concentrated (e.g. $n_d = 30$). In both cases we consider three different values of the prior mode, $\theta_d = 10, 12, 15$. Table 3. reports the values of PoS computed for the same choices of the design

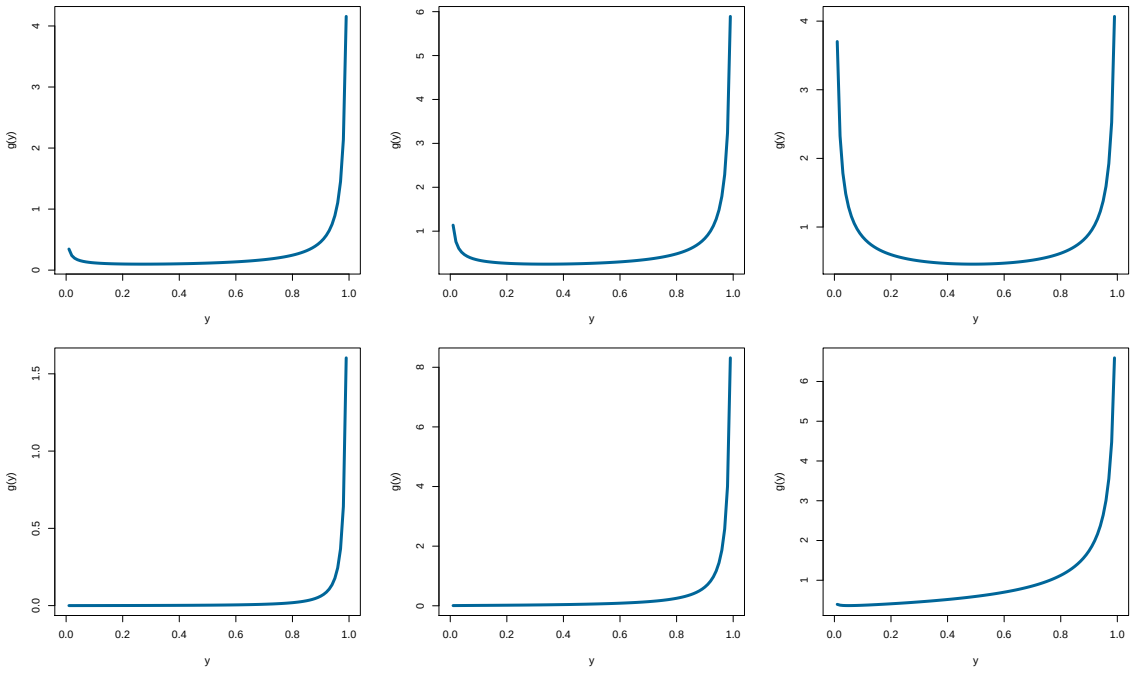

Figure 1: Behavior of $g(y)$ for $n = 20$, $\theta_0 = 15$ and for several choices of $\theta_d = 10, 12, 15$ (from left to right) and of $n_d = 10, 30$ (from top to bottom).

parameters. Note that, when $n_d = 30$, despite the choice of θ_d, the density of the power is always an increasing function of y that assigns large density to values of the power close to 1, as it must be in a well-designed experiment. Conversely, if the design prior sample size is not large enough, $g(y)$ is not well-behaved, i.e. it shows a u-shape that is more and more evident as θ_d gets closer and closer to the test threshold θ_0. In particular, for $\theta_0 = \theta_d$ and $n_d = 10$, PoS gets as small as 0.511, a value with very low density: as highlighted in (5), this implies that PoS is not a representative summary of $g(y)$. Furthermore $g(y)$ assigns considerably high density to power values very close to 0, which is not desirable in practice.

Similar considerations on the qualitative features of $g(y)$ may be helpful in driving a more careful choice of the design parameters for selecting the sample size. As an example, we consider a square inverse gamma prior with mode at $\theta_d = 12$ and prior sample size $n_d = 30$. Figure 2 compares the frequentist power function evaluated at the design value $\theta_d = 12$ and PoS with the above design prior assumption, as the sample size increases. We notice a well known behavior of these two functions, highlighted for instance in (6): averaging with respect to a design prior fairly concentrated on H_1 has the effect of slightly raising PoS for small values of the sample size; whereas, when n increases (in this example, $n > 40$), PoS becomes smaller than the frequentist power. Correspondingly, given a threshold $\lambda = 0.8$, we obtain $n^{\star}_{\text{PoS}} = 22$ and $n^{\star}_{\text{pow}} = 33$; but, if for instance $\lambda = 0.9$ to fulfill the sample size criteria (6) and (8) we obtain $n^{\star}_{\text{PoS}} = 97$ and $n^{\star}_{\text{pow}} = 45$, respectively. As a final remark, note that the standard approach for sample size determination, based on the power function, and the predictive Bayesian approach, based on PoS, coincide when the point-mass prior on the design value is assumed as design prior.

n_d	θ_d		
	10	12	15
10	0.923	0.797	0.511
30	0.997	0.967	0.717

Table 1: Values of PoS for $n = 20$, $\theta_0 = 15$ and for several choices of θ_d and n_d.

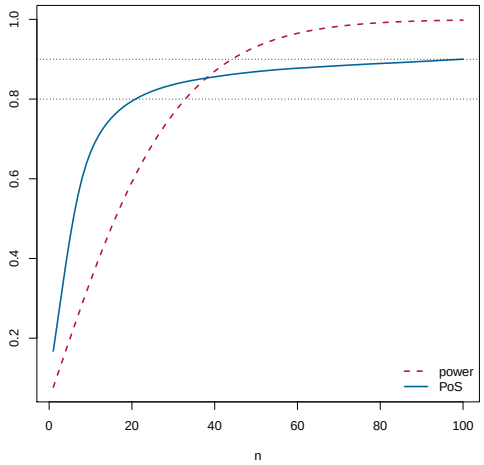

Figure 2: Power function (at design value $\theta_d = 12$) and PoS (with design prior parameters $\theta_d = 12$ and $n_d = 10$) as functions of the sample size.

4. Concluding remarks

PoS is a useful hybrid Bayesian-frequentist sample size determination tool, since it is based on the widely used frequentist power function of a test, but it also allows to take into account uncertainty on the design value. However, PoS is not always a suitable summary of the distribution of the power, as in the case of a u-shaped density of the power. In this sense, a deeper investigation on qualitative features of the density of the power in terms of the design parameters may be helpful: if the choice of the design prior is cautious, then bad-shaped densities can be avoided. When the goal of the experiment is to prove inferiority ($H_1 : \theta < \theta_0$), the design prior should be strongly concentrated on values of the parameter in $(0, \theta_0)$. In fact the design prior does not express information on the parameter to be combined with experimental evidence in order to obtain the posterior distribution. It rather models the scenario under which the study is planned. (See (6) for a discussion on the distinction between design and analysis priors). Finally, note that we here consider a conjugate design prior for the sake of analytical tractability. However, alternative choices are possible: for instance, the choice of truncated distributions fully concentrated on H_1 could be explored. In this case the proposed method can be easily implemented numerically via Monte Carlo.

Abstract

In the Bayesian framework, the power priors have been increasingly used in the context of the analysis of clinical trials and similar studies to incorporate external and past information, usually into the prior distribution of some treatment effect. Their use has been shown to be particularly effective in small sample size scenarios and when strong prior information is available. In a fully Bayesian approach, eliciting the initial distribution of the weight parameter controlling the amount of historical information remains a challenge, since it must be carefully chosen to reflect the available prior information accurately and not dominate the posterior inferential conclusions. We propose a novel preliminary method for eliciting the distribution of the weight parameter based on the Bayes factor, which allows the prior distribution will be updated based on the strength of the evidence the data provides.

Keywords: Clinical trial, Historical information, Prior elicitation, Strength of evidence.

1. Introduction

In recent years, incorporating historical data into the design and analysis of new clinical trials has gained significant attention, especially for ethical reasons and when patient recruitment is challenging. Particularly, Bayesian methods have gained increasing popularity in this context (Liu, 2018; Nikolakopoulos et al., 2018; Ollier et al., 2020). Furthermore, one of the critical advantages of the Bayesian approach is the ability to elicit informative priors on the model parameters, allowing for the integration of historical data into the analysis. However, informative prior elicitation is widely recognized as a complex undertaking, given the inherent complexity of quantifying and synthesizing prior information into an appropriate prior distribution. Hence, there is a pressing need for developing techniques and methods that can facilitate synthesizing and quantifying prior information more effectively and efficiently (Ibrahim et al., 2015). Specifically, there is a growing concern regarding the adaptive incorporation of historical data, particularly in the presence of data heterogeneity and rapid changes of the initial trial conditions (Ollier et al., 2020).

In this context, one possible approach is using *power priors* (Chen and Ibrahim, 2000), which allows the historical data to influence the prior distribution in a flexible and controlled way. A pivotal role in the power prior methodology is played by a *weight parameter* δ, defined between 0 and 1, that determines the degree to which historical data influences the prior distribution. Multiple strategies exist to specify the parameter δ. One straightforward approach involves fixing δ on a predetermined value that is considered reasonable based on background knowledge regarding the similarity of the two studies. Particularly,

let consider an historical dataset D_0 with corresponding likelihood $L(\boldsymbol{\theta}\,|D_0)$: the basic power prior formulation is

$$\pi\left(\boldsymbol{\theta}|D_0,\delta\right) \propto L\left(\boldsymbol{\theta}|D_0\right)^{\delta}\pi_0(\boldsymbol{\theta}), \tag{1}$$

where $0 \leq \delta \leq 1$ is the scalar weight parameter and $\pi_0(\boldsymbol{\theta})$ is the *initial prior* for $\boldsymbol{\theta}$ before observing the historical data D_0. The parameter δ plays a crucial role in determining the shape of the prior distribution for $\boldsymbol{\theta}$, as specified in Equation (1). As δ decreases, the tails of the distribution become heavier (Ibrahim et al., 2015). When the analyst fixes the weight parameter, sensitivity analysis should be used to identify an appropriate level of borrowing information while accounting for prior-data conflict (Evans and Moshonov, 2006). Several statistical methods have been proposed, including the penalized likelihood-type criterion (PLC), marginal likelihood criterion (MLC), deviance information criterion (DIC), logarithm of the pseudo-marginal likelihood (LPML) criterion, as well as the empirical Bayes (EB) method (see Ibrahim et al., 2015; Gravestock and Held, 2017).

A modification of the power prior, which includes a normalizing factor, allows specifying a hierarchical prior specification by taking δ as a random quantity (Chen and Ibrahim, 2000; Duan et al., 2006). Hence, the *joint normalized power prior* for $(\delta, \boldsymbol{\theta})$ is

$$\pi\left(\boldsymbol{\theta},\delta|D_0\right) = \frac{L\left(\boldsymbol{\theta}|D_0\right)^{\delta}\pi_0(\boldsymbol{\theta})\pi_0(\delta)}{\int_{\Theta} L\left(\boldsymbol{\theta}|D_0\right)^{\delta}\pi_0(\boldsymbol{\theta})d\boldsymbol{\theta}}, \tag{2}$$

where $\pi_0(\delta)$ is an initial prior distribution for δ. One of the primary advantages of the joint normalized power prior is its adherence to the likelihood principle, which ensures that the posterior distributions accurately reflect the compatibility between the current and historical data. Therefore, it enables adaptive borrowing according to prior-data conflict (Ye et al., 2022).

In the context of a power prior approach, the ability to effectively elicit an appropriate initial prior distribution for the weight parameter δ is a critical step. However, as far as we know from the current literature, this issue has yet to be explored and fully motivated. To achieve the goal mentioned above, we propose to compare the Bayes factor (Jeffreys, 1998; Kass, 1993; Kass and Raftery, 1995), henceforth BF, of competing prior distributions for δ to determine which one provides the best fit for the available data. This sort of reverse-Bayes approach (Good, 1950) would allow for a more reliable and informed choice between competing priors, which is crucial in ensuring improvements on the robustness and accuracy of the results. Specifically, we aim to present some preliminary results concerning a well-known example consisting of two clinical trials about the efficacy of an interferon treatment by using the probabilistic programming language Stan (Carpenter et al., 2017) and the `bridgesampling` `R` package (Gronau et al., 2020).

2. Elicitation of the δ initial prior

Determining the optimal value for the weight/discount parameter through sensitivity analysis can only be applied in cases where the parameter δ is fixed. However, eliciting an appropriate initial prior distribution has proven challenging when the discount parameter is a random variable. Only a few methods have been developed for this aim.

The Bayes factor constitutes a valuable statistical tool in prior elicitation by comparing the marginal likelihoods associated with the joint posterior of competing models that incorporate different initial prior distributions for the weight parameter. This approach is beneficial when prior information is limited and can aid in selecting a prior distribution well-supported by the observed data. Specifically, given the joint power prior distribution (2) and in light of the current data D, the joint posterior is

$$\pi\left(\boldsymbol{\theta},\delta|D,D_0\right) = \frac{L\left(\boldsymbol{\theta}|D\right)L\left(\boldsymbol{\theta}|D_0\right)^{\delta}\pi_0(\boldsymbol{\theta})\pi_0(\delta)}{\int_{\Theta} L\left(\boldsymbol{\theta}|D_0\right)^{\delta}\pi_0(\boldsymbol{\theta})d\boldsymbol{\theta}} \times \left[\int_{\Psi} \frac{L\left(\boldsymbol{\theta}|D\right)L\left(\boldsymbol{\theta}|D_0\right)^{\delta}\pi_0(\boldsymbol{\theta})\pi_0(\delta)}{\int_{\Theta} L\left(\boldsymbol{\theta}|D_0\right)^{\delta}\pi_0(\boldsymbol{\theta})d\boldsymbol{\theta}} d\boldsymbol{\psi}\right]^{-1}, \tag{3}$$

where $\boldsymbol{\psi} = \{\boldsymbol{\theta}, \delta\}$ contains both the model parameters $\boldsymbol{\theta}$ and the weight parameter δ. The second term in Equation (3) represents the inverse marginal likelihood. Moreover, the normalized power prior yields a

marginal likelihood that is not analytically tractable and must be approximated using numerical methods. In recent years, a popular approach for estimating the marginal likelihood is the so-called *bridge sampling* (Meng and Wong, 1996). This method is a Monte Carlo technique that involves generating samples from an auxiliary distribution that bridges the model's prior distribution and posterior distribution. The generated samples are then used to calculate the bridge sampling weights, through which then the bias introduced by the auxiliary distribution is corrected, and an unbiased estimate of the marginal likelihood is obtained.

As far as we know from reviewing the existing literature, no author addressed using BFs to discriminate between alternative power prior choices. Given two competing model specifications, $\mathcal{M}_1$ and $\mathcal{M}_2$, with different initial priors on the weight parameter δ, the corresponding Bayes factor can be expressed as follows

$$BF_{12} = \frac{\displaystyle\int_{\Psi} \frac{L\left(\boldsymbol{\theta}|D\right) L\left(\boldsymbol{\theta}|D_0\right)^{\delta} \pi_0(\boldsymbol{\theta}) \pi_0(\delta|\mathcal{M}_1)}{\int_{\Theta} L\left(\boldsymbol{\theta}|D_0\right)^{\delta} \pi_0(\boldsymbol{\theta}) d\boldsymbol{\theta}} d\boldsymbol{\psi}}{\displaystyle\int_{\Psi} \frac{L\left(\boldsymbol{\theta}|D\right) L\left(\boldsymbol{\theta}|D_0\right)^{\delta} \pi_0(\boldsymbol{\theta}) \pi_0(\delta|\mathcal{M}_2)}{\int_{\Theta} L\left(\boldsymbol{\theta}|D_0\right)^{\delta} \pi_0(\boldsymbol{\theta}) d\boldsymbol{\theta}} d\boldsymbol{\psi}}, \tag{4}$$

where $\pi_0(\delta|\mathcal{M}_1)$ and $\pi_0(\delta|\mathcal{M}_2)$ denote the initial prior distribution for δ under the two model specifications, respectively. As suggested by Jeffreys (1998), Bayes factors larger than one suggest evidence in favor of model $\mathcal{M}_1$. In contrast, values smaller than one suggest evidence in favor of model $\mathcal{M}_2$: values close to one indicate inconclusive evidence.

As illustrated by a practical application in the next section, the use of BFs proposed in Equation (4) could then serve as a further comparison tool to discriminate between choices for the weight parameter δ. Moreover, this represents to us only a procedural starting point: it would then be of interest to explore some theoretical properties of the power priors BF above, such as the consistency and the information consistency (Kass and Raftery, 1995), and formulate an advanced calibrated protocol for a better elicitation of δ, in the same spirit with the calibration purposes of Garcia-Donato and Chen (2005).

3. Application

To illustrate the application of the Bayes factor in the context of prior elicitation for the weight parameter, we consider a scenario in which a current clinical trial is analyzed in conjunction with historical information obtained from a previous study, possibly to corroborate the earlier results about medical treatment. The analysis involves data from two well-known clinical trials on phase III melanoma, a two-arm and a three-arm trial conducted by the Eastern Cooperative Oncology Group (ECOG)—see Ibrahim et al. (2012, 2015) for further details. Specifically, we examine data from the historical trial, E1684, and the current trial, E1690, which involved 284 and 427 patients, respectively. The clinical trials under consideration assigned patients to either receive interferon treatment (IFN) or a placebo. The primary outcome variable was the survival time, which was measured from the time of randomization to death. The analysis also included three covariates: standardized age, sex, and performance status (PS), an indicator of the patient's activity level.

As widely documented by Ibrahim et al. (2012), this is a paradigmatic example of the use of previous practical information in clinical trials: the E1690 was conducted to corroborate the efficacy results from the previous E1684 trial about the IFN treatment; however, the two studies appear to be in conflict one each other. Therefore, the choice/elicitation for δ is crucial and may lead to controversial clinical findings.

Here, we consider the cure rate model developed by Chen et al. (1999). This statistical model can estimate the proportion of individuals who experience long-term survival and the distribution of survival times for the remaining subjects. Particularly, let N denote the number of carcinogenic cells that remain after initial treatment. We assume that N follows a Poisson distribution with rate parameter θ. Moreover, consider a set of i.i.d random variables R_k, with $k = 1, \ldots, N$, characterized by the distribution function $F(t) = 1 - S(t)$. Thus, the variable of interest is represented by the time of relapse and is denoted by

$T = min(R_k)$, with $0 \leq k \leq N$. Let suppose to observe a set of i.i.d durations $\boldsymbol{Y} = (y_1, \ldots, y_n)$ with an associated right censoring vector $\boldsymbol{C} = (c_1, \ldots . c_n)$ and a $n \times p$ design matrix $\boldsymbol{X}$, the likelihood function is then

$$L(\boldsymbol{\beta}, \boldsymbol{\xi} \mid \boldsymbol{Y}, \boldsymbol{C}) = \prod_{i=1}^{n} \left\{ p\left(y_i \mid \boldsymbol{\xi}\right) \theta_i \right\}^{c_i} e^{-F(y_i|\boldsymbol{\xi})\theta_i},$$

where $\boldsymbol{\beta}$ is the regression coefficient vector, $\theta_i = \exp(\boldsymbol{X}_i^\top \boldsymbol{\beta})$ and $\boldsymbol{\xi} = (\alpha, \lambda)$ is the parameter vector of a Weibull distribution. We adopt a hierarchical prior structure, which is designed as follows

$$\begin{aligned} \boldsymbol{\beta} &\sim \mathrm{N}\left(\mathbf{0}, 10\boldsymbol{I}_p\right), \\ \lambda &\sim \mathrm{N}(0, 10), \\ \alpha &\sim \mathrm{Gamma}\left(1, 1\right), \end{aligned}$$

where $\boldsymbol{I}_p$ is the identity matrix of rank p. Furthermore, let $D_0 = (\boldsymbol{Y_0}, \boldsymbol{C_0}, \boldsymbol{X_0})$ be the historical dataset, then the normalized joint power prior takes the following form:

$$\pi\left(\boldsymbol{\beta}, \boldsymbol{\xi}, \delta | D_0\right) = \frac{L\left(\boldsymbol{\beta}, \boldsymbol{\xi} | D_0\right)^{\delta} \pi_0(\boldsymbol{\beta}, \boldsymbol{\xi}) \pi_0\left(\delta\right)}{\int_{\Phi} L\left(\boldsymbol{\beta}, \boldsymbol{\xi} | D_0\right)^{\delta} \pi_0(\boldsymbol{\beta}, \boldsymbol{\xi}) d\boldsymbol{\phi}},$$

where $\boldsymbol{\phi} = \{\boldsymbol{\beta}, \boldsymbol{\xi}\}$. Consequently, the joint posterior distribution is

$$\begin{aligned} \pi\left(\boldsymbol{\beta}, \boldsymbol{\xi}, \delta | D, D_0\right) = & \frac{L\left(\boldsymbol{\beta}, \boldsymbol{\xi} | D\right) L\left(\boldsymbol{\beta}, \boldsymbol{\xi} | D_0\right)^{\delta} \pi_0(\boldsymbol{\beta}, \boldsymbol{\xi}) \pi_0(\delta)}{\int_{\Phi} L\left(\boldsymbol{\beta}, \boldsymbol{\xi} | D_0\right)^{\delta} \pi_0(\boldsymbol{\beta}, \boldsymbol{\xi}) d\boldsymbol{\phi}} \times \\ & \times \left[\int_{\Psi} \frac{L\left(\boldsymbol{\beta}, \boldsymbol{\xi} | D\right) L\left(\boldsymbol{\beta}, \boldsymbol{\xi} \mid D_0\right)^{\delta} \pi_0(\boldsymbol{\beta}, \boldsymbol{\xi}) \pi_0(\delta)}{\int_{\Phi} L\left(\boldsymbol{\beta}, \boldsymbol{\xi} | D_0\right)^{\delta} \pi_0(\boldsymbol{\beta}, \boldsymbol{\xi}) d\boldsymbol{\phi}} d\boldsymbol{\psi} \right]^{-1}, \end{aligned}$$

where $D = (\boldsymbol{Y}, \boldsymbol{C}, \boldsymbol{X})$ denotes the current dataset. We assume as the initial prior for the discount parameter a Beta distribution, $\delta \sim \text{Beta}(\eta, \nu)$, with different choices for the hyper-parameters (η, ν), as described in Table 1.

To establish the most suitable initial prior specification for the weight parameter δ, we calculate the BF in Equation (4) for some competing model combinations. Additionally, we consider optimal fixed values of δ that have been previously identified by Ibrahim et al. (2012) and Ibrahim et al. (2015) as the options that yield the best model fit according to some Bayesian criteria, such as the Deviance Information Criterion (DIC) and the logarithm of the pseudo-marginal likelihood (LPML). By doing so, we can evaluate the strength of evidence in favor of each model specification and select the one that best fits the data. Table 1 shows twice the natural logarithm of the Bayes factor for all the assumed competing models. We can notice that the Beta distribution with hyper-parameters $\eta = 1$ and $\nu = 5$ emerges as the most favorable initial prior specification for the weight parameter δ. Specifically, we observe that the BF transformation associated with the Beta$(1, 5)$ distribution largely exceeds 0—as a consequence, the original BF is much greater than 1—indicating that this specification outperforms the other priors and the fixed values choices across all the considered scenarios. Notice that the chosen prior specification implies an average value for δ equal to 0.17 (with an approximated variance of 0.02), which is less than half of the suggested value of $\hat{\delta} = 0.4$, previously obtained by Ibrahim et al. (2012) using the DIC criterion

We posit that through the above prior elicitation, we imply a more conservative procedure for incorporating historical information into the model. This result makes sense, given the conflict between the two trials' outcomes. Thus, our approach based on the Bayes factor has the potential to minimize the impact of subjective biases and ensure robustness in the inferential results.

	$\delta \sim \text{Beta}(\eta, \nu)$									Fixed δ

Table 1: Upper triangular matrix of twice the natural logarithm of the Bayes factor, with distinct choices for the Beta hyper-parameters (η, ν) and three optimal fixed values for δ. Models in the BF numerators appear in rows, and models in the BF denominators in columns, respectively.

4. Discussion

This paper provides a preliminary and concise assessment of applying the Bayes factor for power prior elicitation in a fully Bayesian approach where a Beta distribution is specified for the discount parameter δ. Our preliminary application suggests that the Bayes factor is a valuable and powerful measure of evidence for discriminating between some competing prior specifications.

However, there are many directions for future research. First, using the BF as a sole criterion is limited due to its asymmetric prior-predictive distribution across models. Therefore, there is a need to explore the potential of a calibrated version of the Bayes factor because, before observing the data, the Bayes factor is a random variable that follows its own sampling distribution (Garcia-Donato and Chen, 2005). Then, we should derive a specific version of the prior-predictive p-value that considers and assesses the possibility of a prior-data conflict. Such an approach would permit the selection of competing models based on a more accurate assessment of the available evidence. Finally, consistency checks for the proposed BF should be addressed and studied.

Abstract

Bayes factors represent one of the most well-known and commonly adopted tools to perform model selection and hypothesis testing according to a Bayesian flavour. Nevertheless, they are often criticized due to some interpretative and computational aspects, including that of not being able to be used with improper priors, or their intrinsic lack of calibration. Another criticism refers to the fact that they measure the model weight of evidence in terms of prior-predictive distributions, but they are rarely used to measure the predictive accuracy arising from competing models. In this paper we tried to fill this gap by proposing a new algorithmic protocol to transform Bayes factors into measures that evaluate the pure and intrinsic predictive capabilities of models in terms of posterior predictive distributions.

Keywords: model selection, calibration, predictive accuracy, algorithmic protocol, posterior predictive distribution.

1. Introduction

Nowadays Bayes factors—hereafter, BFs—(7; 8; 9) still represent one of the cornerstones commonly adopted for Bayesian model selection and hypothesis testing. Given some data denoted by $\boldsymbol{y}$ and two competing parametric statistical models $\mathcal{M}_1, \mathcal{M}_2$, the Bayes factor $BF_{12}(\boldsymbol{y})$ is defined as the ratio between the two model marginal likelihoods, and measures the amount of evidence provided by the first model over the second one; ultimately, the BF is used to select which of the two models fits the data better according to their marginal likelihoods.

Although their recognised relevance in Bayesian model selection and hypothesis testing to discriminate between two candidate models or two alternative hypotheses, their use is limited and constrained by some well-known computational and interpretative issues.

First, BFs cannot be applied with improper prior distributions, say $p(\theta) \propto k$, otherwise the ratio would depend on some subjective constants, making then model selection driven by the numeric constant k itself. To fix this issue, BF variants such as the intrinsic Bayes factors (1) and the fractional Bayes factor (11) have been proposed.

Second, the scale of evidence favouring one model against another (7) based solely on the observed value of the BF is usually not appropriate, for such reason BFs could benefit from a calibration via prior-predictive distribution (4) to obtain more robust results.

Third, BFs are usually considered as the Bayesian counterpart of classical p-values (6), and as such characterized by a non-negligible amount of subjectivity for choosing between alternative models/hypotheses; on the other hand, the weight of evidence is usually expressed by use of Jeffreys' or similar subjective numerical scales (7).

Fourth, BFs measure the weight of model evidence by use of pairwise model comparisons with respect to some training data, and this comparison could be carried out even *before* the single models are fitted; as brilliantly remarked by (2), Bayes factors measure prior predictive performance rather than posterior predictive performance.

From the aforementioned criticisms, it emerges how BFs represent a valid but somehow controversial tool to perform model selection in the Bayesian framework. However, we feel their use could be extended towards a pure prediction setting (13) to embrace and capture the *'prediction fever'* raised by the modern statistical learning field, given the need for reliable and scientific predictive tools. For such reasons, developing theoretically solid and calibrated Bayes factors with a predictive purpose (12) could be fruitful in many settings and applications, especially for those fields at the boundaries between pure statistical methods and machine learning. To this aim, we propose in this paper a new approach based on the notion of predictive Bayes factors, consisting of a BF evaluation with respect to posterior predictive distribution samples corresponding to distinct test sets. This proposal could be then used as an alternative measure to evaluate predictive accuracy between two competing models, with the desirable property of reporting a measure of the uncertainty arising from the posterior predictive distributions (hereafter, ppd).

The remainder of the paper is organized as follows. Section 2. briefly describes the predictive BF algorithmic protocol. In section 3. we propose an illustrative example of linear regression with g-priors, whereas Section 4. concludes.

2. A new predictive protocol

Before observing the data $\boldsymbol{y}$, the Bayes factor $BF(\boldsymbol{Y})$ is a random variable following its own distribution (4). We could mimic the same argument not for the data at hand $\boldsymbol{Y}$, but, rather, for some observable but not yet observed test/out-of-sample data, $\boldsymbol{Y}^{pred}$. The final aim could then be that of exploring some theoretical and practical properties of the resulting BF between two candidate models according to a predictive protocol, and select then the best model on the ground of a pure forecasting comparison.

To this aim, we could generate hypothetical test-data replications from the models' posterior predictive distribution for many distinct test/training set configurations, and use these new values for a predictive BF evaluation. In such way, we would have a pure predictive discrimination tool, and the BFs would be evaluated under a posterior predictive perspective; then, the distribution of the predictive BFs, or some credible intervals, could be displayed against the observed value of the BF computed on the test set as a further comparison. We summarise the main steps from our algorithmic protocol in Algorithm 1.

The steps described in Algorithm 1 provide an intrinsic uncertainty coming from the posterior predictive distribution of the generated samples: the only evaluation of the observed BF on the distinct test sets obtained at each algorithmic iteration is not sufficient for acknowledging the amount of variability in the predictions from the ppds, and would not provide a pure probabilistic measure of predictive accuracy. Rather, we need some probabilistic statements about the identification of the best model in forecasting terms, and this can be obtained only by inspection of the posterior predictive distribution.

Note that in our protocol many inputs could be let to the users' preferences, such as the training and test set sample sizes, the model formulation, the prior distributions, or the choice of eventual hyper-prior distributions with hyper-parameters.

3. Sketch of application: linear regression with g-priors

As an illustrative example, we consider two nested linear regression models $\mathcal{M}_o \subset \mathcal{M}_f$, where $\mathcal{M}_o$ ($\mathcal{M}_f$) has p_o (p_f) parameters, with $p_o < p_f$. We assume some g-priors (14; 10) for

Algorithm 1 Predictive Bayes factors

Inputs: dataset $\boldsymbol{y}$; training and test set sample sizes, n_{train}, n_c
Models $\mathcal{M}_o, \mathcal{M}_f$
Priors $\pi(\boldsymbol{\beta}_o|\mathcal{M}_o)$, $\pi(\boldsymbol{\beta}_f|\mathcal{M}_f)$
Parameters $\boldsymbol{\beta}_o,\ \boldsymbol{\beta}_f$
Estimates $\hat{\boldsymbol{\beta}}_o,\ \hat{\boldsymbol{\beta}}_f$

For $t = 1, 2, \ldots, T$ repeat:

1. Create a data-split: $\boldsymbol{y} = (\boldsymbol{y}^{O(t)}, \boldsymbol{y}^{C(t)})$, where $\boldsymbol{y}^{O(t)}$ has dimension n_{train}, and $\boldsymbol{y}^{C(t)}$ has dimension n_c.
2. According to both the models considered, generate two datasets from the posterior predictive distributions: $\boldsymbol{y}_o^{pred} \sim p(\boldsymbol{y}^{pred}|\boldsymbol{y}, \mathcal{M}_o)$, $\boldsymbol{y}_f^{pred} \sim p(\boldsymbol{y}^{pred}|\boldsymbol{y}, \mathcal{M}_f)$, each of size n_c.
3. Calculate the two predictive Bayes factors:

$$BF_{of}(\boldsymbol{y}_o^{pred}) = \frac{\int p(\boldsymbol{y}_o^{pred}|\boldsymbol{X}_o, \boldsymbol{\beta}_o, \mathcal{M}_o)\pi(\boldsymbol{\beta}_o|\mathcal{M}_o)d\boldsymbol{\beta}_o}{\int p(\boldsymbol{y}_f^{pred}|\boldsymbol{X}_f, \boldsymbol{\beta}_f, \mathcal{M}_f)\pi(\boldsymbol{\beta}_f|\mathcal{M}_f)d\boldsymbol{\beta}_f}$$
$$BF_{of}(\boldsymbol{y}_f^{pred}) = \frac{\int p(\boldsymbol{y}_o^{pred}|\boldsymbol{X}_o, \boldsymbol{\beta}_o, \mathcal{M}_o)\pi(\boldsymbol{\beta}_o|\mathcal{M}_o)d\boldsymbol{\beta}_o}{\int p(\boldsymbol{y}_f^{pred}|\boldsymbol{X}_f, \boldsymbol{\beta}_f, \mathcal{M}_f)\pi(\boldsymbol{\beta}_f|\mathcal{M}_f)d\boldsymbol{\beta}_f}.$$

4. Produce the ppd for these quantities and derive credible intervals.
5. Compute the observed BF on the test set, $BF(\boldsymbol{y}^C)$, and compare it with the BFs predictive distributions.
6. Assess when $\mathcal{M}_o$ is better than $\mathcal{M}_f$.

the model parameters, denoted by vectors $\boldsymbol{\beta}_o$ and $\boldsymbol{\beta}_f$, with dimensions p_o and p_f, respectively: $\boldsymbol{\beta}_o \sim \mathcal{N}(\mathbf{0}, \frac{g}{\phi}(\boldsymbol{X}_o'\boldsymbol{X}_o)^{-1})$, $\boldsymbol{\beta}_f \sim \mathcal{N}(\mathbf{0}, \frac{g}{\phi}(\boldsymbol{X}_f'\boldsymbol{X}_f)^{-1})$, where $\boldsymbol{X}_o$ ($\boldsymbol{X}_f$) is a $n \times p_o$ ($n \times p_f$) predictor matrix of full rank p_o (p_f), g is the scaling factor controlling variable/model selection, and ϕ is a dispersion parameter. g-prior distributions have been widely used in Bayesian variable and model selection settings because of their computational efficiency for marginal likelihoods evaluation and model search and because of their immediate interpretation. As widely remarked by the related literature, the choice of g affects the model selection, with large g favouring parsimonious models with a few large coefficients, and small g tending to concentrate the prior on saturated models with small coefficients—see (10) for a review about some usual choices for g, including the *unit information prior* by (9).

One of the main advantages from the Zellner's g-priors is that the marginal likelhoods can be written in closed-form expressions; as shown by (10), the resulting Bayes factor in the null-based approach, computed by comparing the posed model $\mathcal{M}_o$ with the null model $\mathcal{M}_n$ having only the intercept, is given by:

$$BF_{on}(\boldsymbol{y}) = (1+g)^{(n-p_o-1)/2}[1+g(1-R_o^2)]^{-(n-1)/2}, \tag{1}$$

where R_o^2 represents the usual coefficient of determination under the model $\mathcal{M}_o$. The Bayes factor under the full-based approach, computed by comparing the model $\mathcal{M}_o$ with the full model $\mathcal{M}_f$, is instead given by:

$$BF_{of}(\boldsymbol{y}) = (1+g)^{-(n-p_f-1)/2}\left[1+g\frac{1-R_f^2}{1-R_o^2}\right]^{(n-p_o-1)/2}, \tag{2}$$

where R_f^2 represents the coefficient of determination under the model $\mathcal{M}_f$.

To implement the protocol procedure described through the Algorithm 1 in Section 2, we consider a total of $T = 10^3$ data-splits for a sample of $n = 100$ simulated data, where the sample sizes for the training and test set are fixed to $n_{train} = 70$ and $n_c = 30$, respectively; for each data split t, we generate $n_{rep} = 10^3$ replicated datasets under both the models from the posterior predictive multivariate student-t distribution as follows:

$$\boldsymbol{y}_o^{pred} \sim t_{n_c}(\omega \boldsymbol{X}_o \hat{\boldsymbol{\beta}}_o, s_o^2(\boldsymbol{I} + \omega \boldsymbol{X}_o(\boldsymbol{X}_o'\boldsymbol{X}_o)^{-1}\boldsymbol{X}_o')),$$
$$\boldsymbol{y}_f^{pred} \sim t_{n_c}(\omega \boldsymbol{X}_f \hat{\boldsymbol{\beta}}_f, s_f^2(\boldsymbol{I} + \omega \boldsymbol{X}_f(\boldsymbol{X}_f'\boldsymbol{X}_f)^{-1}\boldsymbol{X}_f')),$$

where $\omega = g/(g+1)$; $s_o^2 = RSS_o + \frac{1}{g+1}\boldsymbol{\beta}_o'\boldsymbol{X}_o'\boldsymbol{X}_o\boldsymbol{\beta}_o$ and $s_f^2 = RSS_f + \frac{1}{g+1}\boldsymbol{\beta}_f'\boldsymbol{X}_f'\boldsymbol{X}_f\boldsymbol{\beta}_f$ are the sample variance estimates; $\boldsymbol{X}_o, \boldsymbol{X}_f$ denote the predictor matrices for the two models, with dimensions $n \times p_o$ and $n \times p_f$, respectively; and $\hat{\boldsymbol{\beta}}_o = (\boldsymbol{X}_o'\boldsymbol{X}_o)^{-1}\boldsymbol{X}_o'\boldsymbol{y}$, $\hat{\boldsymbol{\beta}}_f = (\boldsymbol{X}_f'\boldsymbol{X}_f)^{-1}\boldsymbol{X}_f'\boldsymbol{y}$ are the maximum likelihood estimates for $\boldsymbol{\beta}_o$, $\boldsymbol{\beta}_f$, respectively. The 95% credible intervals for the Bayes factors $BF_{of}(\boldsymbol{y}_o^{pred})$ and $BF_{of}(\boldsymbol{y}_f^{pred})$ under two distinct simulated scenarios are reported in Figure 1. The top panel displays the distribution of the two Bayes factors under the hypothesis that the original data have been generated from the 'true' model $\mathcal{M}_o$: $y = \beta_0 + \beta_1 x + \epsilon$, with $\beta_0 = 3, \beta_1 = 0.3$, whereas in the bottom panel the data have been generated from the 'true' full model $\mathcal{M}_f$: $y = \beta_0 + \beta_1 x + \beta_2 x^2 + \beta_3 x^3 + \epsilon$, with $\beta_0 = 3, \beta_1 = 0.3, \beta_2 = 0.5$ and $\beta_3 = 0.7$. It is worth noting that both the plots display a large evidence for the true model in terms of predictive BFs: in the first scenario $\mathcal{M}_o$ is dramatically favoured with respect to both the predictive datasets $\boldsymbol{y}_o^{pred}$, $\boldsymbol{y}_f^{pred}$, even if the predictive BF is higher for the data generated from the true model $\mathcal{M}_o$, as expected. In the second scenario we have instead an apparent disagreement between the two BFs, since the predictive BF for $\boldsymbol{y}_o^{pred}$ would indicate a clear preference for $\mathcal{M}_o$, whereas $BF_{of}(\boldsymbol{y}_f^{pred})$ definitely suggests the choice of $\mathcal{M}_f$. This apparently controversial finding in the second scenario is not surprising: the predictive BF evaluated for $\boldsymbol{y}_o^{pred}$ is likely to favour the nested and simpler model $\mathcal{M}_o$ over the full and more complex model $\mathcal{M}_f$ due to the well-known *Occam's rasor* issue. In fact, when predictive data $\boldsymbol{y}_o^{pred}$ are generated from the nested model $\mathcal{M}_o$ but the true model is instead the full $\mathcal{M}_f$, $BF_{of}(\boldsymbol{y}_o^{pred})$ will clearly privilege the simpler model, and the posterior predictive distribution for $BF_{of}(\boldsymbol{y}_o^{pred})$ will serve as a sort of upper benchmark of comparison; conversely, $\mathcal{M}_f$ is chosen only when data complexity goes beyond that implied by the simpler model $\mathcal{M}_o$, for instance when $\boldsymbol{y}_f^{pred}$ is generated from the true model $\mathcal{M}_f$, as in the bottom part of the bottom panel.

This example helps guide the choice between the two competing nested models: from the whole configuration, it emerges that $\mathcal{M}_o$ is clearly favoured in the first scenario—where both the ppds are far from zero and quite close each other—whereas $\mathcal{M}_f$ is definitely suggested in the second scenario—where the ppd for $BF(\boldsymbol{y}_f^{pred})$ converges at zero—as expected. Moreover, we conclude with a look at the test BF, $BF(\boldsymbol{y}^c)$, over the T splits: in the first scenario the median value is 14.6, whereas in the second scenario is 0. These values show a further confirmatory effect on the choice of the models in the two scenarios.

4. Discussion

We proposed a novel predictive protocol to assess model predictive accuracy by evaluating Bayes factors on samples from the posterior predictive distributions of two competing models. In such way, we try to transform BFs into some purely predictive-based tools and make them appealing from a forecasting accuracy perspective.

Many points of future research remain open. We would need to check and prove the consistency of our proposed BFs and the connection with some existing predictive information criteria, such as the BIC, and with leave-one-out cross validation. We should then formalize the final model choice with some *ad-hoc* metrics, possibly based on the Kullback-Leibler divergence.

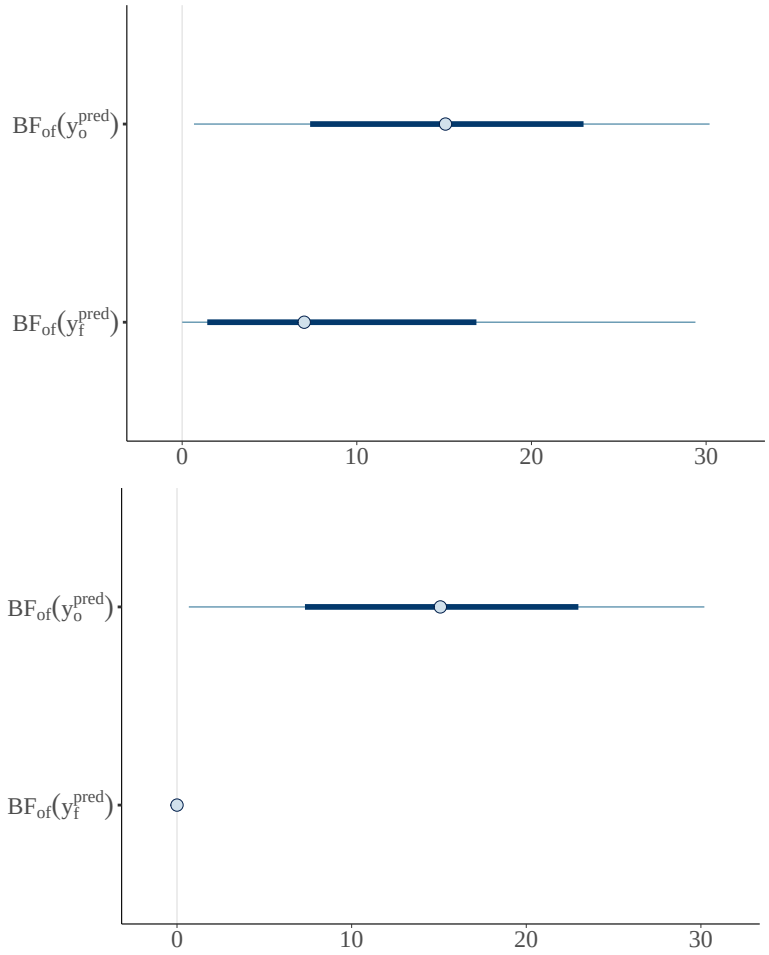

Figure 1: Linear regression with g-priors: predictive Bayes factors $BF_{of}(\boldsymbol{y}_o^{pred})$ and $BF_{of}(\boldsymbol{y}_f^{pred})$ according to two simulated scenarios: $y = 3 + 0.3x + \epsilon$ (top panel); $y = 3 + 0.3x + 0.5x^2 + 0.7x^3 + \epsilon$ (bottom panel).

Moreover, the application of the algorithmic protocol in more complex settings where BFs are not available in closed-forms is required.

We feel our tentative and preliminary procedure is transparently posed and computationally feasible: open-source softwares such as Stan (3), combined with the R package `bridgesampling` (5), may be used for BFs derivation and computation in complex settings.

Abstract

In this work, we present a clusterwise algorithm based on a new regression method for distributional data. The first contribution of this work is the definition of a new regression model for distributional data, which maps density functions into a Hilbert space through a Logarithmic transformation of the Derivative Quantile functions (LDQ). Then, the proposed clusterwise regression method predicts the response variable by partitioning the set of objects into K clusters, according to the best fit of local regression models. Preliminary results on synthetic data have confirmed the effectiveness of our proposal.

Keywords: Distributional data, Clusterwise regression, clustering

1. Introduction

In this work, we present a new regression method and a clusterwise strategy for distributional data. The input consists of distributional variables $Y, X_1, \ldots, X_p$, where Y is the response variable and X_j's are the predictors. Each object is represented by $p+1$ probability functions or empirical ones. Our approach is to predict the response variables by partitioning the set of distributional-valued data into subgroups using a K-means like clustering algorithm. The centroids of the clusters are represented by linear regression models, and objects are assigned to the cluster which minimizes the prediction error. The first contribution of the paper is to define a suitable regression model for distributional data. Previous works, such as (7) and (4), proposed regression models for distributional data based on Non-Linear Least Squared methods and the Wasserstein metric in a linear space, however they imposed the constraint of non-negativity to ensure that the outcome remains a distributional variable. Considering recent developments in distributional data analysis (DDA), we introduce a transformation of the quantile functions into quantile density functions (8), which allows for mapping density functions into a Hilbert space addressing some issues in DDA.

Based on this new regression model, the clusterwise method predicts the response variable by performing a partitioning of the set of objects in K clusters according to the best fit of the local regression models. The clustering process is performed in two alternating steps. Fixed a predefined K number of clusters, the first step involves representing the clusters with regression models; in the second step the elements are assigned to the clusters according to the minimum sum of the squared errors. This process is repeated until convergence to stable clusters.

2. Distributional-valued data

Let E be a set of objects. A modal (1; 7) variable X with domain $\mathscr{D}$ on the set E is a mapping $E \to \mathscr{M}$ of all possible measures π on $\mathscr{D}$ (completed by a σ-field):
$e \to X(e) \in \mathscr{M}$, for $e \in E$.

Histograms are a suitable way of representing empirical distributions. In the context of SDA, histogram data are realizations of histogram-valued variables and are considered a special case of modal-valued variables. In this framework, a variable X is considered a histogram-valued variable if each object e is represented by a probability or frequency distribution in the form of a histogram (1).

Formally, let's x be a realization of X with support $S(e) = [a_H, b_H]$, that is partitioned into a set of contiguous intervals (or bins) $I_h = [a_h, b_h]$, such that $I_h \cap I'_h = \emptyset$; $\forall h : I_h \subseteq S(e)$. A non negative weight π_h (a probability or a relative frequency) is associated to each I_h, so that, a histogram data is defined by a sequence of intervals (bins) with associated the respective weights:

$$x = X(e) = [(I_1, \pi_1), \ldots, (I_h, \pi_h), \ldots, (I_H, \pi_H)] \tag{1}$$

A cumulative distribution function $F(x)$ is associated to each x. $F(x)$ is a continuous function and, for empirical distributions, it is a piece-wise function, strictly increasing in the interval $[a_1, b_H]$; $0 \leq F(x) \leq 1$; $F(x) = 0 \ \forall x \leq a_1$ and $F(x) = 1 \ \forall x \geq b_H$; $F(x)$ is differentiable on $[a_1, b_H]$.

The inverse of a distribution function $F^{-1}(x) = Q(t)$ is a quantile function which is a monotone increasing function with support in $[0,1]$ (for histogram variables, it is a piece-wise function). $Q(t)$ is also differentiable on $[0,1]$.

2.1 Linear regression model for distributional data

In the framework of distributional-valued data analysis, many statistical analysis methods have been proposed, as clustering methods, regression models, factorial approaches, and many others. A reference book on these themes is (2).

Regression models have been developed to study the dependence relationship between a response variable Y and a set of explanatory variables $X_1, ..., X_p$. Both response and independent variables are distributional valued variables. The main regression model approaches (4; 7) are based on a suitable metric to compare distributions: the Wasserstein's squared distance (also known as Mallow's distance). In the unidimensional space, this metric corresponds to the Euclidean distance between the two quantile functions, $Q_i(t)$ and $Q_{i'}(t)$, associated to the two objects $e_i, e_{i'}$:

$$d_W(e_i, e_{i'}) = \int_0^1 (Q_i(t) - Q_{i'}(t))^2 dt. \tag{2}$$

The squared distance Wasserstein d_W has been assumed as metric between distributional valued data for solving an OLS minimization problem:

$$SSE_{OLS-LDQ} = \left(\tilde{\mathbf{y}}(t) - \tilde{\mathbf{X}}(t)\beta\right)^\top \left(\tilde{\mathbf{y}}(t) - \tilde{\mathbf{X}}(t)\beta\right)$$

Where $\mathbf{y}(t)$ and $\mathbf{X}(t)$ are the matrices of quantile functions associated to the distributional-valued data of Y and $X_1, \ldots, X_p$, while β is the vector of the regression coefficients.

The estimation problem is solved differently in the two main regression approaches for distributional-valued data (4; 7), but in both cases, a non-negativity constraint is imposed to the coefficients to ensure that the predicted $\tilde{\mathbf{Y}}(t)$ is a vector of quantile functions.

The main challenge is that probability density functions as well as cumulative distribution functions and their inverse, the quantile functions, are not in a Hilbert space. The solutions introduced in the two previous regression methods only in part address this problem by proposing a symmetrical transformation and a centring transformation of the regression variables.

More recently a suitable transformation has been introduced for mapping probability densities to a Hilbert space of functions through a continuous and invertible map (8). A probability density function is firstly transformed by the derivative of its quantile function:

$$q(t) = \frac{dQ(t)}{dt} = \frac{dF^{-1}(t)}{dt} = \frac{1}{f(Q(t))}$$

which is strictly positive and continuous in its domain $[0,1]$, and then, by the logarithmic transformation of $q(t)$, as follows:

$$l(t) = \ln q(t) = \ln \frac{1}{f(Q(t))} = -\ln f(Q(t))$$

Let $l(t)$ denote the Logarithm Derivative of the Quantile function (LDQ). On these functions it is possible to define the addition and scalar multiplication operations, the inner product and the Euclidean norm. The squared Euclidean distance between two LDQ functions $l_1(t)$ and $l_2(t)$ is given by:

$$d^2_{LDQ}(l_1(t), l_2(t)) = \|l_1(t) - l_2(t)\|_2 = \int_0^1 (l_1(t) - l_2(t))^2 \, dt$$

The main problem with LDQ transformation is that it loses information on the location parameters of the density distribution. In fact, the derivatives of two quantile functions that differ by a constant term are equal.

A linear model on the LDQ transformation functions of $y_i(t)$ and x_{ij}(t) was proposed in (10). However, it does not effectively solve the problem concerning the position of the density functions. The new regression model, here proposed, attempts to overcome this issue by dividing the model into two regression models, as follows:

$$y_i^m = \beta_0^m + \sum_{j=1}^{p} \beta_j^m x_{i,j}^m + \varepsilon_i^m$$

$$y_i^l(t) = \beta_0^l(t) + \sum_{j=1}^{p} \beta_j^l x_{i,j}^l(t) + \varepsilon_i^l(t)$$

where:

y_i^m is related to the minimum values x_{ij}^m;
$y_i^l(t)$ and $x_{i,j}^l(t)$ are the LQD function of $y_i(t)$ and $x_{i,j}(t)$;
ε_i^m is the i-th residual error of the minimum values;
$\varepsilon_i^l(t)$ is the i-th residual error function of the LDQ function.

The parameters of the models are estimated by minimizing the sum of the square errors, given by:

$$SSE_{OLS-LDQ} = \int_0^1 \left[\left(\tilde{\mathbf{y}}^l(t) - \tilde{\mathbf{X}}^l(t)\beta^l \right)^\top \left(\tilde{\mathbf{y}}^l(t) - \tilde{\mathbf{X}}^l(t)\beta^l \right) \right] dt + \\ + (\mathbf{y}^m - \mathbf{X}^m\beta^m)^\top (\mathbf{y}^m - \mathbf{X}^m\beta^m) \quad (3)$$

The least squares estimators for $\beta^l(t)$ and β^m represent the solutions of the two independent systems.

3. The CRL-LDQ Clusterwise Regression Method

The CRL-LDQ method combines the dynamic clustering algorithm (6) with the OLS-LDQ regression method for distributional-valued data. For a fixed number K of clusters, it seeks the better partition $P_k = C_1, \ldots, C_K$ and the best fitting models $\hat{y}^k$, for each cluster C_k, by minimising the $SSE_{OLS-LDQ}(P_k, \hat{y}^k)$:

$$SSE_{OLS-LDQ}(P_k, \hat{y}^k | \beta^l_{j(k)}, \beta^m_{j(k)}) = \sum_{k=1}^{K} \sum_{e_i \in P_k} \left[\|\tilde{\varepsilon}^l_{i(k)}(t)\|^2 + (\varepsilon^m_{i(k)})^2 \right]$$

After setting the number K of clusters, the algorithm is performed alternating the following two steps, until the convergence to a stationary value.

- *Step 1 - Representation step* (best fitting):
  The local regression models are estimated by minimizing the objective function $SSE(P_k, \hat{y}^{k*})$ on the parameters $\beta^l_{(k)}(t)$ and $\beta^m_{(k)}$ $(1 \leq k \leq K)$.
  The OLS estimations are provided as solutions of the two independent systems.

- *Step 2 - Assignment step* (partitioning P_k):
  The optimal clusters P_k which minimize the criterion $SSE(P^*_k, \hat{y}^k)$, are obtained according to the following assignment rule:

$$P_k = \left\{ e_i \in E : \left[\|\hat{\varepsilon}^l_{i(k)}(t)\|^2 + \left(\hat{\varepsilon}^m_{i(k)}\right)^2 \right] = \min_{h=1}^{K} \left[\|\hat{\varepsilon}^l_{i(h)}(t)\|^2 + \left(\hat{\varepsilon}^m_{i(h)}\right)^2 \right] \right\}$$

  Thus, the observation e_i is assigned to cluster P_k if the sum-of-squared errors are minimal for this cluster regression model.

The convergence of the algorithm is guaranteed by the decreasing of the criterion according to the improvement of the cluster regression models fitting.

4. Preliminary results on simulated data

The proposed method's efficacy was tested using simulated data. The performance of the regression model was evaluated by measuring its ability to fit the data, which was determined by using values of K ranging from 1 to 4. A value of $K = 1$ represents the use of the model without partitioning the data into clusters. The simulated data consisted of 600 individuals and included one response variable and two predictors, which were generated from Gamma random variables with varying parameters. The response was a combination of the predictors with added Gaussian error. A pseudo R^2 index was calculated using a suitable decomposition of the deviance, and the result was 0.59 for $K = 1$. When the clusterwise procedure was introduced, the results improved to 0.61, 0.74, and 0.95 for $K = 3$, which corresponded to the number of clusters in the data.

Abstract

We present a semi-parametric linear mixed-effects model for a generalized response which assumes the random effects to follow a discrete distribution. The estimated support points of the discrete distribution are collapsed along the iterations of a tailored EM algorithm - through which the parameters of the model are estimated - inducing a clustering of the higher level of hierarchy. The novelty lies in the collapsing criteria: the two closest estimated support points for which the confidence regions overlap are collapsed. At convergence, an a priori unknown optimal number of statistically different support points is identified. Moreover, the model is applied to the Programme for International Student Assessment (OECD) schools' data for modelling their innumeracy rates considering the school-country nesting.

Keywords: Semi-parametric generalized linear mixed-effects model, Discrete random effects, EM algorithm, Innumeracy rates, Administrative databases

1. Introduction

We present a novel method based on statistical significance for clustering groups in Semi-Parametric Generalized Linear Mixed-effects Models (SPGLMMs). Hierarchical data, often encountered in longitudinal studies and repeated measurements, necessitate the use of specialized models to account for both the group and individual levels. Mixed effects models (1) are a common choice, being able to handle both random and fixed effects. Recently, Semi-Parametric Linear Mixed-effects Models (SPLMMs) have been proposed in literature for continuous (2), multinomial (3) and Bernoulli (4) responses. Such a family of models assume the random effects to follow a discrete distribution and make use of a tailored Expectation-Maximization (EM) algorithm (5) for the estimation of the parameters. This approach offers several advantages, such as dimensionality reduction and improved interpretability; it reveals a clustering structure of the hierarchy, a priori latent, being more flexible than the parametric version as it does not require the assumption of normal distribution. However, the main drawback of the state-of-the-art SPLMMs is the collapsing criterion, performed at each iteration of the algorithm, being dependent on the choice of a threshold that determines the merging of discrete masses with lower Euclidean distance.

The presented method involves the computation of confidence regions of a certain level of confidence centred on the two closest support points estimated using Maximum Likelihood Estimators (MLEs) and their asymptotic properties, as described in (6). The overlapping of the confidence regions leads to the merging of the two discrete masses. The advantage of this criterion lies in the identification of the latent structure solely by choosing a level of confidence rather than an arbitrary threshold.

The SPGLMM, formulated for a Poisson response, is applied to data extracted from the Programme for International Student Assessment (PISA) (7) to cluster countries based on their levels of mathematical illiteracy (e.g., innumeracy levels). Specifically, we aim at profiling the percentage of low-achieving students in mathematics within schools standing on the average size of the school and socio-economic index of the students within that school. We are interested in identifying latent clusters of countries. The results show that the proposed method can effectively identify statistically different clusters and provide more interpretable solutions compared to traditional methods.

2. The model formulation and the EM algorithm

Given $i = 1, ..., N$ groups, Generalized Linear Mixed-effects Models (GLMMs) (8) are defined such that, conditioned on the random effects $\mathbf{b}_i$ in the i^{th} group, the expectation of the dependent variable $\mathbf{y}_i$ (n_i-dimensional vector), being $\mathbf{y}_i$ distributed according to the exponential family, is related to the linear predictor $\mathbf{X}_i\beta + \mathbf{Z}_i\mathbf{b}_i$ via a link function $g(\cdot)$, as follows: $g(\mathbb{E}[\mathbf{y}_i|\mathbf{b}_i]) = \mathbf{X}_i\beta + \mathbf{Z}_i\mathbf{b}_i$ for $i = 1, ..., N$ where $\mathbf{X}_i$ and $\mathbf{Z}_i$ are, respectively, the $[n_i \times P]$ and $[n_i \times Q]$ matrices of fixed and random covariates in the i^{th} group; β is the P-dimensional vector of fixed coefficients and $\mathbf{b}_i$ the Q-dimensional vector of random coefficients in the i^{th} group, being $\mathbf{b}$ normally distributed within the parametric framework.

In the semi-parametric approach, $\mathbf{b}$ is assumed to follow a discrete distribution P, with an a priori unknown M support points $(\mathbf{c}_1, ..., \mathbf{c}_M)$ for $M \leq N$, where each $\mathbf{c}_m \in \mathbb{R}^Q$, $m = 1, ..., M$, corresponds to the m^{th} cluster. Each group i is assigned with a certain probability ω_m to a cluster m allowing the identification of a latent structure among the groups, in the following fashion:

$$\mathbf{b}_i = \begin{cases} \mathbf{c}_1 & p(\mathbf{b}_i = \mathbf{c}_1) = \omega_1 \\ ... & \\ \mathbf{c}_M & p(\mathbf{b}_i = \mathbf{c}_M) = \omega_M \end{cases} \qquad \sum_{m=1}^{M} \omega_l = 1,\ \omega_m \geq 0 \qquad \forall i \in N$$

so that the SPGLMM formulation is

$$g(\,\mathbb{E}[y_{ij}|\mathbf{c}_m]\,) = \mathbf{x}'_{ij}\boldsymbol{\beta} + \mathbf{z}'_{ij}\mathbf{c}_m \quad \text{for} \quad i = 1, ..., N,\ j = 1, ..., n_i,\ m = 1, ..., M$$

where $\mathbf{x}_{ij}$ is the $[P \times 1]$ vector of fixed covariates and $\mathbf{z}_{ij}$ the $[Q \times 1]$ vector of random covariates. The marginal loglikelihood can be expressed, as proposed in (9), as follows:

$$\ln \mathcal{L}(\boldsymbol{\beta}, \mathbf{c}_1, ..., \mathbf{c}_M|\mathbf{y}) = \sum_{m=1}^{M} \omega_m \sum_{i=1}^{N} \sum_{j=1}^{n_i} \ln\, p(y_{ij}|\boldsymbol{\beta}, \mathbf{c}_m)$$

being $p(y_{ij}|\boldsymbol{\beta}, \mathbf{c}_m)$ the conditional probability mass (or density) function of y_{ij} given random and fixed effects.

The tailored EM algorithm is inspired by the one proposed in (10) and consists of the computation of the expected log-likelihood and its maximization with respect first to random effects and then to fixed effects, in an iterative framework, as described in (4; 6). The pointwise estimates updates of the unknown parameters $\hat{\boldsymbol{\beta}}$, $(\hat{\mathbf{c}}_1, ..., \hat{\mathbf{c}}_M)$ and $(\hat{\omega}_1, ..., \hat{\omega}_M)$ are obtained while proving the increasing likelihood property given a fixed number of clusters M. Refer to (6) for a more detailed algorithm formulation. Furthermore, the point estimate $\hat{\mathbf{b}}_i$ of the coefficients $\mathbf{b}_i$ for each group $i = 1, ..., N$, is obtained by maximizing over m the conditional probability $p(\mathbf{b}_i = \hat{\mathbf{c}}_m|\mathbf{y}_i, \hat{\boldsymbol{\beta}})$.

3. The statistical significance-based support reduction criterion

As foreseen in Section 1, the state-of-the-art methods (10; 2; 3; 4) reduce support through a check performed at each iteration k of the EM algorithm. This check entails merging two points, $\hat{\mathbf{c}}_l^{(k)}$ and $\hat{\mathbf{c}}_m^{(k)}$, into a single point $\hat{\mathbf{c}}_{l,m}^{(k)} = \frac{\hat{\omega}_l^{(k)}\hat{\mathbf{c}}_l^{(k)} + \hat{\omega}_m^{(k)}\hat{\mathbf{c}}_m^{(k)}}{\hat{\omega}_l^{(k)} + \hat{\omega}_m^{(k)}}$ with weight $\hat{\omega}_{l,m}^{(k)} = \hat{\omega}_l^{(k)} + \hat{\omega}_m^{(k)}$, if their Euclidean distance is lower than a fixed threshold t. In real data applications, these methods could result in being computationally expensive because requiring multiple fits of the model with different t for the identification of the best-performing one[1].

In view of untying from the choice of t, as explained in (6) we propose to (i) to compute the confidence regions (intervals) of level $1-\alpha$ centered in each of the two closest - in terms of Euclidean distance - estimated support points, exploiting the asymptotic properties of the Maximum Likelihood Estimators (MLEs) and (ii) if the two confidence regions (intervals) overlap, to collapse the two discrete masses to a unique point $\hat{\mathbf{c}}_{l,m}^{(k)}$ with weight $\hat{\omega}_{l,m}^{(k)}$ as in the state-of-the-art methods; if not, the *overlapping condition* is checked for all the other pairs of mass points (ordered by increasing Euclidean distance) until either two confidence regions (intervals) overlap or all pairs have been checked. From a practical point of view, the variance-covariance matrix is computed at each iteration of the algorithm as the inverse of the Information Matrix, retrieved by means of finite differences approximation of the MLE.

Moreover, the *overlapping condition* for $Q = 1$ reduces to a simple inequality which checks the reciprocal position of the extremes of the two confidence intervals, while for $Q \geq 2$ reduces to a unidimensional minimization[2]. As a final check, empty clusters (i.e. the estimated support points to which no groups are associated) or clusters with zero weight are removed; when one or more mass points are deleted, the remaining weights are renormalized in such a way that they sum up to 1.

4. The innumeracy levels within schools across countries

We apply the SPGLMM with the support reduction criterion - described in Section 3. - to data concerning mathematical performances PISA (OECD) survay of 2018 (7). The global indicators for the United Nations Sustainable Development Goals identify a minimum Level of Proficiency that all children should acquire by the end of secondary education: students below this level are considered *low-achieving* students. We restrict the analysis to schools with at least 10 students. After removing missing values and aggregating student data at the school level, we are left with 12620 schools across 50 countries. We consider, for each school j within a country i, the Poisson distributed response variable $\texttt{Y\_MATH}_{ij}$, (i.e., the rounded percentage of low-achieving students) and the two independent variables at school level (i) $\texttt{avg\_ESCS\_std}_{ij}$ (i.e., the average students' index of economic, social and cultural status, subsequent to standardization to mean 0 and standard deviation 1 within the country of the school, for keeping into account differences between countries) and (ii) $\texttt{SCHSIZE}_{ij}$ (i.e., the sum of students of school j), both standardized to mean zero and standard deviation 1. The SPGLMM with Poisson response is

$$\ln(\,\mathbb{E}[\texttt{Y\_MATH}_{ij}|c_m]\,) = \mathbf{x}_{ij}'\boldsymbol{\beta} + c_m$$

for $i = 1, ..., 50,\ j = 1, ..., n_i,\ m = 1, ..., M_\alpha$ where $\mathbf{x}_{ij}'$ is the two-dimensional vector of fixed effects covariates at the school level that contains $\texttt{SCHSIZE}_{ij}$ and $\texttt{avg\_ESCS\_std}_{ij}$; $\boldsymbol{\beta} = [\beta_1, \beta_2]'$ is the vector of fixed effects coefficients; c_m is the random intercept relative to the m^{th} cluster of countries and M_α is the total number of clusters the model identifies and depends on the level of confidence α chosen. We run the model with different α and we get $\hat{M}_{0.01} = 13$, $\hat{M}_{0.05} = 16$ and $\hat{M}_{0.10} = 18$. As expected, higher values of α correspond to higher values of M. Indeed, the higher α, the smaller the confidence intervals and the less likely to overlap. By choosing $\alpha = 0.01$, we obtain $\hat{\beta}_1 = -1.361$ and $\hat{\beta}_2 = -0.094$

[1] See S6 of Supplementary Materials in (6) for the description of an *entropy*-based method for the selection of the best t.

[2] The *Fast Ellipsoid Intersection Test*, see https://github.com/NickAlger/nalger_helper_functions/blob/master/tutorial_notebooks/ellipsoid_intersection_test_tutorial.ipynb for details concerning the implementation.

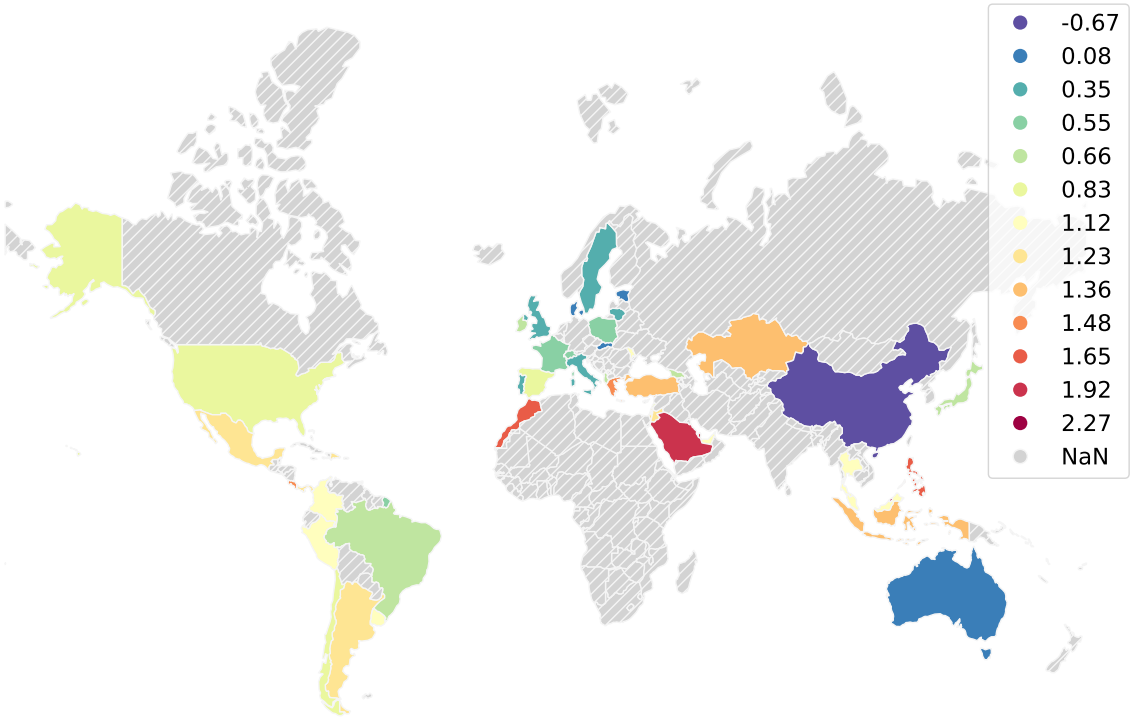

Figure 1: Choropleth map of the clusters of countries identified by the random intercepts for α = 0.01. Countries represented with the same colour belong to the same cluster. The blue-most the colour, the lower the random intercept. Grey-striped countries are missing data.

(having both a statistically significant p-values[3]) and the obtained random intercepts are plotted in Fig. 1. For this specific application, the running time for fitting the SPGLMM with a fixed α is a few hours and the obtained results are stable among different runs. Such an amount of time is mainly due to the iterative nature of the algorithm, whose pseudo-code is reported on page 11 in (6). The running time is much higher than fitting a parametric GLMM, which has the drawback of not being able to identify a clustering structure, but much lower than the SPGLMM based on the choice of the threshold t, because it does not require tuning t by fitting multiple models: we can rely on the conventional meaning attributed to the statistical confidence levels.

5. Simulation study

In order to evaluate the performance of the proposed model and the reliability of the results in Section 4, we propose a simulation study to test the SPGLMM considering a Poisson-distributed response with a single random intercept and two fixed-effects covariates, to be in line with Section 4. We consider $N = 10$ groups of data, where each group contains $n_{i=1,\dots,N} \sim U(70, 100)$ and we induce the presence of three clusters. The linear predictor $\boldsymbol{\eta}_i = \boldsymbol{\beta}_1 \mathbf{x}_{1i} + \boldsymbol{\beta}_2 \mathbf{x}_{2i} + c_{1i} \mathbb{1}_{n_i}$ is defined by the following Data Generating Process (DGP):

$$\boldsymbol{\eta}_i = \begin{cases} 0.3\mathbf{x}_{1i} + 0.9\mathbf{x}_{2i} + 2.5\ \mathbb{1}_{n_i} & \text{if } i = 1, 2, \\ 0.3\mathbf{x}_{1i} + 0.9\mathbf{x}_{2i} + 1\ \mathbb{1}_{n_i} & \text{if } i = 3, 4, 5, 6, 7, \\ 0.3\mathbf{x}_{1i} + 0.9\mathbf{x}_{2i} - 1\ \mathbb{1}_{n_i} & \text{if } i = 8, 9, 10 \end{cases} \tag{1}$$

[3]Computed through likelihood-ratio test.

Variables $\mathbf{x}_{1i}$ and $\mathbf{x}_{2i}$ follow a distribution $\mathcal{N}(0,1)$. We perform 500 runs of the SPGLMM. Results obtained by using Section 3.'s criterion are shown in Table 1: estimates are reported in terms of mean (sd) on the runs in which the SPGLMM identifies 3 clusters. If the DGP in Eq. (1) is fitted by using the state-of-the-art collapsing criterion (4), the proportion (over 500 iterations) in which 3 clusters are identified (which is maximized for $t = 0.25$) is 0.922, a value that needs to be compared with 0.956 obtained in the best case ($\alpha = 0.01$) and 0.870 obtained in the worst case ($\alpha = 0.10$).

Table 1: Results obtained by SPGLMM for the Poisson response through DGP in Eq. (1).

α	Proportion (over 500 iterations) in which 3 clusters are identified	$\hat{\omega}$ (sd)	$\hat{c}_1$ (sd)	$\hat{\beta}_1$ (sd)	$\hat{\beta}_2$ (sd)
$\alpha = 0.01$	0.956	0.20 (0.00) 0.50 (0.00) 0.30 (0.00)	2.50 (0.02) 1.00 (0.03) -1.01 (0.08)	0.30 (0.01)	0.90 (0.02)
$\alpha = 0.05$	0.934	0.20 (0.00) 0.50 (0.00) 0.30 (0.00)	2.50 (0.02) 1.00 (0.03) -1.01 (0.08)	0.30 (0.01)	0.90 (0.02)
$\alpha = 0.10$	0.870	0.20 (0.21) 0.50 (0.31) 0.30 (0.07)	2.49 (0.12) 0.99 (0.12) -0.99 (0.09)	0.30 (0.01)	0.90 (0.02)

6. Conclusions

We presented a statistical significance-based method for the estimated support points reduction within SPGLMMs, and, more in general, any kind of SPLMMs (2; 3; 4). By choosing a level of confidence α, such criterion allows the identification of a latent structure by clustering groups while having no prior knowledge of the "true" number of clusters. Simulation studies proved that the approach outperforms the state-of-the-art approaches, based on the choice of a discretionary threshold, which selection can often be computationally expensive. We applied the criterion to PISA (OECD) for obtaining a clustering of the countries as an alternative to the ranking proposed by a classical parametric GLMM. Yet, the method can be applied in various contexts, such as healthcare or any scenario where clustering groups is a more desirable approach than simply dealing with individual groups.

Introducing a novel directional distribution depth function for supervised classification

Edoardo Redivo[a] and Cinzia Viroli[a]

[a]University of Bologna; edoardo.redivo@unibo.it, cinzia.viroli@unibo.it

Abstract

Statistical depth functions are introduced as a way to provide a center-outward ordering of the sample points in multidimensional space, which can be used for outlier detection, classification, and other exploratory tools. In this work we propose a novel definition of depth function for multivariate data using random directions, which preserves the Mahalanobis distance of the points in the original space. The proposed method is evaluated through simulated experiments and real data applications, and is shown to be effective in supervised classification problems.

Keywords: depth functions, random projection, supervised classification

1. Introduction

In multivariate analysis the identification of order statistics, quantiles and typical or atypical patterns is very challenging due to the lack of an order among observations, which is instead natural in the real line $\mathbb{R}^1$ (3; 7).

To this aim, the most important line of research is rooted in the concept of statistical depth, which leads to a natural center-outward ordering of the sample points in $\mathbb{R}^p$ with $p \geq 2$. More specifically, a depth function is a function that assigns a real number to each point of a multivariate dataset measuring the outlyingness of the point with respect to the barycenter. Thus, it provides a way to quantify how far an observation is from the center of the dataset, and is often used in outlier detection, clustering, classification.

Popular depth functions are the Mahalanobis depth, which is based on the Mahalanobis distance between a point and the center of the dataset and the halfspace depth, which measures the depth of a point as the probability that it lies inside a randomly chosen halfspace that contains the center of the dataset. (4) described different depth functions as valuable exploratory tools in multivariate analysis.

In this paper we propose a novel definition of depth function for multivariate data using random spherical directions. The method is defined to satisfy the essential properties of depth functions (8; 7) while also preserving the Mahalanobis distance of the multivariate points in the original space of dimensionality p. The proposed depth function is the expectation of all depths along the potentially infinite random directions, which are, in turn, functions of the point percentiles estimated via parametric or nonparametric models. The proposed strategy is very general thanks to the model choices in the projected spaces, with the flexibility of the *fgld* quantile distribution being a valuable option (6; 1). Additionally, the theoretical definition of the depth function allows prediction out-of-sample. This enables the method to be used as a tool in supervised classification problems, where it can provide a distance measure for points in the test set with respect to the distributions of the different classes. The performance of the proposed method is evaluated through simulated experiments and real data application, and is shown to be very good, especially when compared to other classification methods.

2. Directional Distribution Depth

Let X be a multivariate random variable of order p with a probability distribution F. A data depth measures how deep (or central) a given value x of X is with respect to the data cloud or a given distribution function. A simple example is the Mahalanobis depth (5), which is inversely proportional to the Mahalanobis distance:

$$MD(x) = \left[1 + (x-\mu)\Sigma^{-1}(x-\mu)\right]^{-1},$$

where μ and Σ are the mean vector and dispersion matrix of the theoretical distribution of X, that can be estimated by the data obtaining the sample version of $MD(x)$. (8) introduced a general definition of depth function and defined four essential properties a depth function should have. More precisely, a depth function is a nonnegative and bounded function, which is: (i) invariant to the coordinate system or to the scale of the underlying measurements (affine invariance); (ii) maximum at its center; (iii) monotonically decreasing when a point moves away from the deepest central point and (iv) it should approach zero as a point approaches infinity. In addition, a depth function should be consistent, as the sample size increases, and computationally efficient, *i.e.*, it should be possible to compute the depth values of data points efficiently even for large p.

Here we introduce a novel notion of depth function that satisfies the previous properties under the constraint of sphered data and, in addition, it has two additional desirable features. It is general enough to comprise in its definition arbitrary probabilistic formulations and it preserves the Mahalanobis distances of the values to the data barycenter (as the $MD(x)$ naturally does).

Let S be a random vector of length p with a uniform distribution on the sphere. In other terms, a random value of S is a unit-norm direction $s \in \mathbb{S}^{p-1}$ with $\|s\| = 1$. At each random projection, the depth can be defined an inverse function of the percentile of the univariate value $s^\top x$. More specifically, for a whitened random variable the projection depth is the mapping $\mathbb{R}^p \times \mathcal{F} \to [0,1]$ defined as

$$D(x,F) = E_S\left[1 - 2|F_{S^\top X}(S^\top x) - 0.5|\right], \tag{1}$$

where E_S is the expectation with respect to the random vector S, F is the probability distribution of the multivariate data and $F_{S^\top X}$ is the marginal probability distribution of the transformation $S^\top X$ evaluated at $S^\top x$. $F_{S^\top X}$ can be any (probabilistic or nonparametric) univariate distribution function differently parameterized along each direction. In this work we will focus and compare the depth based on the Gaussian distribution, on the *fgld* quantile function due to its large flexibility (6; 1) and the nonparametric kernel density estimation. Figure 1 shows the depth contourns obtained by applying the proposed depth with three distributions on data generated from a standard Gaussian and from a Chi-squared distribution with 3 degrees of freedom.

Given whatever model choice of F_S, the depth defined in (1) is a proper depth function in the sense of the definition given by (8). Another interesting property of the proposed depth function is that the expected value of the distances between univariate projections on sphered data is proportional to the Mahalanobis distance in the original multivariate data. This is very important from the empirical point of view because it ensures coherence to the depths. Take, for example, the point cloud represented in the first panel of plot 2. The red point with coordinates $\{2,1\}$ is clearly further away from the point cloud than the green point with coordinates $\{3.5,4.5\}$. Their Mahalanobis distances are 6.4 and 2.6, respectively. Table 1 shows the depths obtained on sphered and non-sphered data.

Table 1: Computed depths for the two points on raw data and on sphered data.

	$\mathbf{x}_a = \{2,1\}$	$\mathbf{x}_b = \{3.5,4.5\}$
without sphering	0.193	0.085
with spering	0.082	0.206

From this example, it is clear that on raw data the green point $\mathbf{x}_a$ is projected far from the barycenter of the data in a limited number of directions, while $\mathbf{x}_a$ is projected far from the barycenter for most

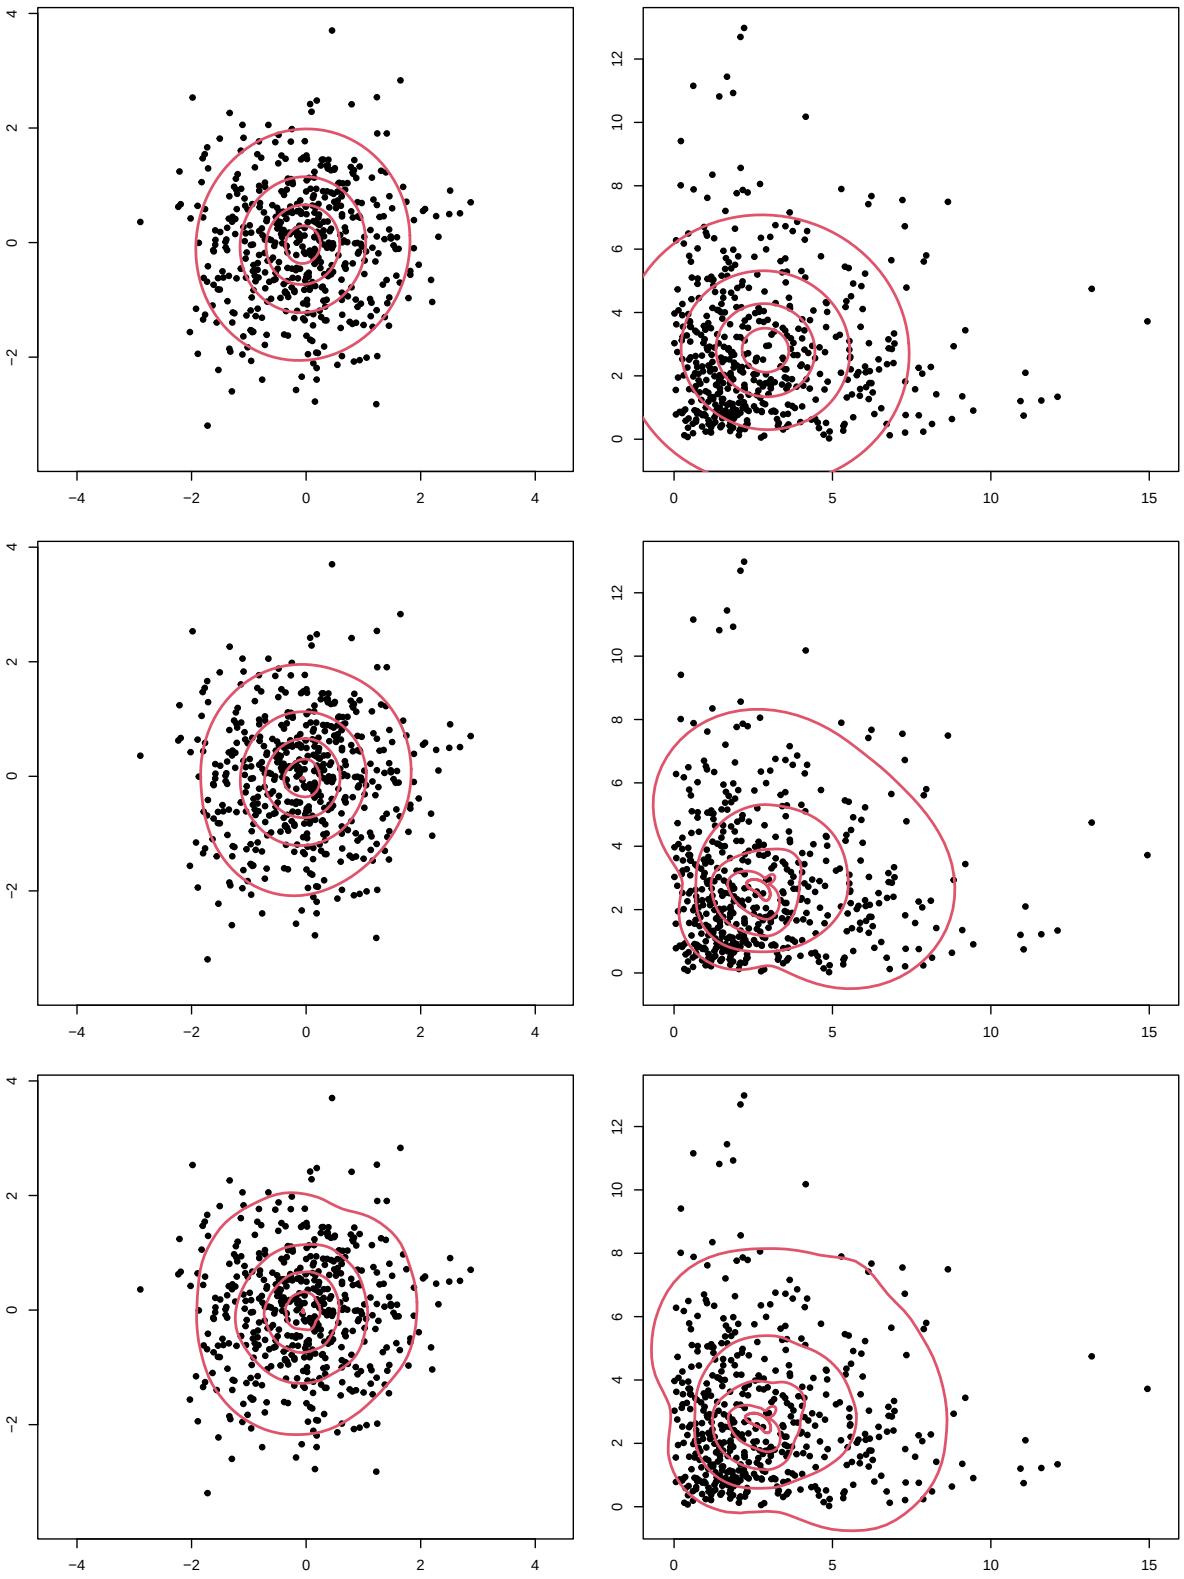

Figure 1: Normal, fgld and nonparametric contourns for p=0.25, 0.5, 0.75 and 0.95 on data drawn from a standard Gaussian and a Chi-squared distribution with 3 degrees of freedom.

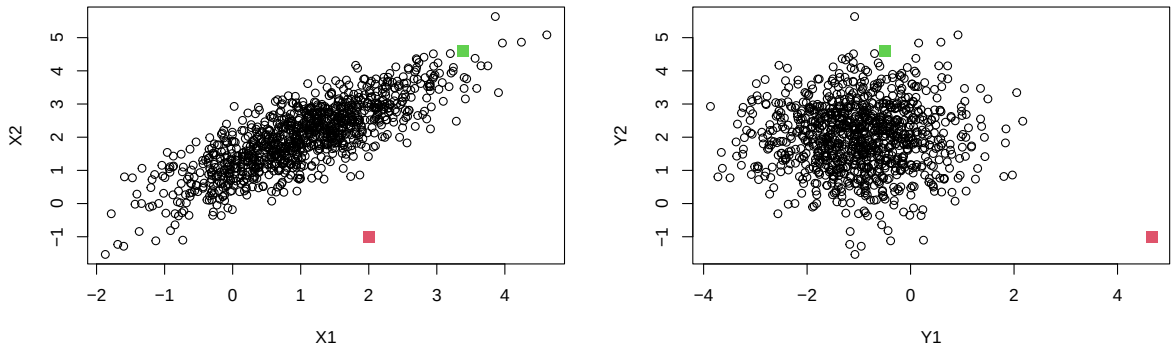

Figure 2: First panel: data drawn from a multivariate Gaussian. Second panel: sphered data.

directions. But sphering makes angles and distances constant along the different projections, and on sphered data the depth indicated that $\mathbf{x}_b$ is deeper than $\mathbf{x}_a$. This is also evident from the second panel of Figure 2.

2.1 Sample version

Let X_n be a sample of size n from X, without loss of generality we assume it to sphered. Let $\mathbf{s}$ be a set of B spherical directions. Then the sample version of the directional distribution depth for a generic point x_i is

$$D_n(x_i, F) = \frac{\sum_{b=1}^{B} \left[1 - 2|\hat{F}_{s_b^\top X_n}(s_b^\top x_i) - 0.5|\right]}{B}, \tag{2}$$

Please note that unit norm projections of sphered data produce marginal distributions with the same variability. In fact, the marginal distribution along each direction has unit variance. This result is advantageous from a computational point of view, for (at least) two reasons. It simplifies the estimation problem in cases where a parameter represents data dispersion and makes the distributions comparable along different directions.
In the following result we prove the strong consistency of $D_n(x, F)$.

Theorem 1. *As $n \to \infty$ and $B \to \infty$*

$$D_n(x, F) \xrightarrow{a.s.} D(x, F) \tag{3}$$

Proof. By the strong law of large numbers we first observe that

$$D_n(x, F) \xrightarrow{a.s.} E_S[1 - 2|\hat{F}_{S^\top X_n}(S^\top x) - 0.5|]$$

as $B \to \infty$. Now, let $\Psi_n(x, F) = 1 - 2|\hat{F}_{S^\top X_n}(S^\top x) - 0.5|$ and $\Psi(x, F) = 1 - 2|F_{S^\top X}(S^\top x) - 0.5|$. Notice that $\Psi_n(x, F) = O_p(1)$. Thus by the theorem of dominate convergence

$$E[\Psi_n(x, F)] \to E[\Psi(x, F)]$$

as $n \to \infty$.

Remark 1. *Direction importance.*

One might wonder if the directions s could contribute differently to determining the depth of a point. Therefore, the problem arises as to whether it makes sense to weigh the directions by transforming formula (1) into a weighted average using coefficients w_b to be determined according to some criterion. Intuitively, a direction is good when it is able to concentrate the units more around the barycenter. However, as previously observed, the variability along each direction is constant. Furthermore, for each direction, the sum of the depths of all points is also constant. In particular, given $d_{ib} = 1 - 2|\hat{F}_{s_b^\top X_n}(s_b^\top x_i) - 0.5|$, we have

$$\sum_{i=1}^{n} d_{ib} = \frac{n}{2},$$

for every b. Therefore, surprisingly, for the purpose of determining the depth, the directions have the same importance.

Remark 2. *Prediction.*

The proposed depth is based on a model (parametric or non-parametric) given by F_S and thus it allows for a population version. This is a great advantage in terms of prediction. In other words, unlike other depth functions are defined only for empirical distributions, it is possible to estimate the depth for new out-of-sample values once the distributions along each direction have been estimated. The ability to make prediction makes this depth function a candidate tool for supervised classification purposes, as will be shown in the next sections.

3. Application to Supervised Classification

We apply to proposed depth function to supervised classification by allocating a new observation to the class with the maximum depth among the K populations (2). Thus for a statistical unit x the predicted class is

$$\arg\max_{k \in K} D(x, F_k).$$

The performance of the proposed classifier is evaluated through a large simulation study and on real data sets. We compare it with other maximum depth classifiers, based on Mahalanobis, projection and halfspace depths, with linear and quadratic discriminant analysis, and for the real data sets also with K-nearest neighbours and SVM.

Clustering alternatives in the preference-approval context

Alessandro Albano[a], José Luis García-Lapresta[b], Mariangela Sciandra[a], and Antonella Plaia[a]

Abstract

Preference-approval structures combine preference rankings and approval voting to express preferences over a set of alternatives. This paper proposes a new method for clustering and visualizing alternatives in the context of preference-approvals. Firstly, we present a new family of pseudometrics defined on a set of alternatives, evaluated via preference-approvals. The distances among alternatives are used as input in the Ranked k-medoids algorithm to find clusters. Finally, clusters are visualized in a two-dimensional space using non-metric multidimensional scaling. We show, through an application to real data, that our approach allows for reducing the complexity of the preference-approval space and facilitates its interpretation.

Keywords: Preference rankings, Approval voting, Preference-approvals, Kemeny distance

1. Introduction

Preference-approval structures involve collecting data about people's opinions on a set of alternatives to discover which they prefer and which they consider unacceptable. In preference-approval structures, voters are asked to classify the alternatives as acceptable or unacceptable and rank them in order of preference. This information can then be used to make decisions or to understand how people feel about the different options.

Preference-approval structures have been the subject of recent research from various perspectives, as shown in several papers (3; 4; 2; 1). However, there has been little focus on creating clustering algorithms specifically for preference-approvals.

This paper introduces a method for clustering and visualizing alternatives in the preference-approval context. Firstly, we define a new family of pseudometrics on the set of alternatives in the preference-approval context. Then, the Ranked k-medoids algorithm (see (5)) is employed to create clusters of the alternatives based on the similarities calculated using these pseudometrics. Finally, the clusters are represented in a two-dimensional space using non-metric multidimensional scaling. This method allows for visualizing data in reduced dimensions while preserving the relationships between points. We demonstrate how our approach can be applied to create meaningful clusters of the alternatives and visualize them.

The paper is organized as follows. Section 2 introduces basic notation and concepts we use throughout the article. Section 3 contains our proposal for clustering alternatives. Section 4 includes a case study. Finally, Section 5 concludes the paper with some remarks.

2. Notation

Suppose a set of voters $V = \{v_1, \ldots, v_m\}$, with $m \geq 2$, are asked to order n different alternatives, the ranking π is a mapping function from the set of alternatives $X = \{x_1, \ldots, x_n\}$ to the set of ranks $\pi = \{P_\pi(x_1), \ldots, P_\pi(x_i), \ldots, P_\pi(x_n)\}$, where $P_\pi : X \longrightarrow \{1, \ldots, n\}$ assigns the rank of each alternative. If the n alternatives are ranked in n different ranks, a complete (full) ranking or linear order is achieved. In certain cases, some alternatives could receive the same rank, and then a tied ranking or a weak order is obtained.
In the framework of preference-approval modelling, each preference ranking, π, is paired with an approval vector, A. For any given set X of alternatives, we define approvals by partitioning X into G, the set of good alternatives, and $U = X \backslash G$ the set of unacceptable alternatives, where G and U can be empty sets.
We represent a voter's preference-approval profile by a top-down order of alternatives with a horizontal bar: alternatives above the bar are approved, and those below are rejected.

$$\begin{array}{c} x_2 \\ x_1 \\ \hline x_3 \\ \hline x_4 \end{array}$$

The previous representation indicates that the voter's three top-ranked alternatives ordered as: $x_2 \succ x_1 \succ x_3$ are approved and and the voter's bottom-ranked alternative x_4 is disapproved. The preference-approval profile is codified as follows:

$$\pi_1 = (2, 1, 3, 4) \quad A_1 = (1, 1, 1, 0).$$

3. The proposal

Given a profile $\big((\pi_1, A_1), \ldots, (\pi_n, A_n)\big) \in \mathcal{R}(X)^n$, where $\mathcal{R}(X)$ denotes the set of preference-approvals on X, and two alternatives $x_i, x_j \in X$, we now present two indices that quantify the distance between these alternatives in terms of preference and approvals, respectively, for each voter $v_k \in V$.
The *preference-discordance* between x_i and x_j for the voter $v_k \in V$ is defined as

$$p_{ij}^k = \frac{1}{n-1} \cdot |P_{\pi_k}(x_i) - P_{\pi_k}(x_j)|, \tag{1}$$

where $p_{ij}^k \in [0, 1]$. The *approval-discordance* between x_i and x_j for the voter $v_k \in V$ is defined as

$$a_{ij}^k = |I_{A_k}(x_i) - I_{A_k}(x_j)|, \tag{2}$$

where $a_{ij}^k \in \{0, 1\}$. In order to define an overall measure of discordance between each pair of alternatives, we consider the family of *weighted means*, $h : [0, 1] \times [0, 1] \longrightarrow [0, 1]$, where λ is the weighting parameter, defined as

$$h(x, y) = \lambda \cdot x + (1 - \lambda) \cdot y, \tag{3}$$

where $\lambda \in [0, 1]$. Taking into account the preference and approval discordances introduced in Eqs. (1) and (2), respectively, and the family of weighted means defined in Eq. (3), we now introduce a global measure of discordance between pairs of alternatives.

Definition 1. *Given a profile* $\big((\pi_1, A_1), \ldots, (\pi_n, A_n)\big) \in \mathcal{R}(X)^n$ *and* $\lambda \in [0, 1]$, *the mapping* $\delta_\lambda : X \times X \longrightarrow [0, 1]$ *is defined as*

$$\delta_\lambda(x_i, x_j) = \frac{1}{m} \cdot \sum_{k=1}^{m} \Big(\lambda \cdot p_{ij}^k + (1 - \lambda) \cdot a_{ij}^k\Big). \tag{4}$$

The δ_λ measure is used in the clustering procedure.

3.1 Clustering procedure and visualization

In this paper, we use the *Ranked k-medoids* (RKM) algorithm (see Zadegan et al. (5)) to find clusters. The Ranked k-medoids (RKM) algorithm is a distance-based clustering technique used to find clusters in a dataset. It works by assigning a rank to each pair of alternatives in the dataset based on how similar they are to each other. The rank matrix, K, is a measure of the hostility relationship between the alternatives in the dataset, with lower ranks indicating greater similarity. The ith hostility value, hv_i, is computed by summing all of the ith object's ranks with respect to a set of alternatives. The RKM algorithm first selects the medoids randomly, then selects the group of most similar objects to each medoid, calculates the hostility values of each object in the group, and selects the object with the highest hostility value as the new medoid. This process is repeated until the objects are assigned to the most similar medoid. The procedure needs the number of clusters to be specified in advance, but the best configuration can be found by using methods such as the Silhouette Coefficient. The resulting clusters can be visualized in a 2-dimensional space using multidimensional scaling (MDS), specifically Non-metric Multidimensional Scaling in this case. MDS attempts to represent a distance matrix as a simple geometrical model or map, such that the perceived distance between two alternatives is reflected in the distance between the points representing them in the model. Non-metric MDS preserves the rank order of the proximities, and the coordinates are found by minimizing the Stress function, which is based on the squared differences between the observed proximities and the derived disparities.

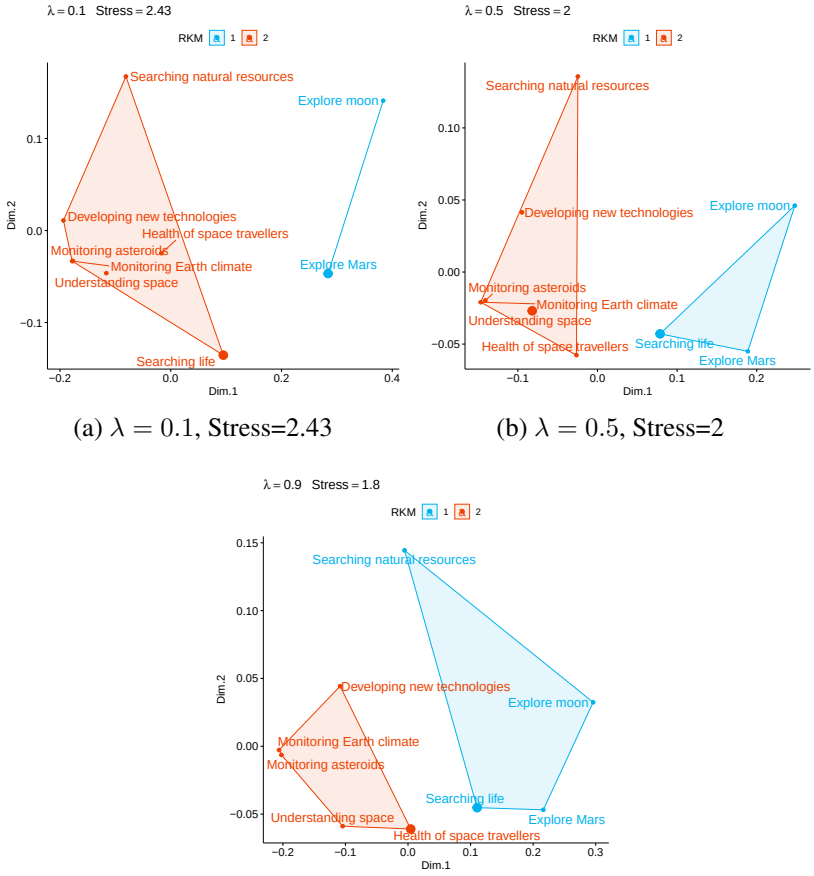
4. Case study

Data used in this section comes from the survey "American Trends Panel Wave 33" conducted by the Pew Research Center. This research organization conducts data-driven social science research, including public opinion surveys and demographic studies. In this particular analysis, the survey is used to gather opinions from United States citizens on the priorities of the space agency NASA. The survey was conducted from March 27 to April 9, 2018, and a total of $m = 2541$ respondents were asked to assess the priority that NASA should give to a list of $n = 9$ lines of action. The respondents used a qualitative scale to express their opinions, where l_1 indicates a top priority option, l_2 an important but lower priority, l_3 not too important, l_4 should not be done, and l_5 indicates no answer.
This data is used to assess the priorities of United States citizens for NASA.

Table 1: The $n = 9$ alternatives (NASA lines of action).

Alternatives	Names
x_1	Searching for life and planets that could support life
x_2	Searching for raw materials and natural resources that could be used on Earth
x_3	Conducting basic scientific research to increase knowledge and understanding of space
x_4	Developing technologies that could be adapted for uses other than space exploration
x_5	Monitoring asteroids and other objects that could potentially hit the Earth
x_6	Monitoring key parts of the Earth's climate system
x_7	Sending human astronauts to explore the moon
x_8	Sending human astronauts to explore Mars
x_9	Conducting scientific research on how space travel affects human health

To remove neutral answers from the survey data, the respondents who provided at least a "No answer" response were excluded from the analysis. This represented about 3% of the total sample size m. The remaining responses were then arranged into a preference-approval, with the linguistic terms "l_1" and "l_2" indicating an acceptable alternative. This allows for a more focused analysis of the respondents' preferences and approval ratings for the different lines of action.
The clusters estimated by the RKM algorithm, using three different values of $\lambda = 0.1, 0.5, 0.9$, are shown in Fig 1. For each scenario, the clusters, medoids and Stress values reached by the MDS are illustrated for graphical representation.



(a) $\lambda = 0.1$, Stress=2.43 (b) $\lambda = 0.5$, Stress=2

(c) $\lambda = 0.9$, Stress=1.8

Figure 1: Graphical representation of RKM clusters.

The Stress coefficient, which measures the model's goodness of fit, varies between 1.8 and 2.43 in this analysis, indicating an excellent fit that tends to improve as λ increases. The optimal number of clusters, as determined by the Silhouette criterion, is 2, regardless of the value of λ.
The parameter λ has a visible effect on the formation of the clusters. When $\lambda = 0.1$, Cluster 1 includes only the alternatives related to space exploration (Moon and Mars), the respondents tend to give similar approval ratings to these two alternatives. Increasing the value of λ to 0.5 causes Cluster 1 to include the alternative "Searching life". When $\lambda = 0.9$, giving more weight to the rankings, Cluster 1 also includes the alternative "Searching natural resources". As a result, Cluster 1 includes the four alternatives that are most frequently placed at the bottom of the respondents' preference-approvals.

5. Conclusions

This paper presents a new method for clustering alternatives in preference-approval structures, which are increasingly important in social choice because they allow decision-makers to describe their preferences using more flexible and intuitive ordinal information. The method involves introducing a family of pseudometrics, δ_λ, which can quantify the distance between alternatives based on the "preference-discordance" and "approval-discordance", and a parameter λ that regulates the weight given to each component. The Ranked k-medoids partitioning algorithm is used to find clusters based on the similarities between pairs of alternatives calculated using the pseudometrics. The resulting clusters are visualized in a 2-dimensional space using Non-Metric Multidimensional Scaling.

Abstract

This paper proposes an alternative method for the choice of the number of centroids in a cluster analysis, when the groups' order is relevant. Differently from commonly used approaches, aimed at finding the minimum number of clusters, the illustrated method aims at finding the maximum one. Given that the clusters are ordered, this allows to define a granular ranking among them. The *k*-means partitioning algorithm is applied to an index resulting from a Structural Equation Model. The procedure is implemented on a measure of air pollution in urban areas: a clustering of main Italian cities, according to the optimal number of air pollution levels, is the final result. The analysis' interpretation provides useful information to design policies aimed at reducing air pollution.

Key words: Cluster analysis, Computational assessment, Structural Equation Models, Air Pollution, Latent variable models, Environmental statistical models.

1. Introduction

Most of the commonly used methods to identify the optimal number of clusters in a cluster analysis aim at finding the minimum *k* (Gap statistics [16]; Silhouette method [13]; Elbow method [14]). In this paper, the idea behind the choice of *k* is the opposite: the goal is to find the maximum number of "*distinguished*" clusters: what are the "well-distinguished" clusters is defined by means of bootstrap confidence intervals for clusters' centroids. Given a sample of units and a number of clusters *k*, these intervals can be computed by bootstrapping those units a number B of times and computing each time the *k*-means. The results are B vectors of *k* centroids. The final estimates of the *k* clusters' centroids as well as their empirical distributions can be obtained computing the mean and plotting the histograms of the bootstrap replicates, respectively. Given the *k* centroids' point estimates with the corresponding $\alpha/2$ and $(1-\alpha/2)$ percentile estimates, it is possible to build *k* percentile confidence intervals of the desired confidence level α. If some of these confidence intervals do overlap by more than a fixed small constant ε, then the clusters are not "well-distinguished". The optimal number of clusters k^* will be the maximum *k* such that none of the *k* intervals do overlap by more than ε.

A new air quality index has been estimated by means of the application of a Structural Equation Model (SEM) to pollutants variables, as it takes into account the multivariate relationships among contaminants ([2]). The analysis of the new index distribution among the Italian metropolitan areas can be useful to draw policy conclusions devoted to reducing air pollution levels.

The clustering analysis homogeneously groups Italian cities with respect to different air pollution levels. Assigning a rank to the cities within the same cluster, it is possible to classify them from the most to the less polluted.

The paper is structured as follows: Section 2 presents data used for the empirical study, Section 3 introduces SEM's specifications and modelling and the cluster analysis technique employed. In Section 4, an application on air quality for Italian cities is provided. In Section 5 concluding remarks are drawn.

2. Data

The dataset on which the study is conducted comes from the European Environmental Agency (EEA) and refers to 6 pollutants' emissions of 106 Italian provinces in 2022. For each city, the pollutant emission is computed as the average over the 365 days of daily median emissions. These 6 gases are the ones that the Environmental Protection Agency (EPA) individuated as major air pollutants and they are regulated by the Clean Air Act. They are: Ground-level ozone (O3), Particle pollution (also known as Particulate Matter (PM), including PM2.5 and PM10), Carbon monoxide (CO), Sulfur dioxide (SO2) and Nitrogen dioxide (NO2).

3. Methods: Structural Equation Model and Cluster analysis

In this paper, an index is built employing a Structural Equation Model. This model combines Confirmatory Factor Analysis and Multiple Regression Analysis into a comprehensive modelling framework that involves both endogenous and exogenous variables. In the so called "measurement part" of the model, the relations between the observed (manifest) variables (MVs) and the latent factors (LVs) can be studied. Moreover, the "structural part" of the model studies the causal relationships of the latent constructs among themselves. All these relations are estimated simultaneously ([8]; [3]; [15]; [6]).

In order to rank units with respect to the SEM-based index, the centroid-based model of *k*-means ([17]) is employed. The *k*-means method assumes that each observation is equal to one of the *k* centroids. All the observations assigned to each centroid, perturbed by error in measuring the features, forms a cluster. The clustering goal is to partition the units in a disjoint set of *k* clusters to maximise the dissimilarity between centroids of the clusters.

In this analysis, a centroid of a cluster is the mean value of the index. For this univariate clustering problem, the optimal number of clusters k^* is chosen to be the highest possible, as long as centroids are statistically different according to a desired confidence level α. The idea is to rank clusters by their centroids, so that units belonging to a cluster have the rank of that cluster. Hence, k^* is the maximum value for which all k^* centroids' confidence intervals at significance level (1-α) do not overlap by more than a fixed constant ε.

However, because of its deterministic nature, *k*-means does not yield confidence information about centroids' distribution and estimated cluster memberships, although this could be useful for inferential purposes. It is possible to obtain such information by means of a non-parametric bootstrap procedure. This procedure provides centroids' distributions ([9]) which can be used to derive probabilistic membership information on each object from all bootstrap samples. It also yields confidence information about the centroids in the form of confidence intervals ([7]).

Given a sample of size n, for a given *k*, the partitioning algorithm is run. The corresponding *k* centroids' estimates and corresponding confidence intervals are built applying bootstrap to that sample of n units.

For each of the B bootstrap iterations, the *k* centroids are ordered from the smallest to the largest. This allows to easily match the centroids over different bootstrap samples. Once the matching is done, the final estimate of each of the *k* centroids is obtained as the mean of the corresponding B centroids' values. The α/2% and (1- α/2)% centroids' percentiles can be estimated in a similar way and the (1-α)% percentile bootstrap confidence intervals can be computed as follows: $\left[percentile_{\frac{\alpha}{2}}\,;\, percentile_{\frac{1-\alpha}{2}}\right]$.

The partitioning algorithm chosen is a centroid-based 1-dimensional *k*-means and units are classified according to the SEM-based index. In this particular, unidimensional case, an optimal dynamic programming *k*-means algorithm has been developed by Froese et al. ([5]). The algorithm is implemented in the Ckmeans.1d.dp R package ([18]).

The clustering algorithm is run for different values of *k*, starting from $k = 2$. At each iteration, if the *k* bootstrap confidence intervals do not overlap by more than ε, the *k* clusters can be considered well separated. Then, *k* is increased by one and the partitioning algorithm is run again. The procedure is

iterated until two overlapping confidence intervals are found. A crucial point is the need of ordering the clusters with respect to their centroid value, from the smallest to the largest. This allows to find the consecutive clusters' confidence intervals to be compared.

4. Application to urban air pollution for Italian metropolitan areas

In this study, a multidimensional index to measure air pollution is built by means of a hierarchical SEM ([4]). This flexible model has the advantages of taking simultaneously into account a number of levels in the hierarchy and to exploit the information available in meaningful explanatory variables.

Based on the results of a preliminary Explanatory Factor Analysis on the six main pollutants, a hierarchical, two latent factors model is estimated using the "sem" function from the R "lavaan" package ([12]). This function automatically standardizes the six pollutants, assigning negative weights to the variables that the factor reconstructs in the opposite direction from the others.

The resulting index, called Model Based-Air Pollution Index (MB-API), is normalized in 0-1. This index allows to rank cities with respect to their air pollution level.

The estimated model can be written as follows.

$$\begin{cases} f1 = 0.64PM2.5 + 0.62PM10 - 0.37O3 + 0.41SO2 \\ f2 = CO - 0.65NO2 \\ MBAPI = f1 + 0.79f2 \end{cases} \quad (1)$$

Fig.1 shows the different levels of air pollution, according to the MB-API, for the 106 Italian cities. The most polluted areas are in Piedmont, Lombardy, Veneto and Emilia-Romagna, while the less polluted cities are in the islands and in Calabria.

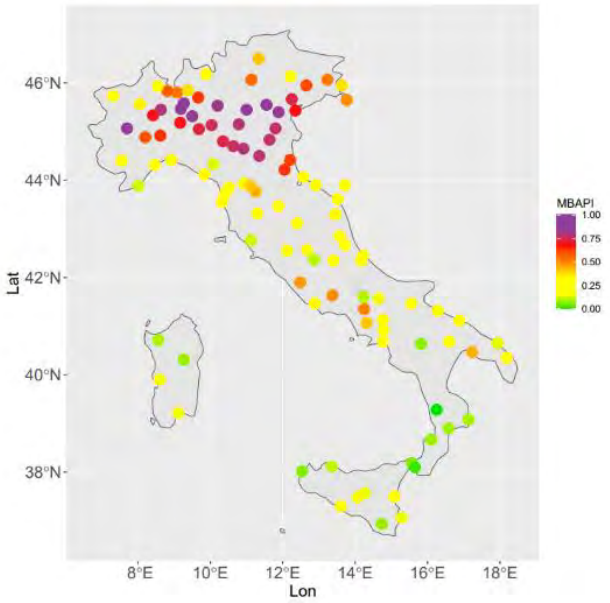

Figure 1: Air pollution index values in Italian metropolitan areas.

Cluster analysis is then applied to find groups of cities homogeneous with respect to the air pollution level. The Italian cities are grouped into clusters, each represented by a centroid that corresponds to an index value. It is important to note that to allow cities' ranking, cluster must be ordered with respect to the corresponding centroids. The clustering algorithm is run for $k = 2$ up to 10. The bootstrap procedure (with a number of bootstrap replicates equal to 10000) is used to compute the corresponding centroids' confidence intervals at 90% shown in Fig. 2.

Two clusters are considered well separated if the difference between the upper bound of a cluster and the lower bound of the consecutive one is smaller than a constant $\varepsilon = 0.01$ (1% of the index range, equal to 1). It is possible to note that for $k = 6$ the clusters do overlap by more than ε and therefore the optimal k should be 5. However, for $k = 7$ the clusters are well distinguished and therefore the optimal maximum number of non-overlapping clusters k^* is 7.

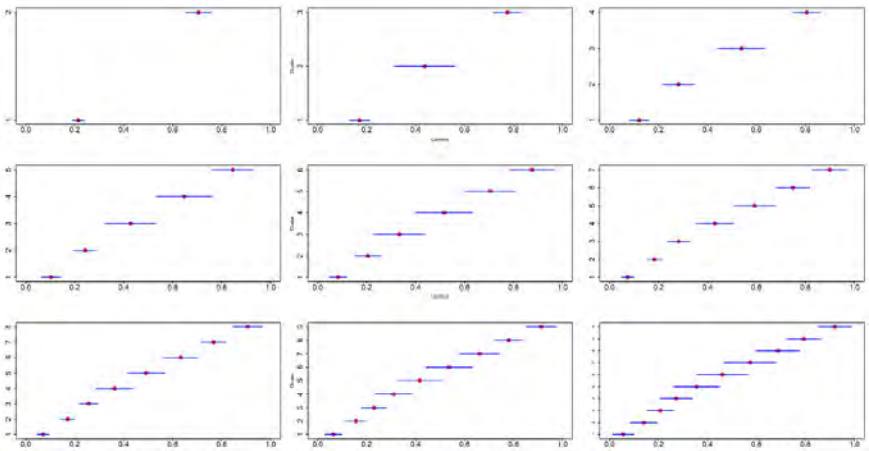

Figure 2: 90% bootstrap confidence intervals for *k*-means centroids. *k* ranges in 2-10.

Of course, the optimal number k^* depends on the α and ε values chosen *a priori*. It is worthy to note that this method of choosing *k* is very different with respect to the classical Elbow, Silhouette and Gap Statistics methods, whose aim is to find the minimum (and not the maximum) *k* such that the clusters are well defined. In all 3 cases, in fact, $k^*=2$ (as shown in the plots of Fig.3).

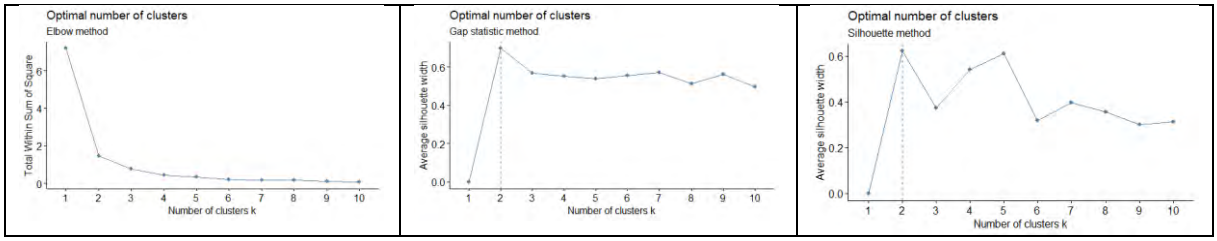

Figure 3: Choice of the optimal number of clusters according to the most widely used methods.

The maximum optimal number of clusters can be found also considering the maximum number of clusters whose centroids are simultaneously significantly different, according to nonparametric Wilcoxon tests ([10]), with confidence level chosen following the Bonferroni's correction ([1]). In this case, $k^*=10$ and therefore the more parsimonious solution $k^* = 7$ seems even more reasonable.

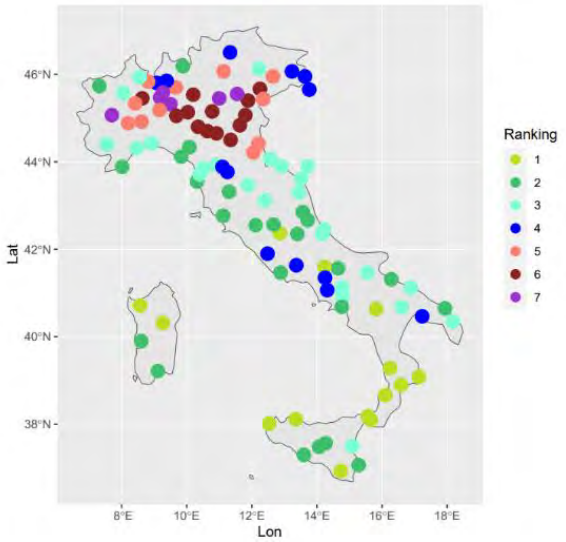

Figure 4: Choice of the optimal number of clusters according to the most widely used methods.

Basing on the previous results, groups are ranked from 1 to 7 considering the centroids' values from the highest to the lowest: rank 1 corresponds to the lowest centroid and therefore to the group of less air polluted cities.

The map in Fig. 4 shows air pollution distribution in Italy in 2022, highlighting groups of cities with a similar situation in terms of air pollution levels. It is possible to note that close points tend to have the same colour: cities in the same region often have a similar air pollution level.

5. Concluding remarks

The novelty of our paper resides in the fact that the *k*-means cluster analysis is employed in order to estimate the maximum number of significantly different centroids. The significance is assessed by means of percentile confidence intervals, built with a bootstrap procedure.

The performance of the proposed method is shown by an air pollution analysis: a measure of air quality in metropolitan areas has been developed based on a structural equation model. The procedure obtain a ranking of Italian cities, according to the optimal number of clusters of air pollution.

As a possible extensions of the study, the air pollution index can be improved considering also exogenous explanatory variables in the Structural Equation Model, such as the number of cars in the city or the percentage of green spaces. The model immediately integrates the new covariates. In case of adding more covariates, a different multidimensional clustering technique must be used and the obtained results can be compared with the unidimensional case.

Furthermore, a sensitivity and robustness analysis of the ranking can be conducted in a simulation framework, for instance computing average absolute shift in ranking index.

Thanks to this granular ranking, policy makers can easily identify the most polluted metropolitan areas and employ the estimated index as a unique measure of air pollution.

Handling missing data in complex phenomena: an ultrametric model-based approach for clustering

Francesca Greselin[a] and Giorgia Zaccaria[a]

[a]Department of Statistics and Quantitative Methods, University of Milano-Bicocca, Milan, Italy;
francesca.greselin@unimib.it, giorgia.zaccaria@unimib.it

Abstract

In the model-based clustering literature, we find several methodologies to study latent structures underlying the data, among which mixtures of factor analyzers. However, none of them can detect hierarchical relationships among latent variables. The Ultrametric Gaussian Mixture Model (UGMM) is intended to reach this goal by identifying a hierarchy of variables, starting by partitioning the variables into a reduced number of groups per mixture component. Nonetheless, up to now, it requires complete observations, which is often not the case in real data collections. In this paper, we propose the extension of UGMM in the missing data framework. The proposal is applied to a real data set for inspecting the relationships among features of songs of different genres.

Keywords: ultrametricity, Gaussian mixture models, missing information, hierarchy of latent concepts, heterogeneous populations, features of songs

1. Introduction

Model-based clustering is one of the most well-known approaches to model heterogeneous multivariate data by specifying a probability distribution (2). The central statistical methodology for clustering assumes the data coming from a heterogeneous population defined by a finite collection of G sub-populations, and is based on finite mixture models. Specifically, the dominant model is the Gaussian mixture model in which the distribution of the mixture components is Gaussian with mean vector and covariance matrix representing its parameters (9). In the specialized literature, different parameterizations of the component-covariance matrix have been proposed with a twofold goal: (i) specifying more parsimonious models by reducing the number of parameters that mostly derive from the component-covariance matrices, i.e., $Gp(p+1)/2$ parameters, and (ii) introducing models able to inspect latent structures underlying the data, e.g., factorial structure. The parameterization introduced by (1), and extended by (4), fits the first aim and is based upon the eigen-decomposition of the covariance matrix. Indeed, its number of parameters can vary between 1 and $Gp(p+1)/2$, by constraining them to be equal within and/or across components. The models proposed by (6), and further developed by (10), are instead able to reach both goals previously described by parameterizing the component-covariance matrices via a factorial structure with q factors, whose number of parameters varies between $(pq - q(q-1)/2)$ and $G(pq - q(q-1)/2) + Gp$ depending on constraints. Nonetheless, none of these models is able to detect hierarchical relationships among variables within components. To fill this gap, (3) introduced a Gaussian mixture model with an extended ultrametric covariance structure which is able to pinpoint the hierarchical structure of variables. This model assumes that, within each component, the variables are partitioned into q groups characterized by three features: the group variance, the covariance within the groups and

the covariance between the groups identifying their aggregation in pairs (under the ultrametricity constraint). The ultrametric parameterization leads to the estimation of $2q + p - 1$ parameters for each component of the mixture.

Although useful in several real applications, the aforementioned methodologies can only handle the occurrence of missing information (i.e., a data matrix in which some entries are not observed) by using ad hoc methods. Case deletion or imputation are used to force the incomplete data set into a rectangular complete-data format beforehand the model estimation. To overcome this issue, assumptions on the missing data probability have to be taken into account (11). The missing mechanism can be of three types: Missing Completely At Random (MCAR), Missing At Random (MAR) and Missing Not At Random (MNAR), where the probability of a missing datum in an observation does not depend on the other values, is independent of the missing value or depends on the missing value itself, respectively. Under the MCAR and the less restrictive MAR assumptions the missing mechanism is considered to be ignorable, i.e., the parameters of the missing data distribution are distinct from the parameters of the observed data distribution (8; 12). The extension of Gaussian mixture models in the missing data framework was introduced by (7), whereas (15) proposed mixtures of factor analyzers models with missing information, both under the MAR mechanism. Only recently, Gaussian mixture models were studied under the MNAR mechanism (14).

In this paper, we introduce the Ultrametric Gaussian Mixture Model (UGMM) that handles incomplete information when the missing mechanism is assumed to be MAR. The proposal is intended to identify hierarchical structures of variables characterizing a multidimensional phenomenon within heterogeneous populations, when the data are affected by missingness, as often occurs in real data applications. The proposed methodology is applied herein for studying the hierarchical relationships among features of songs pertaining to different genres.

The outline of the paper is as follows. In Section 2, the ultrametric Gaussian mixture model with missing data handling is described in details together with its estimation. A real data application is provided in Section 3. A final discussion concludes the paper in Section 4.

2. The model

Let $\boldsymbol{x}$ be a random sample composed of n observations of dimension p, that is $\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n$, where $\boldsymbol{x}_i = (x_{i1}, \ldots, x_{ip})'$. The GMM density of $\boldsymbol{x}_i$ is defined by a mixture of G multivariate Gaussian distributions as follows

$$f(\boldsymbol{x}_i \mid \boldsymbol{\Psi}) = \sum_{g=1}^{G} \pi_g \, \phi(\boldsymbol{x}_i; \boldsymbol{\mu}_g, \boldsymbol{\Sigma}_g), \tag{1}$$

where π_g is the probability that an observation has been generated by the gth component of the mixture, so that $\pi_g > 0, g = 1, \ldots, G$, and $\sum_{g=1}^{G} \pi_g = 1$, and $\boldsymbol{\mu}_g$ and $\boldsymbol{\Sigma}_g$ are the mean vector and covariance matrix of the gth normal component, respectively. In UGMM, the latter has a particular form defined by

$$\boldsymbol{\Sigma}_g = \boldsymbol{V}_g(\boldsymbol{\Sigma}_{\mathrm{W}_g} + \boldsymbol{\Sigma}_{\mathrm{B}_g})\boldsymbol{V}_g' - \mathrm{diag}(\boldsymbol{V}_g\boldsymbol{\Sigma}_{\mathrm{W}_g}\boldsymbol{V}_g') + \mathrm{diag}(\boldsymbol{V}_g\boldsymbol{\Sigma}_{\mathrm{V}_g}\boldsymbol{V}_g'), \tag{2}$$

that is extended ultrametric (Definition 2 in 3) if, for each component g of the mixture, $\boldsymbol{V}_g$ is binary and row-stochastic, $\boldsymbol{\Sigma}_{\mathrm{B}_g}$ is symmetric with zero diagonal entries and off-diagonal values whose triplets comply with the ultrametric condition and whose maximum is lower than or equal to the minimum of $\boldsymbol{\Sigma}_{\mathrm{W}_g}$, and such that $\boldsymbol{\Sigma}_g$ is positive definite. Thus, the parameters in $\boldsymbol{\Psi}$ are $\boldsymbol{\pi} = [\pi_g]_{g=1}^G, \boldsymbol{\mu} = [\boldsymbol{\mu}_g]_{g=1}^G, \boldsymbol{V} = [\boldsymbol{V}_g]_{g=1}^G, \boldsymbol{\Sigma}_{\mathrm{V}} = [\boldsymbol{\Sigma}_{\mathrm{V}_g}]_{g=1}^G, \boldsymbol{\Sigma}_{\mathrm{W}} = [\boldsymbol{\Sigma}_{\mathrm{W}_g}]_{g=1}^G, \boldsymbol{\Sigma}_{\mathrm{B}} = [\boldsymbol{\Sigma}_{\mathrm{B}_g}]_{g=1}^G$, where $\boldsymbol{V}_g$ is the variable-group membership matrix that specifies a partition of the variable space into a reduced number q of groups in each component, $\boldsymbol{\Sigma}_{\mathrm{V}_g}$ is the diagonal group-variance matrix identifying the variance of each of the q groups per component, $\boldsymbol{\Sigma}_{\mathrm{W}_g}$ is the diagonal within-group covariance matrix representing the covariance within the variable groups for each mixture component, and $\boldsymbol{\Sigma}_{\mathrm{B}_g}$ is the component between-group covariance matrix.

Commonly, Gaussian – and more generally finite – mixture models are estimated via the Expectation-Maximization algorithm (EM, 5) that works in an incomplete data framework, where the source of miss-

Table 1: Song features and their description

Song feature	Description
Danceability	Sustainability for dancing based on a combination of musical elements
Energy	Perceptual measure of intensity and activity
Loudness	Overall loudness in decibel
Speechiness	Presence of spoken words
Acousticness	Measure of acousticness
Instrumentalness	Non-vocal presence
Liveness	Presence of an audience in the recording
Valence	Musical positiveness
Tempo	Overall estimated tempo in beats per minute

ingness originates from the unit-component membership variable $\boldsymbol{w} = (\boldsymbol{w}_1, \ldots, \boldsymbol{w}_n)'$, with $w_{ig} = 1$ if the ith observation belongs to the gth component, $w_{ig} = 0$ otherwise. When missing information occurs in the data as missing values at random (i.e., MAR), a second source of missingness has to be considered. In this case, each observation can be split in two parts: the *observed* part of dimension p_i and the *missing* part of dimension $(p - p_i)$. The complete data log-likelihood function of UGMM, i.e., subject to the aforementioned constraints on the component-covariance matrix expressed in (2), is

$$\ell_c(\boldsymbol{\Psi}; \boldsymbol{x}^{\text{obs}}, \boldsymbol{x}^{\text{mis}}, \boldsymbol{w}) = \sum_{i=1}^{n} \sum_{g=1}^{G} w_{ig} \ln\Big(\pi_g \phi(\boldsymbol{x}_i^{\text{obs}}, \boldsymbol{x}_i^{\text{mis}}; \boldsymbol{\mu}_g, \boldsymbol{\Sigma}_g)\Big). \tag{3}$$

Under the MAR mechanism, $\phi(\boldsymbol{x}_i^{\text{obs}}, \boldsymbol{x}_i^{\text{mis}}; \boldsymbol{\mu}_g, \boldsymbol{\Sigma}_g) = \phi(\boldsymbol{x}_i^{\text{obs}}; \boldsymbol{\mu}_g^{\text{obs}}, \boldsymbol{\Sigma}_g^{\text{obs}}) \times \phi(\boldsymbol{x}_i^{\text{mis}} \mid \boldsymbol{x}_i^{\text{obs}}; \boldsymbol{\mu}_g^{\text{mis}}, \boldsymbol{\Sigma}_g^{\text{mis}})$ thanks to the separability assumption and the properties of the Gaussian distribution. It has to be noticed that the pattern of missingness depends on the observation, even if this specifying is removed herein for simplicity reasons.

The EM algorithm can be thus implemented to obtain the estimates of the model parameters in $\boldsymbol{\Psi}$. Particularly, after setting initial values $\boldsymbol{\pi}^{(0)}$, $\boldsymbol{\mu}^{(0)}$, $\boldsymbol{V}^{(0)}$, $\boldsymbol{\Sigma}_{\text{V}}^{(0)}$, $\boldsymbol{\Sigma}_{\text{W}}^{(0)}$, $\boldsymbol{\Sigma}_{\text{B}}^{(0)}$, the two following steps are repeated until convergence.

E-step. At iteration r, the expectation of the complete-data log-likelihood in Eq. (3) has to be computed. It corresponds to the calculation of the expected values of W_{ig}, $W_{ig}\boldsymbol{X}_i^{\text{mis}}$ and $W_{ig}\boldsymbol{X}_i^{\text{mis}}\boldsymbol{X}_i^{\text{mis}\prime}$ given the observed data $\boldsymbol{x}_i^{\text{obs}}$ and the current estimates of the unknown parameter, i.e., $\widehat{\boldsymbol{\Psi}}^{(r-1)}$.

M-step. At iteration r, the estimates of the prior probabilities π_g and the mean vectors $\boldsymbol{\mu}_g$ are derived (see 9, among others), as well as those of the component-covariance matrices $\boldsymbol{\Sigma}_g$ (see 3, for the estimation of $\boldsymbol{V}_g$, $\boldsymbol{\Sigma}_{\text{V}_g}$, $\boldsymbol{\Sigma}_{\text{W}_g}$ and $\boldsymbol{\Sigma}_{\text{B}_g}$).

3. Clustering songs with respect to their features in the presence of missing information

The proposed methodology is applied herein for classifying songs with respect to their genre (*Rhythm and Blues (RnB)*, *hardstyle* and *techno*) and identifying relationships among song features within different genres. Indeed, musical elements can play different roles in the definition of the pleasantness of a song, depending on the song genre.

The data set analyzed in this paper is composed of 165 songs – 52 RnB, 39 hardstyle and 74 techno – characterized by the nine features described in Table 1. The missing rate over the total number of values is 7%. UGMM is estimated by fixing $G = 3$, i.e., the number of genres in the data set, and selecting q into the set $\{1, \ldots, 5\}$ according to the Bayesian Information Criterion (13). The best q turns out to be $q = 3$.

Table 2: Clustering structure of songs in genres

Theoretical	Estimated		
	1	2	3
RnB	50	0	2
hardstyle	5	0	34
techno	0	69	5

The clustering structure is summarized in Table 2, where the theoretical and the estimated partitions in genres are compared. The latter is obtained by considering the membership of each song to the component of the mixture on which it has the highest posterior probability (i.e., maximum a posteriori). As a result, the theoretical partition in genres turns out to be recovered except for twelve songs, corresponding to a misclassification rate of 7%. Specifically, the estimated components can be labeled as follows: component 1 represents the RnB songs, component 2 the techno songs and component 3 the hardstyle songs of the sample.

The hierarchical structure of variables per component is depicted in Figure 1. By analyzing the song features' partition in groups, we can notice that the main features characterizing each genre are component-specific. For instance, in the RnB component, the first aggregation in group occurs among *Danceability*, *Energy*, *Loudness*, *Liveness* and *Tempo* with a positive relationship of among these song features, that reasonably seem to be the most important ones. For this genre, it can be noticed that the variables *Speechiness*, *Valence* and *Acousticness* are lumped together in a group, at the same level at which they are merged with the first group previously described and the singleton composed of *Instrumentalness*. Moreover, their aggregation (covariance) level is around 0, revealing that each of these features defines a unique part of the song pleasantness. In the component representing techno songs, the group with the highest internal consistency is defined by *Valence*, *Energy* and *Loudness*. The aggregation of the three groups occurs at a low level of covariance by highlighting, also in this case, the evidence of uncorrelated groups that separately contribute to the definition of the pleasantness of techno songs. This characteristic is even shared by the hardstyle songs, whose highly consistent group is defined by *Instrumentalness*, *Liveness* and *Danceability*. Furthermore, the hierarchical structure results in Figure 1 show "recurring relationships" between song features across components that can find a theoretical explanation. For instance, *Energy* and *Loudness* are in the same variable group for each genre; indeed, energetic songs are usually loud. The differences among genres and the definition of song pleasantness within them prove the need of introducing a new methodology in the literature able to detect component-specific hierarchical structure of variables also in the presence of missing values.

4. Conclusions

In this paper we introduce a model-based clustering approach for detecting hierarchical latent structures of variables when missing information occurs in the data. To reach this goal, the component-covariance matrices of a Gaussian mixture model are parameterized by an extended ultrametric covariance structure able to pinpoint a variable partition into groups and their hierarchical relationships within each component (3).

The proposal is applied herein on a data set with 7% of missing values, referring to three genres of songs that represent the clustering structure. Within each genre, the hierarchy of song features is inspected and component-specific characteristics defining the song pleasantness are highlighted. It has to be noticed that the three variable groups identified for each mixture component – that differ across components – result to be uncorrelated. Furthermore, this happens also within groups, e.g, for the Rnb songs where a higher number of groups would probably provide a better fit ($q = 3$ for each genre). For this reason, a further development of the proposed methodology can address this problem by allowing the number of variable groups q to vary across components.

Abstract

Unemployment among young adults has always been a relevant topic. To be employable, it is fundamental that young people learn how to plan and manage their careers and they need to be aware of their their skills and competences. This study focuses on the identification of the skills that students in the late stages of their university journey perceive as important and which of them they were able to develop. To this purpose data were collected through a survey and analyzed using the NonParametric Combination (NPC) methodology and a multivariate ranking procedure.

Keywords: NPC, ranking, employability

1. Introduction

Unemployment among young adults has always been a relevant topic for the European Commission (2009) and the Organization for Economic Cooperation and Development (OECD, 2012). A misalignment does exist between young people's skills and the skills required by the labor market and in this the lack of dialogue between higher education institutions (HEIs) and businesses plays a central role.

To be employable, it is fundamental that young people learn how to plan and manage their careers (3), but also their personal and professional development (2). To this aim, they need to be aware of their self-perceived employability (6), their skills and competences, and knowledge of labor market demands and opportunities.

This study focuses on investigating the perception of higher education students on their skills and the existing gaps between the skills they feel they have developed and the skills they consider to be important in order to be employable. A survey was administered to students of the faculty of Engineering at the University of Padua in Italy, in order to collect data about students' labor market perceptions and their career planning and control. To analyze these data, we take advantage of the NonParametric Combination (NPC) methodology (5) and the multivariate ranking procedure by Arboretti et al. (1). These techniques are adopted in order to rank a number of skills according to their perceived importance, to their degree of development and according to both these aspects. This allows us also to identify eventual discrepancies between the skills the students were able to develop during their academic studies and the most important skills according to their students.

Section 2 is devoted to the introduction of the case study, the definition of the adopted methods and the presentation and discussion of the achieved results. In Section 3 conclusions are drawn.

2. Case study

A survey was administered to students of the faculty of Engineering at the University of Padua, selected people from the final year of undergraduate courses, from both years of Master's degree courses, and from the last three years of single-cycle courses, given that students at these stages of their university journey are more aware of their career goals and the challenges of university-to-work transition than the other undergraduates. The final sample size was equal to 2129.

Part of the questionnaire concerned the identification of the skills being perceived relevant for the labor market. The considered skills were: analytical thinking and innovation; active learning and strategies; resolving complex problems; critical thinking; creativity, originality and initiative; leadership; use of technologies; technological design and programming; resilience, stress tolerance, and flexibility; reasoning and ideation; emotional intelligence; persuasion and negotiation. Given this set of skills, the respondents were asked to which ones he considered relevant and should be promoted by university, so that a skill-specific binary variable (Yes: if this skill is perceived relevant - No: if this skill is not perceived relevant) was achieved for each skill.

For each skill, the respondent was also asked to choose the skills that he felt to have developed. Skill-specific binary variables were again collected.

The analysis of collected data had two main objectives:

- identify the main skills in terms of perceived relevance and development,
- identify eventual discrepancies between the skills the students were able to develop during their academic studies and the most important skills according to their students.

To this purpose, we adopted appropriate methods to rank a number of skills according to their perceived importance, to their degree of development and according to both these aspects.

2.1 Methods

The NonParametric Combination (NPC) (5) is a permutation-based methodology, widely adopted in multivariate scenarios thanks to the fact that it allows us to implicitly take into account any forms of dependency.

NPC does not make any strict assumption about data distribution, given that the key assumption of permutation tests is in relation to their exchangeability with respect to groups. Provided that the exchangeability condition is satisfied, they are conditional on a set of sufficient statistics (i.e. the data set itself) and independent of the likelihood model related to the unknown data distribution (5; 8; 4). Given these characteristics, this methodology can be applied for the analysis of multiple data types, such as continuous, ordinal and even mixed data. This makes it particularly suitable for the case study of interest, given that the variables of interest do not follow a normal distribution and are not even continuous, but they can assume only two different levels: "Yes" and "No".

NPC can be applied to both two-sample and C-sample problems even when the samples are dependent. In fact, by accurately decomposing the system of hypotheses, by defining the permutation test statistic and the permutation approach, it is even possible to compare multiple paired samples.

According to the NonParametric Combination methodology, the global system of hypotheses is initially decomposed into several sub-systems. Considering a generic multivariate equality in distribution problem:

$$\begin{cases} H_0 : \mathbf{F}^X = \mathbf{F}^Y \\ H_1 : \mathbf{F}^X \neq \mathbf{F}^Y. \end{cases}$$

where $\mathbf{F}^X$ and $\mathbf{F}^Y$ are the multivariate distribution functions of $\mathbf{X}_{n\times V}$ and $\mathbf{Y}_{n\times V}$, n is the sample size and V is the number of variables. According to Pesarin and Salmaso (5) it is possible to re-write this system of hypotheses as:

$$\begin{cases} H_0 : \bigcap_{v=1}^{V} H_{v0} = \bigcap_{v=1}^{V} [F_v^X = F_v^Y] \\ H_1 : \bigcup_{v=1}^{V} H_{v1} = \bigcup_{v=1}^{V} [F_v^X \neq F_v^Y]. \end{cases}$$

Each sub-system can then be addressed individually using appropriate permutation tests.

Let us now suppose that $\mathbf{X}$ and $\mathbf{Y}$ are paired samples and $\mathbf{Z}_{n\times V} = \mathbf{X} - \mathbf{Y}$, the algorithm continues as follows:

1. Compute the V-dimensional vector of test statistics $\mathbf{T} : \mathbf{T}^o = \mathbf{T}(\mathbf{Z})$, applying the chosen test statistic to each component of the multivariate $\mathbf{Z}$.
2. Randomly generate $s_i^* \sim \text{Bin}(1, 0.5), \forall i = 1, \ldots, n$, compute $\mathbf{Z}^* = \mathbf{Z} \cdot s^*$ and $\mathbf{T}^* = \mathbf{T}(\mathbf{Z}^*)$. Perform B independent repetitions of this step (Conditional Monte Carlo - CMC). The CMC results $\{\mathbf{T}_b^*, b = 1, \ldots, B\}$ represent a random sampling from the permutation multivariate distribution of $\mathbf{T}$.
3. Use the CMC results to compute a consistent estimate of the marginal p-value $\lambda_v = \Pr\{T_v^* \geq T_v^o | \mathcal{Z}_{/\mathbf{Z}}\}$ for each test statistic T_v as $\hat{\lambda}_v = \hat{L}_v(T_v^o | \mathcal{Z}_{/\mathbf{Z}}) = \frac{\sum_b I(T_{vb}^* \geq T_v^o)}{(B+1)}$, $v = 1, \ldots, V$.
4. Simulate the distribution of $\hat{\lambda}_v$ using $\hat{\lambda}_{vr}^* = \hat{L}_v(T_{vr}^* | \mathcal{Z}_{/\mathbf{Z}^*}) = \frac{\sum_b I(T_{vb}^* \geq T_{vr}^*)}{(B+1)}$, $v = 1, \ldots, V$.

After obtaining marginal p-values, the combination steps takes place:

5. By applying an appropriate combining function $\theta(\cdot)$, combine the V observed p-values estimated by $\hat{\lambda}_v = \hat{L}_v(T_v^o | \mathcal{Z}_{/\mathbf{Z}})$ (see Table **??**) using $T''^o = \theta(\hat{\lambda}_1, \ldots, \hat{\lambda}_V)$ and the V-dimensional vectors $\{\hat{\lambda}_{vb}^* = \hat{L}_v(T_{vb}^* | \mathcal{Z}_{/\mathbf{Z}^*}), v = 1, \ldots, V\}$ using $T_b''^* = \theta(\hat{\lambda}_{1b}^*, \ldots, \hat{\lambda}_{Vb}^*)$.
6. Estimate the p-value of the combined test T'' as $\hat{\lambda}_\theta'' = \sum_b I(T_b''^* \geq T''^o)/B$.

The choice of combining function is a fundamental step in this procedure. A suitable non-degenerate combining function $\theta : [0, 1]^V \to \mathbb{R}^1$ is non-increasing in each argument, attains its supremum value (possibly not finite) when one or more of its arguments attain 0, and provides a finite critical value for a certain significance level α which is strictly smaller than the supremum value. In this study we considered Fisher's $\theta_F(\lambda) = -2 \cdot \sum_v \log(\lambda_v)$.

Another fundamental step is the choice of partial test statistics according to the nature of sub-hypotheses defined in the initial phase. In this study we have to deal with binary data, so we choose to simply use $T(Z_v) = \sum_{i=1}^n |Z_{iv}|$ for two-sided alternative hypotheses and $T(Z_v) = \sum_{i=1}^n Z_{iv}$ for one-sided ones.

2.2 Ranking of multivariate populations

When $C > 2$ groups need to be compared, multivariate ranking procedures can be extremely useful. The procedure proposed by Arboretti et al. (1) takes advantage of the aforementioned NPC methodology and allows us to rank C populations $\mathbf{X}_c$, $c = 1, \ldots, C$, using the p-values achieved by conducting all the possible pairwise comparisons between groups:

$$\begin{cases} H_0(s,t) : \mathbf{F}^s = \mathbf{F}^t \\ H_1(s,t) : \mathbf{F}^s < \mathbf{F}^t. \end{cases}$$

Let $\mathbf{\Lambda}$ denote the $C \times C$ matrix containing the p-values $\hat{\boldsymbol{\lambda}}^{s,t}$, $\forall s, t = 1, \ldots, C$ and $s \neq t$ related to the one-sided comparison between the samples $\mathbf{X}_s$ and $\mathbf{X}_t$. A multiplicity correction is firstly applied to $\mathbf{\Lambda}$ by using one of the many suitable methods proposed in the literature, such as the Bonferroni-Holm-Shaffer correction (7). A matrix of adjusted p-values $\mathbf{\Lambda}_{adj}$ is therefore achieved. A significance matrix $\mathbf{S}$ is then created to keep track of the significant comparisons, where:

$$\begin{cases} S_{s,t} = 1, & \text{if } \hat{\boldsymbol{\lambda}}_{adj}^{s,t} \leq \alpha/2 \\ S_{s,t} = 0, & \text{otherwise} \end{cases}$$

and α is the desired significance level.

For $s = 1, \ldots, C$, we compute the upward rank estimate as $\left\{r_u^s = 1 + \#\left[(C - \sum_{t=1}^C S_{s,t}) > (C - \sum_{t=1}^C S_{s',t})\right], s' = 1, \ldots, C, s' \neq s\right\}$, where $\#$ means number of times. Then, for $t = 1, \ldots, C$

we calculate the downward rank estimate as $\left\{r_d^t = 1 + \sum_{s=1}^{C} S_{s,t}\right\}$. The vector $\mathbf{r}$ of ranking estimates is finally achieved as $\left\{r^c = 1 + \#\left[\frac{(r_u^c + r_d^c)}{2} > \frac{(r_u^t + r_d^t)}{2}\right], t = 1, \ldots, C, c \neq t\right\}, c = 1, \ldots, C$.

This procedure can be applied on both the partial and global p-values obtained using the aforementioned NPC methodology, so that we can decide to focus on a single component or multiple components of interest.

2.3 Results and discussion

A descriptive analysis was initially conducted. looking at Figure 1, a few interesting insights were achieved.

The five skills which are believed to be most relevant are use of technologies, analytical thinking and innovation, creativity, originality and initiative, critical thinking, and active learning and strategies, all with a percentage of Yes among the respondents greater than 40%.

The five skills which most of the respondents believe they posses are critical thinking, resilience, stress tolerance, and flexibility, active learning and strategies, use of technologies, and reasoning and ideation. With the only exception of analytical thinking and innovation and resolving complex problems, all the remaining skills were chosen by less than the 25% of the students.

For some of the observed skills, there is a substantial misalignment between their perceived importance and their development:

- creativity, originality and initiative: 43.4% of the respondents consider it relevant, but only 20.9% of the students stated that they have developed it;
- critical thinking: 42.4% of the students answered it is relevant and 59.2% of the respondents feel that they have developed it;
- resilience, stress tolerance, and flexibility: 24.1% of the respondents consider it relevant and 59.2% of the students stated that they have developed it;
- technological design and programming: 35% of the students answered it is relevant and 24.9% of the respondents believe that they have developed it;
- persuasion and negotiation: 14.6% of the respondents consider it relevant and 24.9% of the students stated that they have developed it;
- analytical thinking and innovation: about 44% of respondents consider this skill important and about 37% of them feel they have developed this skill.

For the ranking analysis we then set the significance level equal to 0.05 and the number of permutations B equal to 2000. The achieved rankings are reported in Table 2.3.

Use of technologies and analytical thinking and innovation are the skills which are perceived as most relevant and stochastically dominate the others. On the other hand, in terms of development, the percentage of Yes for critical thinking is significantly larger than the percentage of Yes for the others. We can see that persuasion and negotiation is at the same time the least relevant and the least developed skill.

The achieve rankings highlight the existence of discrepancies between relevant and developed capabilities, as already shown by the descriptive analysis. For example, creativity, originality and initiative is among the most important skills (with a ranking position equal to 3), but at the same time it is among the least developed ones (with a ranking position equal to 10).

Considering the global ranking, we can finally see that use of technologies and critical thinking are the skills that are at the same time most important and most developed among the considered ones, while the opposite goes for persuasion and negotiation, emotional intelligence, and leadership.

3. Conclusions

This study focuses on the analysis of data related to a particularly relevant topic: employability of young adults. A survey was conducted in order to collect information on how students in the late stages of their university journey perceive the labor market and their career planning and control. In particular,

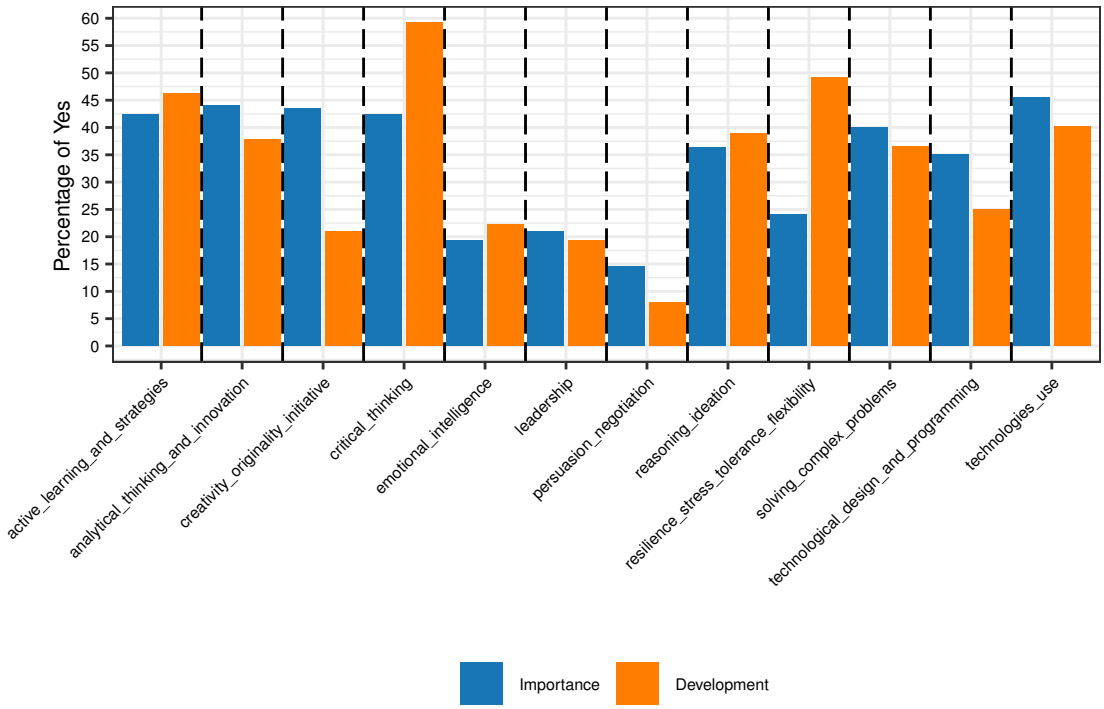

Figure 1: Descriptive analysis results

Table 1: Partial and global rankings

Skill	Importance	Development	Global
active_learning_and_strategies	3	3	3
analytical_thinking_and_innovation	1	6	4
creativity_originality_initiative	3	10	9
critical_thinking	3	1	1
emotional_intelligence	11	10	11
leadership	10	9	9
persuasion_negotiation	12	12	12
reasoning_ideation	7	4	8
resilience_stress_tolerance_flexibility	9	2	6
solving_complex_problems	6	6	4
technological_design_and_programming	8	8	6
technologies_use	1	4	1

we wanted to identify the skills that are perceived as most important for employability and the ones that the students believe they have developed the most, but also identify eventual misalignment between this aspects.

The adoption of the NonParametric Combination (NPC) methodology and the multivariate ranking procedure by Arboretti et al. (1), allowed us to see that the use of technologies and critical thinking are the skills that are at the same time most important and most developed among the considered ones. It also showed that creativity, originality and initiative is a skill that is perceived as really important, but it rarely developed in students at the end of their university journey.

Abstract

Gender inequality is a complex and multidimensional phenomenon. In recent decades, its measurement has become a focus of interest not only for academic researchers, but also for political institutions and policy makers. However, due to the epidemic from Covid-19, the advancement of gender equality has faced multiple setbacks, especially in the labour market. The objective of this study is to support the implementation of policy makers' strategies and to contribute to the existing literature by shedding light on the importance of quantifying the impact of certain key characteristics related to the workplace and to the individual on the gender pay gap. In particular, we focus on the Italian job market, exploring the phenomenon using updated official statistics data coming from Istat by means of a regression analysis. This study shows how workers are treated differently on the basis of the demographic group to which they belong, providing also an in-depth knowledge of key determinants behind women discrimination in the labour market.

Key words: gender pay gap, gender equality, discrimination, labour market, Covid-19, linear regression models

1. Introduction

The gender pay gap is commonly defined as the percentage difference in average gross hourly earnings between women and men (EIGE, 2019). At the European level, the principle of equal pay for men and women was, first, enforced in the Treaty of Rome (1957). In the following years, the European Union commitment has been steadily renewed through a series of strategies and action plans, such as: i) the Roadmap for Equality between Women and Men (2006-2010); ii) the Gender Equality Strategy (2010-2015); iii) the European Pact for Gender Equality (2011-2020); iv) the Strategic Commitment to Gender Equality (2016-2019); v) the new Gender Equality Strategy (2020-2025). This increasing interest and the need of measuring the targets' achievement level show how important became developing a reliable index to assess this phenomenon. Over the past decades, academic researchers and international organizations have gradually developed a variety of indicators to measure gender inequality. Indeed, the gender pay gap measurement is not a straightforward task, as the results heavily depend upon peculiar background choices. The main options in the gender pay gap measurement relate to its estimate according to an unadjusted or to an adjusted form (Klammer *et al.,* 2018). Unlike the unadjusted gender pay gap – which is simply estimated as the difference between the average gross hourly earnings of men and women – the adjusted gender pay gap takes into account all possible factors that can play a role in explaining the gap, such as differences in terms of education level, employment sector, job title, working hours, etc. (Klammer *et al*., 2018). Thus, the adjusted gender pay gap makes it possible to measure the part of the gap related to differences in the characteristics of male and female workers, distinguishing this from the part that, instead, can be attributed to discrimination (Klammer *et al*., 2018).

To date, the most commonly used index is the Global Gender Gap Index. This was introduced by the World Economic Forum (2006) in order to benchmark progress towards gender parity and to compare different countries' gender gap. The index covers four dimensions: Economic Participation and Opportunities, Educational Attainment, Health and Survival, and Political Empowerment (World Economic Forum, 2022). Each of these dimensions is ranked on a 0 to 100 scale, which can be interpreted as the distance covered towards parity (i.e., the percentage of the gender gap that has been closed). In 2022, the overall Global Gender Gap Index was equal to 68.1%. This means that the remaining gap to close stands at 31.9%. This level represents an improvement of 0.4 percentage points, if compared to the previous index estimate (World Economic Forum, 2022). Such a slight progress is not even sufficient to compensate for the generational loss which occurred between 2020 and 2021.

In particular, the gender gap referred to the dimension of Economic Participation and Opportunities is the second largest of the four key gaps tracked by the index. This subindex includes three concepts: the participation gap, the remuneration gap and the advancement gap. The participation gap originates from the difference between women and men in labour-force participation rates. The remuneration gap evaluates the female-to-male difference in earned income. The advancement gap is estimated as the ratio of women to men among legislators, senior officials and managers, and as the ratio of women to men among technical and professional workers (World Economic Forum, 2022). In 2022 only 60.3% of this gap has been closed. Moreover, estimates say that it will take another 151 years to close the gap (World Economic Forum, 2022). Among all considered regions, South Asia is the farthest from achieving gender equality (only 35.7% of the gap has been close so far), whereas North America leads all regions, with 76.9% of gender gap closed (World Economic Forum, 2022). In this scenario, Italy is one of the least performing countries: in the general ranking, it is placed at the 63rd position (on 146), but when it comes to the gender gap in labour market, Italy slips to the 110th place (World Economic Forum, 2022).

The 2022 Report highlights an overall stalemate of gender parity, partly due to the impact of the Covid-19 pandemic. This is especially true for the female labour market. Despite the most recent studies (e.g., McKinsey Global Institute, 2020) showed that both men and women were hit hard during and after the pandemic, the most negative impact was suffered by women. This leaded to a setback in the advancement of gender equality, in terms of employment and labour force participation, work structure and intensification of childcare and domestic education activities (International Labour Organization, 2021).

Despite the epidemic from Covid-19 negative impact, signs of good omen for the future are certainly not lacking, nowadays, in Europe: in fact, during the pandemic years, many important decisions were taken by women, such as the President of the European Commission, Ursula Von Der Leyen, and the President of the European Central Bank, Christine Lagarde. In Italy, within the National Plan for Recovery and Resilience (PNRR), approved in July 2021, the need to close the gender gap in the labour market has been strongly marked. Focused on inclusion and social cohesion, Mission V enforces targeted policies and action plans to fight gender discrimination and towards women's empowerment in the five-year period 2021-2026. For this purpose, with the aim of sustaining female entrepreneurship, the Italian Ministry of Economic Development has established the *Women's Enterprise Fund*. The Ministry also introduced the *Gender Equality Certification*, issued starting from January 1st, 2022, to all businesses having adopted targeted policies and measures in order to reduce the gender gap in terms of employment, equal pay and equal opportunities, according to 33 specific key performance indicators (KPIs).

To date, most of the studies have focused primarily on the quantification and isolation of the discriminatory component of the gender pay gap. This study aims at showing not only how workers are treated differently on the basis of the demographic group to which they belong, but provides also an in-depth knowledge of key determinants behind women discrimination in the labour market.

2. Literature review

Since the late 1950s, several sociological and economic theories have been advanced to explain the underlying causes of the presence of gender discrimination in payment. One of the first contributions, by Becker and Schulz (1960), highlights the relationship between human capital, individual productivity and economic growth. Human capital can be defined as the set of knowledge, skills and abilities possessed by the workforce and offered to the market in exchange for remuneration (Becker, 1964). In this

sense, human capital can be considered as a resource subjected to accumulation processes through investment in education, training and experience. The level of education, in particular, is a key factor in assessing the wage differential. This is crucial to access more lucrative career paths (Becker, 1964), as well as to affect employment levels. Thus, Becker's theory of human capital links the gender pay gap to differences in terms of investment in human capital.

Contrarily, the segregation theory justifies the gender pay gap starting from the employment (Geiler and Renneboog, 2015). In particular, two forms of occupational segregation are distinguished in the economic literature: horizontal (or sectoral) segregation and vertical segregation. The first refers to the concentration of female employment in certain productive sectors and professions; the second is linked to the gender uneven distribution in the different hierarchical levels of a same occupation (Geiler and Renneboog, 2015). This phenomenon is the result of socio-cultural stereotypes that, together with the organisational rigidities of enterprises, lead to more or less explicit forms of discrimination (or sometimes exclusion) against female labour supply. All this perpetuated the gender characterisation of certain occupations. This concept is also closely related to the phenomena of glass ceilings and sticky floors (Booth *et al*., 2003; Haslam *et al*., 2009).

The comparable worth theory was first proposed by Treiman and Hartmann (1981). The authors studied the issue of the devaluation of women's work. According to their work, the gender pay gap stems from the fact that society, due to socio-cultural mechanisms and stereotypes, ascribes less value to female-dominated industries (Treiman and Hartmann, 1981). In other words, occupations with a higher proportion of women receive lower wages, as women positions are considered socially less valuable than men ones and, therefore, less deserving of financial recognition.

The crowding theory (Bergmann, 1974) analyses the effects of women's limited access to certain occupations and professions on their pay level. In fact, the high concentration of workers in a narrow segment of the market leads to the emergence of an artificially high labour supply. This, accordingly to the market principles, results in lower wages than the ones expected in case of a more equal division of labour among the different segments (Bergmann, 1974). In other words, due to discriminatory mechanisms, women cannot move freely in the labour market. Hence, female labour supply is higher in certain occupations rather than others, resulting in a reduction in the equilibrium wage (Bergmann, 1974).

Another cause of the gender pay gap is wage bargaining. It is the main tool for regulating industrial relations and issues concerning pay aspects and working conditions. Wage bargaining takes place at two levels: as individual and as collective bargaining. The economic literature showed that the degree of centralisation of the collective bargaining system has a significant impact on the gender pay gap (Calmfors and Driffill, 1988).

In conclusion, the literature confirms the existence of a gender gap (in labour force and in income) that may vary in size and nature depending upon the different determinants considered. Consequently, it becomes clear how important is to reliably assess the level of women discrimination in order to identify its key determinants and in order to set and implement policies helpful in reducing this phenomenon and to identify tools capable to assess policies efficacy and the linked progress.

3. Empirical analysis

This study contributes to the existing literature by shedding light on the importance of certain characteristics related to the job position and/or to the individual worker in causing the gender pay gap. We focus on the Italian context and, by means of identifying key factors, we aim at providing support to policy makers in implementing targeted strategies and policies in order to reduce gender pay differentials and to promote gender equality at all levels.

3.1 Data and methodology

The analysis is based on the latest release of Istat data on "Labour and Wages" (2014-2019) (link: https://www.istat.it/it/dati-analisi-e-prodotti/banche-dati/statbase). In particular, we analyse the gross hourly earnings for men and women with relation to the following variables: i) educational level, ii) type of contract, iii) job title, iv) company size, v) industry. First, we derive the gender wage differential. This is computed as the ratio of the percentage difference between the men gross hourly earnings and the women ones on the average hourly earnings of men. Then, the data were split into two separate

datasets. The first one was used to conduct exploratory analyses, focusing on the wage differential. It was also used to estimate a benchmark model, at the national level, and other sub-models related to each of the Italian macro-area set by Istat (North-West, North-East, Centre, South, Islands). The second dataset was the base to estimate OLS linear models aimed at investigating the linkage between the gender wage differential, the worker position and individual characteristics. Alphanumeric variables were recoded into dummies as follows:

(a) Educational level: 1 = the worker has at least a degree, 0 = otherwise.
(b) Contract type: 1 = the worker has a permanent contract, 0 = otherwise.
(c) Job title: 1 = the worker is qualified as manager or employee, 0 = otherwise.
(d) Company size: 1 = large enterprise, 0 = otherwise.
(e) Industry: 1 = female-dominated sector, 0 = otherwise.

Table 1 shows the main works developed on the gender pay gap focusing on the Italian context: they guided us in the selection of data sources and of the variables used in our regression analysis.

3.2 Results

Table 2 summarizes the main descriptive statistics at the national level about the gender pay gap by some key variables (educational level, contract type, job title, company size and industry). The average pay differential in earnings between men and women increases with an higher level of education (9.35% among non-graduates, 19.86% for graduates), with more stable job contract (3.66% among fixed-term contracts, 9.68% for permanent contracts), with a higher qualification level (10.5% among unskilled workers, 23.36% for employees and managers), according to the company size (9.14% among SME, 16.86% for large enterprises) and when considering male-dominated industries (Financial and insurance fields 20.19%; Professional, scientific, and technical fields 13.74%), if compared to female-dominated industries (Education 9.78%; Health

Table 2: Gender pay gap (percentages) by key variables (national level)

Educational level	**N. obs.**	**Mean**	**Std. dev.**	**Min.**	**Max.**
High school	30	9,35	2,59	5,65	13,41
Degree	30	19,86	3,99	13,51	26,63
Contract type					
Fixed-term	30	3,66	1,60	1,30	6,77
Permanent	30	9,68	2,49	5,40	13,04
Job title					
Worker	30	10,50	1,29	8,37	13,30
Employee, Executive	30	23,36	4,29	16,00	29,63
Company size					
Small-medium enterprise	30	9,14	1,34	6,75	11,82
Large enterprise	30	16,86	1,88	13,60	20,41

Industry					
Financial and insurance fields	30	20,19	1,57	17,12	23,43
Scientific and technical fields	30	13,74	6,67	5,91	25,96
Education	30	9,78	5,88	0,53	23,84
Health and social assistance	30	4,59	1,81	1,71	8,88

and social assistance 4.59%). Table 3 shows simple linear regression models estimates obtained at the national level to study the relationship between the gender wage differential (dependent variable) and, as regressors, the key variables related to the worker position and to the individual previously listed, recoded as dummies. As the gross hourly earnings of men and women provided by Istat is specifically computed each time in relation to the variable considered, it was not possible to estimate one unique multiple regression model. Thus, we estimate five simple regression models.

Table 3: Simple linear regression models for gender pay gap (%) vs key variables (national level).

	Iterc./Regr. (key var.)	**Coeff.**	**Std. Err.**	**t-value**	**Pr > |t|**	**R²**
MOD. 1	Intercept	9.35	0.61	15.21	<.0001*	0.72
	Educational level	10.51	0.87	12.08	<.0001*	
MOD. 2	Intercept	3.66	0.38	9.56	<.0001*	0.68
	Contract type	6.02	0.54	11.13	<.0001*	
MOD. 3	Intercept	10.5	0.58	18.15	<.0001*	0.81
	Job title	12.86	0.82	15.73	<.0001*	
MOD. 4	Intercept	9.14	0.3	30.61	<.0001*	0.85
	Company size	7.72	0.42	18.27	<.0001*	
MOD. 5	Intercept	16.97	0.7	24.17	<.0001*	0.45
	Industry	-9.78	0.99	-9.85	<.0001*	

All models obtained in Table 3 show a statistically significant relationship between the gender pay differential and the key dummy variables related to the workplace and the individual (for $\alpha = 0.01$). In fact, in each model the *p*-value of the independent variable (<,0001) is lower than alpha. Moreover, the estimated models, despite including one regressor only, show a good predictive capacity: the R^2 ranges between 0.45 (considering, as regressor, *Industry*) to over 0.8, including *Job title* (0.81), and *Company size* (0.85) as regressors. The empirical findings confirm the existence of a statistically significant relationship between the gender pay differential and all the considered key variables. As few studies have been carried out in the literature to this regard, the results obtained in this work might represent a starting point for future studies to deepen the impact of these variables on the gender pay gap, eventually estimating multiple regression models, when possible. Moreover, since the analysis was carried out on data covering a relatively short time period of six years (2014-2019), it would be interesting to repeat the analysis by integrating the data that will be available for more recent years (2020, 2021 and 2022), in order to deepen the impact of the Covid-19 pandemic on the labour market and to assess how the labour market itself has faced the recovery process.

4. Conclusions

The results obtained in this study are useful for policy makers, shading light on a phenomenon still affecting the job market in Italy. In particular, the level of education is a key factor in the assessment of the wage differential, as it affects not only employment levels but it is also crucial to access more lucrative career paths (Becker, 1964). Moreover, it is observed that in Italy the average gender pay differential increases as the level of contractual framing increases, resulting in phenomena such as glass-ceiling and sticky floor that cause women to be under-framed by being stuck in unprofitable career paths (Geiler and Renneboog, 2015). The empirical results obtained in this study also confirm crowding theory (Bergmann, 1974) and comparable worth theory (Treiman and Hartmann, 1981), which consider the employment sector as one of the primary causes of the gender pay gap. At the same time, however, the results obtained highlight the current need to: i) increase women labour force in all industries and, in particular, in those occupations that traditionally have been a male prerogative; ii) encourage female entrepreneurship and career advancement in managerial roles and top positions; iii) level out differences in human

capital, especially improving the education level, and encouraging women to become more involved in STEM fields; iv) promote the continuous participation of women in the labour market through stable career paths and contracts; v) develop binding national control systems to monitor the gender gap in employment, pay and equal opportunities in each company on a regular basis.

However, it is necessary to highlight how acting on the key variables considered in this study may not be sufficient to fill the gender pay gap. In fact, results obtained in this study highlight a part of gender pay gap that remains unexplained and that can be presumably attributed to a discrimination effect. Overcoming gender discrimination in the labour market, indeed, requires a deep cultural change, based on the deconstruction of all stereotypes of cultural, social and psychological nature that for centuries have dictated a categorization of male and female roles in our society. Hence, social dialogue can be a real keystone, in reducing gender inequalities and in defining a future of gender equality. The full achievement of gender equality should not be an exclusively female issue, but it should be a priority and a moral imperative for every truly modern, inclusive and egalitarian society as a whole.

Evaluating the effect of home-based working employing causal Bayesian networks and potential outcomes

Lorenzo Giammei[a]

[a]University of Milan-Bicocca, Piazza dell'Ateneo Nuovo 1 Milan; lorenzo.giammei@unimb.it

Abstract

Covid-19 generated an unprecedented shock on the Italian economy, which severely affected firm performance. This work focuses on estimating the causal effect of implementing home-based working (HBW) after the pandemic outbreak on firms' expected revenues. The analysis uses a unique firm-level dataset, which captures a rich set of features before and after the spread of the virus. Causal effect estimation is performed implementing an integrated approach that merges Causal Graphs and Potential Outcomes frameworks. The results are consistent with the fact that HBW equips firms with greater flexibility and helps contain productivity decreases in Covid times.

Keywords: Causal Bayesian Networks, Potential Outcomes, Home-based Working

1. Introduction

The outbreak of Covid-19 in March 2020 had unprecedented consequences on the Italian economy. As the virus spread, consumer spending dropped, and lockdown policies forced many firms to temporarily cease their activity, thus generating both a demand and a supply shock. As soon as the economic consequences of the covid outbreak became clear, firms tried to do everything possible to minimize losses.

This work focuses on the implementation of home-based working (HBW), one of the key firms' countermeasures to the pandemic. The implications of switching to HBW have been thoroughly studied over the past years and its related literature has spiked in covid times. The benefits of home working on employees performance have been studied in (4). On the other hand, evidence from workers who switched to home working in covid times suggests that being far from the workplace for a prolonged period can negatively affect mental health (5). (3) use firm-level surveys to investigate the spread of home-based working during the pandemic. The authors find out that industries with more educated workers are associated with a higher rate of remote working and perceive a lower productivity loss associated with this kind of work. In addition, about 40% of interviewed firms declare that at least 40% of their workers that switched to homeworking will continue doing so even after the crisis, and this represents a strong indicator of the persistence of the phenomenon. This work contributes to the fast-growing literature of home-based working by evaluating the effect of implementing home working in covid times on future expected firm revenues. A rigorous causal evaluation of this kind seems to be missing in the literature and could provide a quantifiable measure of the impact of enabling employees to work from home.

2. Data

The analysis uses a unique firm-level dataset provided by MET, a research centre based in Rome, which conducts one of the most comprehensive surveys on the Italian manufacturing and production service sectors. The dataset originates from merging two different MET surveys over the same panel of firms. The same data source has already been employed to study the economic effects of the Covid-19 shock in (2).

The first survey is the 2019 wave of the MET survey on the italian industrial system. The questionnaire covers a vast group of firm features such as structure, performance and strategies. Almost 24000 firms were interviewed according to their size, sector, and area to obtain a representative sample of the Italian manufacturing and production services population. Reaction to Covid-19 was then measured with another questionnaire between March 24 and April 7, 2020, administered to the 24000 respondents of the 2019 MET survey. The exceptional timing thus produces two snapshots of the same group of firms, just before and after the spread of the pandemic. The answers to both surveys have been merged to obtain a final dataset of 7800 respondents.

The treatment variable originates from the post-covid questionnaire and is a binary variable defining if a firm has implemented home-based working for a portion of their employees right after the lockdown policies introduction. The outcome variable describes post-covid expectations towards future variation in revenues with respect to past revenues. The variable derives from the post-covid survey and can take four different modalities, which identify increase, stability, decrease or strong decrease in expected revenues.

3. Methodological background

Causal graphs, also known as causal Bayesian networks, are models providing a clear representation of causal problems and a set of tools to derive causal estimates (8). A graph $G = (\mathbf{X}, \mathbf{E})$ is a collection of nodes $\mathbf{X}$ and edges $\mathbf{E}$. When an edge goes out from a node into another is called a directed edge, if there is no such orientation the edge is undirected. A graph that contains only directed edges is a directed graph. Given a graph G with ensemble of nodes $\mathbf{X}$ and two nodes X_i and X_j belonging to $\mathbf{X}$, any sequence of edges which connects X_i and X_j, regardless of their direction, is called a path. If every edge of the path is directed and has the same orientation along the path, then it is called a directed path. A directed path which begins and ends with the same node is a cycle. If a directed graph does not contain cycles then it is a directed acyclic graph (DAG). In the context of this work, the nodes of the DAG represent random variables and edges describe the causal relations between them. For a given DAG G, the structure of the graph allows factorizing the joint probability distribution of its nodes $(X_1, ..., X_n)$ as follows

$$P(X_1, ..., X_n) = \prod_i P(X_i|pa_i) \tag{1}$$

where pa_i is the set of nodes that have an outgoing edge pointing to X_i, according to the graph.

To answer causal queries, we are interested in studying how the model would react to an $intervention$ on one or more variables. (9) introduces the notation $do(X_i = x_i)$ to denote that a variable X_i is set to the value x_i through an intervention. The quantity $P(X_j|do(X_i = x_i))$ represents then the distribution of X_j given that X_i is forced to take value x_i, while $P(X_j|X_i = x_i)$ describes the distribution of X_j given that we observe X_i take value x_i. Interventional quantities can be used to estimate causal effects, that can be expressed as comparison of interventional distribution summary statistics. A common way to represent causal effects is the *average treatment effect* (ATE) (7).

In observational studies, the interventional distribution $P(X_j|do(X_i = x_i))$ is not directly measured. In order to express this distribution through observational quantities, (8) introduces a graphical test called the back-door criterion. In particular, given a graph G with ensemble of nodes $\mathbf{X}$, a treatment T and an outcome Y belonging to $\mathbf{X}$, if a set $\mathbf{S} \subset \mathbf{X}$ satisfies the back-door criterion, then interventional distributions can be expressed in observational terms:

$$P(Y|do(T = t)) = \sum_{\boldsymbol{S}} P(Y|\mathbf{S} = \mathbf{s}; T = t)P(\mathbf{S} = \mathbf{s}) \tag{2}$$

A set **S** that satisfies the assumptions is called a *sufficient adjustment set*. As shown in (2), given a known causal graph, an adjustment set obtained through the back-door criterion allows the estimation of unbiased interventional distributions. Note that the proposed methods strongly rely on the structure of the graph, which is often partially or entirely unknown when dealing with real problems. However, in this case, the causal graph can be recovered from a dataset containing the variables of interest through structural learning algorithms (12).

Potential outcomes (11) are an alternative framework to deal with causality. This approach is widely used in economics and allows estimating causal effects from experiments and some specific observational contexts. Let us consider an outcome variable Y and a treatment T. We denote $T = 0$ and $T = 1$, respectively, the treated and the not treated condition. Then we can define $Y_i(T = 1)$ the potential outcome we would have observed if unit i had received the treatment and as $Y_i(T = 0)$ the potential outcome we would have observed if the same unit had not received the treatment. The methods that belong to the framework usually require the *unconfoundedness* assumption, implying that the treatment assignment mechanism is conditionally independent of the potential outcomes given the covariates.

Here *full matching* (6) to estimate the treatment effect will be used. This technique groups all the units into a series of matched subclasses, containing at least one treated and one control unit. Similar units are gathered in the same subclass and its size depends on the number of comparable units: the more the available similar units, the larger the generated subclass and vice-versa. The similarity between units i and j is described by discrepancy measure δ_{ij}, which is usually calculated as a difference of distance measures, such as a propensity score. Full matching has been chosen because it allows the estimation of the ATE, and thus the results of the matching procedure are coherent with the interventional do-notation defined in the context of causal graphs.

4. Analysis and results

The first stage of the analysis will consist in estimating a causal graph on the dataset to study the interactions between the considered variables. In a second step, given the structure of the obtained graph, a sufficient adjustment set will be selected via the back-door criterion. Lastly, the selected set will be used to implement a full matching procedure and estimate causal effects.

A score-based algorithm called *Tabu Search* (12) has been implemented to learn the causal graph from data. Tabu Search has been selected because it is faster and more accurate than most algorithms for both small and large sample sizes (14). This part of the analysis has been carried out employing the *Bnlearn* package (13) in R Statistical Software (10). Most structural learning algorithms, including Tabu Search, allow the inclusion of prior knowledge in the learning procedure by introducing constraints on the graph's structure. A known causal relationship between variables or the absence of it is encoded in the graph by imposing or forbidding a directed edge between two nodes. Prior knowledge of the subject matter has been synthesized in Table 1. The variables have been divided into four logical groups according to their type. The first group is *Precovid demographics* and contains primary firms' features such as their size, the geographical area where they operate and their business sector. The second group contains additional firms' traits that characterized them before the outbreak. The variation in their revenues and number of employees relative to the last three years, their past strategical activities and exposure to credit rationing are, among others, included in this category. The third group contains the variable which describes the firms' future expectations concerning revenues, measured prior to the pandemic. Post-covid features, such as the number of confirmed covid infections in their province and if they have been targeted by lockdown measures or not, belong to the fourth and last group.

The idea behind this logical categorization is that we assume that variables belonging to a specific group cannot affect the preceding groups described in Table 1. For example, a variable of the last group cannot cause variables of the other three groups, the third group cannot affect the first two and so forth. The four categories are then translated into constraints in the graph structure and used in the structural learning procedure.

In addition to the mentioned constraints, some additional assumptions have been included in the model. Firstly, the treatment and the outcome variable are not allowed to cause any of the pre-treatment

Table 1: Logical variable groups

Precovid demographics	Other precovid features	Precovid expectations	Postcovid features
Size (n. of employees)	Innovation, R&D	Pre-covid delta expcted revenues	Confirmed covid infections
Geographical area	Credit rationing		Essential business sector
Business sector	Export		
Manager education	Delta number of employees		
	Digital litteracy		
	Past delta revenues		

variables. This constraint originates from the fact that pre-treatment variable cannot be affected by the treatment or the outcome since they are measured before the treatment is applied. It is also assumed that *geographical area* cannot be affected by the other variables in the first group. Lastly, we assumed that the variable *Essential business sector* could only be affected by the firms' business sector by definition.

The graph learnt by the algorithm is shown in Figure 1. Dashed arrows denote edges that have been forced to be present, based on assumptions regarding the existence of causal relations between variables. This set of assumptions, based on prior knowledge, complements the forbidden arcs assumptions deriving from the logical categories in Table 1.

The causal graph unveils the complex network of causal relations between the variables. The graph is dense, and the emerging structure highlights how all the different considered dimensions contribute to shaping the outcome variable *Post-covid delta expected revenues*. The obtained causal graph is then used to select a sufficient adjustment set of covariates to estimate the effect of implementing home-based working on expected revenues. The R Statistical Software (10) package *Dagitty* (17) has been employed. Given the graph in Figure 1, the minimal set which satisfies the back-door criterion for the effect of T on Y is

$$S_{adj} = \{\textit{Essential business sector}; \textit{Pre-covid delta expected revenues}\}.$$

Full matching is employed for causal effect estimation. The methodology has been implemented in R Statistical Software (10), using the package *MatchIt* (16). Covariate balance improves considerably after matching. Once propensity score is estimated and balance is achieved, the average causal effect of T on Y is calculated by regressing the outcome on the treatment and the adjustment set in a weighted regression model, also referred to as the *outcome model*. The fitted model is then used to predict the distribution of the outcome if all units were controls and if all units were treated. This kind of procedure, also called *g-computation* (15), is required when we include additional covariates in the outcome model and we are interested in estimating a marginal effect. The obtained distribution of the outcome under treatment administration Y_1 and control administration Y_0 are then averaged and used to compute the causal risk ratio

$$ATE = \frac{E[Y_1]}{E[Y_0]}. \tag{3}$$

Standard errors are computed through block bootstrap (1). ATE point estimates, and bootstrapped 95% confidence intervals (C.I.) are shown in Table 2. The different width of confidence intervals is primarily due to an uneven frequency distribution in the outcome variable levels.

Table 2: ATE estimates of HBW implementation on post-covid Δ expected revenues

Post-covid delta expected revenues	Point Estimate	95% C.I.
Increase (>+5%)	1.80	(0.96, 3.13)
Stable (between -5% and +5%)	2.11	(1.67, 3.03)
Decrease (between -15% and -5%)	0.97	(0.61, 1.43)
Strong decrease (<-15%)	0.73	(0.56, 1.07)

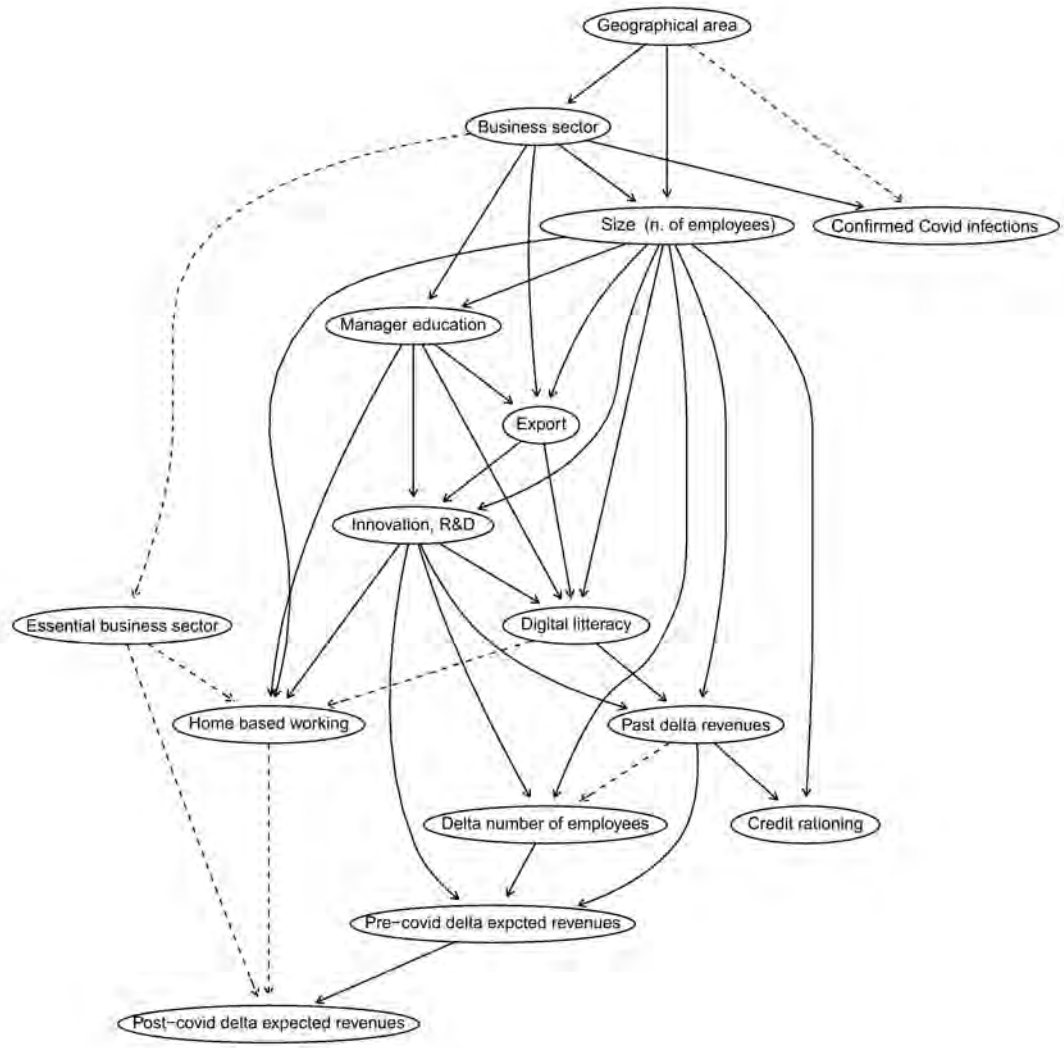

Figure 1: Causal graph learnt with the Tabu Search algorithm

5. Discussion

Causal graphs are yet to be the most used approach in economic causal inference literature, but we believe they constitute an irreplaceable resource. Learning a causal graph from data is a process that translates causal information into a more transparent medium. The graph constitutes itself a set of assumptions concerning the causal relationships between variables on which causal estimates are based. Encoding information into a causal diagram thus improves the analysis's clarity and understandability of how results are derived. In addition, the graph learning step allows the introduction of prior knowledge into the model, imposing theory or evidence-based relations between variables. Estimation of ATE using the adjustment set selected from the graph via back-door criterion can be then performed with a method of choice, such as simple regression or matching, depending on the assumptions being made. Regardless of the chosen method, using the graph-selected adjustment set ensures unbiased ATE estimation if the implied assumptions are satisfied. The estimated ATE shows that implementing HBW from the beginning of the pandemic helps mitigate the harmful effects of Covid-19. In particular, treated firms have a higher probability of expecting stable or increasing future revenues and a lower probability of a strong decrease. In other words, the outcome variation generated by the treatment always goes in the opposite direction of the observed change induced by the pandemic outbreak. This finding is coherent with HBW literature and, in particular, with its impact on flexibility and productivity. However, this mitigating effect was yet to be quantified in a comprehensive causal framework.

Abstract

In recent years, the debate on flexible employment has been at the center of political and scientific discussion in Europe. Findings on mobility from flexible to permanent employment can be severely biased due to measurement error, usually present in the data used for analysis. The aim of this paper is to use a mixed hidden Markov model (MHMM) to study the effect of measurement error on the role of flexible employment in the life course. Specifically, we employ a MHMM with two indicators for the employment contract, coming from linked data from the Labour Force Survey and the Employment Register of the Netherlands for the period 2007-2015.

Keywords: mixed hidden Markov model, latent variable model, multisource data, employment careers

1. Introduction

In recent years, the debate on flexible employment has been at the center of political and scientific discussion in Europe. In Eurozone countries, in 2021, 11.4% of all employees were employed on a temporary contract (14), while the probability of getting a job on a temporary contract increased by 36 percent between 2013 and 2019 (11). The Netherlands also experienced a sharp increase in the incidence of temporary employment, that increased from 13.2% in 2010 to 20.5% in 2021. The role of temporary contracts can be evaluated from a dynamic or life course perspective: in particular, one of the main questions the research seeks to answer is when temporary work is a stepping stone to permanent employment and when it becomes a trap of precarious jobs (12).

Research has shown that findings on mobility from flexible to permanent employment can be severely biased due to measurement error, usually present in the data used for analysis. In fact, even a small amount of error in the measurement of the type of the employment contract may considerably inflate transitions e.g. from a temporary to a permanent contract, and lead thus to wrongly informed policy decisions (16; 15). In survey data, this measurement error is the result of issues related to cognitive processes, social desirability, design and implementation problems. In register data, measurement error is the result of administrative delays, wrong registration, or erroneous administrative procedures.

A possible approach to deal with measurement errors when multiple data sources are available is based on the use of latent variable models. More specifically, when all the sources contain information

*This paper is part of the project DYNANSE that has received funding from the European Research Council (ERC) under the European Unionâs Horizon 2020 research and innovation programme (grant agreement No 864471)

closely related to the target variable, but none can be assumed to be a corrected measure of the target variable, the latent variable models can be used to predict the true target value given the observed measurements in the data sources (7). In this context, Latent Class Analysis (LCA) is considered as a method to identify a latent categorical construct of interest using observed variables that can be used to evaluate measurement errors (18; 5): hidden Markov Models (HMMs) represent a potential extension when longitudinal data are available. Their particular usefulness is that they do not require the use of an auxiliary dataset that has to be considered as error-free ('gold standard'). These models have been used to correct for measurement error in mobility between employment states (3) and employment contracts (16; 15). Moreover, they have been used to estimate employment status in the Italian employment register (6; 7).

The aim of this paper is to use a mixed hidden Markov model (MHMM) to extend our knowledge on the effect of measurement error on the role of flexible employment in the life course. Specifically, we employ a MHMM with two indicators for the employment contract, coming from linked data from the Labour Force Survey (LFS) and the Employment Register of the Netherlands for the period 2007-2015.

The rest of the paper is organized as follows. In section 2, we present the data. Section 3 and 4 present the MHMM that is used togther with some results. In Section 4 some conclusions are briefly described.

2. The data

The data sources providing information on flexible employment are the Labour Force Survey (LFS) administered by Statistics Netherlands and the Employment Register of the Netherlands (ER). LFS represents the main source of information on the labour market for official statistics. It produces information on employment and on the main aggregates of the job offer - profession, sector of economic activity, hours worked, type and duration of contracts, training. LFS is harmonized at the European level as established by the EU Regulation 2019/1700 of the European Parliament and the Council. In the Netherlands, the LFS has a rotating trimonthly scheme and is representative for the Dutch population older than 15 years. The survey was launched in 1987, and its longitudinal component was introduced in 1999. Since 1999, respondents are interviewed at 5 consecutive panel waves. The information that is collected refers to the moment of the interview, and the interviews are carried out during every week of the trimester. As described by (16), measurement errors in LFS may result from different sources. For example, they may depend on misreporting by respondents, mistakes in the recording of responses by interviewers and the use of proxy interviews.

The ER is a register dataset administered by the Institute for Employee Insurance (UWV), containing information on labour market and income for all insured workers in the Netherlands (2). The ER is constructed by collecting and matching information from various sources, i.e. the Tax Office, declarations from temporary work agencies and the Population Register. There is no missing data as the submission of tax-reporting statements is compulsory for employers. However, whereas the dataset contains monthly information, employers typically submit the relevant information only once per year. This may create possible mistakes for the period between two consecutive submissions. As introduced, additional sources of measurement error in ER may result from administrative delays, wrong registration, and erroneous administrative procedures.

For our research, we employ a MHMM with two indicators for the employment contract. These indicators come from linked data from the Labour Force Survey and the Employment Register of the Netherlands for the period 2016-2019. We work with trimester data from this period, for a total of 15 time points. In more detail, we selected all individuals that entered the LFS as from January 2016 until December 2019. From the LFS, we retained information from all the waves for which these individuals participated in the survey. For the same individuals, we also used monthly information from the ER covering all the months from January 2016 until December 2019. Information from the two datasets was linked at the individual level using a pseudonimised version of the Social Security Number (in Dutch: BRP).

3. The model and the estimation strategy

As introduced, the aim of this work is to use a mixed hidden Markov model to study the effect of measurement error on the role of flexible employment in the life course.

The true (latent) target variable of the model is the contract type X_{it} at time t for subject i, where $t = 0, ..., T$ and $i = 1, ..., N$. We have two measurements for the outcome variable, C_{it} and E_{it}, denoting the observed contract type of person i at time point t according to the register and the survey. C_{it}, E_{it}, and X_{it} can take on four values representing the categories of the contract type (permanent, fixed-term, temporary agency or on call, and other); we refer to a particular category of these variables by c_t, e_t, and x_t, respectively. The latent contract type X_{it} follows a first-order Markov process; that is, the true contract at time point t, X_{it}, is independent of the contract at time point t', $X_{it'}$, for $t' < t - 1$, conditionally on the state at $t - 1$, $X_{i(t-1)}$.

As indicated in the previous section, we use trimester data from 2007-2015, which means that t runs from 0 to $T = 31$. The probability of following a certain observed path over the $T + 1$ months period can be expressed as follows (HMM):

$$P(\mathbf{C}_i = \mathbf{c}_i, \mathbf{E}_i = \mathbf{e}_i) = \sum_{x_0=1}^{4} \sum_{x_1=1}^{4} ... \sum_{x_T=1}^{4} P(X_{i0} = x_0) \prod_{t=1}^{T} P(X_{it} = x_t | X_{i(t-1)} = x_{t-1})$$

$$\prod_{t=0}^{T} P(C_{it} = c_t | X_{it} = x_t) \prod_{t=0}^{T} P(E_{it} = e_t | X_{it} = x_t)^{\delta_{it}} \quad (1)$$

The relevant probabilities are the initial state probabilities $P(X_{i0} = x_0)$, the time-specific transition probabilities $P(X_{it} = x_t | X_{i(t-1)} = x_{t-1})$, the measurement error probabilities for the register $P(C_{it} = c_t | X_{it} = x_t)$, and the measurement error probabilities for the survey $P(E_{it} = e_t | X_{it} = x_t)$. In the model, we assume that the observed states are independent of one another within and between time points, which is referred to as the local independence assumption or the assumption of independent classification errors (ICE). To deal with the fact that E_{it} is observed only every third month for the rotating scheme of LFS, we use the indicator variable δ_{it} which equals 1 if the survey information is available for the month concerned and 0 otherwise.

The model in equation 2 has been extended to deal with more realistic assumptions in our context. First of all, since the ICE assumption is unrealistic, we used the covariate $\mathbf{V}_{it}$ introducing across-time correlation in the measurement error in the survey data. Furthermore, the model is further expanded with - possibly time-varying - observed variables affecting the initial state and latent transition probabilities. We denote these control variables by $\mathbf{Z}_{it}$. In addition, we used a finite mixture models with K latent classes to account for additional unobserved heterogeneity in the initial latent state and in the latent transition probabilities that is not captured by $\mathbf{Z}_{it}$.

In our mixed hidden Markov model, the joint probability of having a particular observed state path conditionally on covariates $\mathbf{V}$, $\mathbf{Z}$ and $\mathbf{L}$ can be expressed as:

$$
\begin{aligned}
P(\mathbf{C}_i = \mathbf{c}_i, \mathbf{E_i} = \mathbf{e}_i | \mathbf{V}_i, \mathbf{Z}_i, \mathbf{L}_i) \quad = \quad & \sum_{k=1}^{K} \sum_{x_0=1}^{4} \sum_{x_1=1}^{4} ... \sum_{x_T=1}^{4} P(w_i = k|\mathbf{L}_i) P(X_{i0} = x_0 | w_i = k, \mathbf{Z}_{i0}) \\
& \prod_{t=1}^{T} P(X_{it} = x_t | X_{i(t-1)} = x_{t-1}, w_i = k, \mathbf{Z}_{it}) \\
& P(C_{i0} = c_0 | X_{i0} = x_0) \\
& \prod_{t=1}^{T} P(C_{it} = c_t | X_{it} = x_t, X_{i(t-1)} = x_{t-1}, C_{i(t-1)} = c_{t-1}) \\
& \prod_{t=0}^{T} P(E_{it} = e_t | X_{it} = x_t, \mathbf{V}_{it})^{\delta_{it}} \qquad (2)
\end{aligned}
$$

Equation 2 specifies a finite mixture model with K latent classes to account for unobserved heterogeneity in the initial latent state and in the latent transition probabilities. $P(w_i = k|\mathbf{L}_i)$ is the probability of belonging to the latent class k conditional on the respective covariates $\mathbf{L}_i$, $\mathbf{V}_{it}$ is the vector of covariates affecting the measurement error and $\mathbf{Z}_{it}$ is the vector of the covariates affecting the structural model.

Compared to equation 1, in equation 2, the error probabilities in the survey data are allowed to depend on covariates ($\mathbf{V}_{it}$). Moreover, the error probabilities in the register data are allowed to depend on the lagged observed and lagged true contract type. Note that $X_{i(t-1)}$ and $C_{i(t-1)}$ can take on 4 values, which implies that there are 16 ($4 * 4$) different sets of error probabilities in the register data, one for each possible combination of lagged observed and latent contract. Because it is not meaningful to estimate all these error probabilities freely, we used a more restricted model. More specifically, we define a constraint logit model when the same error is made between adjacent time points and otherwise being equal to 0. This model expresses that the likelihood of making a specific error depends on whether *the same error* was made at the previous time point. Similar restricted correlated error structures were used by (13) in a latent Markov model for retrospectively collected responses.

Maximum likelihood estimates of the model parameters are obtained using a variant of the Expectation-Maximization (EM) algorithm referred to as the forward-backward or Baum-Welch algorithm (4). We use an extension of this algorithm for MHMM with covariates as described - among others - in (20) and (17). This algorithm is implemented in the program Latent GOLD (19).

The analysis involves several steps and comparisons, requiring the estimation of several computationally-intensive models. In all steps of our strategy, we had to choose between models with different specifications. The choice between these models was done on the basis of model fit measures, namely the BIC, AIC and AIC3 as well as theoretical considerations on the relevance of the mixtures. As the models we estimate become computationally intensive when adding components, we decided to follow the two-step procedure that was suggested by (1).

4. Results

The final model was selected in 3 steps: first, we selected the model with the best-fitting specification of measurement error. Then, with this model at hand, we selected the model with the optimal number of trajectories (i.e. mixtures) by following the approach of (1). Finally, we tested whether adding covariates to the model improves model fit.

The final model has an extra error coefficient for the cases where the error made in time point $t-1$ could be repeated in t in the LFS and in the ER. It has 7 Mixtures, and does not use other covariates (other than time) in the equation of latent transitions.

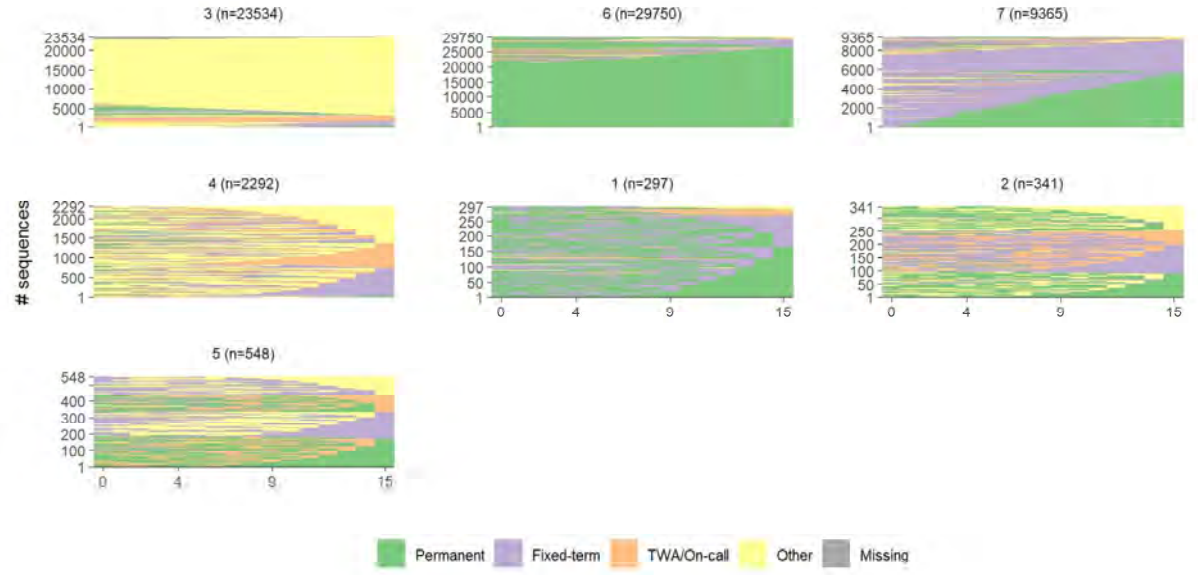

Figure 1: Employment trajectories with measurement-error correction

The results of the final model show that the largest group of individuals (trajectory 6 in Figure 1, 45% of the sample) included individuals that are mostly employed with a permanent contract throughout the observation period. The second largest group (trajectory 3 in Figure 1, 35.6%) belongs to a trajectory that is dominated by non-participation in paid employment. We should mention here that this does not only include unemployed individuals but also people in education and self-employment. The third group (trajectory 7, 14.2%) includes individuals whose employment includes long spells of fixed-term contracts. Some of them manage to get employment with a permanent contract, while others work with a fixed-term contract throughout the period of reference. Another, much smaller group (trajectory 4, 3.5% of the sample) includes careers with a lot of 'churning' between non-(paid) employment, and employment with a fixed-term contract, temporary agency work and on-call work. Clearly this seems to be much more disadvantaged group than other groups with people in employment. The last 3 Mixtures (trajectories 1, 2 and 5) are very small. One could easily classify them as 'residual' trajectories. However, these may also represent true but uncommon careers on the labour market. Mixture 1 (0.4%) includes individuals who switch often between employment with fixed-term and permanent employment. Mixtures 2 (0.5%) and 5 (0.8%) are not well separated as they include individuals that move often across all 4 states.

5. Conclusion and future work

In recent years, the debate on flexible employment has been at the center of political and scientific discussion in Europe. In the work, we implemented a MHMM with two indicators for the employment contract to show the effect of measurement error on the role of flexible employment in the life course. We used information coming from linked data from the Labour Force Survey and the Employment Register of the Netherlands for the period 2007-2015. The final model takes into account the longitudinal structure of the data, the measurement error structure of both data sources, and the heterogeneity coming from the population in the flexible employment dynamics.

An important parallel work concerns the comparison of the results obtained through the application of the MHMM to data for the Dutch territory with those for the Italian territory. The aim is to analyze the differences between the most suitable models in the two countries and thus what are the substantial differences in the labour market, particularly concerning the patterns of flexible employment careers.

Abstract

Employee well-being has gained the attention of scholars and practitioners over the past two decades. However, despite the increasing number of theoretical works on the topic, empirical studies are still limited. In this study, we aim to define the well-being construct through an exploratory and data-driven approach, and examine its impact on employee retention. We first used a nonlinear dimensionality reduction technique for categorical variables to identify the four main dimensions of work-related well-being. Then, we analyzed these dimensions in a fractional regression framework to predict employee retention. The empirical results suggest that the most significant aspects that discourage employee turnover are related to career growth opportunities, job satisfaction, and interpersonal relationships among coworkers.

Keywords: employee well-being, retention, turnover, nonlinear PCA, fractional logistic regression.

1. Introduction

The roots of human well-being can be traced back to Ancient Greece, where philosophers such as Aristippus and Aristotle first began to explore the nature of happiness [19]. Recently, well-being has emerged as a central theme in the organizational context, and it is considered a tool to enhance employee engagement and, ultimately, to improve corporate performance [7]. In addition, over the past two decades, well-being has gained increasing attention on the agenda of public institutions as a key aspect of social sustainability and sustainable development, as reflected in Sustainable Development Goals (SDGs) 3 and 8 [21]. In particular, the latter seeks to promote sustainable economic growth and decent working conditions for all, while SDG 3 aims to improve global health and well-being. The COVID-19 pandemic has threatened progress on both fronts [12], emphasizing the critical importance of coordinated efforts to achieve these goals. In today's globally competitive environment, organizations must prioritize attracting and retaining talented human capital, often at the cost of its well-being. This tendency leads to increased job stress and higher turnover rates, incurring substantial costs for the organization [1; 15; 16]. The objective of this study is to operationally define an individual-level well-being construct using data-driven methods, and to examine its effect on employee retention. Integrating well-being goals into human resource policies may contribute to improving employee retention, optimizing human capital investments, and allowing firms to achieve sustainable development goals, such as SDG 3 and 8. This paper is organized as follows. First, we review the concept of well-being. Second, we present the methodology used to define a new well-being construct. Then, the main results and findings are discussed. Finally, we draw conclusions and suggest managerial implications of the work.

2. Literature review

The concept of well-being in social science research has evolved since the 1960s, with the emergence of positive psychology [5]. In general, two distinct yet overlapping perspectives can be distinguished: subjective well-being (SWB) and psychological well-being (PWB). SWB is largely determined by an individual's life satisfaction and evaluations, which are often influenced by objective factors [4]. The multidimensional model of SWB, proposed by Diener (1984) encompasses life satisfaction, positive feelings, and the absence of negative feelings, reflecting the hedonic orientation to happiness [19]. On the other hand, PWB refers to self-realization and has been operationalized as a six-component model, including self-acceptance, positive relations with others, autonomy, environmental mastery, purpose in life, and personal growth [20]. In organizational research, PWB is typically operationalized as job satisfaction or eudaimonic aspects, such as engagement and meaning [9]. From an organizational perspective, well-being has primarily been studied at the individual level, with positive impacts identified for both employees and organizations [6; 25]. The concept of well-being can be defined as "the overall quality of an employee's experience and functioning at work" [22] and is commonly measured through attitudes such as work engagement, job satisfaction, and affective organizational commitment [20; 6]. However, there is a lack of consensus on how to measure subjective work-related well-being due to its multifaceted nature [17].
This work aims to empirically define employee well-being through a data-driven approach and nonlinear methodology. In this regard, we define employee well-being as the outcome of five major areas encompassing both SWB and PWB: economic aspect, interpersonal relationships, personal and professional growth, embeddedness, and innovative behavior. Then, in the second part of our work, we explore the relationship between work-related well-being and retention to guide practitioners in the development of HR retention-oriented strategies.

3. Data and methods

The data for this study was collected by the research group through an online survey sent to employees of 12 small and medium enterprises (SMEs) in Northern Italy. The survey consisted of two sections: the first collected demographic information, while the second measured the work-related experiences of the participants through 40 items retrieved from the literature on a 5-point Likert scale [23]. The sample consisted of 196 employees, with roughly equal representation of male and female participants and a majority of respondents between 36 and 60 years old with a university degree (45%). Approximately 90% of the participants had a full-time contract, and the average organizational tenure was nine years. Finally, we used demographic information to define our proxy variable for employee retention as the ratio between the organizational tenure of each individual, and their total number of working years. The resulting variable is continuous and takes values within the bounded range $[0, 1]$, where 1 identifies employees that spent their whole working career in the same company.

3.1 Methodology

To define the well-being construct, we employed Categorical Principal Component Analysis (CATPCA). This methodology was used to reduce the dimensionality of a dataset in an interpretable way while retaining most of its variability [13; 11]. Unlike linear PCA, which is limited to continuous numeric variables, CATPCA allows for the introduction of categorical variables (i.e., nominal and ordinal) through optimal scaling, which is used to quantify category labels [14]. The scaling level was defined as ordinal, based on monotonic transformations that maintain the original categories' order, as the questionnaire items were measured on a 5-point Likert scale. Once the scaling level and the variable weight is defined, the final solution is generated by an iterative algorithm that alternates optimal scaling and dimension reduction, through the minimization of a least squares loss function. For an extensive technical review of CATPCA we refer to Gifi [8]. Then, we used the objects scores extracted from CATPCA as explanatory variables in a fractional logistic regression to predict the employee retention. Fractional logistic regression is a nonlinear regression model designed for fractional response variables, with observations lying inside the unit interval. Given a sample of 'n' observations, let 'y' be the dependent variable $(0 \leq y \leq 1)$, and 'x' the explanatory variable, for each i^{th} observation $(i = 1, \ldots, n)$, we specify the fractional model as follows:

$$E(y_i|x_i) = G(x_i\beta) \tag{1}$$

where $G(.)$ is the logistic function satisfying $0 < G(z) < 1$ for each $z \in \mathbb{R}$. The unknown parameters are estimated using Quasi-Maximum Likelihood Estimation (QMLE), an efficient method under the Generalized Linear Model assumptions [18].

4. Results

The first step of our analysis consisted in the extraction of the latent dimensions underlying employee well-being. In order to check for multicollinearity between variables and justify the adoption of Categorical PCA, the association between variables was checked by using Kendall's Tau-b, which was performed for pairs of variables between groups [3]. All the correlations are within the range .204 to .356, suggesting that more than one component is needed to summarize the information in the data. This assumption is also confirmed by the results of Bartlett's test of sphericity, which provided a test statistic of 5101.06, statistically significant at a 1% level

($p < .001$). All the Likert-scale variables were scaled at ordinal level, so that the transformed categories respect the rank order of the original variables. Transformation plots showed monotonic and non-decreasing curves, so the ordinal treatment was appropriate. The whole analysis was run considering a weight $= 1$ for all the variables. To maximize Variance Accounted For (VAF) across principal components while keeping the orthogonal constraint, Varimax rotation was chosen. Following the guidelines of Linting et al. [13], we selected four principal components on the basis of the VAF and interpretability. Besides, the comparison between the most (i.e., numeric) and the least (i.e., nominal) restrictive analysis produced a 2% increase, meaning that accounting for nonlinearity improves the proprortion of variance explained.

Table 1: CATPCA model summary

	Variance Accounted For		
Dimension	Cronbach's Alpha	Total (Eigenvalue)	% of Variance
1	.955	8.445	21.653
2	.950	6.765	17.346
3	.936	4.691	12.027
4	.842	2.736	7.014
Total	**.981**	**22.636**	**58.040**

Note(s): Total Cronbach's Alpha is based on the total Eigenvalue.

The model summary indicates that the four components extracted account for the 58.04% of the quantified variables. Cronbach's Alpha scores confirm the good internal consistency between items, with values greater than $.842$. We only retained in the analysis variables with a VAF greater than $.25$, that is, at least 25% of the variance in a quantified variable is explained across the principal components. Based on the common traits of the variables selected for each dimension, we labelled them as follows. Dimension 1, which explains 21.65% of variance, is related to self-realization through work and skills and is labelled 'Realization'. Dimension 2 captures 17.35% of variance and was labelled 'Equity' as it refers to financial reward and career advancement, traditional HR management, and work-life balance. The third dimension, 'Responsibility', covers 12% of variance and includes non-ordinary matters management, critical issues, and teamwork aspects. Finally, the fourth dimension captures 7% of observed variance and represents interpersonal relationships aspects ('Connections').

4.1 Well-being and retention

After the dimensionality reduction performed by CATPCA, we fitted a predictive model to investigate the impact of the four principal components on employee retention. Since the outcome variable is measured as a fraction taking values within the interval $[0, 1]$, we employed a fractional logistic regression. Prior to fitting the model, the Ramsey's regression specification error test (RESET) was performed to identify any general functional form misspecification [24]. The RESET statistic yielded a value of $.40$ with an associated *p-value* of $.672$, indicating that the fractional model is correctly specified. The fractional model equation can be expressed as:

$$E(retention|x_k) = G(\beta_0 + \beta_1 Realization + \beta_2 Equity + \beta_3 Responsibility + \beta_4 Connections) \quad (2)$$

where x_k is the k^{th} predictor $(k = 1, \ldots, p)$ and $G(.)$ is the logistic function ensuring predictions to be within the unit interval. We estimated the nonlinear model in equation (1) using the logit link function and QMLE. In the following table, we report the baseline model estimates

and their relative average marginal effects (AME).

Table 2: Fractional logistic regression

	Model estimates		**AME**	
	Coefficient	Std.Error[a]	Coefficient	Std.Error[a]
constant	.780	.095		
Realization	.304***	.097	.065***	.021
Equity	.144	.108	.031	.023
Responsibility	.062	.089	.013	.019
Connections	.162**	.083	.034**	.018
$R^2 = .052$				

Note(s): [a]Robust standard errors. * $p < .1$; ** $p < .05$; *** $p < .01$.

As can be seen from Table 2, all the dimensions are positively related to employee retention. In particular, 'Realization' and 'Connections' are statistically significant at .01 and .05 significant level, respectively. Thus, model estimates suggest that the most relevant elements encouraging employee retention relate to personal and professional growth opportunities, perceived job satisfaction, social capital, and relational aspects. In the second column, AME, or partial effects, indicate the impact of the four PCs on the response variable for every unit increase. In fact, because of its nonlinearity, partial effects should be preferred in the interpretation of the model [10]. For example, employee retention is expected to decrease, on average, by .65 with a marginal change in the 'Realization' dimension, holding the other predictors constant. Finally, since the Breusch-Pagan test underlined heteroscedastic disturbances in the model ($BP = 9.612$, $p - value = .047$), robust (i.e., White) standard errors were computed based on a heteroskedasticity-consistent covariance matrix.

5. Conclusions

In recent years, work-related well-being has attracted the attention of scholars and practitioners, becoming a primary focus with the onset of the Covid-19 pandemic. In our paper, we adopt an exploratory and data-driven approach to investigate the main components of employee well-being and their impact on employee retention. Retaining talented workers is a strategic element in maximizing the organization's investment in human capital and generating a competitive edge. Data collection for this study was conducted through an online survey, which consisted of 40 variables designed to measure various dimensions of work-related well-being. The sample consisted of 196 employees from 12 SMEs. The results of the nonlinear PCA revealed four latent dimensions of well-being, which refer to personal growth ('Realization'), monetary and non-monetary rewards ('Equity'), employee autonomy and critical issues management ('Responsibility'), and relationships among coworkers ('Connections'). The fractional logistic regression employed to predict employee retention revealed that all four dimensions had a positive impact on the response variable, with 'Realization' and 'Connections' being the most significant aspects in reducing employee turnover. These findings add to the existing literature on employee well-being by proposing a new data-driven construct. Results suggest that HR professionals should focus on providing professional growth opportunities and creating a positive and supportive work environment that fosters social connections to retain employees. Besides, embedding well-being objectives in HR strategies may contribute to meeting sustainable development targets, as reported in SDG 3 and 8.

The CAP instruments impact on GVA and employment: a multivalued treatment approach

Montezuma Dumangane[a] and Marzia Freo[a]

[a]European Commission, Joint Research Centre (JRC), Ispra;
Montezuma.DUMANGANE@ec.europa.eu, Marzia.FREO@ec.europa.eu

Abstract

This study provides an EU NUTS3 level evaluation of the CAP impact on employment and Gross value added by assessing the relative merits of its instruments. The policy implementation is interpreted as a discrete set of policy mixes, and modelled as a multivalued discrete treatment. The treatment levels represent the prevalence of the three main types of CAP funds -Market Measures, Direct Payments, and Rural Development- and a reference Low CAP level. The Treatment Effects estimates confirm the role of all CAP instruments, particularly Market Measures, in preserving jobs in the agricultural sector and the effectiveness of decoupling Direct Payments.

Keywords: Generalised Propensity Score, CAP, Counterfactual Impact Evaluation

1. Introduction

Evaluating the CAP instruments has been the object of empirical studies using a diverse range of methodological approaches (see (9) for a comprehensive review of the literature on the CAP impact). This literature has become increasingly rich in analysing the effect of Pillar 1 instruments and Pillar 2 vast array of measures under Rural Development funding. However, the individual evaluation of its instruments does not address the relevant issue of assessing their relative effectiveness nor provides guidance on the efficient allocation of resources. Treating the CAP as a multidimensional policy and acknowledging the quantitative and qualitative differences in its implementation instead provides such insight to the policymaker. Furthermore, few studies address the challenge of robustly identifying the causal effect of the policy using the methods from the Treatment-Effects literature (8), while the region's economic and agricultural profile are potential determinants of the funds' allocation and outcomes and the evaluation of CAP causal effect need a Counterfactual Impact Evaluation (CIE) method. The existing empirical literature on the CAP impact with an EU regional dimension provides evidence of the policy performance that, however, is not derived from the toolkit of CIE methods. On the other side, most counterfactual studies are focused on a single country and the limited geographical coverage makes the results scarcely generalisable. Thus, the literature on the CAP evaluation lacks a counterfactual impact evaluation analysis that: provides an EU-level performance of the CAP, and inspects the effectiveness of the multiple CAP instruments. The present study attempts to address these issues by focusing on regional output and employment growth.

2. The CAP as a multivalued treatment

This study adopts an identification strategy to evaluate the CAP with causal methods while preserving its multidimensionality. The main feature of the identification strategy is that each region is treated

by a policy mix composed of three types of subsidies: Market Measures, Direct Payments, and Rural Development expenditure. As the policy mixes are as many as the regions, they are clustered into a discrete number of mutually exclusive groups. These are chosen to preserve their similarities within the groups as much as possible. The groups of policy mixes become distinctive of the treatment levels of a multivalued treatment design. This procedure reduces the dimensionality of a continuous multivariate treatment while preserving the qualitative aspects associated with the different policy mixes.

Consequently, regions within the same treatment level do not display perfectly homogeneous policy mixes. In this regard, the empirical literature on impact evaluation often neglects the inner composition of the treatment levels. While it is common practice to discretise continuous treatments or aggregate different policy instruments, to the best of our knowledge, very few analyses explicitly state that treatment levels should often be heterogeneous combinations of essential components with different intensities: (4) highlights that "the effective intervention plan usually contains multiple treatment components," and (10) acknowledges that "many applications involve simultaneous intervention on multiple variables". Of course, this only happens for practical reasons. Indeed, under continuous multivariate treatment, it is unfeasible to identify groups with units treated with the same level of each intervention. Allowing for heterogeneity within each treatment level makes the impact analysis feasible, as different units under the same (heterogeneous) treatment can be grouped.

The Generalised Propensity Score (GPS) method of (7) is applied to the discrete multivalued representation of the CAP to eliminate the selection bias. The GPS is estimated using the Covariate Balancing Propensity Score method of (6) (CBPS), which models the treatment assignment while optimising the covariate balance, and mitigates the consequences of the possible misspecification of propensity score models. Given an estimate of the propensity score, the Weighted Least Squares regression estimator (11), as a variant of the Horvitz and Thompson (5), is implemented.

3. Empirical analysis

The analysed period, 2011-2015, corresponds to the implementation of the 2009 Health check reform, which reinforced the funding of Rural Development programmes and further promoted the decoupling of Direct Payments. The analysis is based on a sample that aggregates some of the original NUTS3 units to produce a more homogenous territorial representation of the EU28. The combined effect of several types of CAP funds is considered: the Pillar 1 subsidies are grouped into three categories: Market Measures, granted to farmers to stabilise agricultural markets, prevent market crises from escalating, boost demand and help EU agricultural sectors to better adapt to market changes; Direct Payments, which include all forms of payments linked to the production of specific products or granted to farmers in advance and detached from the production level; and Rural Development Programmes, which payments do not target specifically the agricultural sector but aim to improve the quality of life in rural areas and achieve a balanced territorial development of rural areas and communities. Finally, the CAP funds' are measured as intensities (1; 2), the Pillar 1 funds as the ratio to the average GVA of agriculture and the Rural Development funds as the ratio to the average total GVA, computed from the two years previous to the beginning of the CAP implementation.

The analysis starts by identifying the treatment design by grouping the regions' mixes of Direct Payments, Market Measures and Rural Development Programmes intensities according to a two-step procedure. First, since all regions are CAP recipients, it is convenient to define a reference treatment level by identifying those with low intensity in all CAP funds. The resulting Low CAP group selected 98 regions with simultaneously all treatment level intensities of Pillar 1 and Pillar 2 below respectively the fifth and sixth decile. This treatment level is the natural counterfactual against which the impact of any other treatment level is to be evaluated. Second, the remaining regions are grouped using a hierarchical cluster algorithm on the three funds' intensities. The algorithm identified three groups, which, together with the Low CAP, form the treatment. Table 1 shows an index of the CAP funds' intensity in the treatment. The index measures the treatment level average intensity to the overall sample average intensity. The figures confirm Low CAP group of regions limited funding. These receive Market Measures, Direct Payments and Rural Development funds' intensities, respectively, equal to 15%, 43%,

Table 1: Treatment levels intensity index[a] across treatment designs

	No. of Regions	Market Measures	Direct Payments	Rural Development
Low CAP	98	15	43	28
PRD	224	72	71	211
PDP	342	65	150	71
PMM	132	301	62	40

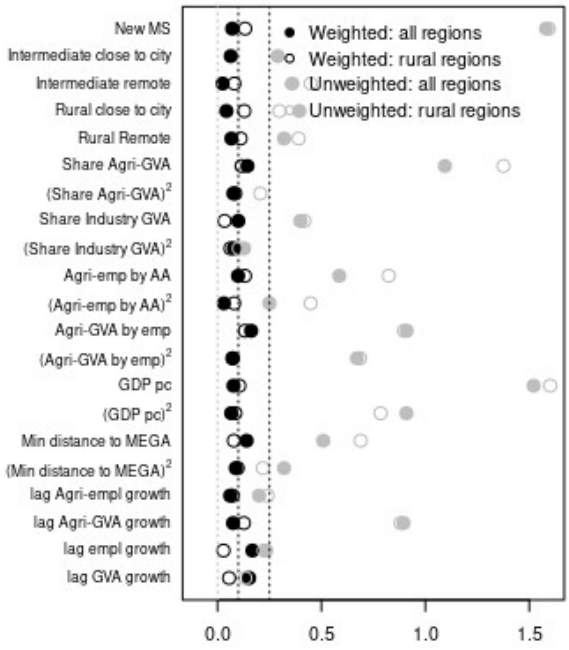
[a] *Note*: Table entries show ratio of average treatment level intensity in treatment group to overall average treatment level intensity.

and 28% of the overall average. The clustering exercise produced three treatment levels. Because they are relatively more intense in each one of the CAP funds, the baseline treatment levels will be labelled with the prefix "Predominantly" to underline the prevalence rather than its homogeneity within the category. The Predominantly Rural Development (PRD) group has, on average, around twice the overall average intensity of these funds, the Predominantly Direct Payments (PDP) group, around 1.5 times, and the Predominantly Market Measures (PMM), exactly three times the overall average intensity. The treatment levels also exhibit a heterogeneous overall CAP intensity, computed as a weighted average of funds' intensities with weights equal to their share of the total CAP. On average, regions in the Low CAP group received 37% of an average EU region. In contrast, regions on the PMM and PRD receive, on average, respectively 64% and 96%, while the PDP receive 135%, reflecting the highest share of these funds in the total CAP.

Interest lies in measuring the CAP contribution to the EU regions' agricultural economy and their spillovers to the regional economy. Two economic indicators are considered: GVA at constant prices and Employment, in the agricultural sector and in the regional economy. Both are measured as growth rates, between one year before the beginning of the CAP period and one, two and three years after its end. This allows us to infer the impacts' time path while simultaneously providing a robustness check. To investigate it, particularly the CAP's effectiveness in promoting balanced territorial growth, a heterogeneity analysis is carried out in the sub-sample of rural regions here defined as the non-predominantly urban areas from the Eurostat classification (3). The empirical strategy relies on the ability to identify a set of pre-treatment variables (see Figure 1) that satisfy the (weak) unconfoundedness assumption (7). The CBPS has been estimated over a set of control variables, describing the regions in several dimensions that influence both the potential outcomes and the treatment levels' assignment, one year before the policy period, i.e., in 2010. Except for the dummy indicators and the lagged outcomes, squares of the pre-determined variables were added, thus enriching the balancing property by extending it to the second moments. Figure 1 shows the absolute standardised maximum mean differences for assessing covariate balancing in the treatment. The figure illustrates how the procedure successfully balanced the means and variances of the covariates across the treatment levels.

Figure 2 shows the ATEs estimates for the entire sample and the sub-sample of rural regions. In both representations, $t+1$, $t+2$ and $t+3$ correspond to growth rates between 2011 and respectively 2016, 2017, and 2018. The estimated Low CAP Expected Potential Outcomes (EPO) growth at $t+1$ and $t+3$ (here not presented) is respectively, -14% and -17%. They reflect the negative trend of employment in the sector between 2011 and 2016 (2018). The same is observed in GVA in agriculture growth, where the EPOs at $t+1$ and $t+3$ are respectively, -5.9% and -6.3%. The ATEs show how all forms of CAP support contributed to attenuating the job losses and GVA decline in the agri-sector. The ATEs of regions treated with a high intensity of Market Measures reveal that this type of support contributed to preserving most agricultural jobs. The remaining CAP treatments only attenuate the negative trend in agri-employment, with the PDP group exhibiting a higher impact than the PRD. Conversely, while all CAP support positively impacts GVA in agriculture growth above the Low CAP EPO, PRD mixes induce the highest medium term growth. In fact, the policy mix predominantly funded by Rural Development measures is the only one to display an ATE that induces a non-negative expected growth GVA in agriculture. These results reveal that the CAP stimulates the agri-economy by safeguarding jobs through interventions that support the farmers' activity (PMM) and direct income support while Rural

Figure 1: Maximum absolute standardised mean differences before and after weighting: all and rural regions.

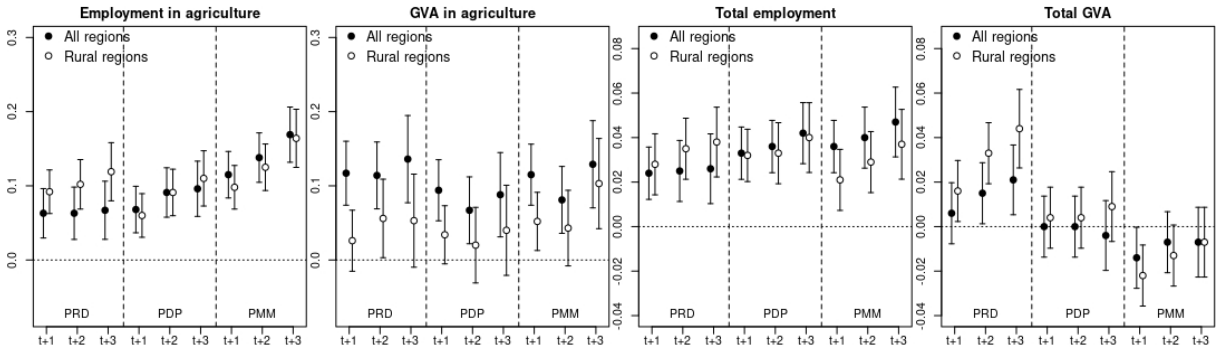


Development expenditure promotes consistent growth in the agricultural sector output. The results in the sub-sample of rural regions show that, there are no substantial differences in the negative trend of the agri-employment nor on how the Pillar 1 funds sustain its growth. Instead, the PRD interventions are more effective in safeguarding jobs in rural regions. The Low Ates estimates on GVA in agriculture are associated to a non significant impact of the PRD and PDP mixes and to smaller ATEs of PMM. Thus these results suggest that the structural changes induced under the PRD interventions do not close the GVA growth gap in the rural areas' agri-sector.

The last two graphs of Figure 2 show the CAP impact on the local economy outcomes. These (spillover) effects are, as expected, significantly smaller and are, under Low CAP support, associated with less negative trends in employment and a positive trend in GVA growth. However, while all CAP treatments induced growth in employment of around 3 percentage points above the Low CAP, only the PRD group exhibited a positive but negligible impact on total GVA growth. This treatment effect is significantly stronger in the sub-sample of rural regions. The longer term $t+3$ ATEs imply a yearly total GVA growth above the Low CAP of 0,7 percentage points, showing that although PRD support for the agricultural sector was relatively less effective in these regions, it contributes to the convergence of the rural regions' economy.

The paper's main findings shed light on how the different CAP instruments promote regional growth and safeguard jobs in the EU regions. All three forms of CAP support contribute to attenuating the job losses in the regional agricultural with limited spillovers to the local economy. However, although their positive contribution to GVA in agriculture growth does not unequivocally extend to the rural regions, Rural Development expenditure promotes growth and convergence of the rural economies. In fact, the policy mix predominantly based on Rural Development measures positively and significantly impacts all other outcomes. Despite being the least funded, the CAP mix intensive on Market Measures is found to be the most effective in promoting agricultural employment, with significant spillovers on regional jobs. Conversely, policy mixes based on Direct Payments, despite being more intensively financed, are found not to provide the highest impacts in any outcome.

Figure 2: Average treatment effects estimates: Full sample and rural regions



4. Conclusions

A recent review of the empirical literature on the socioeconomic impacts of the CAP causal impact found around 60 contributions. These analyses range from considering the whole CAP to analysing specific policy instruments. Most studies focused on a single country, or a part of it, providing limited geographical coverage, which hinders external validity given the regional differences across the EU regions. Furthermore, most existing evaluations of the CAP use methods that do not allow inferring the causality link between the policy and the outcomes. The present paper evaluates the CAP impact on regional employment and GVA growth in the agricultural sector and total local economy. The analysis provides two important contributions. First, the evaluation covers the EU28 regions and brings insight into the nature of the impacts in the rural areas. This is made possible by using a NUTS3 level dataset with disaggregated data on the different CAP funds. Secondly, the study proposes a procedure to investigate policies characterised by multiple joint interventions. Indeed the detailed info on the CAP is exploited to study the combined impact of different funds' categories using the Generalised Propensity Score framework of Imbens (7).

Abstract

Using the longitudinal structure of the Istat Italian Labor Force Survey, we follow for 15 months the 77.700 young people aged 19-34 who, at the first interview during 2012-18, lived in their parental home, dividing them into four groups (Italian men, Italian women, foreign men, foreign women). In the fourth interview, 15 months after the first one, 16% of them are no longer resident with their parents. The main objective of this work is to model the probabilities of leaving the parental home with the characteristics of young people at the first interview, using logistic regression. The young Italians most likely to leave their parental home are those employed full-time, regardless of gender and type of contract (fixed-term or open-ended). Students remain more frequently with parents irrespective of gender and citizenship. Only for Italians, leaving home is faster if the family of origin is large and the parents are more educated.

Keywords: leaving home, young people, employment, gender, citizenship

1. Introduction

Leaving parental home is a key marker in the transition to adulthood [12, 29] and can have important consequences for young adults' life course outcomes. If on one hand a late exit from parental home may prolong the transition to adult roles [15, 17, 19], on the other one an early exit may instead be associated with earlier experiences of other events, such as exit from education, entry into work or forming a family, that could prevent young people from acquiring adequate human capital for later in life [24, 26].

A large demographic research literature has therefore addressed a broad array of individual, parental, and contextual characteristics shaping the decision of young adults to leave parental home in Western societies [1, 2, 9, 11, 12, 16, 20, 21, 22, 27, 30].

Among the numerous factors influencing this decision, difficulties in labour market integration and unstable working conditions may play an important role. Several studies showed the negative effects of job precariousness on the propensity of youth to leave the parental household [6, 16, 22, 32], that can vary depending on the institutional and cultural context, as well as according to gender and reason for leaving home [2, 16, 27]. Not only unemployment or inactivity may limit young people's opportunities to leave their parental home [2], but also the instability of employment [4, 5, 14], irrespective of the level of income received by young adults. An Italian study [3], confirmed by a comparative analysis between Italy and Spain [8], observed that being employed is a prerequisite to exit from the family household more important than income itself. However this results true only for men: being employed, unemployed or inactive does not influence women's propensity of leaving their parents.

From another body of literature it emerges that also the family background, that is linked to young adults' opportunity and need structure, may influence the transition out of the parental home. In particular

the parental education, that is a predictor of young adults' occupational achievement stronger than parents' occupational status and income [13], seems affect the probability of exiting from family home [10, 18, 23, 28, 31] depending on the modality of leaving home (i.e. with or without a partner) and young adults' gender [7].

This study focuses on Italy where the youth unemployment rate is one of the highest among the EU members and leaving home traditionally occurs at later ages than in Northern or Western Europe. In Southern-European countries, characterised by a familist welfare model, national policies to support individuals from job loss or in housing costs are less generous than those of Scandinavian countries and therefore the relationship between the labour market condition and the transition to residential autonomy tends to be stronger [25].

Our aim is to investigate the factors associated to the exit from the family household in recent years, considering both young adults' characteristics, their working condition and their familiar background. We intend to pay special attention to the gender dimension, and also introduce a citizenship perspective, that is still little explored.

2. Data and methods

The analysis is based on microdata from the Italian Labour Force Survey (ILFS) carried out by Istat. The ILFS is the largest survey conducted in Italy to monitor the quarterly dynamics of the labour market and it provides data on employment, wages, and workforce. This survey follows a rotating sample design, where households participate for two consecutive quarters; they exit for the following two quarters, and come back into the sample for a further two consecutive quarters. Therefore, 50% of the households interviewed in the course of a quarter are re-interviewed after 3 months, 50% after 12 months, 25% after 9 and 15 months, respectively. If an individual leaves the sampled family, he/she is not re-interviewed, but it is possible to know – in fact – that he/she no longer belongs to that family unit.

The access to this dataset with wider information than the free version was possible thanks to a data sharing agreement between Istat and the University of Padua.

The present work uses data for the period 2012-18 (first interview) and 2013-19 (fourth interview), and it focuses on the around 77 thousand individuals aged 19-34 living with their parents when the household was enrolled in the survey. We were interested to observe which subjects left the parental home during the 15-month follow-up in order to identify their main characteristics. We divided young respondents in four groups according to their gender and citizenship, and then we ran four separate logistic regressions to highlight the different factors associated to the propensity to leave the parental home in each group.

We estimated three models for each group by including explanatory variables according to three thematic blocks: socio-demographic characteristics (i.e. age, geographic repartition and year of enrolment); employment status (i.e. temporary/permanently fully/partially employed, students, jobseeker, inactive); household characteristics (i.e. educational level of parents and number of household members). Therefore, the first model (that will be called *m1* in Table 2 of the results section) includes only the socio-demographic characteristics of the individual; in the second one (*m2*) we added the variable on the employment status; finally in the last model (*m3*) we included all the three blocks of variables.

3. Results and preliminary conclusion

Among the 77.711 individuals aged 19-34 living with parents when their household was enrolled in the survey 6% have foreign citizenship (Table 1). The percentage of men is greater than that of women (55% among Italians and 58% among foreigners). Although the foreign subjects are younger than Italians, they are less involved in the educational process and more employed (also with open-ended contracts).

The foreign presence is concentrated in central-northern regions. Focusing on family characteristics, about one third of foreigners live with at least 4 people and nearly half of them have poorly educated parents.

During 15-month follow-up 16% of the total sample left the parental home: this percentage is higher among Italians and among women of both citizenships.

The logistic regression shows that age has a positive and significant effect on leaving the parental home among Italian males and females, but not for foreigners. Moreover, in comparison with Italians living in the Centre, those living in the South and the Islands are more likely to exit from the household during the

follow-up; among Italian females also living in the North-east has a positive effect on the propensity to leave the parental home. For the foreigners, there is no significant effect of the geographic repartition of residence.

[a] Full time; [b] Part time

Focusing on the job condition, it emerges that students remain in the parental home more frequently than other occupational groups, regardless of their gender and citizenship. The same results are observed also for self-employed people, but only among Italians. Moreover, among Italian men and women what matters is not so much the duration of the contract but the working time: people with a part-time job have indeed a lower probability to leave than full-time workers while the duration of the contract has a not significant effect. The duration of the contract and the working time seem not to affect the propensity of foreign males of leaving their family; foreign females that work part-time with an open-ended contract are less likely to exit from the parental home than those with the same contract but a full-time position.

[a] Full time; [b] Part time; * $p<0.05$

Finally, the inclusion of variables on family size and parental education does not modify the effects previously described. We observe a significant effect of the number of household members and the parental education exclusively among Italian men and women: individuals living in large families and with parents having a middle/high education show a greater likelihood of leaving the parental home during the 15 months following the first interview. Since in Italy income is strongly and positively connected with the education, and since income is not a variable available for all the families interviewed, this result could also indicate that leaving the parental home is easier for the children of wealthier parents.

The present work contributes to the study of transition out of the parental home by differentiating according to young adults' gender and citizenship. Unfortunately, the information collected by ILFS is less

rich than that available for other dedicated surveys (such as Family and Social Subjects), and we do not have the characteristics of young people after they leave home (for example, we do not know their working conditions and their living arrangement). However – unlike what happens for dedicated surveys – ILFS has the advantage of being available every quarter of year, a few months after the survey, with large, statistically controlled samples, because they are used to measure employment and unemployment rates. It is therefore our intention to also analyse the data for subsequent years, for example by observing the effect on leaving home of the Covid-19 epidemic of 2020-21, and the subsequent recovery in employment.

Abstract

Po Valley is well known to be one of the most polluted areas in Italy, because of its large population density, its shape and climate. Thus, there is an obvious interest in monitoring the air quality in several stations scattered across the whole territory. In this work, we develop a Bayesian spatio–temporal model describing the PM_{10} pollution in Lombardy to assess how station features and weather factors affect the PM_{10} concentration. We will rely on *Stan* for posterior inference.

Keywords: Bayesian inference, Gaussian processes, auto-regressive hierarchical model

1. Introduction

Air pollution is defined as the release by human activities of gases and particulate matter (PM) into the atmosphere. Due to their impact on human health, we are interested in studying fine dusts, which are characterized by their micrometre size PM_{10} to $PM_{2.5}$. *Po Valley* is a well-known hotspot for PM pollution in Europe (3). Many factors might be responsible: for instance the high population density, together with a high level of urban and industrial areas, its geographic shape and climate. In this work we consider air quality data of the Po valley, specifically focusing on PM_{10} in Lombardy. PM_{10} ambient concentration data are collected as daily averages by fixed monitoring stations at 64 different sites, which are distributed across the whole region. Given the well established relation between meteorological conditions and air pollution, we considered also weather-related data collected by a dedicated monitoring network in Lombardy. Both datasets store spatio-temporal information thanks to the geolocated monitoring stations providing multiple time series, as for each location we have both air quality and meteorological data. The spatial dependence characterizing point-referenced data is usually modeled via Gaussian processes (GP), though there is a plenty of different models for (multiple) time series analysis in the Bayesian setting (see (8)). In this paper we propose a Bayesian hierarchical model for the analysis of PM_{10} spatio-temporal data in the Po valley, including also the weather as influential factor. The model also accounts for clustering of the monitoring stations, since we want to assess if there are differences in the magnitude of PM_{10} dependence on past values across different locations. The paper is organized as follows: in Section 2. we briefly describe the two datasets we analyze; then in Section 3. we present the Bayesian model for PM_{10} data and in Section 4. we provide initial findings based on posterior inference along with possible future developments.

2. The data

The dataset we analyze has been recorded by the air quality monitoring network of the Po Valley, the area of interest. This network is managed autonomously by the Regional Agencies of Environmental Protection (ARPA) of Emilia Romagna, Lombardy, Piedmont and Veneto. Data about concentrations of pollutants are collected through fixed monitoring stations, distributed over the whole valley. Each station collects, through time, the concentration of many pollutants, in particular: nitrogen dioxide (NO_2), benzene (C_6H_6), ammonia (NH_3) and particulate matter (PM_{10}, $PM_{2.5}$). In particular, we focus on PM_{10} values, which are recorded as daily averages in all regions.

The dataset also provides information about the PM_{10} monitoring sites. For each monitoring station, we know its location (lat–long coordinates and altitude on sea level), whether or not the station is exposed to a specific emission source (traffic, industry or background station) and the level of urbanization of the surroundings (urban, suburban or rural area). Data also provide the altitude of the station, which could be a relevant factor affecting the PM_{10} concentration. Exploratory data analysis of this dataset can be found in (5). It is well-known that meteorological conditions might drive PM_{10} concentration (e.g. (7)). Consequently, focusing only on Lombardy, we have considered data from the meteorological network, which is also managed by ARPA and involves over 200 weather stations across the region. However, this second dataset is recorded at different sites and time scale than the PM_{10} dataset. To overcome the first problem, we associated each PM_{10} station to the closest meteorological station. Secondly, PM_{10} values are provided as daily averages while meteorological factors are recorded every 10 minutes. Adopting proper summaries for the various phenomena (e.g. rainfall, wind speed, solar radiation etc.) we have defined average daily values also for weather information, making the two datasets at the same spatial and temporal scale.

3. The Bayesian model

We focus on modeling PM_{10} daily concentrations collected by all stations in Lombardy during 2018. Since we know the exact location of each monitoring station (lat–long coordinates), we model the PM_{10} time-series as point-referenced spatio-temporal data. In this context many interesting models can be found in literature, see (8) Chapter 7. Some of them may be generalized and tailored for the data we focus on. We denote by $y(\boldsymbol{s}, t)$ the logarithm of PM_{10} concentration collected at location $\boldsymbol{s}$ at time t, for $\boldsymbol{s} \in \mathcal{D} \subset \mathbb{R}^d$, with $d = 2$ and for $t \in [0, T] \subset \mathbb{R}^+$. In our analysis the spatial domain $\mathcal{D}$ is given by Lombardy territorial extension, while each time instant t corresponds to a Julian day of the year. We rearrange our data as the collection of temporal independent spatial processes, one for each time instant, adopting the following vector notation:

$$\boldsymbol{Y}_t = [y(\boldsymbol{s}_1, t), \ldots, y(\boldsymbol{s}_n, t)]' \qquad t = 1, \ldots, T. \tag{1}$$

In particular, for our case study we set $n = 64$ (number of monitoring stations in Lombardy) and $T = 365$. We consider the following AR(1) model, specifying the auto regression on the centered random effects $\boldsymbol{O}_t$ and not directly on $\boldsymbol{Y}_t$ (see (1; 8; 9)):

$$\boldsymbol{Y}_t = \boldsymbol{O}_t + \boldsymbol{\epsilon}_t \qquad t = 1, \ldots, T \tag{2}$$

$$\boldsymbol{O}_t = diag(\boldsymbol{\rho})\boldsymbol{O}_{t-1} + X_t\boldsymbol{\beta} + \boldsymbol{w}_t \qquad t = 1, \ldots, T \tag{3}$$

where $\boldsymbol{\epsilon}_t \overset{iid}{\sim} \mathcal{N}(0, \sigma^2_\epsilon)$ is the $n \times 1$ pure error term, $\boldsymbol{\rho} = [\rho_1, \ldots, \rho_n]$ is the $1 \times n$ row vector of station-specific autoregressive parameters, X_t is the $n \times p$ design matrix and $\boldsymbol{\beta}$ is the $p \times 1$ vector of regression coefficients. The *hierarchical centering* mean parameter $\boldsymbol{O}_t$ (see (6)) is the $n \times 1$ vector representing the *true* value corresponding to data $\boldsymbol{Y}_t$ and we assume an autoregressive structure for $\boldsymbol{O}_t$ as in (1). The spatial residual term $\{\boldsymbol{w}_t\}$ in (3) is assumed to be independent from the pure error terms $\{\boldsymbol{\epsilon}_t\}$ in (2).

For the spatial process $\{\boldsymbol{w}_t\}$ we assume the following Gaussian Process (GP), as in (8):

$$\boldsymbol{w}_t \overset{iid}{\sim} \mathcal{N}_n(\mathbf{0}, \sigma_w^2 H) \qquad t = 1, \ldots, T \tag{4}$$

$$H_{i,j} = exp\{ -\frac{1}{R} ||\boldsymbol{s}_i - \boldsymbol{s}_j||_e \} \qquad i, j = 1, \ldots, n. \tag{5}$$

Hence each $\boldsymbol{w}_t$ is modeled as a zero-mean GP having covariance matrix defined by the exponential correlation function, which depends on the Euclidean distance $||\cdot||_e$ between the monitoring sites. Moreover the spatial residuals are assumed to be temporally independent.

Covariates The design matrix X_t is composed by spatio-temporal covariates, including spatial characteristics of the stations (fixed-time covariates) and information about meteorological phenomena recorded at time t. In particular we will consider as influential factors: the altitude of each station, a dummy variable specifying whether or not the station is located in a traffic or industrial zone, rainfall amount, wind speed, total solar radiation and a sinusoidal function with annual frequency in order to provide the mean of the response with the typical U-shaped behaviour of $\log(\text{PM}_{10})$ time-series.

Prior The model just described is then completed with suitable marginal prior distributions for each parameter involved in the spatio-temporal model, i.e. $\boldsymbol{\rho}$, $\boldsymbol{\beta}$, σ_ϵ^2, σ_w^2. For the moment, we focus on a model that assumes all component of $\boldsymbol{\rho}$ as given by $\widetilde{\rho}$, a common random parameter, with $\widetilde{\rho} \sim \mathcal{N}(0, 1)$. In the Bayesian framework, there is no need to impose strict constraints about the autoregressive parameter domain, since we are not assuming a priori the stationarity (or non-stationarity) of the series. The rest of the parameters are given the following marginal priors:

$$\begin{aligned}
\beta_j &\overset{iid}{\sim} \mathcal{N}(0, 1) \quad j = 1, \ldots, p \\
\sigma_\epsilon^2 &\overset{iid}{\sim} InvGa(a, b) \\
\sigma_w^2 &\overset{iid}{\sim} InvGa(a, b)
\end{aligned}$$

It is a common choice to provide $\mathbb{E}[\sigma_\epsilon^2] = \mathbb{E}[\sigma_w^2] = 1$ and $Var[\sigma_\epsilon^2] = Var[\sigma_w^2] = 2$, leading to the prior hyperparameters fixed to $a = 3$, $b = 2$. Note that, in this context, the standard Gaussian prior for the regression parameters turns out to be sufficiently vague, since $\log(\text{PM}_{10})$ ranges between 0 and 5 and all the numerical covariates have been standardized. We complete prior specification assuming:

$$\begin{aligned}
\boldsymbol{O}_0 &\sim \mathcal{N}_n(\boldsymbol{m}_0, \sigma_0^2 H) \\
\boldsymbol{O}_t &\sim \mathcal{N}_n(\widetilde{\rho}\, \boldsymbol{O}_{t-1} + X_t \boldsymbol{\beta}, \sigma_w^2 H) \qquad t = 1, \ldots, T.
\end{aligned}$$

We fix $\boldsymbol{m}_0$ to be a $n \times 1$ vector having all components equal to the overall mean $\log(\text{PM}_{10})$ value, while $\sigma_0^2 \sim InvGa(3, 2)$ providing $\mathbb{E}[\sigma_0^2] = 1$ and $Var[\sigma_0^2] = 2$. Block of parameters are assumed a priori independent. Finally, we fix the spatial range parameter in expression (5) to $R = 70km$ (estimated through empirical variogram techniques).

BNP Clustering Assuming a convenient BNP prior for $\rho_1, \ldots, \rho_n$, we can cluster together stations showing a similar trend in their time-series, providing interesting information about the data outline. We assume a Dirichlet process mixture (DPM) model (see (4)) for $\rho_1, \ldots, \rho_n$ without modifying any of the other terms in model (2)-(3). The DPM model is then defined as:

$$\rho_i \overset{iid}{\sim} \sum_{g=1}^{+\infty} \eta_g \mathcal{N}(m_g, s_g^2) \quad i = 1, \ldots, n. \tag{6}$$

We also assume the mixture hyperparameters as $(m_g, s_g^2) \overset{iid}{\sim} P_0$, $g = 1, \ldots, G$, where P_0 is a suitable distribution on $\mathbb{R} \times (0, +\infty)$. The mixture weights $\{\eta_g\}$ come from the truncated stick-breaking representation of a Dirichlet process and can be written as:

$$\eta_1 = v_1 \tag{7}$$

$$\eta_g = v_g \prod_{j=1}^{g-1} (1 - v_j) \qquad g = 2, \ldots, G \tag{8}$$

$$v_g \overset{iid}{\sim} Beta(1, \alpha) \qquad g = 1, \ldots, G \tag{9}$$

where G is fixed and the total mass parameter is $\alpha \sim Gamma(c, d)$. It can be proven that the weights sum to one, i.e. $\sum_{g=1}^{G} \eta_g = 1$.

4. Preliminary data analysis and posterior inference

The dataset collected in Lombardy during 2018 contains daily average concentrations of PM_{10} at the 64 monitoring stations for every day of the year ($T = 365$). In addition we also have weather information coming from the nearest meteorological station, providing data for each day of the year. Specifically, we consider as influential factors the daily averages of *solar radiation intensity*, *humidity* and *temperature*. The information about the presence of *rain* or *wind* is instead summarized by two binary variables: one indicating very rainy days (more than 8 over 24 hours raining) and the other indicating days of calm (more than 8 over 24 hours without wind). These are the time-varying covariates X_t in (3). We assume as regressors of interest also the *altitude* of each PM_{10} station and a binary variable indicating the proximity of *traffic* or *industrial* sources of pollution. These latter are fixed-time covariates. We fix prior hyperparameters as follows: $a = 3$, $b = 2$, $c = d = 3$. We rely on *Stan* probabilistic programming language (2) for posterior simulation, i.e for computing the posterior of all parameters involved in model (2)-(9). We run two parallel MCMC chains in *Stan*, assuming $1,000$ burn-in iterations and $1,000$ sampling iterations. Figure 1 displays 95% posterior credible intervals for the regression coefficients. Note that all regressors are quite significant. As expected, air quality improves with altitude, while traffic and industrial areas are associated to higher levels of pollution. As for as weather covariates are concerned, we see that rainy days and high temperatures are associated to lower PM_{10} concentrations, while the absence of wind, together with high solar radiation and humidity, contributes to raise the pollution level.

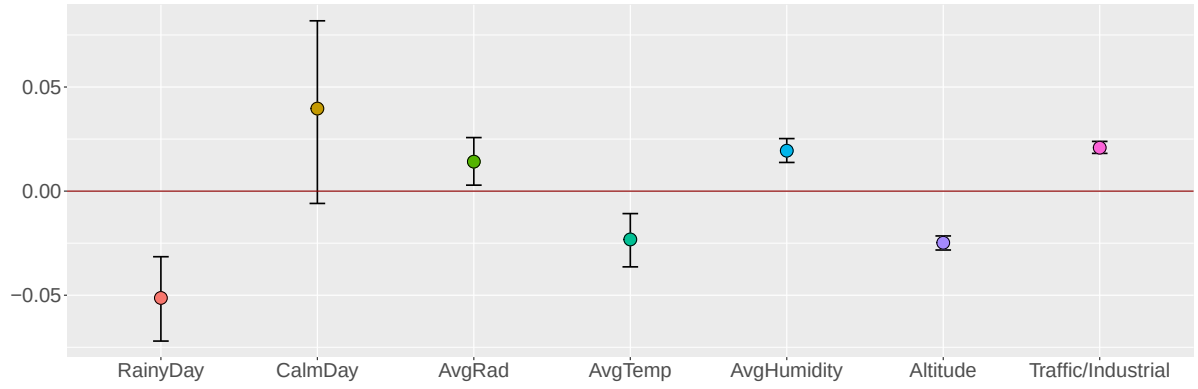

Figure 1: 95% marginal posterior credible intervals (CI) for regression coefficients $\boldsymbol{\beta}$.

Figure 2 shows the model 95% credible intervals of the posterior predictive distribution for $\log(\ PM_{10})$ at a specific station (*Pavia-Piazza Minerva*) where the last 30 days of the year have been removed from training set. The model provides reasonable prediction for the $\log(\ PM_{10})$ values in these latter days,

since all the true values (in blue) are fully inside the 95% predicted credible intervals. We obtain similar results for the majority of locations, but few stations seem to follow a different trend. Figure 3 shows the 95% credible intervals of the posterior predictive distribution for $\log(\ \mathrm{PM}_{10})$ at *Moggio*, one of the stations whose posterior predictive distributions seem different from all the other ones. As in Figure 2, we removed the last 30 days from the training set and computed the posterior predictive distribution of $\log(\ \mathrm{PM}_{10})$ in these latter days, using the model here described. It is clear that most of the datapoints (blue line) are not included in the associated 95% credible intervals. These patterns suggest the presence of at least two different temporal trends among the stations under study, corroborating the usefulness of a Bayesian cluster model able to find all the possible different scenarios. Future work includes implementing in *Stan* the Bayesian non-parametric clustering presented in Section 3.

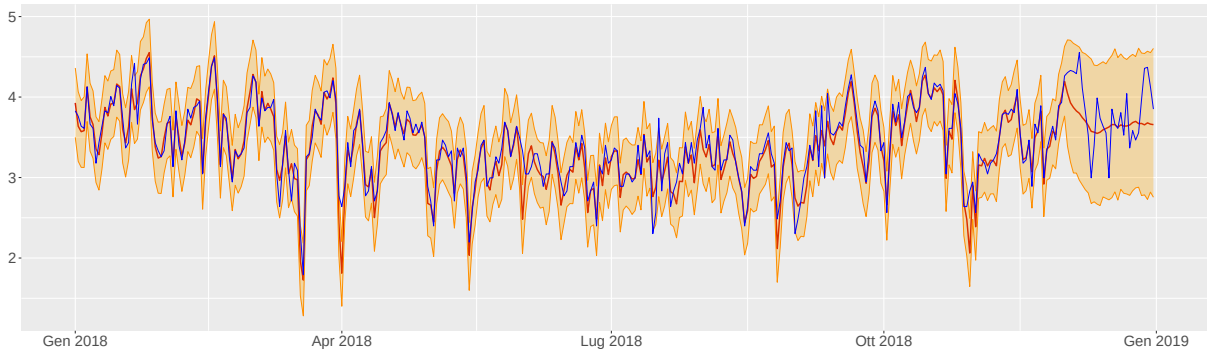

Figure 2: Observed values (in blue) , 95% credible intervals (in orange) and median (in red) of the posterior predictive distribution for PM_{10} log-concentrations at Pavia - Piazza Minerva.

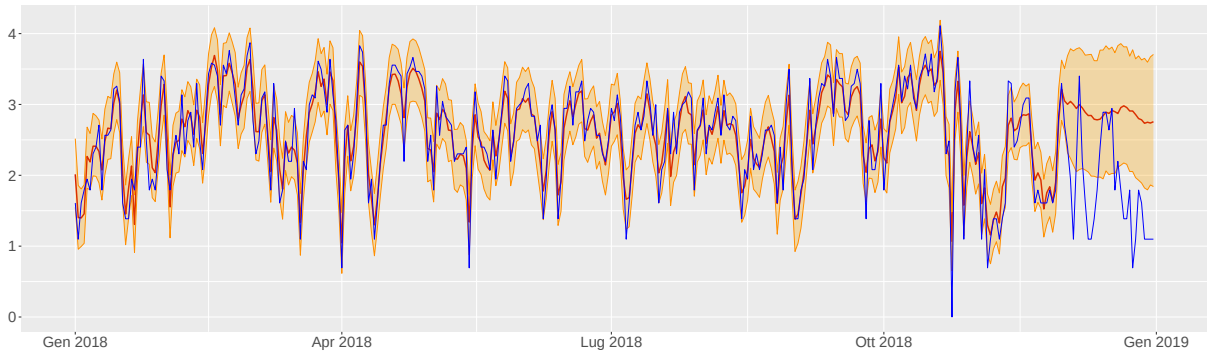

Figure 3: Observed values (in blue) , 95% credible intervals (in orange) and median (in red) of the posterior predictive distribution for PM_{10} log-concentrations at Moggio.

Abstract

In this study we investigate the reliability of shape descriptors in providing a more detailed characterization of microplastics ingested by fish. In particular, a new approach based on shape descriptors is compared with the traditional approach, in the explanation of species-specific selection mechanisms in the ingestion of MPs. In accordance with the traditional information available, the first question is whether the rate of ingestion depends on the species. Correspondence analysis was then performed to highlight possible differences in the types of MPs ingested by the three species in terms of shape categories, color and size classes. The traditional approach does not provide enough information on the selection mechanism of MPs. New quantitative shape descriptors were therefore used to identify a relationship between MPs characteristics and species. PCA technique and Kruskal-Wallis test were used.

Keywords: Hurdle model, Correspondence analysis, Kruskall-Wallis, Microplastics, Fish

1. Introduction

Microplastics (MPs) are commonly defined as little pieces of plastic less than 5 mm in size. MPs are documented as pervasive and ubiquitous environmental contaminants (Arthur et al., 2009). MP pollution is one of the main environmental issues of current times (Horton et al. , 2017). Most studies about MP emphasize contamination of oceans and seas, paying particular attention to the ingestion of these particles by marine animals (Gouin , 2020). Despite the low toxicity associated to most plastic polymers, MPs are noxious particles that can negatively affect the physiology of marine organisms by determining physical damages (such as the obstruction of the gastrointestinal tract) or acting as carriers of hazardous chemicals like plastic additives (e.g., plasticizers, flame retardants, and dyes) or other adsorbed pollutants (Rai et al., 2021). Since MPs overlay the size range of prey of many marine species, MP ingestion may happen either accidentally, or intentionally (i.e., by confusing plastic particles with natural or potential preys), as well as due to trophic transfer (i.e., secondary ingestion of MPs already ingested by prey) (Fossi et al., 2018). In other words, MP ingestion maybe not depend only on its detectability, but likely also on the foraging decision-rules of organisms. The full comprehension of patterns that define the

environmental fate of MPs is a key step for assessing the impact of plastic pollution on marine biota and to drive effective management policies (Valente et al., 2020). Current methods to characterize MPs extracted from biological samples are based on visual identification and classification according to shape categories and size classes. The qualitative operator-based classification of MPs often implies loss of objective information and is subject to observer bias (Primpke et al., 2017). Furthermore, MP categories used in different studies are not always congruent and clearly defined, resulting in the lack of a standard, globally shared glossary (Miller et al., 2020). Then, the use of categorical variables to describe the shape and size of MPs may limits cross-studies consistency, and therefore our understanding of the fate of different MP types within ecosystems (Cowger et al., 2020).

Shape descriptors are quantitative measures describing the geometry of a given shape. Although a particle cannot be redrawn from shape descriptors, these should be sufficiently different to distinguish specific geometric features. Therefore, image processing approaches aimed at shape quantification are regarded as good candidates for developing a new MP characterization framework (Valente et al., 2022a). In this study we perform the first investigation on the reliability of shape descriptors in providing a more detailed description of MPs ingested by marine fish. To hit this goal, we analyzed MPs ingested by three different fish species from the upper slope (400-600 m depth) of the Tyrrhenian Sea (Western Mediterranean), namely the Shortnose greeneye *Chlorophthalmus agassizi*, the Mediterranean slimehead *Hoplostethus mediterraneus*, and the Hollowsnout grenadier *Coelorinchus caelorhincus*. Following the traditional approach, the ingested MPs were firstly counted and classified according to customary shape categories and size classes. Then, all the MPs were photographed using a camera-equipped dissecting microscope and the obtained pictures were processed to obtain a shape characterization based on the following shape descriptors: surface area, perimeter, major axis, minor axis, aspect ratio, solidity, and circularity. The information obtained from the two different MP characterization approaches were compared to verify the ability of shape descriptors in highlighting differences in the amount and diversity of MP types ingested by the three species.

2. Materials and Methods

Sampling and laboratory analyses A total of 90 fish (30 for each species) were sampled during a single fishing trip carried out in April 2021 out off Rome (41°20′24.5″ N; 012°17′20.6″ E), within a marine area representing an optimal pilot zone for studies on MP ingestion. Indeed, this is a prospective site of MP accumulation due to the discharge of the Tiber River, high coastal urbanization, and very variable current patterns creating unique conditions for the accumulation of waste from local inputs (Valente et al., 2019, 2022b). Laboratory analyses were performed following the guidelines provided in Matiddi et al. (2021).

Characterization of microplastics and data reporting Following the traditional approach, all the MPs extracted from the gastrointestinal contents were visually identified, counted, and classified according to the customary shape categories (*i.e.*, fiber, filament, film, fragment, foam, granule, and pellet) and size classes (S1: 100 - 330 μm; S2: 330 μm - 1 mm; S3: 1 - 5 mm) defined within the European research project INDICIT 2 (`https://indicit-europa.eu`). Therefore, the amount of MP ingested was expressed as no. of MPs ingested by each individual, while the diversity of ingested MP types was evaluated according to the combination of the categorical variables describing the shape and size of each particle. Thereafter, all the MPs were photographed using a ZEISS Stemi 2000-C dissecting microscope equipped with an Axiocam 208 color camera. Following the image analysis protocol developed in Valente et al. (2022b), the obtained pictures were processed using the open-source software ImageJ (`https://imagej.nih.gov.ij/`) to compute the following shape descriptors: surface area (i.e., no. of pixels in the particle), perimeter (no. of pixels in the boundary of the particle), aspect ratio (height-to-width ratio, $\frac{\text{major axis}}{\text{minor axis}}$), solidity (ratio of the area of an object to the area of the convex hull of the object, $\frac{\text{area}}{\text{convex area}}$), and circularity (ratio of the particle's area to the area of a circle with the same perimeter, $4\pi \cdot area \cdot perimeter^2$). Surface area measurements were used to both assess the amount of ingested MP and the size of the particles. All the other shape descriptors were considered to summarize

the geometric features of each MP and highlight the variety of MP types ingested by the three species.

Statistical analyses The workflow diagram in Figure 1 describe the experimental set-up developed to compare the two MP characterization approaches.

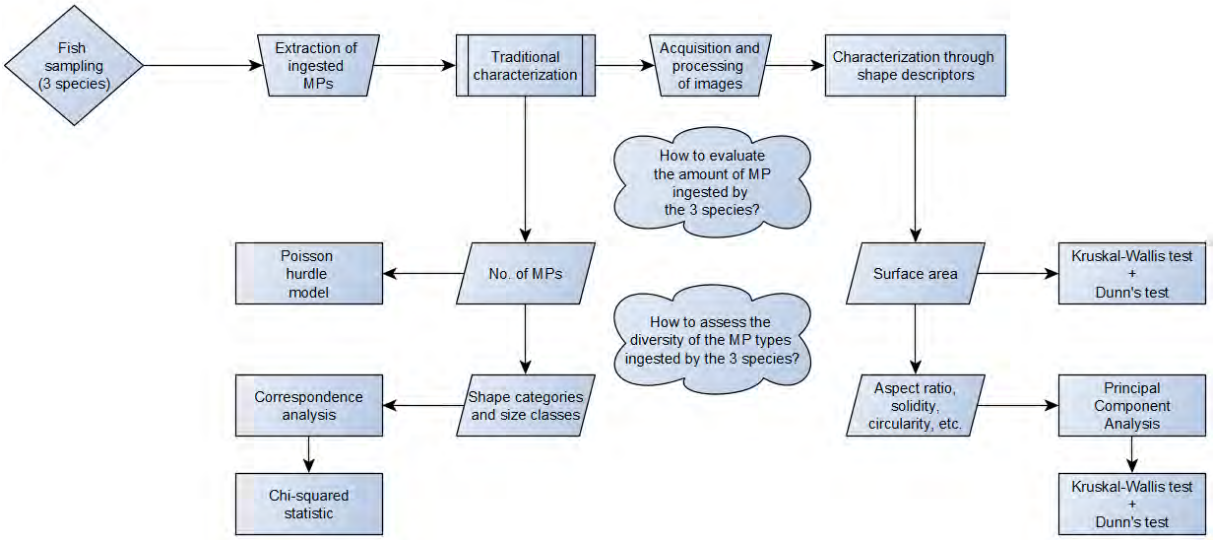

Figure 1: Workflow

According to the traditional approach, the amount of MP ingested by the three species was expressed as no. of MPs found in each individual. Given the large proportion of 0s coupled with a right-skewed distribution, the Poisson hurdle model (Mullahy, 1986) was used to test for differences in microplastic ingestion rates among the three species. Let's consider Y_i the number of microplastics ingested by the subject $i = 1, \ldots, n$. The Hurdle model is given by

$$\begin{aligned} P(Y_i = 0) &= 1 - p, & 0 \leq p \leq 1 \\ P(Y_i = k) &= p \cdot \frac{\mu^k e^{-\mu}}{k!\{1 - e^{-\mu}\}} & k = 1, \ldots, \infty, \quad 0 < \mu < \infty \end{aligned} \tag{1}$$

With:

$$\begin{aligned} log\left(\frac{p}{1-p}\right) &= \alpha_0 + \mathbf{X}^T\alpha \\ log\left(\mu\right) &= \beta_0 + \mathbf{X}^T\beta. \end{aligned} \tag{2}$$

were μ is the mean of an untruncated Poisson distribution, $\mathbf{X}$ is a set covariates with linear effects α and β to be estimated.

Correspondence analysis (Greenacre, 1984) was performed to highlight possible differences in the types of MPs ingested by the three species in terms of shape categories, color and size classes. Association between variables was tested through chi-square statistics. Shape descriptors were analyzed in parallel to test their ability in detecting possible differences in MP ingestion among the three examined species. PCA was performed to investigate the relationship between shape descriptors and species. Then, due to the invalidation of one of the assumptions for parametric analysis (namely homoscedasticity, as tested by Levene's test), the Kruskal-Wallis test for multiple comparisons (Kruskal et al., 1952) was used. Post-hoc multiple pairwise comparison based on Dunn's z-test-statistic with Bonferroni correction (Dunn, 1964) was finally performed whether significant differences among species were detected.

All statistical analyses were performed with R v4.2.2 (R Core Team , 2021). The significance level was set at $p<0.05$ for all analyses.

3. Results

MP ingestion was detected in all the three examined species, with an overall frequency of occurrence of 34.4% and an average number of microplastics per individual equal to 0.56 $\pm$ 1.03 (1.68 $\pm$ 1.11 considering only the individuals with ingested MP). Results by species are available in Table 1.

Table 1: Summary statistics by species

	C. agassizi	H. mediterraneus	C. caelorhincus
Frequency of Occurrence	26.7%	40.0%	36.7%
Average number of MPs ($\pm$ sd)	0.53 $\pm$ 1.20	0.70 $\pm$ 1.09	0.50 $\pm$ 0.78
Average number of MPs ($\pm$ sd) (individuals with ingested MP)	2 $\pm$ 1.60	1.75 $\pm$ 1.06	1.36 $\pm$ 0.67

No significant differences in MP ingestion rates were detected among the three species. The estimated values for the Hurdle model parameters together with the standard deviations and the relevant p-values are shown in Table 2.

Table 2: Hurdle coefficients estimates

Count model coefficients	mean	standard error	p-value
β_0	0.466	0.325	0.151
$\beta_{C.caelorhincus}$	-0.888	0.577	0.124
$\beta_{H.mediterraneus}$	-0.245	0.448	0.585
Zero hurdle model coefficients	mean	std	p-value
α_0	-1.012	0.412	0.014
$\alpha_{C.caelorhincus}$	0.465	0.560	0.407
$\alpha_{H.mediterraneus}$	0.606	0.556	0.279

Correspondence analysis showed no significant association between species and the classical categorical variables "shape category", "color" and "size class". PCA performed on the computed shape descriptors well highlights that *C. caelorhincus* ingested the widest variety of MPs. In particular, it turns out that for the species *C.agassizi* and *H.mediterraneus* the main characteristic of the microplastics ingested is linked to the circularity and the roundness, while for *C.caelorhincus* influence the shape descriptors area and the Feret's diameter, all descriptors linked to the amplitude of the microplastic (Figure 2).
To confirm what the PCA showed, the Kruskall-Wallis test and the Dunn's test revealed that *C. caelorhincus* ingested lager MPs than *H. mediterraneus* and *C. agassizi* (Table 3).

Table 3: Dunn's test estimation

Comparisons	Z	adjusted p-value
C.caelorhincus - H.mediterraneus	2.65	0.012
C.agassizi - C.caelorhincus	-1.95	0.045
C.agassizi - H.mediterraneus	0.54	0.88

Table 4 summarizes the main differences between the two approaches.

4. Discussion

The idea of the study is to compare a new approach (based on shape descriptors) with the traditional one in particularizing the ingestion of microplastics according to the species. This study further confirms

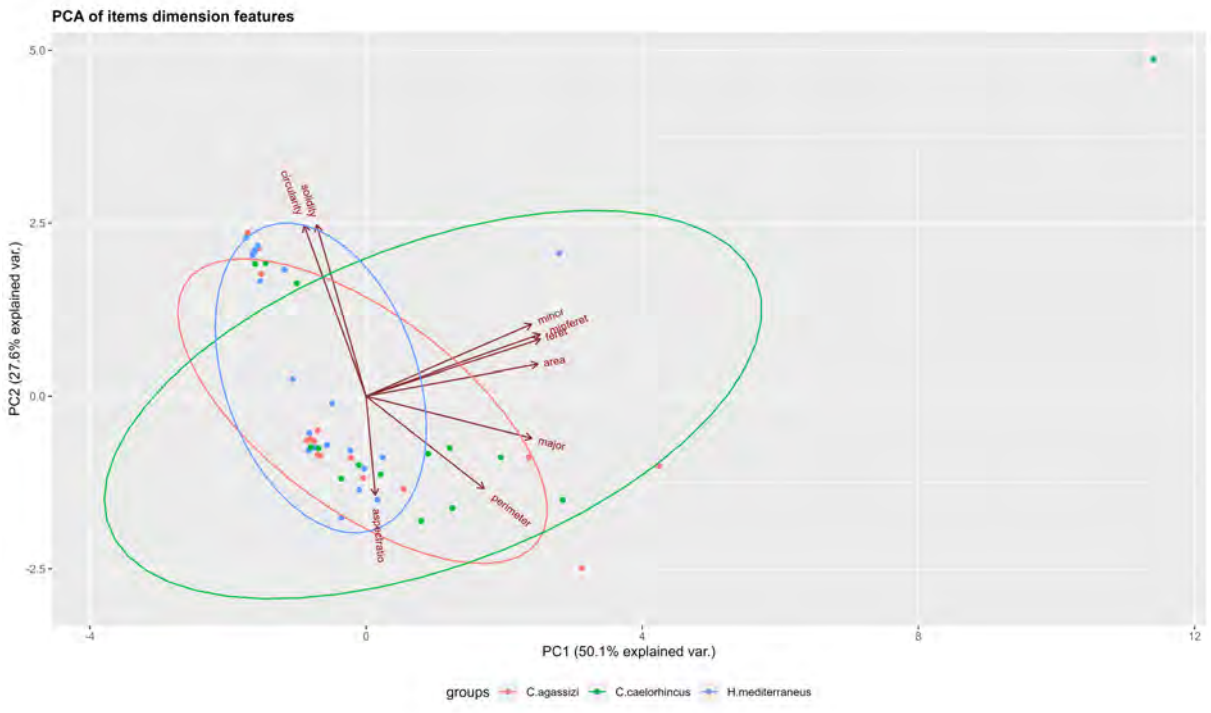

Figure 2: Principal Component analysis results.

Table 4: Differences between the two approaches

Topic	Traditional approach	Shape descriptors	Detected differences (TA/SD)
Amount of ingested MPs	number of ingested MPs	surface area of ingested MPs	N/Y
Shape of MPs	shape categories (i.e. fiber, film, foam, fragment)	aspect ratio, circularity, solidity	N/N
Size of MPs	size classes	perimeter, major, minor	N/Y

that MP ingestion by fish is widespread in deep-water habitats (Valente et al., 2019). Through a snapshot in time, our results highlight that MP ingestion rates show no remarkable differences according to the examined species, as previously highlighted in other marine compartments within the same area (Valente et al., 2022b). The use of the rate of ingestion and of the categorical variables of shape and color is not sufficient to discriminate the characteristics of the microplastics with respect to the species. However, differences among species emerge when considering the variety of ingested MP types using the quantitative shape descriptors. In particular, it was noted that *H. mediterraneus* ingesting smaller MPs than the other two species, and *C. caelorhincus* ingesting the highest diversity of MPs. The observed differences - likely due to the different feeding habits of the three species (Miller et al., 2020), show that the use of categorical variables to describe MPs limits the comprehension of the pathways that different MP types may follow through the marine food webs. According to our preliminary results, the characterization of MPs through shape descriptors could represent a simple way to translate categorical data into quantitative variables, avoiding the loss of information. In this view, a more detailed description of MPs could improve our knowledge about the diversity and distribution of MPs between and within environmental compartments. Although the shape cannot be redrawn from shape descriptors, these are sufficiently different to distinguish different shapes, allowing the clarification of the selection mechanisms that might

determine the uptake of these hazardous particles by marine organisms, such as size, circularity and solidity.

Abstract

The reduction of emissions of unpleasant odour generated by treatment plants is one of the most crucial aspects in air quality monitoring. In this context, the estimation of odour concentrations from a multiparameter sensors system is a very complex procedure and in the literature most of the studies have applied multilinear regression methods to assess odour concentration. In this paper, an Artificial Neural Network (ANN) has been performed to estimate the odour concentrations from emission sources and identify an estimation function of the odour concentrations, starting from data collected by a multi-parametric set of 10 sensors of gaseous compounds.

Keywords: Odour concentration, emission sources, multilayer perceptron

1. Introduction

In twenty-eight European Union (EU) countries, dangerous odour emissions are regulated through the Directive 2010/75/EU of the European Parliament and of the Council of 24 November 2010 on Industrial Emissions (the Industrial Emission Directive or IED). The IED establishes a general framework for determining limits, including odour limits for many industrial activities/processes intending to control odour emissions. The covered sectors include, for example, the energy industry, metals production and processing, waste management, chemical and mineral industry, and agriculture sectors such as animal production.

Olfactory pollution is one of the main reasons for citizens to complain about the environment since often it constitutes an important problem which negatively affects the quality of life (6). However, the monitoring and estimation of the odour emissions present complex aspects to deal, due to a) the nature of the phenomenon itself, which is the resulting of a mixture of numerous chemical substances, and b) the impossibility of carrying out continuous measurements of the odour concentration.

Many studies have been carried out to appreciate the odour concentration (1) and most of them were based on single or multilinear regression methods. However, more effort is still needed in this area. The most critical issue concerns the concrete difficult for a sensory system of acting to the olfactory stimulus with the same sensitivity as the human nose.

*The paper is one of results from the research project titled "Modelli intelligenti di correlazione per la valutazione dell'inquinamento olfattivo" (project code f3f76727) approved by the Regional Program "RIPARTI" of the Apulian Region.

On the basis of the above considerations, the present paper aims to illustrate the development of a multivariate statistical model which is able to estimate odour concentrations through the responses obtained from a multi-parametric system (IOMS - Instrumental Odour Monitoring System). An ANN will be properly implemented for the aim of the study and the main results will be discussed in the following sections.

2. The dataset

The analyzed data, which have been collected from a company specialized in environmental assistance and consultancy services for private and public enterprises, refer to the responses from 10 sensors of a multi-parametric system of odour monitoring. The sensor array is composed by 10 metal oxide semiconductors (MOS) used to detect the emitted volatile organic compounds (VOCs) at all the stages of the plants. These sensors reported in in Tab. 1 allow to detect specific odour compounds whose values are expressed in mA (milliamperes). The data set consists of 354 measurements for 10 sensors at several stages of various treatment plants and the response variable is the odour concentration of gaseous compounds, expressed in ou_E/m^3 (European odour unit per m^3), The analyzed dataset does not contain missing values.

Table 1: Sensors description

Label Sensor	Description
W2W	Are found in garlic and in crude oil. Causes extreme global warming and acid rain
W1S	A colourless gas with a pungent odour. Toxic to human and aquatic organisms.
W1C	Affect the skin, eyes, and respiratory tract. Used in the production of paints and rubber
W5S	Produced by biogenic sources such as plants and yeasts. Some are toxic, and all contribute to ozone.
W3C	A liquid that smells like gasoline and boils at 80 .
W6S	It is found in oil , human and animal waste, and sewage treatment. Used for producing chemicals
W5C	Produced from crude oil refinement. Causes headaches, dizziness, and even death.
W3S	A gas with important greenhouse gas properties. Fuel production and engines.
W1W	A compound gas with distinctive aromatic flavours like citrus. Prevent inflammatory diseases.
W2S	A poisonous gas. Originates from vehicle engines, waste burning and forest wildfires.

The exploration data analysis has been performed to detect the presence of possible extreme values (outliers) among the olfactometric measurements. Fig. 1 displays the box-plot for the distribution data before and after removing the outliers. The median absolute deviation (MAD) has been applied for removing outliers from the data set, which finally consists of 255 observations. Tab. 2 gives the descriptive statistics for the 10 sensors and the odour concentration. Sensors W1C, W3C, and W5C have registered the lowest mean values (0.76, 0.80, and 0.84, respectively), while sensors W1W and W2W the highest mean values (9.80 and 6.65, respectively). This very different behaviour of sensors could be attributed to their impact on odour concentration.

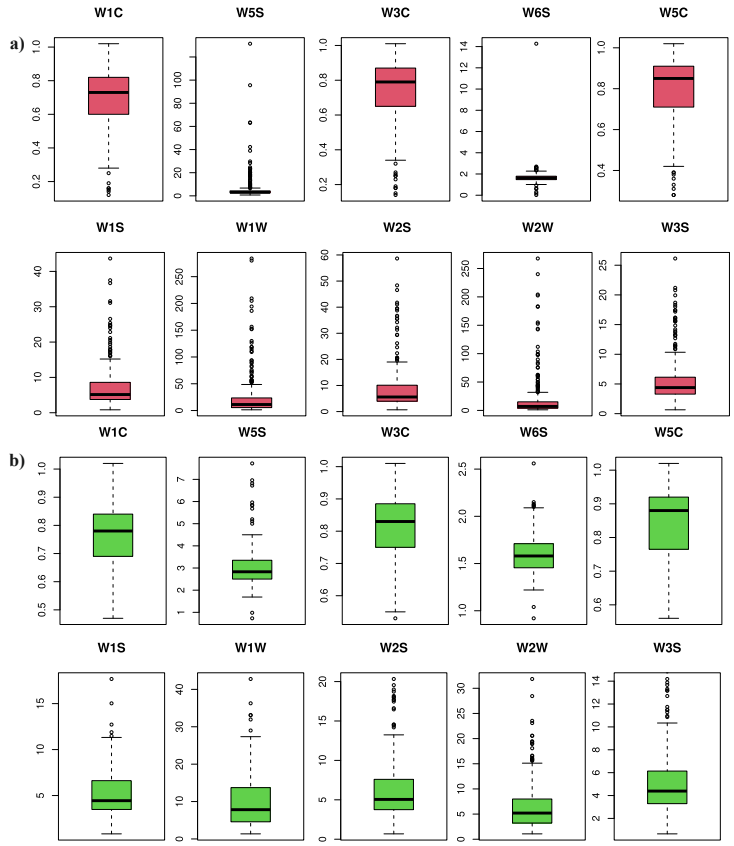

Figure 1: Box-plots of the distribution data related to the 10 sensors a) before removing the outliers, b) after removing the outliers.

Table 2: Descriptive statistics for the study variables

Variable	Minimum	Mean	Median	Maximum	Std. Dev.
Odour concentration	11	587	260	3153	707
W1C	0.47	0.76	0.78	1.02	0.10
W5S	0.73	3.03	2.83	7.72	0.92
W3C	0.53	0.80	0.83	1.01	0.10
W6S	0.92	1.59	1.58	2.56	0.20
W5C	0.56	0.84	0.88	1.02	0.10
W1S	0.83	5.30	4.44	17.68	2.66
W1W	1.36	9.80	7.83	42.78	6.92
W2S	0.68	6.38	5.05	20.33	3.91
W2W	1.07	6.65	5.20	31.85	4.87
W3S	0.65	4.51	4.01	14.19	2.13

2.1 MultiLayer Perceptron architecture

The MultiLayer Perceptron (MLP) is an ANN which is suitable to represent any smooth measurable functional relationship between the inputs (predictors) and the outputs (outcome). It is composed of at least three layers of neurons: the input layer that allocates the data in the network, the hidden layer(s) that processes the data and the output layer, namely the results extracted from specific inputs. The MLP could be represented as an Neural Simulation Language (3). Each hidden layer consists of nodes constructed by an activation function, which is used to transform summed input value of each neuron to its output value. In other words, the activation function is a function of input that the neuron receives, in order to convert the input signal on the node of ANN to an output signal.
The MLP architecture is characterized by its simple design and can be used for solving various classification and regression problems (2).
In the present research, the hyperbolic tangent activation function (3) has been adopted to develop the ANN-based model; this function has been chosen to accommodate the non linearity relationships between the input (sensors' data) and the output variable (odour concentrations).The information is processed within one single hidden layer (5) which enables the neural network to model non-linear relationships between parameters and provides a better generalization than a single-layer perceptron. In mathematical notation, it is given by:

$$m_t(x) = g(h_0 + \sum_{i=1}^{p} x_i h_{it}) \tag{1}$$

where $g(.)$ is the activation function, x_i is the input variable with $i = 1, \dots p$, h_{it} is the weight on $i - th$ variable at node t and h_0 is the bias value between each variable and the corresponding hidden node (t). This $m_t(x)$ value is simply the output of hidden node t. After choosing the number of hidden nodes in the hidden layer, the outcome value can be similarly defined as a linear combination of the nodes as follows (4):

$$f(x) = v_0 + \sum_{i=1}^{p} v_t m_t, \tag{2}$$

where v_0 is the bias value between the hidden node t and the output, v_t is the output of hidden node t, m_t is the network weights from node t, and $f(x)$ corresponds to the estimated outcome values. In an ANN, the parameters are updated to minimize or reduce the sum of the squared residuals. It should be noted that there is no guarantee to reach the global optimum solution (4).

3. Results and discussion

As previously mentioned, the observed data have been processed to predict odour concentration and define a possible relationship between odour concentration and olfactometric measurements, by using the ANN approach. In this context, two different layer structures have been proposed to estimate the odour concentration from the sensor array. The first layer structure is based on 10 input, 1 hidden and 1 output. The second layer structure is based on 10 input, 2 hidden and 1 output. To evaluate the quality of the trained neural network as well as to compare the two layer structures the following measures are considered: mean square error (MSE), root mean square error (RMSE), and mean absolute error (MAE). Three different options of partitioning the dataset into training, validation, and hold-out data have been used; in particular, the first option is based on 70%, 20%, 10%, and the second option on 80%, 10%, 10%, of respectively training, validation, and hold-out data. At each epoch both both the traning and the validation data are randomly selected from the original data set, and finally the hould out set is used to evaluate the performance of the ANN.

Results in Tab. 3 show that the architecture 10/1/1 (in details, 10 input variables, i.e. the sensors, 1 hidden layer and 1 output variable, the odour concentration) with data partition based on 70% for training data, 20% for validation and 10% for hold out data, is the best fitted model, with R^2 equals to 61.6%

which indicates that a large proportion of the variation in odour concentrations has been explained by the study sensors. In this latter case, the MSE is equal to 0.016, the RMSE 0.126 and MAE 0.019 which indicates a better fit in predicting odour concentration. Computational aspects associated to the proposed ANN architecture have been performed by using statistical software package SPSS neural networks version 25.

Table 3: ANN results by using the sensor array composed by 10 metal oxide semiconductors.

Data partition:70%; 20%; 10%	Architecture	MSE	RMSE	MAE	R^2
	10/1/1	0.016	0.126	0.019	0.616
	10/2/1	0.061	0.247	0.027	0.512
Data partition:80%; 10%; 10%	Architecture	MSE	RMSE	MAE	R^2
	10/1/1	0.019	0.138	0.021	0.612
	10/2/1	0.035	0.187	0.026	0.541

4. Conclusions

In this paper, the ANN was used to define an apt model to estimate odour concentration levels by using the responses from a multi-parametric sensors system. The obtained model was based on all the available sensors and, thanks to its accuracy level, allows the analyst to obtain reliable estimation of odour concentrations from the data recorded by the sensors. This study also showed the applicability of neural network by using a small dataset. Further developments of the research will be focused on the possible identification of a few number of sensors that most influence the odour concentration as well as to combine neural networks and tree based methods to improve the performance.

Acknowledgments The authors are grateful to Prof. Sandra De Iaco and Prof. Monica Palma from University of Salento, for their precious comments and suggestions.

Bayesian analysis of PM_{10} concentration by spatio-temporal ARIMA and STS models

Michela Frigeri[a] and Ilenia Epifani[a]

[a]Department of Mathematics, Politecnico di Milano, Milano, Italy;
michela.frigeri@polimi.it, ilenia.epifani@polimi.it

Abstract

Po Valley is well known to be one of the most polluted area in Italy, due to its population density, shape and climate. In this work we focus on Emilia Romagna region and analyse the panel data of its daily PM_{10} concentrations collected at 49 monitoring stations in 2018. We use different Bayesian spatio-temporal models. Specifically, we model the data time series following two popular techniques: structural time series (STS) and autoregressive integrated moving-average (ARIMA) process. Then in both cases we complement the model with some geographical and topographical covariates, a trigonometric seasonal component and a latent spatial Gaussian process. Based on the posterior inference made with the Stan software, the estimates of the effects of the station features on PM_{10} concentrations are robust with respect to the time trend modeling choice, but the STS strategy performs better than ARIMA process in fitting PM_{10} data.

Keywords: ARIMA, Bayesian inference, PM_{10}, spatio-temporal models, structural time series

1. Introduction and data description

Po Valley is a well-known hotspot for the *atmospheric particulate matter* (PM) (or fine dust) pollution in Europe (6). Many factors might be responsible: a high population density, along with a high level of urban and industrial areas are the main contributors to the high level of emissions (from vehicle exhaust, high number of industries, residential heating), while its geographic shape and climate prevent an adequate dispersion of the emitted pollutants. PM is characterized by its micrometre size: PM_{10} (less than 10 micrometre in diameter) to $PM_{2.5}$ (less than 2.5). Particulate matter is carefully monitored, because of its capability to reach the respiratory tract and hence have a significant effect on human health.

Given its relevance, in the environmental statistics literature there is a huge number of studies on the evolution and the prediction of PM_{10} concentrations for different areas around the world. As an example, we cite the review (8) of the statistical models (basically multiple linear regression, Bayesian autoregressive time series and discrete Markov chain model with finite state space of the pollutant concentrations) and machine learning methods (multilayer perceptron, artificial neural network) applied to PM_{10} concentrations prediction in Malaysia. In addition to the methods in (8), univariate and multivariate PM_{10} data were also modeled as Structural Time Series (STS) or as Auto-Regressive Integrated Moving-Average (ARIMA) processes, with or without spatial components, with or without covariates, in a frequentist or Bayesian framework; see for instance (4) for a rigorous review of the STS applied to air pollution data, (9) for a frequentist univariate ARIMA modeling without spatial component, and (5) for a Bayesian multivariate autoregressive spatio-temporal model. Finally, we refer to (7) for a general overview on Bayesian modeling of spatio-temporal data.

In this work, we analyse the multivariate time series of PM_{10} collected in Emilia Romagna in 2018, via fixed monitoring stations at 49 sites scattered across the region. As this data from multiple monitoring stations is intrinsically time-dependent and spatially-correlated between stations, we developed (and compared) two alternative Bayesian spatio-temporal models: in the first model the temporal process is of STS type and in the second is an ARIMA(p, d, q) process. In both cases we include some geographical and topographical covariates, a trigonometric specification of the seasonal component and a latent spatial Gaussian process with exponentiated quadratic covariance. Instead, (2) and (3) proposed a spatio-temporal Bayesian model for PM_{10} concentration in the Po Valley, where the temporal process is modelled via a harmonic regression model.

The dataset was gathered by the public environmental monitoring institution ARPA Emilia Romagna. Each of the 49 stations collects the concentration of many pollutants over time, such as nitrogen dioxide NO_2, benzene C_6H_6, ammonia NH_3 and PM_{10}, $PM_{2.5}$ particles. PM measurements are collected as daily averages and are always bounded from below by a *lower limit of detection*. Although PM_{10} concentrations were available starting from 2014, our analysis focused on data collected in 2018. We were motivated by the intention of creating a general model, whose predictive capabilities would not be hindered by post-Covid anomalies, or by considerable amounts of missing or unreliable data. Moreover, as environmental pollution data are known to display annual periodicity related to seasons, one year is conceptually enough to collect observations for all the relevant climatic conditions, albeit preventing further considerations on annual and interannual periodicity. The dataset also provides exogenous information on the 49 monitoring stations that cover multiple altitudinal levels, and have been chosen to represent different degrees of anthropic pollution and human activities. For each station, we have information on its position (lat–long coordinates) and altitude (in meters above sea level), its *type* which summarizes the main emission source to which the given station is exposed and which is coded as traffic, industrial or background, the *area* in which the station can be located, which expresses the level of urbanization of the surroundings (e.g. urban, suburban, rural) and its *zoning* which translates the specific geographic cores of the region and can be East plain, West plain, Agglomerate, Apennines mountain chain.

A preliminary exploratory data analysis for PM_{10} concentrations shows that rural areas tend to have a different behaviour over time and a lower overall PM_{10} concentration level. Additionally, nearly all stations exhibit a gradual decline in PM_{10} concentrations in the spring, followed by consistently low records in the summer, before measurements date back to the onset of the colder season. This type of time pattern is well described by a loose U-shape in the time series for almost all stations, and is in agreement with previous findings available in literature. The only six stations that do not have a visible U-shaped trend, but rather an inverse pattern, all belong to the Apennine zoning, and perhaps share some peculiar atmospheric characteristics. A more detailed exploratory analysis of the entire dataset can be found in (2).

2. Bayesian models

Bayesian STS and ARIMA models developed here for the log-transformed PM_{10} concentration data collected in Emilia Romagna share the following additive hierarchical structure:

$$\begin{aligned} Y_{i,t} &= f_i(t) + g_i(t) + \boldsymbol{x}_i'\boldsymbol{\beta} + w(\boldsymbol{s}_i) + \epsilon_{i,t} \\ \epsilon_{i,t} &\overset{\text{iid}}{\sim} \mathcal{N}(0, \sigma_\epsilon^2) \end{aligned} \tag{1}$$

where $Y_{i,t}$ is the $\ln PM_{10}$ concentration measurement at station $i = 1, \ldots, 49$ and day $t = 1, \ldots, 365$, $f_i(t)$ models the station-specific temporal trend function, $g_i(t)$ is the trigonometric adjustment for data seasonality, $\boldsymbol{x}_i$ provides both continuous and categorical station-specific regressors, $\{w(\boldsymbol{s}_i)\}_i$ are the spatial residuals modeled through a proper Gaussian process such that the spatial dependence is a function of the stations' coordinates $\{\boldsymbol{s}_i\}_i$, and the pure error terms $\{\epsilon_{i,t}\}_{i,t}$.

Likelihood and covariates As regard to the ARIMA(p, d, q) specification of the trend $f_i(t)$ of $\ln PM_{10}$, after a preliminary exploratory analysis of its sample autocorrelation and partial

autocorrelation functions separately for each station i, we chose $p = 2, d = 1, q = 1$ for all stations, and assumed different first and second order AR parameters for each station but a common parameter for the MA term. Hence we modelled $f_i(t)$ as follows:

$$f_i(t) = Y_{i,t-1} + \phi_{i,1}\Delta Y_{i,t-1} + \phi_{i2}\Delta Y_{i,t-2} + \theta\tau_{i,t-1} + \tau_{i,t} \quad i = 1, \ldots, 49 \quad t = 1, \ldots, 364 \tag{2}$$

where $\Delta Y_{i,t} = Y_{i,t} - Y_{i,t-1}$ and

$$\{\tau_{i,t}\}_{i,t} \overset{\text{iid}}{\sim} \mathcal{N}(0, \sigma_\tau^2) \tag{3}$$

are the error terms.
As regard to the STS choice of $f_i(t)$, following (4) we assumed an i-specific stochastic Markov trend $\mu_{i,t}$ given by:

$$\begin{aligned} f_i(t) &= \mu_{i,t} \\ \mu_{i,t+1} &= \mu_{i,t} + \xi_{i,t} \\ \xi_{i,t} &\overset{\text{ind}}{\sim} \mathcal{N}(0, \sigma_i^2) \end{aligned} \tag{4}$$

for $t = 1, \ldots, 365$, where $\xi_{i,t}$ is the level disturbance for the *i-th* station at day t; note that $\epsilon_{i,t}$ and $\xi_{i,t}$ are all assumed to be mutually independent.
In order to catch the different patterns of the PM_{10} annual trend, pointed out in the data description, we included the station-specific seasonality correction

$$g_i(t) = c_i \cos\Big(\frac{2\pi}{365}t\Big) \qquad i = 1, \ldots, 49 \tag{5}$$

As far as the regression component $\boldsymbol{x}_i'\boldsymbol{\beta}$, the regressors $\boldsymbol{x}_i$ of station i consist of:

- the station *altitude* expressed in meters and standardized,
- the station *zoning* that provides the part of Emilia Romagna the station is in (East plain, West plain, Agglomerate, Apennines),
- the station *type* (traffic, industrial, background),
- the station *area* (rural, urban, suburban).

Finally, for the spatial residuals $\{w(\boldsymbol{s}_i)\}_i$ in (1) we assumed a Gaussian process centered in zero with *exponentiated quadratic covariance* $\Sigma_{\sigma^2,\,\rho}$. Hence we have

$$\begin{aligned} (w(\boldsymbol{s}_1), \ldots, w(\boldsymbol{s}_{49})) &\sim \mathcal{N}(\mathbf{0}, \Sigma_{\sigma^2,\,\rho}) \\ \Sigma_{\sigma^2,\,\rho}(\boldsymbol{s}_i, \boldsymbol{s}_j) &= \sigma^2 \exp\Big\{-\frac{1}{2\rho^2}\|\boldsymbol{s}_i - \boldsymbol{s}_j\|^2\Big\} \end{aligned} \tag{6}$$

Further details can be found, for instance, in (7) and references therein.

Prior To complete the Bayesian models, we considered suitable marginal prior distributions for each parameter included in the spatial and temporal components of the likelihood, and we assumed independence between blocks of parameters.

We used a $\mathcal{N}(0, 1)$ prior for each component of the regression coefficients' vector $\boldsymbol{\beta}$ in (4) and for the cosine regression coefficients c_i's in (5). In this context the standard Gaussian prior turns out to be sufficiently vague, since $\ln PM_{10}$ ranges between 0 and 5 and all the covariates have been standardized. To avoid infinite variances, the variances σ_ϵ^2 of the pure errors $\epsilon_{i,t}$'s and σ_w^2 of $w(\boldsymbol{s}_i)$'s are all provided with $IG(3, 2)$ prior density. Finally, following (7), we fixed the spatial range parameter ρ equal to three times the inverse of the maximum distance (in km) between the available monitoring stations, obtaining $\rho = 0.05$ in (6); this choice is made to avoid well–known issues that prevent spatial models to be completely identifiable.

As regard the prior for $f_i(t)$, in order to properly share information across stations, in case of the ARIMA(2,1,1) model in (2)-(3), the prior scheme is

$$\begin{aligned}
\phi_{i,j}|\mu_{\phi_j}, \sigma^2_{\phi_j} &\sim \mathcal{N}(\mu_{\phi_j}, \sigma^2_{\phi_j}) && \text{for } j = 1, 2 \\
\mu_{\phi_j} &\sim \mathcal{N}(0, 5) && \text{for } j = 1, 2 \\
\sigma^2_{\phi_j} &\sim IG(2.1, 1.1) && \text{for } j = 1, 2 \\
\theta &\sim \mathcal{N}(0, 1), \\
\sigma^2_\tau &\sim \text{Half-Cauchy}(0, 5)
\end{aligned}$$

Instead, in case of the STS model in (4), each level disturbance $\xi_{i,t}$ is modeled as $\xi_{i,t} = \sigma_i \gamma_t$ with

$$\begin{aligned}
\gamma_t &\overset{\text{iid}}{\sim} \mathcal{N}(0, 1) \quad t = 1, \ldots, 365 \\
\sigma_i &\overset{\text{iid}}{\sim} \mathcal{U}_{(0,2)} \quad i = 1, \ldots, 49
\end{aligned}$$

As already discussed for the β priors, also in this case the chosen hyperparameters provide sufficiently vague distributions, with respect to the observed values of the response variable.

3. Model selection, estimation and prediction

We used Stan (1) for computing the posterior distribution of all parameters involved in the two models. In both cases, we run two parallel MCMC chains, assuming 1,000 burn-in iterations and 1,000 sampling iterations. We compared the two models using Widely Applicable Information Criterion (WAIC) and Leave One Out Cross Validation (LOO-CV). In addition we also computed the coverage (CVG) as the percentage of true data falling inside the 95% posterior credible intervals; we expect this value to be close to 0.95 in well specified models. From Table 1 we see that the lowest values of both predictive model selection criteria are achieved by the STS model, which seems to provide better results also in terms of coverage. However, the posterior estimates of the effects of the station features on PM_{10} concentrations are robust with respect to the competing time-trend models ARIMA and STS. In both models we can evaluate the presence of spatial correlation, supporting our choice to include a residual spatial term. Furthermore, analyzing the posterior 95% credible intervals of the regressors, only the altitude and traffic covariates appear to affect the concentration level of PM_{10}. In particular, as might be expected, higher altitudes are associated with a lower PM_{10} concentration, while the proximity to traffic areas increases the level of pollution. Finally, the effects of the other geographical and topographical factors are completely obscured by the relevance of the random spatial process $\{w(\boldsymbol{s}_i)\}_i$. A further meaningful finding concerns the posterior predictions of $\ln PM_{10}$ under the ARIMA(2,1,1) time-trend (in Figure 1 in blue) and under the STS model (in Figure 2 in blue), both compared with the real observed $\ln PM_{10}$ (in pink).

Table 1: Predictive model selection criteria and coverage percentage for ARIMA and STS models.

	ARIMA	STS
WAIC	16313.1	10846.8
LOO-CV	16320.7	10849.7
CVG	0.9482	0.9514

Due to space constraints, we only show the case of *Ceno* monitoring station. We see that the posterior STS estimated trend follows the data very closely, with also a lower uncertainty than the estimates under the ARIMA model. However we still need to overcome a poor mixing performance for the STS model, that is due to an identification problem involving $f_i(t)$, $g_i(t)$ and caused by the specification of multiple station-specific parameters.

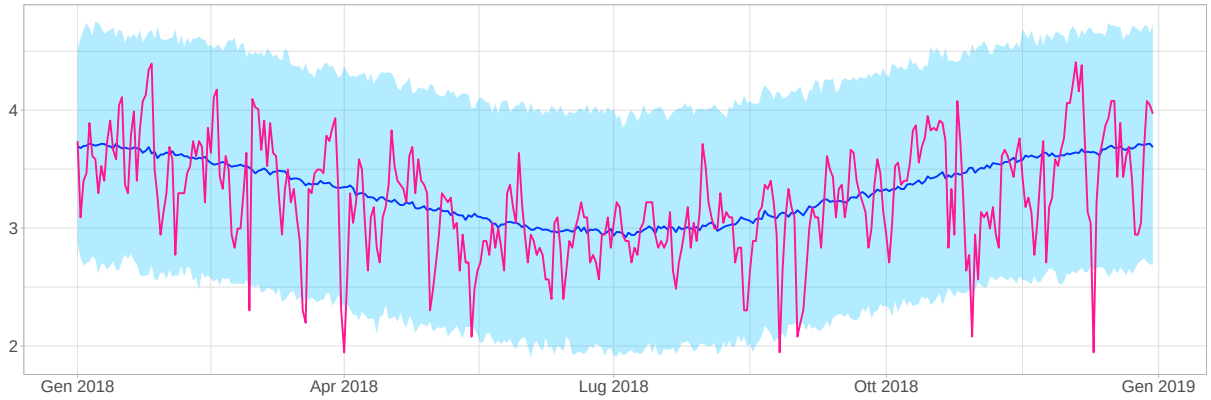

Figure 1: 95% credible intervals (light blue) and median (blue) of the posterior predictive distribution provided by ARIMA$(2, 1, 1)$ model for *Ceno* monitoring station. True recorded values are displayed in pink.

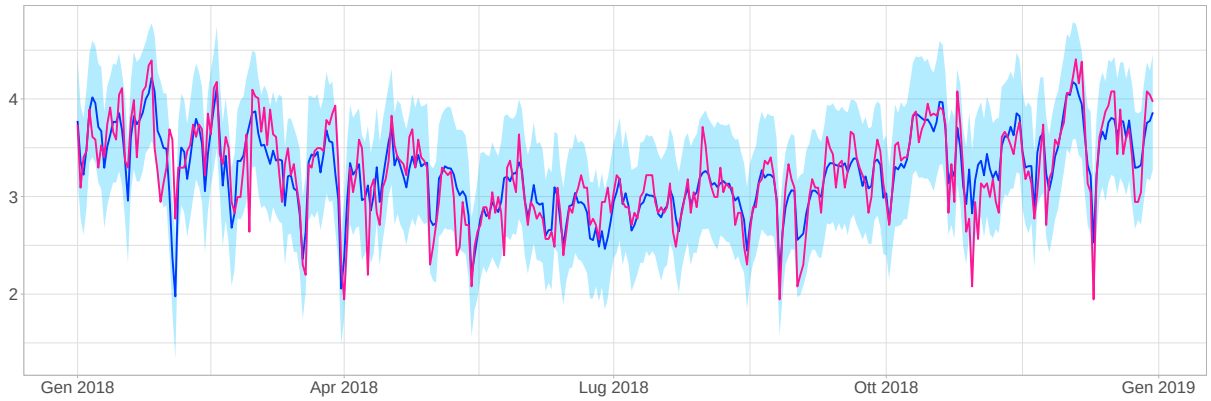

Figure 2: 95% credible intervals (light blue) and median (blue) of the posterior predictive distribution provided by STS model for *Ceno* monitoring station. True recorded values are displayed in pink.

Acknowledgments We would like to thank the students of the MSc course of Bayesian Statistics (MSc in Mathematical Engineering of Politecnico di Milano): Arrigoni F., Baracchi F., Cantalini C., Gjyli E., Ferrara S. and Ursino B. for the support in writing some code for posterior simulations.

Abstract

Temperature rises in marine habitats have been shown to have a variety of effects on biodiversity, such as algal blooms, altering biotic factors and disrupting life cycles. The aim of this study is to propose a Functional Analysis of Variance (FANOVA) to analyse the yearly sea temperature variations in the coastal zone of Abruzzo Region (Central Italy). Within this aim different FANOVA tests have been used to assess functional mean differences. FDA applied to marine temperature data found no evidence to reject similarity between temperature samples acquired at different depths, confirming the absence of temperature anomalies across the time period analysed.

Keywords: Temperature sea rising, Adriatic sea, FDA, Functional Analysis of Variance, Functional mean differences

1. Introduction

Over the last years, there has been an increasing interest in acquiring a broad knowledge about temperature behaviour in the Mediterranean sea which is crucial for ensuring a sustainable development and conservation of its marine environments. It is well documented that temperature changes affect marine communities in a variety of ways, both directly and indirectly (9). On one hand, the variations in sea temperature directly impact the physiology, growth, reproduction, recruitment and behavior of poikilothermic organisms, like fishes. On the other hand, sea temperature rising has also indirect effects that may be mediated by biota interactions or by marine currents. For instance, the recent bleaching and subsequent massive mortality of corals in all marine environments is the visible response of the marine biota to prolonged anomalous increase in sea temperature. According to a new study conducted by international scholars, the Mediterranean experienced five consecutive years of marine heatwaves and mass mortality events between 2015 and 2019 (3). Moving along these lines of research, this paper analyses sea temperature series measured at seven geographical locations along the coast of Abruzzo (Central Italy). Specifically, we are aimed to investigate if there are yearly anomalies in the Adriatic sea temperature data. We ask the question: "does the shape of the overall temperature profile over the studied period depend on which year we focus on? Is there any footprints of temperature rise in the sea water off Abruzzo?". In analysing the dynamics of sea temperature series, provided by the Regional Agency for the Environmental Protection of Abruzzo (ARTA), and adressing the question, we followed a Functional

Analysis Data approach.
Functional Data Analysis (7) is a branch of statistics working with observations that come from a continuous process that is evaluated at discrete points. Accordingly, FDA tools have been developed to analyse intrinsically infinite-dimensional data, usually measured discretely. Two ideas make FDA unique: it takes into account the domain correlation structure of the data and leads to a global view of the problem through curve analysis instead of individual observations, enlarging the possibilities of research. Over the last years, FDA has expanded to a wider number of scientific fields, including, among others, the environment (1), health and medical research (2), industrial processes (6), econometrics (5), all involving continuous time monitoring process. In our study, the FDA enables the complete analysis of depth spectrum, along which the sea temperatures were recorded. To be specific, we contrast the similarities between sea temperature samples obtained at different levels of depth over the studied period (2011-2020) by means of Functional Analysis of Variance (FANOVA). The remaining part of this paper is organized as follows. Section 2. describes the study region and the data. Section 3. presents the methodology applied in the statistical analysis. Section 4. provides with the results of FANOVA and some concluding remarks.

2. Region of study and data

In our work,we focus our attention on the Adriatic Sea, that is the articulation of the Mediterranean Sea that separates the Apennines Peninsula from the Balkan Peninsula and the Apennines from the Dinaric Alps. The Adriatic Sea has a land area of 138,595 km^2, a length of 738 km, an average width of 159.3 km, and a depth of 173 m. Our study area is the Abruzzo coast, which is enclosed between the Tronto and Trigno rivers and has a variable morphology due to the geological structure of the immediate hinterland. We exploited data collected by the Regional Agency for the Environmental Protection (ARTA), that over the last years, according to the agreement with the Abruzzo Region, carried out the monitoring activities of the marine-coastal environment. The monitoring network of Abruzzo's marine-coastal waters consists of fourteen stations identified for sampling different environmental matrices, distributed along seven transects perpendicular to the coast and placed at 500 and 3000 m (Fig.1). The data set used for the statistical analysis consists of eleven years (2011-2021) of monthly measurements of temperature acquired at different depth (up to 11 m) in the water columns, sampled in the stations that were at 3000 m offshore.

3. Functional Anova (FANOVA)

Before applying functional methods to determine whether sea temperatures differ significantly in various years, we need to transform the discrete sea data into smooth functions $y(t)$, measured at $t = 1, \ldots, T$. In functional data analysis, t typically represents a real-valued time variable, but in the current problem it denotes depth at which sea temperature was recorded; $y(t)$ is the smoothed sea temperature value. The smoothed functions $y(t)$ are obtained as a linear combination of independent basis functions ϕ_k, with coefficients, c_k, as:

$$y(t) = \sum_{k=1}^{K} c_k \phi_k(t). \tag{1}$$

The basis function can be chosen from a variety of options. In our case, cubic β-splines (piecewise polynomial of degree 3) is the most advisable choice as it combines fast computation capabilities and flexibility (10). To perform FANOVA, let us assume to have M independent samples $Y_{gj}(t), j = 1, \ldots, ng, \quad t \in [a, b]$, extracted from $\mathcal{L}^2(l)$ processes $Y_g(t), g = 1, \ldots, M$, and their mean function is $E(Y_g(t)) = m_g(t)$ (11). FANOVA, like vector analysis, compares the distance between the mean levels of the factor variables. The goal of this comparison is to determine whether the set of functions under consideration is statistically distinguishable. When the functional sample is classified in several groups,

Figure 1: Localization of the sampling stations of the Regional Network.

such as $\{\mathcal{Y}_j\mathcal{G}_j\}_{i=1}^n$, $\in \mathcal{F} \times \mathcal{G} = 1, \ldots, G$, where G is a discrete variable indicating the membership group, the null and alternative hypotheses can be specified as follows:

$$\begin{cases} H_0 : \bar{Y}_1(t) = \bar{Y}_2(t) = \ldots \bar{Y}_G(t) \\ H_1 : \exists \quad h, e \quad s.t. \bar{Y}_h(t) \neq \bar{Y}_e(t). \end{cases}$$

The model for $j-th$ observation in the $g-th$ group can be expressed as:

$$Y_{jg}(t) = \mu_t + \alpha_g(t) + \epsilon_{jg}(t) \tag{2}$$

where $Y_{jg}(t)$ is the functional value of temperature in the group g, $\alpha_g(t)$ is the effect of being part of a determined group and $\epsilon_{jg}(t)$ represents the unexplained variability for $j-th$ observation of group g. Adopting the matrix notation, the model in Equation 2 can be expressed as:

$$\boldsymbol{Y}(t) = \boldsymbol{Z}\gamma(t) + \boldsymbol{\epsilon}(t) \tag{3}$$

where $\boldsymbol{Y}(t)$ is a N-dimensional vector, $\gamma(t) = (\mu(t), \alpha_1(t), \ldots \alpha_M(t))^T$ a $(M+1)$ dimensional vector, $\boldsymbol{\epsilon}(t)$ a vector of N residual functions and $\boldsymbol{Z}$ the design matrix with dimension $(N, M+1)$. It is worth noting that each row of the matrix $\boldsymbol{Z}$ corresponds to a single observation; the first column consists entirely of 1 to represent the overall mean and M columns correspond to different groups, with value 1 if the observation belongs to the $g-th$ group and 0 otherwise. In order to assure the identifiability of the functional effects $\alpha_g(t)$, the sum to zero is introduced:

$$\sum_{g=2}^{M+1} \gamma(t) = 0 \quad \forall(t). \tag{4}$$

The parameter vector $\gamma(t)$ in Equation 3 can be estimated minimizing the standard least squares

$$LMSSE(\gamma) = \int [\boldsymbol{Y}(t) - \boldsymbol{Z}\gamma(t)]^T [\boldsymbol{Y}(t) - \boldsymbol{Z}\gamma(t)] d(t) \tag{5}$$

To compare the similarity of samples, a number of test statistics were proposed. For example, similar to the regular analysis of variance, one can compare between and within group variations:

$$Fn_t = \frac{SSR_n(t)/(M-1)}{SSE_n(t)/(n-Q)}$$

where

$$SSR_n(t) = \sum_{g=1}^{M} n_g(\bar{Y}_g(t) - \bar{Y}(t))^2$$

and

$$SSE_n(t) = \sum_{g=1}^{M}\sum_{j=1}^{n} g(\bar{Y}_g j(t) - \bar{Y}_g(t))^2$$

represents the variations between groups and within groups, respectively. As in classical ANOVA, a large $F_n(t)$ value indicates that the variance described by the model is greater than the variance not explained. The main difference between this method and traditional ANOVA (both univariate and multivariate) is that the value of $F_n(t)$ varies across the entire domain instead of being fixed. Note that, the classical significance level was designed to be used for a single hypothesis rather than a continuum of hypotheses. To overcome the possibility to have falsely claiming around the interval, a viable solution is to use the permutation test (7), which is the functional equivalent of the univariate F-test statistic. Additionally, in this work, we consider a permutation test, based on a representation of the base function, as described in (4), and Zhang and Liang's procedure to implement a global test, obtained via globalising the usual pointwise F-test (12).

4. Results and concluding remarks

A separate one-way FANOVA is run for each marine monitoring station to test the null hypothesis that there is no significant difference between the yearly mean group functions. All analyses were carried out in the R environment (8), using the R packages *fda* and *fdANOVA*. Table 1 summarizes the results of the permutation test based on basis representation (4) and the global point-wise F test (12). A permutation

Table 1: Results of FANOVA TESTS

	FP[a]		GPF[b]	
Monitoring stations	Test	p-value	Test	p-value
Alba Adriatica	0.385	0.960	0.387	0.963
Giulianova	0.514	0.866	0.515	0.889
Pineto	0.494	0.894	0.492	0.914
Pescara	0.407	0.949	0.405	0.955
Ortona	0.433	0.928	0.434	0.942
Vasto	0.255	0.986	0.257	0.992
San Salvo	0.337	0.959	0.339	0.977

Acronyms: [a]FP-permutation test based on basis function representation (FP); [b]GPF-global point-wise F-test.

method is used in both procedures to approximate the null distributions. Furthermore, cubic β-splines and the Bayesian Information Criterion (BIC) are considered for both tests. The statistical analysis performed using the FDA approach finds no significant differences between yearly sea thermal variations,

corroborating the hypothesis of not rejecting the similarity in all years for sea temperature data. We also obtained the same evidence using Ramsay and Silverman's (7) functional F statistic (Fig.2 and 3). FDA proved to be an effective tool for easily monitoring sea temperature changes across the entire depth spectrum analysed, contrasting the results inferred from a simplistic visual inspection of the data.

New perspectives in the measurement of biodiversity

Linda Altieri[a], Daniela Cocchi[a], and Massimo Ventrucci[a]

[a]Department of Statistical Sciences, University of Bologna; linda.altieri@unibo.it, daniela.cocchi@unibo.it, massimo.ventrucci@unibo.it

Abstract

Entropy is widely used in biodiversity studies, where data often present complex interactions. Difficulties arise in linking entropy to available covariates or data dependence structures, as all existing entropy estimators assume independence. We take a Bayesian model-based approach and focus on estimating the probabilities which compose an entropy index, accounting for data dependence. This way, the entropy estimate is not a single value, rather it becomes a curve or a two dimensional surface according to the data structure. We obtain an interpretable index of the latent biodiversity of a system.

Keywords: Shannon's entropy, entropy estimation, diversity indices, CAR models

1. Introduction

Biological diversity, or biodiversity, is the variety of life forms and is commonly used to replace long-established terms such as species diversity and species richness, both indicating the number of species represented in an ecological community. If a lot of individuals are present but they all belong to the same species, there is no biodiversity; if there are few individuals, but they belong to different species, biodiversity is high, and related indices should reflect this. Both environmental variability and continuous colonization and extinction of communities create natural variability of biodiversity in space and time. Studies on biological diversity are a fundamental part of every ecological survey, as biological diversity plays a crucial role in the delivery of a range of ecosystem services such as natural harvests, carbon sequestration, pollination and soil formation (3). At the same time, biodiversity is threatened by climate changes, over-harvesting, pollution, habitat loss and invasive species, all of which can be attributed, either directly or indirectly, to human activities. In 2002, the UN Convention on Biological Diversity set a target "to significantly reduce the rate of biodiversity loss" (http://www.cbd.int/2010-target/); widespread concern about habitat and species loss led the United Nations to declare 2010 as its International Year of Biodiversity. This has stimulated the development of many different research studies, which have produced a large set of diversity indices. One of the most popular ones is Shannon's entropy (10), a successful measure in many fields, able to synthesize several concepts in a single number: entropy, information, heterogeneity, surprise, contagion. The flexibility of such index and its ability to describe any kind of data, including categorical variables, motivate its diffusion across applied fields such as geography, ecology, biology and landscape studies. In particular, the traditional formula of Shannon's entropy has been widely used in ecological studies to measure the biodiversity of a system. In descriptive studies entropy and biodiversity are the same thing, while in the field of estimation entropy is not a synonym of the *observed* biodiversity, rather it describes the *latent* biodiversity of the system. When entropy is low, the two things coincide: one (or few) of the species probabilities is predominant, i.e. no matter how many individuals are present, they tend to belong to one (or few) species. Conversely,

when entropy is high, species probabilities are more evenly distributed, therefore individuals in the area may belong to any of the considered species. When we have very few observations, like 1 o 0, it means that for that specific dataset and in that specific moment the *observed* biodiversity is low, but, *potentially*, new individuals may belong to any species: for example, if animals move from a neighboring site, or if a dependence between species and an environmental covariate is established. The idea should be not just to observe data, but to capture what may happen according to the underlying process behavior.

Typically, the amount of data for different species depends on environmental covariates, spatial location, temporal structures. The main drawback of Shannon's entropy in its traditional form is that it cannot account for such auxiliary information or data dependence. The inclusion of spatial information has been the target of intensive research (2; 5; 1), but there is no study on entropy measures for data with spatial correlation that takes the issue of estimation into account. When the goal is to estimate the biodiversity of a system based on data, the standard approach relies on the Maximum Likelihood (ML) estimator, which substitutes the unknown probability distribution of interest with relative frequencies and performs well when independence is an acceptable assumption. The most popular proposals consist of corrections of the ML estimator bias, e.g., the Miller-Madow correction, the Bayesian Nemenman, Shafee and Bialek estimator (7), or machine learning methods. Two main limits concern entropy estimation. Firstly, the literature only focuses on correcting or improving the performance of the ML estimator regarding the estimator bias. Secondly, independence among realizations is always assumed and no auxiliary information is considered. To our knowledge, no study faces the task of estimating entropy for data presenting dependence on available covariates, spatial/temporal association or other types of dependence. Recently, scientists have shown interest in how data structures are related to entropy; for example, ecological studies attempt at finding a relationship between quantities, such as species abundance and richness, and environmental factors or temporal/spatial effects, with a regression or mixed model approach. Such methods fail to detect any relevant association: they cannot account for absent species and for the possibility that species are not the same across observation sites, moreover, abundance, richness and entropy all depend on the occurrence probabilities of each species. Research would benefit from a focus between probabilities themselves and covariates or effects. Failing to consider data in neighbouring areas (or time points) produces a set of local entropy values, which is usually non-informative and difficult to interpret. Gelfand (4) reviewed recent literature on the distribution of species, and states "the ecology world recognized the need to incorporate spatial dependence in describing presence or abundance at a site. Joint species distribution models are replacing marginal models with a rapidly growing literature, but very little of it is spatial, despite the evident dependence within a site as well as the anticipated dependence across sites. In fact, this path offers an opportunity for future research". The mentioned issues are addressed by our proposal in the present paper.

The main aim of this paper is to present a new, model-based approach for entropy estimation. We take a new perspective that moves the focus from the index itself to its components. If the probability mass function (pmf) of the variable of interest can be properly estimated and any dependence on covariates or spatial/temporal factors can be assessed, such information can be used to enrich an entropy estimator. In the case of categorical variables, where probabilities can be described by a multinomial distribution, the crucial point is to estimate its parameters. A Bayesian model-based approach allows to derive such distribution and can be extended to account for dependence on covariates and/or correlation across realizations. It also exploits the information about the abundance of each category (species) and avoids reducing data to presence/absence with related issues raised by Gelfand (4). After obtaining a posterior distribution for all parameters, the posterior distribution of entropy is straightforward, since the entropy formula only depends on the probabilities. The entropy estimator can be, e.g., the distribution mean; credibility intervals and other syntheses may be obtained via standard tools of Bayesian inference. This approach can be used for any setting, including spatial and/or temporal data, with or without auxiliary information and independence assumptions. In the spatial context, coherently with standard procedures for variables linked to areal and point data, the estimation output is a spatial surface for the entropy over the area under study; for time series, the estimate can be represented by a curve. Curves and surfaces derived including dependence structures take into account the (spatial or temporal) neigbourhood of each observation point, smooth out any random variation in the data and allow to grasp the general behaviour of entropy. When wished, results can be further synthesized in a global entropy value

for the whole dataset, that is well-grounded as it is built out of consideration of data structures and not only relative frequencies. We underline the ability of our estimation approach to draw conclusion on the data at hand and on the relationship between entropy and any covariate or underlying structure.

When biodiversity studies involve an observation area, spatial data may be areal, geostatistical or point process data, and our approach works for any of these types. With point process data, the most common option is to discretize space with a very fine grid. The approximated model is known to converge to the true process (6) and results are very accurate in most applications. We show a case study with the gridding approach, which is usually a satisfying trade-off between complexity and accuracy of the results. A practical advantage of the gridding approach is that it may overcome the issues of spatial misalignment with the resolution of the available covariates. An extension to models in continuous space is possible in our approach, by exploiting the Stochastic Partial Differential Equation (SPDE) approach, available with INLA (Integrated Nested Laplace Approximation, (8)).

2. Model-based entropy estimation

Let X be a categorical variable of interest with I categories (species). Shannon's entropy of X is:

$$H(X) = \sum_{i=1}^{I} p(x_i) \log \frac{1}{p(x_i)}, \tag{1}$$

where $p(x_i)$ is the probability of occurrence of the i-th category, while $\boldsymbol{p}_X = (p(x_1), \ldots, p(x_I))'$ is the probability mass function of X. Entropy ranges in $[0, \log I]$, where 0 is obtained when $p(x_{i^*}) = 1$ for some category i^* and $p(x_i) = 0$ for $i \neq i^*$, and $\log I$ derives from $p(x_i) = 1/I$ for all i. Under the perspective of estimation, a stochastic process is assumed to generate the data according to an unknown probability function and, consequently, an unknown entropy. One realization of the process is observed and employed to estimate such entropy. We take a model-based approach for the estimation of the main components of an entropy index, i.e. $p(x_i)$ for $i = 1, \ldots, I$.

Conditional auto regressive (CAR) models (8) provide a way of including spatial or temporal correlation, by explaining a response via temporally or spatially structured random effects, and are usually defined for binary variables. When the number of species I is greater than 2, an extension to the multinomial logit model arises naturally and modes becomes more complicated. For each observation point $u = 1, \ldots, n$ we have $n_{u1}, \ldots, n_{uI}$, the number of individuals of each species at site u, that may be equal or greater than 0, and we use them as a starting point to estimate $p_{u1}, \ldots, p_{uI}$, with $\sum_{i=1}^{I} p_{ui} = 1$; to ensure that all probabilities are proper, we model them as $p_{ui} = \exp\{g_{ui}\} / \sum_{i=1}^{I} \exp\{g_{ui}\}$, with:

$$g_{ui} = \boldsymbol{z}_{ui}^{'} \boldsymbol{\beta}_i + \phi_u \tag{2}$$

where $\boldsymbol{z}_{ui}^{'} \boldsymbol{\beta}_i$ is the vector of fixed effects associated to the u-th location and i-th species. The vector $\boldsymbol{\phi} = (\phi_1, \ldots, \phi_n)' \sim MVN_n(\mathbf{0}, \boldsymbol{\Sigma})$ is a spatial effect with a structured covariance matrix $\boldsymbol{\Sigma} = [\tau(\boldsymbol{D} - \rho \boldsymbol{A})]^{-1}$, which depends on a precision parameter τ and a dependence parameter $\rho \in [-1, 1]$ quantifying the strength and type of the correlation between neighbouring units. The symbol $\boldsymbol{A}$ denotes the adjacency matrix reflecting the neighbourhood structure, and $\boldsymbol{D}$ is a diagonal matrix, where each element contains the row sums of $\boldsymbol{A}$. By tuning the structure of $\boldsymbol{A}$, different types of dependence in one or two dimensions may be included in the model. Fitting a multinomial model may be very complicated in practice: the presence of the denominator in (2) makes the likelihood problematic. We propose to exploit the Multinomial-Poisson transform, which turns the multinomial likelihood into a Poisson likelihood with extra parameters. It is established that the likelihood kernel of the transform is proportional to the multinomial likelihood kernel, so that the transfom returns the same estimates and asymptotic variances as the original distribution. Computational details on how to implement the multinomial-Poisson transform are given in (9). To model temporal random effects, we apply popular types of Intrinsic Gaussian Markov Random Field (IGMRF), namely the first and second-order Random Walk models RW1 and RW2 (8). To include spatial correlation, the simplest way of representing a neighbourhood system

is via $\boldsymbol{A} = \{a_{uu'}\}_{u,u'=1,\ldots,n}$, a square $n \times n$ matrix such that $a_{uu'} = 1$ when unit u and unit u' are neighbours, and $a_{uu'} = 0$ otherwise. The standard Intrinsic CAR model has been modified to include 12 nearest neighbours for grid data, i.e. two consequent pixels along each cardinal direction plus the four ones along the diagonals, and has recently become of standard use thanks to its implementation in INLA under the name of RW2d effect (8).

Once the probabilities are estimated for each category and observation, an estimate for the entropy is obtained in a deterministic way, using formula (1). Entropy is a function of the probabilities that returns values in $[0, \log I]$; therefore, the posterior of the estimated entropy $\widehat{H}$ is 1-dimensional. Usually, results are delivered using a point estimator, which in our case is:

$$\widehat{H}_u^{BMB}(X) = \sum_{i=1}^{I} \widehat{p}_{ui}^{BMB} \log \frac{1}{\widehat{p}_{ui}^{BMB}} \tag{3}$$

where BMB stands for Bayesian Model Based estimator, and $\widehat{p}_{ui}^{BMB}$ is the posterior mean derived by simulating from the posterior distribution; a credibility interval at any level may be obtained and associated to the estimator value to give an idea of the estimate uncertainty. By taking this approach to estimation, the entropy estimate $\widehat{H}_u^{BMB}(X)$ varies with u when data present some type of dependence structure. By plotting $\widehat{H}_u^{BMB}(X)$, we obtain a curve for continuous covariates or temporal dependence, or a two-dimensional surface for georeferenced data.

Two main improvements must be highlighted with respect to a local (observation-specific) computation of any literature estimator. Firstly, with our approach, estimates can be computed even when very few observations of X (even 1 or none) are available for each observation point/site. Secondly, when random effects are included, estimates take the neighbourhood into account (according to the specific dependence structure) and we obtain smooth curves/surfaces that catch the main behaviour of the data under study and remove the noise. Even when the model only includes covariates, the whole dataset is exploited to estimate the fixed effect coefficients and returns more reliable results. With this method, the resulting entropy curve/surface exploits the maximum amount of information for producing results. Moreover, by looking at the chosen model and at the values for the estimated parameters, we can infer the relationship between entropy and, say, environmental covariates, spatial coordinates and/or time effects.

3. A biodiversity case study

Our motivating dataset documents the presence of tree species over Barro Colorado Island, Panama. The considered dataset is a marked point pattern with $n = 5639$ trees over a rectangular window of

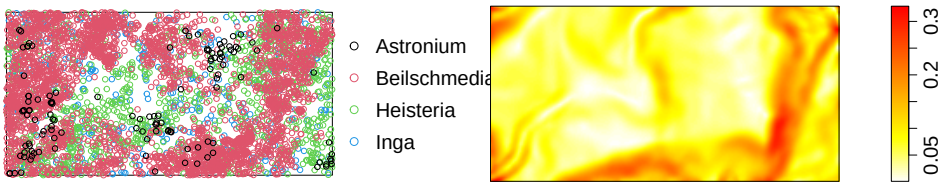

Figure 1: Rainforest tree data and covariate slope

$500000m^2$. The four species are $x_1 =$ *Inga sapindoides*, $x_2 =$ *Heisteria concinna*, $x_3 =$ *Beilschmiedia pendula*, $x_4 =$ *Astronium graveolens*, with $n_1 = 487$, $n_2 = 1141$, $n_3 = 3887$, $n_4 = 124$. Data is shown in Figure 1 together with an environmental covariate which measures the slope of the terrain. It is plausible that the slope somehow affects the growth of trees over the area as regards both richness and abundance, and thus influences the biodiversity of the system. In order to evaluate the biodiversity of the system, we partition the area into 50×100 cells of size 10×10 metres, each containing from 0 to 40 trees. Each cell is considered as one observation site u, and its spatial location is represented by the

centroid's coordinates. For each cell, we know the average values of the slope covariate and the counts of all species: our multinomial response variable is a table of 5000×4 counts.

We fitted the most general model together with all possible sub-models and selected the best one for entropy estimation using the Widely Applicable Information Criterion (WAIC) returned by INLA. The selected model includes covariate slope z and a RW2d spatial effect applied to species 2, i.e. *Beilschmedia Pendula*, for model identifiability: $g_{ui} = \beta_{0i} + \beta_{1i} z_u + I(i = 2)\phi_u$. Based on such model we can derive, for each species, a smooth surface estimating its probability of occurrence over the observation area, and the final surface for the estimated entropy, which is displayed in the left panel of Figure 2. We can conclude that the biodiversity of the rainforest tree system depends on the soil slope, whose effect is significant on 3 of the 4 species. Indeed, *Astronium* trees tend to grow over flat areas, while *Beilschmiedia* and *Heisteria* trees tend to follow the pattern of the steepest areas (Figure 1). Moreover, entropy also shows an underlying spatial structure, whose effect particularly affects species *Beilschmiedia pendula*. By looking at Figure 2, one can detect the cold- and hot-spots as regards the latent biodiversity level. Note that the estimation procedure deals with areas with few or zero trees with no issues, thanks to the exploitation of a model that accounts for neighbouring sites.

All literature entropy estimators start from the estimated probability distribution based on relative frequencies, which is $\widehat{p}_X^{ML} = (0.087, 0.202, 0.689, 0.022)$. Data frequencies are the only needed information; covariates and spatial locations are discarded. In relative terms, the literature ML estimate corresponds to 63% of the maximum possible entropy ($\log 4$). Such value shows a low biodiversity level, which hints at an underlying structure in the data. Unfortunately, nothing more can be said with the literature estimators. In order to make a local comparison, we are forced to choose a rougher grid in order to have enough data per observation site to compute local relative frequencies. For all cells with 1 tree, the ML local entropy value degenerates to zero; for cells with no trees, no ML entropy value can be computed. The local ML estimate is in the right panel of Figure 2, presented in relative terms, i.e. ranging in $[0, 1]$ for comparability purposes. As can be seen, many cells are empty, and the remaining ones look like white noise and allow no conclusions on the behaviour of the biodiversity of the area. One can see that in some parts of the plot the two estimation approaches provide very similar results, for example the "cold spots"(light blue areas) are placed at similar locations, despite the noisy aspect of the ML estimate. A cold spot means low entropy, i.e. low biodiversity. The high entropy areas identified by our model are high *latent* biodiversity areas, according to the structure of the environmental covariate and of the spatial effect.

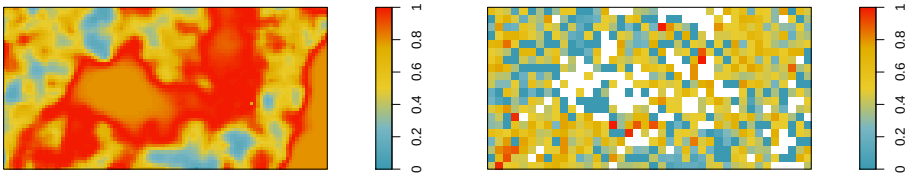

Figure 2: BMB entropy estimator (left); local ML entropy estimator (right)

4. Concluding remarks

The present work proposes a novel approach for entropy estimation suitable for ecological and environmental data, where independence is an unrealistic assumption. We highlight some key novel contributions to the field of biodiversity studies. First, our proposal relates entropy to covariates and/or data dependence structures, exploiting all the available information. Second, it allows to include information about local abundance and which species are present/absent at each observation point and at neighbouring points, by using multinomial data instead of presence/absence. Third, it uses INLA instead of MCMC (Markov Chain Monte Carlo) for estimation, overcoming many computational issues, and allows for extensions to continuous space if wished. In addition, we underline the ability of our estimation approach

to draw conclusions on the latent biodiversity of the system over a variety of situations, to check assumptions, select the most suitable model and evaluate the estimation uncertainty. We also show that it easily deals with empty, or nearly empty, observation points, thanks to the exploitation of a model structure. When wished, results can be further synthesized in a global entropy value for the whole dataset, that is well-grounded as it is built out of consideration of the data structures and not only of relative frequencies.

As for the rainforest tree species, we are able to find a relationship between biodiversity and the significant covariate describing the terrain slope. A smooth spatial effect is included in the model, so that our estimation result is an entropy surface that captures the biodiversity of the system, and where cold- and hot-spots in terms of tree species latent biodiversity can be easily identified. In comparison, we highlight the limit of producing a single number with no interpretation with the available methods, and the difficulties in obtaining a locally varying entropy surface.

Abstract

Genetic biomarkers are believed to be crucial in predicting the development of side effects of radiotherapy in cancer patients, and their inclusion in risk models may substantially improve personalized treatment planning. Feature selection is fundamental in genomic studies because of the high dimensionality of the data, but it is hindered by several complexities such as unbalanced classes, imputation and noise in genomic data collection, and the presence of high-order interactions among genes influencing the development of toxicities. In this study, we propose an interpretable feature selection of the most discriminant genetic variants via an ensemble of anomaly detection autoencoders designed to overcome these challenges. The model properties were studied in a simulation setting, and the method was applied to a case study.

Keywords: Radiogenomics, late toxicity, anomaly detection autoencoder, denoising.

1. Introduction

Thanks to treatments, such as radiotherapy, the survival of patients diagnosed with cancer is increasing. However, approximately 5% of the patients receiving radiotherapy are particularly sensitive to irradiation and are likely to develop long-term side effects (2). These can occur years after radiotherapy, impairing their quality of life. Our work was developed within a large international study, namely RADprecise (2), aimed at personalizing radiotherapy treatment for cancer patients by improving prediction models for radiosensitivity (2). Radiosensitivity is a latent outcome, and it is only inferred through measurements of various types of Late Toxicities (LTs) quantified according to the Common Terminology Criteria for Adverse Events. Traditionally, physicians base treatment decisions on model-based risk

estimates known as Normal Tissue Complication Probabilities (NTCPs). Specifically, NTCPs model the risk of radiation-induced complications in terms of the radiation dose and partial volume irradiated. In recent years, the set of predictors has expanded to include clinical information and biomarkers, such as genetic variations, crucial for predicting LT development (1). A patient's genetic predisposition to a disease can be summarized in a Polygenic Risk Score (PRS). It is usually computed as the score associated with each patient by a predictive model that links the risk of developing LTs to the presence of associated genetic mutations in the patient's DNA. Its inclusion into wider risk prediction models may substantially improve personalized treatment planning.

In general, as with any other classification model, PRS models perform best when fed with highly influential features with discriminant properties for class separability. Moreover, feature selection (FS) is fundamental in genomic studies since variables are many and highly correlated and the curse of dimensionality plays an important role. Indeed, the present work focuses on the task of FS for genetic data. In the peculiar setting of genetic studies, proper FS is hindered by several endogenous and exogenous data complexities: high-dimensional genetic data are usually available for small samples; the study of rare phenotypical traits (such as LT) mostly determines unbalanced settings with very low case-control ratios, that may violate asymptotic assumptions of statistical inference. Additionally, several raw genetic features are not directly measured but estimated via imputation methods to achieve completeness in genetic information. Genetic variations are measured as categorical data representing the absence, or the type of mutation with DNA array-based approaches. However, this process can only be applied to a limited number of genetic variations. Imputation methods estimate genotype probabilities at variants not genotyped thanks to reference populations of more densely typed individuals and introduce genotypic uncertainty and noise in the analysis. Moreover, the latest radiogenic studies on late-toxicity radiotherapy revealed the biological relevance of gene-gene interactions in affecting polygenic susceptibility to common human diseases (1). This introduces another source of complexity: FS methods need to account for the potential predictive power of such interactions during selection. However, traditional FS techniques usually only consider the main effect of covariates when performing the selection, and become suboptimal when the high-order interactions are significant.

Some of the above-mentioned complexities were recently addressed in (3; 4), where the authors developed a Deep Sparse AutoEncoder Ensemble (DSAEE) method for unbalanced data. In brief, the DSAEE FS method exploits Deep Sparse AutoEncoders as weak learners. AutoEncoders are trained to learn the normal patterns in the majority class observations and tested on both the majority and minority class data. The reconstruction of the minority class is expected to be less efficient and the most discriminant features should present the highest reconstruction error difference in the two classes (4). The algorithm ranks feature importance based on the Reconstruction Error difference in the minority and majority class, within the test set, and selects those whose difference is above the predefined threshold. The FS method in (4) presents three major benefits: the ability to deal with heavy class imbalance, interaction-aware selection, and interpretability of the selection method. Notably, the genetic features selected by their DSAEE are subsequently included in an interaction-aware method for polygenic risk scoring (PRSi) (1). However, this effective algorithm does not account for possible noise in the genomic features, considering exclusively imputed continuous data. The main contribution of this study is the improvement of the DSAEE method to achieve robustness to imputation errors and enable an unbiased analysis in genomic studies.

2. Anomaly detection autoencoders for feature selection with imputed data

An AutoEncoder (AE) is a neural network trained to copy its input to its output. Mimicking the identity function, the AE learns an encoded version of the data compressing and aggregating information in input, in the best way for the network to reconstruct the original information from the latent representation. Let the matrix $\mathbf{X} \in R^{NxJ}$ be the set of N training vectors $\underline{x}_i$ characterized by J features. The network can be seen as constituted by two parts: an encoder and a decoder. The encoder maps each input

vector $\underline{x}_i$ into an encoded version of itself (i.e. a latent representation), usually in a low dimensional space of size H, with a function that can be represented as: $\underline{h}_i = f(\mathbf{W}\underline{x}_i + \underline{b})$. Here f is the activation function, usually nonlinear, $\mathbf{W} \in R^{HxJ}$ is the weight matrix and $\underline{b}$ is a H-dimensional bias vector. The decoder maps back the latent representation vector to the original J-dimensional space with a function that can be represented as $\overline{\underline{x}}_i = g(\mathbf{W}'\underline{h}_i + \underline{b}')$. The parameters are defined analogously with $\mathbf{W}' \in R^{JxH}$ and $\underline{b}' \in R^J$. An AE can then be defined as a map $\phi(\underline{x}_i) : R^J \rightarrow R^J$

$$\phi(\underline{x}_i) = g(\mathbf{W}' f(\mathbf{W}\underline{x}_i + \underline{b}) + \underline{b}') \ , \tag{1}$$

and the parameters are optimized so that the reconstruction: $\overline{\underline{x}}_i = \phi(\underline{x}_i)$ is as close as possible, considering some loss $L(\underline{x}, \overline{\underline{x}})$, to $\underline{x}_i$. AEs typically do not provide exact reconstruction since $H <<< J$ but the latent representation is expected to be meaningful and a compact representation of the input (4). Better results can be achieved using constraints that force autoencoders to learn effective representations of such input in the latent space. In a Deep Sparse AutoEncoder (DSAE), the L_1 penalization is applied on $h(l)$, the function generating the latent representation, forcing the model to represent the input in the simplest way and incrementing generalization proprieties of the model.

$$L^S(\underline{x}_i, \phi(\underline{x}_i)) = L(\underline{x}_i, \phi(\underline{x}_i)) + \lambda |h(l)| \ , \tag{2}$$

The parameter λ is usually optimized through grid search.

AEs are used for learning data representations, dimensionality reduction, and anomaly detection. An anomaly is a data point that is significantly different from the remaining data and arouses suspicion that it is generated by a different mechanism. One-class detection AEs are autoencoder-based anomaly-detection methods that exploit the reconstruction error as an anomaly score. In this case, an AE is trained exclusively on normal observations so that it reconstructs normal data very well while failing to do so with anomalous data that has not been encountered in training. Data points with high losses are considered to be anomalies. Our methodology, as the one presented in (3; 4), mimics AutoEncoders' usage in anomaly detection to perform FS.

We considered a binary supervised learning setup with an available set of N (input, target) pairs

$$\tilde{\mathbf{D}} = \{(\underline{\tilde{x}}_1, Y_1), ..., (\underline{\tilde{x}}_N, Y_N)\} = (\tilde{\mathbf{X}}, Y)$$

where Y_i is the endpoint that takes values in $\{0, 1\}$ and $\underline{\tilde{x}}_i \in R^J$ with $i = 1, ..., N$ is the input feature vector of imputed data or, in general, noisy data. Suppose that $\underline{x}_i$ true categorical feature vector is known for each sample present in the training set and that a fixed number of M categories is available for each feature. Therefore a second dataset is available with N (input, target) pairs

$$\mathbf{D} = \{(\underline{x}_1, Y_1), ..., (\underline{x}_N, Y_N)\} = (\mathbf{X}, Y)$$

where $\underline{x}_i \in \{1, ..., M\}^J$ with $i = 1, ..., N$ is the input feature vector of categorical data. In addition, suppose that imbalance in the classes is present, with a minority class $Y = 1$ (case class), whose numerosity will be referred to in the following as O, and a majority class $Y = 0$ (control class). Our full pipeline is illustrated in Figure 1.

The rationale of the denoising DSAEE follows in general the one presented in (3; 4) with the intention of including imputation noise in the reconstruction process. The idea behind the method is to exploit Denoising Autoencoder (DAE) to provide a customized denoising algorithm suited to our data. A DAE is a modification of the autoencoder to improve its generalization ability. Specifically, AEs are highly parametrized models and prompt to overfitting, especially in low sample settings, with the risk of generating a meaningless representation in the latent space. Denoising autoencoders solve this problem by corrupting the input data on purpose, adding noise or masking some of the input values, and forcing the network to reconstruct noise-free versions of their inputs.

In our methodology, we introduced a 'Denoising' version of the Deep Sparse Autoencoders to restore imputed noisy input data to their categorical correspondence under the hypothesis that, as autoencoders

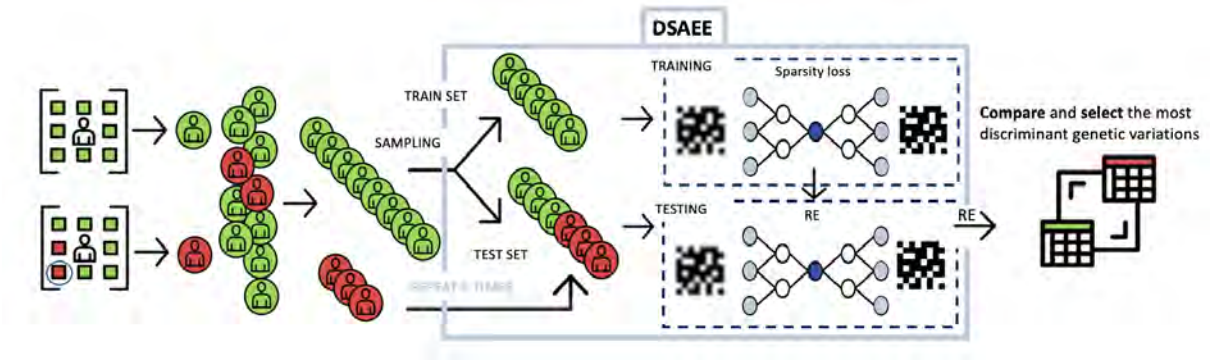

Figure 1: **Illustration of the developed methodlogy.** The method is based on an ensemble of Deep Sparse Autoencoders. In each ensemble iteration, the test set is constructed including all the minority class patients with a random sample of the same size from the majority class. The remaining observations of the majority class are included in the training set. The autoencoders are trained to optimally reconstruct the majority class and tested on a mixed population. Each reconstructs the continuous input into a categorical output so that the possible error due to imputed data is accounted for in the comparison. The most discriminant features are selected as those that present reconstruction error differences in the two classes.

are able to reconstruct corrupted input error, distinguishing between imposed noise and the underlying signal, similarly it is possible to force them to distinguish the true genomic signal from the random imputation noise.

At each iteration, once the train and test sets are defined, the network's weights and reconstruction map are optimized to have the best possible categorical reconstruction of the majority class noisy continuous features exploiting the loss in Equation (4).

$$\overline{\phi(\underline{\tilde{x}})} = argmin_{\phi} L(\underline{x}, \phi(\underline{\tilde{x}}))$$

$$L(x_j, \phi(\tilde{x}_j)) = -\sum_{k=0}^{M} (x_{jk} * log(\phi(\tilde{x}_{jk}))) \quad for \;\; j \in \{1, ..., J\} \tag{3}$$

$$L^S(\underline{x}, \phi(\underline{\tilde{x}})) = \sum_{j=1}^{J} L(x_j, \phi(\tilde{x}_j)) + \lambda |h(l)| \tag{4}$$

where $\underline{\tilde{x}} \in \mathbf{\tilde{X}_{train}}$ and $\underline{x} \in \mathbf{X_{train}}$. Once the network has been trained, the reconstruction error is evaluated on each sample of the test set as in (3). The test set REs from each of the B ensemble repetitions are scored in two matrices $\mathbf{Q_{maj}}, \mathbf{Q_{min}} \in R^{B*OxJ}$ based on each observation belonging to the majority or minority class.

For each feature j, the $B * O$ observations in $\mathbf{Q_{min}}$ and $\mathbf{Q_{maj}}$ are considered as a sample extracted from each feature distribution $re_j|$ minority sample $\sim f_j^{min}$ and $re_j|$ majority sample $\sim f_j^{maj}$. Performing a Smirnov test[1] we can compare the samples for each feature and select those with a p-value lower than the Bonferroni corrected threshold of 0.05.

3. Simualtion studies

Through a simulation study, we verified the capability of the denoising DSAEE to improve imputation error handling with respect to the DSAEE presented in (4), which reconstructs continuous noisy inputs to themselves. In the following, the latter will be referred to as continuous DSAE to better distinguish the two methodologies. Simulated data were built to reproduce the peculiar characteristics of genomic data: 1000 samples with 100 binary covariates, representing the variants, with a 10% relative

[1]The Smirnov test is a non-parametric two-sample test, used to determine if two independent random samples appear to follow the same distribution.

frequency, are considered. The outcome was defined with a minority class of 100 samples. Complex gene-gene interactions are represented by sets of interacting features containing 20 variants with a co-occurrence frequency with the phenotype of 70%. The noisy dataset was generated from the original categorical dataset by adding random exponential noise. The same simple AE architecture was implemented in the continuous and denoising DSAEE. The in-training convergence of both methods was analyzed through accuracy and loss: the MSE in the continuous DSAEE, where the continuous inputs are reconstructed as they are, and the binary-cross-entropy in the denoising DSAEE, where the categorical reconstruction is compared to the true discrete data. The in-train metrics are shown in Figure 2. The training was performed by excluding a validation set to mimic the performance of both algorithms on unseen data. The metrics of the validation sets are also presented in Figure 2.

We can observe that the denoising DSAEE maintains both the validation and training set losses low

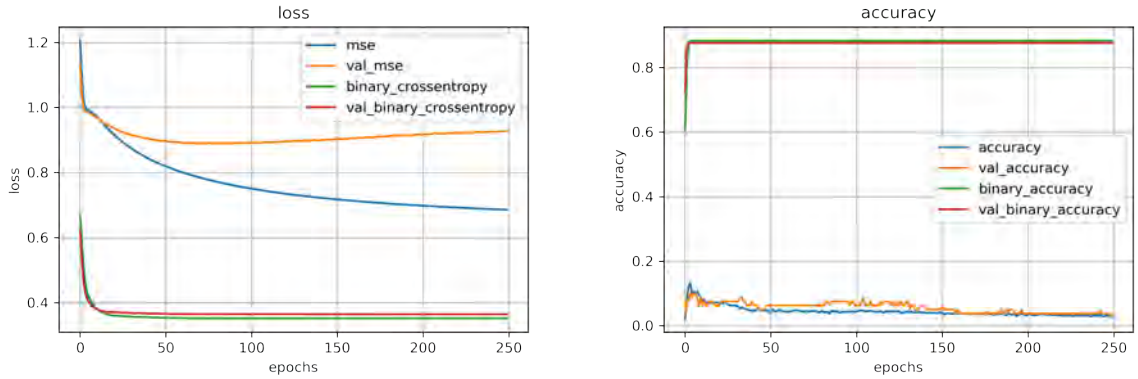

Figure 2: **In-train metrics of the compared methodologies.** The loss was evaluated via MSE in the continuous DSAEE and via cross-entropy in the denoising DSAEE.

and close with respect to the continuous DSAEE, showing a better reconstruction performance on seen and unseen data and better generalization ability. The accuracy in data representation is fundamental to better distinguish the classes of the binary outcome, and consequently to perform a better feature selection. Moreover, both the loss and accuracy plots reveal a faster and smoother convergence in denoising the DSAEE. Reducing the computational effort in training has great advantages in terms of the total computational time, enabling a higher number of repetitions to be performed and higher performance in ensemble learning algorithms.

4. Case study application in radiogenomics

As mentioned in the introduction, the selection and discovery of genomic variants predictive of late toxicities can inform downstream models such as PRSs and NTCPs. Therefore, in this section, we briefly present the case study application of the proposed algorithm on the RADPrecise Breast Cancer Cohort.

The considered sample includes 459 patients with a documented follow-up visit two years after the initial cancer treatment. Seven late toxicity endpoints, referred to as $\{y_1, ..., y_7\}$, are considered: six have an incidence below 10%, while y_1 occurs for approximately 30% of the subjects. The pool of genetic features to select from included 122 variants previously identified in the literature as correlated to radio-induced LTs in breast cancer patients. Both the developed denoising algorithm and the one presented in (4) were applied in this case study. The resulting selected variants were exploited to construct seven interaction-aware PRS for breast cancer late toxicities. The PRSs are computed following the PRSi algorithm presented in (1). In brief, starting from the selected genetic variants a data mining algorithm selects the most informative genetic interaction linked to each toxicity. The PRS is then built by weighting the contribution of each interaction term accordingly to the weights obtained when fitting a Logistic Regression model (LR). This being an unsupervised setting it is hard to comment on the precision of the results. However, the metrics of the logistic regression exploited in the definition of the PRSs reveal bet-

Table 1: AUC of the logistic regression in PRSi definition

	y_1	y_2	y_3	y_4	y_5	y_6	y_7
Continuous DSAEE	0.55	0.54	0.54	0.62	0.36	0.64	0.5
Denoising DSAEE	0.56	0.58	0.71	0.70	0.66	0.54	0.65

ter predictive abilities in the denoising DSAEE with respect to the continuous DSAEE, probably induced by a more effective initial selection. Results are reported in Table 1.

5. Conclusion

The innovation of this study is the development of a methodology capable of performing feature selection in the peculiar setting of genomic studies, overcoming the challenges of feature imputation (i.e., noise), class imbalance, and the need to account for predictive high-order interactions among features. The proposed method builds upon the original work in (4) and, based on our studies, we can say that it succeeds in the improvement of the representation of noisy data and of the selection of the most discriminant features.

The importance of this model is its clinical applicability. In addition to selection, the model can be exploited for the discovery and validation of influential features that determine the phenotype of interest, and for the interpretation of biologically relevant variants. The developed method, which improves the definition of genetic predisposition to general toxicities, may substantially improve personalized treatment planning. Some of the limitations of the developed model are the need for a ground-truth definition of noisy input data and the difficulty in scaling the input features owing to the high computational cost. Further developments can be introduced into this model. Variational autoencoders have already been proposed for anomaly detection, and their theoretical background makes them a more principled and objective method than classical autoencoders. However, variation autoencoders require a large training dataset, which hinders their applicability in this study.

Further considerations on the Spectral Information Criterion

Abstract

In this work, we extend and analyze some aspects of the spectral information criterion (SIC) considering sub-linear and super-linear model penalizations. We provide numerical results applying the method in a variable selection problem with a real dataset.

Keywords: Model selection, Information criteria, AIC, BIC, Spectral Information Criterion.

1. Introduction

Model selection can be considered one of the fundamental tasks of scientific inquiry. Indeed, the majority of the problems in statistical inference can be interpreted in some way as a statistical modeling problems [3]. The information criteria are one of the most important tools for model selection in nested models, that have introduced in the literature [9]. Several information criteria have been proposed, such as a well-known examples are the Akaike information criterion (AIC) and the Bayesian information criterion (BIC) [7; 8]. Here we consider an approach, the spectral information criterion (SIC), which includes several information criteria as special cases [4].

More specifically, in this work we consider an observation model which connects a vector of k parameters $\boldsymbol{\theta}_k = [\theta_1, ..., \theta_k]^\top$, to some observed vector of data $\mathbf{y}$. Namely, we know and can evaluate a likelihood function $p(\mathbf{y}|\boldsymbol{\theta}_k)$. Our goal is make inference about $\boldsymbol{\theta}_k$ given the set of observed data $\mathbf{y}$. In many applications, the interest is also learning the dimension k of $\boldsymbol{\theta}_k$, with $k \leq K$ (this is the case of the so-called *nested models*). Note that k can represent the order of a polynomial function or the number of feature in a regression problem, or the number of clusters in a clustering problem, etc. We remark that the maximum number of components/variables/clusters (depending on the specific application) is denoted as $K < \infty$.[1] In this work, we focus on the task of selecting the optimal number of components $k^* \leq K$. We also refer to k^* as a possible "elbow" of the problem. In several parts of the work, we refer specifically to the nomenclature and notation of a variable selection problem, without loss of generality just clarity in the exposition.

Furthermore, recalling that k is the dimension of the parameter vector parameters $\boldsymbol{\theta}_k$, we consider a

[1]We assume K finite, just for the sake of simplicity. However all the results can be extended $K \to \infty$.

function $V(k)$ represents a generic non-increasing function[2] with a finite value at $k = 0$, i.e., $V(0) < \infty$ (hence $V(k)$ takes always finite values). This fitting term can be obtained directly from the likelihood function, we can have

$$V(k) = -2\log(\ell_{\max}) \quad \text{where} \quad \ell_{\max} = \max_{\boldsymbol{\theta}} p(\mathbf{y}|\boldsymbol{\theta}_k). \tag{1}$$

However, other choices (in some cases equivalent) can be considered. For instance, the root mean square error (MSE) or the mean absolute error (MAE) in a regression problem, i.e., $V(k) = \text{MSE}(k)$, as a function of an integer k, where k can represent the order of a polynomial or the number of variables involved in the regression. We could also set $V(k) = 1 - \text{Accuracy}(k)$ in a classification problem using the first k most important features, or $V(k)$ can present the k-th eigenvalue of the covariance matrix of the data in a principal component analysis (PCA), where the eigenvalues are ordered in decreasing order etc. Note that, as an example, $k = 0$ corresponds to a constant model in a regression problem, when the case of "no variables" are used (in a variable selection example), i.e., $V(0) = \text{var}(\mathbf{y})$ which is the variance of the data. Finally, without of lost of generality, we can always assume

$$\min_k V(k) = V(K) = 0, \tag{2}$$

since we can always set $V'(k) = V(k) - \min_k V(k) = V(k) - V(K)$, where we have used $\min_k V(k) = V(K)$ since $V(k)$ is a non-increasing function. Below, we recall quickly the SIC procedure and its more relevant features.

2. Spectral information criterion (SIC) method

In this section, we recall briefly the spectral information criterion (SIC) method [4]. Considering a linear penalization, we introduce the cost function that we desire to minimize,

$$C(k, \lambda) = V(k) + \lambda k, \quad k = 0, ..., K, \quad \lambda \in [0, \lambda_{\max}], \tag{3}$$

where $V(k)$ is a generic fitting term (we assume $V(k) \geq 0$ without loss of generality; see below), λk is a penalization term of model complexity, where λ is a constant and k represents the dimension of the model. We study all the possible values of $\lambda \in [0, \lambda_{\max}]$ where $\lambda_{\max}$ is defined as

$$\lambda_{\max} = \{\min \lambda : \quad \arg\min_k C(k, \lambda) = 0\}, \tag{4}$$

and can be analytically obtained as

$$\lambda_{\max} = \max_k \left[\frac{V(0) - V(k)}{k} \right], \quad \text{for } k = 1, ..., K. \tag{5}$$

Since above we consider $k = 1, 2, ..., K$, we can perform an exhaustive search and, considering Eq. (11), then obtain $\lambda_{\max}$. The expression above can be easily understood: given $\lambda'_k = \frac{V(0)-V(k)}{k} > 0$, we have $C(k, \lambda'_k) = V(k) + \lambda'_k k = V(0)$, that can be obtained just replacing λ'_k inside Eq. (3). Since $\lambda_{\max} \geq \lambda'_k$ by definition (and $V(k) \geq 0$, $k \geq 0$ are both positive values), we have that $C(k, \lambda_{\max}) \geq C(k, \lambda'_k) = V(0)$. Therefore, the minimum value will be $\min C(k, \lambda_{\max}) = V(0)$ since we are sure that is reached, at least once, at $k^* = 0$.

The underlying idea in SIC is similar to the idea of to "integrating out" λ as usually done in Bayesian analysis, i.e., removing the dependence of λ in our problem. Namely, unlike the other IC schemes in the literature, we avoid picking a specific value of λ. For the sake of simplicity, let assume in this section that $V(k)$ is a decreasing function, with $V(0) < \infty$. With this assumption, it can be proved that $C(k, \lambda)$ has a unique minimum. See a graphical example in Figure 1(a). Now, we study the function

[2] This condition can be relaxed.

$k^*(\lambda) : [0, \lambda_{\texttt{max}}] \subset \mathbb{R} \to \{0, 1, 2..., K\}$, defined as

$$k^*(\lambda) = \arg\min_k C(k, \lambda), \tag{6}$$

which takes real values in the interval $[0, \lambda_{\texttt{max}}]$ and convert them into discrete values within the set $\{0, 1, 2..., K\}$. It is a non-increasing, piecewise constant function where $k^*(0) = K$ and $k^*(\lambda) = 0$ for $\lambda \geq \lambda_{\texttt{max}}$, i.e.,

$$\begin{cases} k^*(0) = K, \\ k^*(\lambda_{\texttt{max}}) = 0, \end{cases} \tag{7}$$

as shown in Figure 1(b). A very important consideration is that some values of $k \in \{0, 1, 2..., K\}$ could not have a corresponding λ associated. Moreover, a complete example of the piecewise constant function $k^*(\lambda)$ is given in Figure 1(b). Several values of λ can be associated with the same minimum k^*, or some value k' could not have any λ associated. Generally, to each k, we can associate an interval of lambda values, $\mathcal{S}_k \subset [0, \lambda_{\texttt{max}}]$. Observe that $\mathcal{S}_0 =$ by definition since we consider $\lambda \in [0, \lambda_{\texttt{max}}]$, so that $|\mathcal{S}_0| = 0$. These intervals, for $k = 1, ..., K$, form a partition of $[0, \lambda_{\texttt{max}}]$, i.e., $\mathcal{S}_1 \cup \mathcal{S}_2 ... \cup \mathcal{S}_K = [0, \lambda_{\texttt{max}}]$, and $\mathcal{S}_k \cap \mathcal{S}_j = 0$, for all $k \neq j$. As stated above, some value $k' \neq 0$ could be never a minimum, so that $|\mathcal{S}_{k'}| = 0$.

We can use the information provided by the measures $|\mathcal{S}_k|$, defining the weights $\bar{w}_k \propto |\mathcal{S}_k|$, i.e.,

$$\bar{w}_k = \frac{|\mathcal{S}_k|}{\sum_{j=0}^{K} |\mathcal{S}_j|} = \frac{|\mathcal{S}_k|}{\sum_{j=1}^{K} |\mathcal{S}_j|}, \quad k = 0, ..., K, \tag{8}$$

where we have used $|\mathcal{S}_0| = 0$, since $\lambda \leq \lambda_{\texttt{max}}$. Note that $\bar{w}_k$, for $k = 1, ..., K$, defines a probability mass function (pmf), $\sum_{k=1}^{K} \bar{w}_k = 1$. The main part of the SIC method is to compute (approximately) the probabilities $\bar{w}_k$. This approximation can be obtained with a quasi-Monte Carlo strategy (i.e., with a simple grid) or with a standard Monte Carlo approach using a number M of samples (see Table 1). The algorithm in Table 1 is generally fast even with choices of M such as $M = 10^6$, $M = 10^7$, or greater.

Table 1: Computation of the weights in the SIC method by Monte Carlo.

- For $i = 1, ..., M$:
  1. Draw $\lambda_i \sim \mathcal{U}([0, \lambda_{\texttt{max}}])$.
  2. Compute $k_i^* = \arg\min_k C(k, \lambda_i) = \arg\min_k [V(k) + \lambda_i k]$.
- Return the number of occurrences of the event $\{k_i^* = j\}$ for $j = 1, ..., K$, or equivalently return the weights

$$\bar{w}_j = \frac{\#\{k_i^* = j\}}{M}, \qquad j = 1, ..., K. \tag{9}$$

The output and main features of SIC. We can define the set $\mathcal{E}$ of indices k such that the corresponding weight is non-zero, $\bar{w}_k > 0$,

$$\mathcal{E} = \{\text{all } k : \ \bar{w}_k > 0\} = \{k^{(1)}, k^{(2)}, ..., k^{(J)}\}.$$

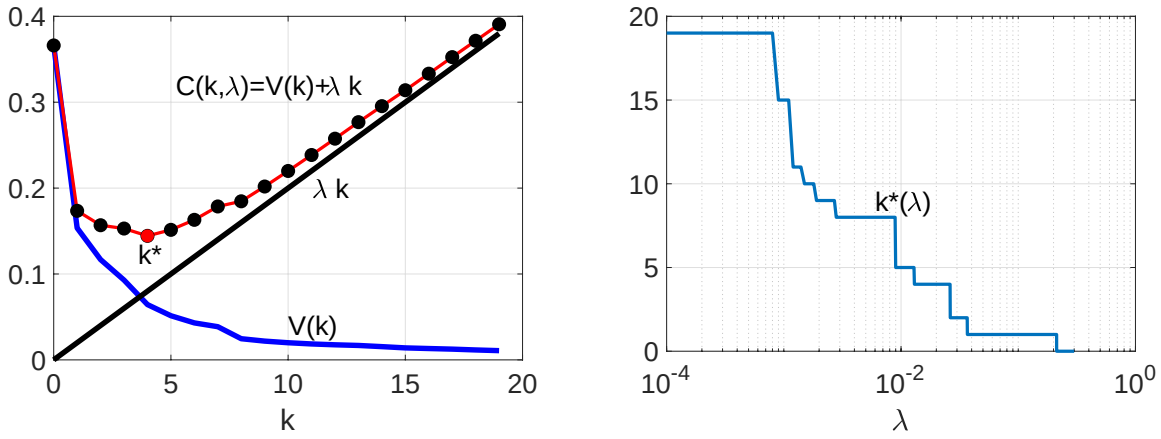

Figure 1: **(a)** An example of function $V(k)$, a penalization term λk, and the corresponding cost function $C(k, \lambda)$ (shown with dots). **(b)** Example of piecewise constant function $k^*(\lambda)$ in log-domain.

They can be interpreted as a possible "elbow" of the curve, i.e., any possible selected model is represented by the index $k^{(j)}$. We have denoted $J = |\mathcal{E}|$. Note that $J \leq K$ and, in some cases, $J << K$. In [4], some strategies for picking a unique index inside $\mathcal{E}$ have been discussed, i.e., choosing a unique specific model. However, in this work we focus on studying the changes in the set $\mathcal{E}$ when we change the type of model penalization.

Remark. Note that the set $\mathcal{E}$, by definition, contains all the IC solutions in the literature which use a cost function of type in (3), such as AIC and BIC, for instance.

Choosing Uniformly in $[0, \lambda_{\max}]$. Moreover, the values of λ's are choosing uniformly in $[0, \lambda_{\max}]$. One could consider a different procedure, similarly to use a generic (non-uniform) prior over λ in a complete Bayesian approach.

Linear penalization. In Eq. (3), we employ a *linear* penalization of the complexity $\lambda \cdot k$, since this linear term appears in different theoretical derivations in the literature [1; 7; 8]. Moreover, it appears not just in several IC formulations but also in other more general approaches, e.g., involving marginal likelihood with uniform priors [2, App. A and B] and alternative geometric solutions [5]. Then, assuming a linear penalty for the complexity seems to have strong theoretical support from different points of view.

However, in this work, we study the behavior of SIC considering different penalizations as power of the number of components k, i.e., k^r.

3. Extended SIC (ESIC): changing the model penalization

In this section, we consider the following cost function,

$$C(k, \lambda, r) = V(k) + \lambda k^r, \quad k = 0, ..., K, \quad \lambda \in [0, \lambda_{\max}^{(r)}], \quad r \in (0, R]. \tag{10}$$

where, for each $r \in (0, R]$, we have

$$\lambda_{\max}^{(r)} = \max_k \left[\frac{V(0) - V(k)}{k^r} \right], \quad \text{for } k = 1, ..., K, \tag{11}$$

that can be computed analytically. Furthermore, for each r, we obtain a probability mass $\bar{w}_k^{(r)}$, with $k = 0, ..., K$. For simplicity, we consider a value of R great enough such that it provides, for any $\lambda \leq \lambda_{\texttt{max}}^{(R)}$, all the weight mass concentrated at $k = 1$, i.e., $\bar{w}_1^{(R)} \approx 1$. Fixing a big M in Table 1, The idea is to analyze the outputs of SIC for different values of $r \in (0, R]$, studying the set of possible models (indices denoting the "elbows", number of parameters in each model)

$$\mathcal{E}_r = \{\text{all } k : \ \bar{w}_k^{(r)} > 0\} = \{k_r^{(1)}, k_r^{(2)}, ..., k_r^{(J_r)}\},$$

where $J_r = |\mathcal{E}_r|$. Note that, for $0 < r < 1$, we have sub-linear penalizations whereas, for $r > 1$, we have super-linear penalizations. This analysis can show that which of the points contained in $\mathcal{E}_r$ obtained by SIC have really a geometric relevance with respect to the non-increasing curve $V(k)$.

4. Numerical results

We test ESIC in a variable selection problem with real data (within a regression framework). Generally, we have a dataset of N pairs $\{\mathbf{x}_n, y_n\}_{n=1}^N$, where each input vector $\mathbf{x}_n = [x_{n,1}, ..., x_{n,K}]$ is formed by K variables, and the outputs y_n's are scalar values. We consider the case that $K \leq N$ and assume a linear observation model,

$$y_n = \theta_0 + \theta_1 x_{n,1} + \theta_2 x_{n,2} + ...\theta_K x_{n,K} + \epsilon_n, \tag{12}$$

where ϵ_n is a Gaussian noise with zero mean and variance σ_ϵ^2, i.e., $\epsilon_n \sim \mathcal{N}(\epsilon|0, \sigma_\epsilon^2)$. Here, we consider a real dataset studied in [6], there are $K = 122$ features and $N = 1214$ number of data. Moreover, the dataset in [6] has two outputs: "arousal" and "valence". Here, we study the "arousal" output.
In this experiment, we set $V(k) = -2\log(\ell_{\texttt{max}})$ with $\ell_{\texttt{max}} = \max_{\boldsymbol{\theta}} p(\mathbf{y}|\boldsymbol{\theta}_k)$ with $k \leq K$ (we also use the trick $V'(k) = V(k) - \min_k V(k) = V(k) - V(K)$ to have $V(K) = 0$), after ranking the 122 variables (see [6]). The likelihood $p(\mathbf{y}|\boldsymbol{\theta}_k)$ is induced by the Eq. (12). Hence, in this experiment, we can compare again with other IC measures in the literature. See Table 2. We employ $M = 10^6$ samples for ESIC (for, $r > 2$ we use $M = 5 \cdot 10^6$ to stabilize numerically the results). Note that, in all the cases, $J_r = |\mathcal{E}_r| << 122$, i.e., the number of suggested models are quite less the total number of possible models. The maximum number of models is $J_{1.905} = 26 << 122$ obtained for a super-linear penalization $r = 1.905$. The information criteria proposed in the literature are the first in appearing and also show a certain resistance in disappearing, as r grows.

5. Conclusions

We have tested an extended version of the spectral information criterion (SIC), which contains as special cases several information criteria given in the literature. The ESIC procedure is able to extract geometric information from the non-increasing curve $V(k)$. The results show that the "elbow points" representing other information criteria in the literature appear easily even with sub-linear model penalizations. This can be seen as a confirmation that these points are particularly relevant "elbows". Moreover, the method introduced in this work could be employed to select the order r (e.g., sub-linear if $r < 1$, or super-linear if $r > 1$) of the model penalization.

Abstract

When analyzing categorical or ordinal data one often comes across sparse contingency tables. One of the biggest problems with this situation is due to the low power of tests for independencies between variables. In this paper, we propose a procedure, based on context-specific independencies, to increase the power of tests. The idea is to focus on sub-tables where the number of null cells is relatively low. In addition, including these kinds of independencies in the Union-Intersection procedure can provide comforting results. These results are shown in a simulative study of different scenarios.

Keywords: Context-specific independencies, sub-tables, union-intersection principle

1. Introduction

The study of relationships between categorical or ordinal variables is often reduced to frequency analysis in contingency tables (see (1)). However, as the number of variables or the number of allowable categories for each variable increases, the corresponding contingency tables become sparse (full of null cells). The main problem when dealing with sparse tables is the low power of the classical statistics and an inaccurate type I error. Many works in the literature have dealt with this topic. For instance, in (7), a study on sparsity, it is showed that Fisher's exact test and the asymptotic X^2 Pearson's test give contradictory results for high levels of sparseness. In (12), it is studied the goodness of fit of the X^2 test, likelihood ratio test G^2, and Cressie-Read statistics. In (6) it is showed that the Gaussian approximation of the likelihood ratio statistic G^2 is more accurate than the χ^2 approximation in sparse contingency tables. Further, the problematic likelihood ratio test's asymptotic properties in sparse tables are studied in (4) and (5).
In the case of sparseness, often, at the exploratory stage, many categories are merged because they are poorly tested in the observed sample. However, this procedure can distort the results obtained by inflating the frequencies of some categories. Moreover, even in the best situations, categorically aggregating leads to a loss of informativeness. In this paper, we propose to take advantage of the study of conditional independencies defined in sub-tables that identify a dense portion of the contingency table related to all the variables under consideration. An example of these relationships is context-specific independencies (CSI) (see (8) and (9)) that study the relationship between two groups of variables in conditional tables. Generally speaking, context-specific independencies are conditional independencies holding for particular values of the variables in the conditioning set. Next, we broaden this concept by considering portions of variables for which independence applies. Subsection 2.1 is devoted to defining these independence relations and the parametric model needed to determine them. Subsection 2.2, on the other hand, explains how the Union-Intersection procedure (see (10) and (11)) can be applied to this type of independence to

extend the previously identified relationships, where possible, over the entire contingency table. Section 3 is devoted to the study of simulations to support the theory presented. Conclusions are reserved for Section 4.

2. Methodology

In the following subsections, we define a new type of independencies defined on contingency sub-tables. We also see how their use can be employed to have greater power in the likelihood ratio test than the standard test on the whole contingency table.

2.1 Context-specific independencies and their extensions

Let us consider a vector of random variables $X_V = (X_j)_{j \in V}$ where each variable X_j takes value i_j in a set of finite categories $\mathcal{I}_j = (1, \ldots, i_j, \ldots, I_j)$. Let $|\cdot|$ be the cardinality of a set. The contingency table of the $|V|$ variables is defined by $\mathcal{I}_V = \times_{j \in V} \mathcal{I}_j$ where each cell is defined as $\boldsymbol{i}_V = (i_j, j \in V)$. The strictly positive probability associated with any cell $\boldsymbol{i}_V$ is denoted with $\pi(\boldsymbol{i}_V)$. The vector of the probability of the whole contingency table is represented by $\boldsymbol{\pi}$, obtained by stacking each $\pi(\boldsymbol{i}_V)$ in the lexicographical order. Similarly, by considering a subset of variables $X_{\mathcal{M}}$ with $\mathcal{M} \subseteq V$ which generates the marginal $\mathcal{M}$-contingency table $\mathcal{I}_{\mathcal{M}} = \times_{j \in \mathcal{M}} \mathcal{I}_j$, the marginal probability of the generic cell $\boldsymbol{i}_{\mathcal{M}}$ is $\pi(\boldsymbol{i}_{\mathcal{M}})$, obtained by summing with respect to the variables in $X_{V \setminus \mathcal{M}}$. The whole set of these marginal probabilities defined on the $\mathcal{M}$-contingency table $\mathcal{I}_{\mathcal{M}}$, is represented by the vector $\boldsymbol{\pi}_{\mathcal{M}}$.
Given three incompatible subsets of variables X_A, X_B and X_C, a CSI is a independence statement like

$$X_A \perp\!\!\!\perp X_B | (X_C = \boldsymbol{i}'_C), \qquad \boldsymbol{i}'_C \in \mathcal{K}_C, \tag{1}$$

where $\boldsymbol{i}'_C$ is the vector of certain level(s) of the variable(s) in X_C, such that $X_j = i'_j$ for all $j \in C$, and it takes value in the list of levels $\mathcal{K}_C \subseteq \mathcal{I}_C$ for which the independence in formula (1) holds. Here, the table obtained as a cartesian product of $\mathcal{K}_C$ and $\mathcal{I}_{AB}$ is the sub-table where the independence is defined. The following formula is a generalization of the previous CSI where also the first two arguments of the independence statement are constrained to a subtable. Hereafter, we refer to this relationship as sub-CSI:

$$(X_A = \boldsymbol{i}'_A) \perp\!\!\!\perp (X_B = \boldsymbol{i}'_B) | (X_C = \boldsymbol{i}'_C), \qquad (\boldsymbol{i}'_A, \boldsymbol{i}'_B, \boldsymbol{i}'_C) \in \mathcal{K}_A \times \mathcal{K}_B \times \mathcal{K}_C \tag{2}$$

or in short $\boldsymbol{i}'_A \perp\!\!\!\perp \boldsymbol{i}'_B | \boldsymbol{i}'_C$, with $(\boldsymbol{i}'_A, \boldsymbol{i}'_B, \boldsymbol{i}'_C) \in \mathcal{K}_A \times \mathcal{K}_B \times \mathcal{K}_C$. Trivially, by replacing $\mathcal{K}_A$ with $\mathcal{I}_A$ and $\mathcal{K}_B$ with $\mathcal{I}_B$ in formula (2), we easily obtain the CSI in formula (1).
Although the class of sub-CSIs may seem difficult to interpret and of little use, a first advantage lies in the fact that the definition of these statements corresponds to linear constraints on log-linear parameters. For a more comprehensive treatment of the phenomenon, below we take advantage of marginal models, see e.g. (2) which impose constraints on marginal distributions of the tables in order to test different independence hypotheses. More specifically, we focus on hierarchical multinomial marginal (HMM) models, see (8) and (9) for interesting applications. In HMM models, the elements of $\boldsymbol{\eta}$ are the parameters based on different types of logits and defined on marginal distributions. The whole parametrization can be expressed in matrix form as

$$\boldsymbol{\eta} = C \log(M \boldsymbol{\pi}) \tag{3}$$

where C is a contrasts matrix and M is a 1's and 0's matrix which elements provide a suitable sum of probabilities. In general, the vector of parameters associated with the variables in $X_{\mathcal{L}}$ and defined in the marginal table $\mathcal{I}_{\mathcal{M}}$, $\boldsymbol{\eta}^{\mathcal{M}}_{\mathcal{L}} = \left\{\eta^{\mathcal{M}}_{\mathcal{L}}(\boldsymbol{i}_{\mathcal{L}})\right\}_{\boldsymbol{i}_{\mathcal{L}} \in (\mathcal{I}_{\mathcal{L}} - \mathbf{1})}$ where $\mathbf{1}$ represents the first (reference) cell used for the *baseline* codification of the parameters. The above parameters are contrasts of logarithms of sums of probabilities.

Theorem 1. *Let us consider a set of variables X_V, with probability distribution $\mathcal{P}$ parametrized through the parameters in formula (3), where the baseline criterion is used. Then, the probability distribution*

$\mathcal{P}$ obeys the sub-CSI in formula (2) if and only if the following constraints on the HMM parameters are satisfied:

$$\sum_{c \subseteq C} \eta_{\mathcal{L}}^{\mathcal{M}}(\boldsymbol{i}_{\mathcal{L}}) = 0 \qquad \textit{where } \mathcal{L} = a \cup b \cup c \textit{ and } \boldsymbol{i}_{\mathcal{L}} \in \mathcal{K}_a \times \mathcal{K}_b \times \mathcal{K}_c, \tag{4}$$

where $a \cap A \neq \emptyset$ and $b \cap B \neq \emptyset$, $\mathcal{K}_a \subsetneq (\mathcal{I}_a - \mathbf{1}_a)$ and $\mathcal{K}_b \subsetneq (\mathcal{I}_b - \mathbf{1}_b)$.

The following example shows how to apply formula (4).

Example 1 In order to test $\boldsymbol{i}'_A \perp\!\!\!\perp \boldsymbol{i}'_B | \boldsymbol{i}'_C$, we need to impose $\eta_{AB}^{ABC}(i'_A, i'_B) + \eta_{ABC}^{ABC}(i'_A, i'_B, i'_C) = 0$. If the constrain is satisfied for $i'_A i'_B \in \mathcal{I}_{ab} - \mathbf{1}$ (all the categories of the variables A and B except the reference category) then the global conditional hypothesis $H_0 : A \perp\!\!\!\perp B | C$ is satisfied.

Before proceeding, two clarifications should be made. First, sub-CSI in formulation (2) differs from CSI in formulation (1) if $\mathcal{K}_{\mathcal{A}}$ and $\mathcal{K}_B$ are proper subsets of $\mathcal{I}_A - \mathbf{1}_A$ and $\mathcal{I}_B - \mathbf{1}_B$. In fact, by construction, the parameter sets associated with the reference cell are worth zero. So if we impose the constraints in formula (4) for all cells except the reference cell, we automatically have that it is also satisfied for the reference cell. The second clarification always concerns the reference categories of the variables. Since the value of the parameters is zero at these categories, it is difficult to discriminate whether the independence statement (2) also involves the reference cell. However, the choice of the reference cell, which by default is defined as the first cell of the contingency table, can be defined as desired without changing the truthfulness of the constraints.

2.2 Union-Intersection principle

The Union-Intersection (UI) principle has been proposed by (10) and (11). In nutshell, the UI test states that we can express a (global) null hypothesis H_0 as the intersection of k several component hypotheses H_{0_i} and a (global) alternative as the union of the k component alternatives $\overline{H}_{0_i}$:

$$H_0 : \bigcap_{i=1}^{k} H_{0_i} \quad H_1 : \bigcup_{i=1}^{k} \overline{H}_{0_i}. \tag{5}$$

We reject the global null hypothesis if any of the tests on the component hypotheses lead to rejection, and we retain the global null hypothesis if none of the component tests leads to rejection.
Note that to test any H_{0_i} it is possible to choose a different level α_i. When H_0 holds it is desirable that the rejection probability of the UI test is not greater than a fixed level α^*. This is ensured if the levels α_i of the component tests are such that $\sum_{i=1}^{k} \alpha_i = \alpha^*$. Bonferroni's correction is a popular choice to achieve this: $\alpha_i = \frac{\alpha^*}{k}$. Generally, the rejection probability of the UI test is not less than the rejection probability of any component test. Thus, when H_0 does not hold, the rejection probability provides the power of the test and, in this case, the global test's power is greater than or equal to that of the component test with the highest power.
In our context, the Union-Intersection principle may offer advantages when the component hypotheses are defined on lower dimensional sub-tables less affected by sparsity than the whole table on which H_0 is defined. Reasoning in terms of sub-CSIs, we can divide hypothesis testing for conditional independence as a set of hypotheses about sub-CSIs, such that the unified support of the variables in all individual tests covers the entire support. For greater clarity, consider the following example.

Example 2 Let us suppose to have a contingency table involving three variables, X_1, X_2 and X_3. Let the suitable $(\mathcal{K}_1 \times \mathcal{K}_2 \times \mathcal{K}_3)$ be dense, while the remaining sub-tables, defined by $(\bar{\mathcal{K}}_1 \times \mathcal{I}_2 \times \mathcal{I}_3)$, $(\mathcal{K}_1 \times \bar{\mathcal{K}}_2 \times \mathcal{I}_3)$, and $(\mathcal{K}_1 \times \mathcal{K}_2 \times \bar{\mathcal{K}}_3)$ are more or less sparse. Here the symbol $\bar{\mathcal{K}}$ denotes the complementary set of $\mathcal{K}$. We can think of H_0 as the conditional independence statement $X_1 \perp\!\!\!\perp X_2 | X_3$. The component hypotheses H_{0_i} can be seen as sub-CSI independence statements $\boldsymbol{i}'_1 \perp\!\!\!\perp \boldsymbol{i}'_2 | \boldsymbol{i}'_3$, where the list of admissible values for $\boldsymbol{i}_{\mathcal{L}} = (\boldsymbol{i}'_1, \boldsymbol{i}'_2, \boldsymbol{i}'_3)$ discriminates between the hypothesis. In detail, we have

that $\boldsymbol{i}_{\mathcal{L}} \in (\mathcal{K}_1 \times \mathcal{K}_2 \times \mathcal{K}_3)$ for H_{0_1}, $\boldsymbol{i}_{\mathcal{L}} \in (\bar{\mathcal{K}}_1 \times \mathcal{I}_2 \times \mathcal{I}_3)$ for H_{0_2}, $\boldsymbol{i}_{\mathcal{L}} \in (\mathcal{K}_1 \times \bar{\mathcal{K}}_2 \times \mathcal{I}_3)$ for H_{0_3} and $\boldsymbol{i}_{\mathcal{L}} \in (\mathcal{K}_1 \times \mathcal{K}_2 \times \bar{\mathcal{K}}_3)$ for H_{0_4}.

The truthfulness of the union of all these hypotheses implies the truthfulness of the global one. The idea is to split the global hypothesis into several sub-CSIs. If we retain all of them then the global conditional hypothesis is satisfied. One way to proceed could be as follows. An exploratory survey is carried out in the whole contingency table to see where the table is most sparse. This would identify blocks in the global table: the dense block, the sparse block, and the middle ground tables. One of the component hypotheses H_{0_i} is constructed in the densest sub-table. If in general some of the H_{0_i} on the sparse sub-tables leads to the rejection of the global hypothesis but the H_{0_i} hypothesis on the dense sub-table is instead in favour of H_0, this provides interesting information on the sub-CSI between the variables involved in the contingency table.

3. Simulation study of the power

In this section, we want to show some preliminary results obtained through simulations as evidence to support the proposed methodology. We considered a simple case where we have 3 variables: $X_1 \in (1, \ldots, 5)$, $X_2 \in (1, \ldots, 5)$ and $X_3 \in (1, \ldots, 5)$. We want to investigate the global hypothesis $H_0 : X_1 \perp\!\!\!\perp X_2 | X_3$ for $\boldsymbol{X} = (X_1, X_2, X_3)$ taking values in $\mathcal{I}_{123} = (1, \ldots, 5)^3$, against the alternative.
In order to perform the Union-Intersection procedure, we divided the contingency table into 4 sub-tables.

- $\mathcal{K}^I = (1, 2) \times (1, 2) \times (1, 2)$, 8 cells;
- $\mathcal{K}^{II} = (3, 4, 5) \times (1, 2, 3, 4, 5) \times (1, 2, 3, 4, 5)$, 75 cells;
- $\mathcal{K}^{III} = (1, 2) \times (3, 4, 5) \times (1, 2, 3, 4, 5)$, 30 cells;
- $\mathcal{K}^{IV} = (1, 2) \times (1, 2) \times (3, 4, 5)$, 12 cells.

Then, we define 4 component hypotheses H_{0_i} to test H_0 in the Union-Intersection procedure as sub-CSI. The null component hypotheses are H_{0_1}: $i_1 \perp\!\!\!\perp i_2 | i_3$ for $\boldsymbol{i} \in \mathcal{K}^I$, H_{0_2}: $i_1 \perp\!\!\!\perp i_2 | i_3$ for $\boldsymbol{i} \in \mathcal{K}^{II}$, H_{0_3}: $i_1 \perp\!\!\!\perp i_2 | i_3$ for $\boldsymbol{i} \in \mathcal{K}^{III}$ and H_{0_4}: $i_1 \perp\!\!\!\perp i_2 | i_3$ for $\boldsymbol{i} \in \mathcal{K}^{IV}$. Since the degree of freedom of the χ^2 for the distribution of the likelihood test is not accurate when the sparseness occurs, we simulated $m = 10000$ samples and we evaluated the MC distribution of the G^2 statistics of the likelihood ratio test as follows.
First, we build a probability distribution P_0 where the independence in H_0 holds. We use that distribution to simulate $m = 10000$ frequency tables under H_0. In particular, we impose that the sub-table A must be dense with 50 observations on 8 cells; the remaining three sub-tables are sparse with $57 \sim 75/4 * 3$ observations for B, $20 \sim 30/3 * 2$ observations for C and $6 \sim 12/2$ observations for D.
Then, we evaluate the statistic G^2 of the LR test in the full table and in each sub-tables of each sample, obtaining the MC distribution under H_0 for $\boldsymbol{G}^2_{\mathcal{I}_{123}}$, $\boldsymbol{G}^2_{\mathcal{K}^I}$, $\boldsymbol{G}^2_{\mathcal{K}^{II}}$, $\boldsymbol{G}^2_{\mathcal{K}^{III}}$, and $\boldsymbol{G}^2_{\mathcal{K}^{IV}}$, respectively.
On the previous distributions, we evaluated the simulated critical values for the tests as the quantile of order $1 - \alpha = 0.95$ ($X^2_{H_0,\alpha}$), for the global hypothesis and as the quantile of order $1 - \alpha_1$, $1 - \alpha_2$, $1 - \alpha_3$, and $1 - \alpha_4$ for the component hypothesis $X^2_{H_{0_1},\alpha_1}$, $X^2_{H_{0_2},\alpha_2}$, $X^2_{H_{0_3},\alpha_3}$, and $X^2_{H_{0_4},\alpha_4}$. The only constraint on the significance level of the component hypotheses is that their sum must be equal to α. The analysis is led for different values of significant levels in order to investigate how it is possible to gain more power.
Further, we proceed in the same way with the generation of $m = 10000$ samples from an alternative distribution, where the global hypothesis does not hold.
In order to cover all possible scenarios we build different probability distributions under H_1:

- P_1 where only the sub-CSI H_{0_1} holds (the dense table);
- P_2 where the sub-CSI H_{0_1} does not hold but the others (in the sparse tables) hold.
- P_3 where all the sub-CSIs do not hold.

In any of the above scenarios, we evaluated the rejection rate as an estimator of the test power. The results were collected in the following subsection.
All the analyses were carried out with the software R and the package `hmmm` (3) for the estimation of parameters.

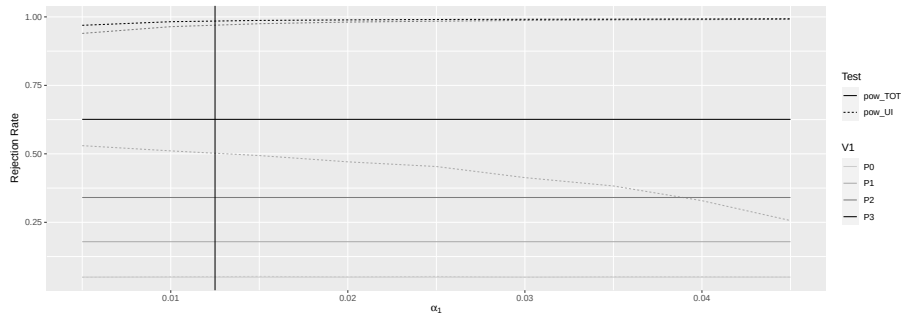

Figure 1: Simulated rejection rate distribution (dashed line) related to the UI procedure by increasing the size α_1 of test H_{0_1} using the alternative distribution P_3. In solid lines are the corresponding (constant) simulated rejection rates for the global test.

3.1 Results description

Table 1 reports the rejection rate in all the scenarios detailed above and also for the case where the alternative distribution satisfies H_0, in order to provide information on the significant level of the Union-Intersection test. It can be seen from the results in Table 1 that the test based on the UI procedure is always more powerful than the test based on the global hypothesis. In particular, the power of the test through the UI procedure gains a lot of power when the null hypothesis does not apply in the dense sub-table (P_2 and P_3). However, due to the segmentation of the entire contingency table, even in the case of P_1 the UI procedure outperforms the test conducted on the entire contingency table. Looking at the row referring to the P_3 distribution, where in each sub-table independence does not hold, it is evident how the power increases in the dense situation.

Table 1: Rejection rates for all possible scenarios evaluated on the distributions P_1, P_2, P_3 and P_0, respectively. The shaded cells show the simulated levels of the tests and non-shaded cells show the simulated power.

n: number of observations; m: number of simulated elements in the MC distributions; $r(H, \alpha)$: rejection rate of the component tests H_{0_1}, H_{0_2}, H_{0_3}, H_{0_4}, and H_0, with test size equal to $\alpha_1 = \alpha_2 = \alpha_3 = \alpha_4 = 0.0125$, $\boldsymbol{\alpha}^T = (0.0125, 0.0125, 0.0125, 0.0125)$, and $\alpha^* = 0.05$.

Further, Figure 1 shows how the power of the UI test changes by varying the significant levels of the component hypothesis and by varying the different degree of connection between the two conditional distribution of X_1 and X_2 given X_3. Note that the scenario reported in Table 1 corresponds to the vertical line in $\alpha = 0.125$. Looking at the solid lines, Figure 1 reports the rejection rates of the different tests. The red line belongs to the global test, the other lines represent the (greater) power of the other tests. The greater power is related to the test evaluated on the P_3 distribution where none of the sub-CSIs holds. Concerning the dashed lines, it is worthwhile to note that the power of the tests evaluated on P_2, P_3 distributions is increasing and always increases the power of the overall test. In contrast, this trend is decreasing with respect to the P_1 distribution, where independence does not hold in the densest table and holds in all others. Moreover, for the different levels of α_1, the red dashed line traces the corresponding value of the classical test.

4. Conclusion and further research

This study proposes a method to increase the power of tests performed in sparse contingency tables. The idea is based on the logic of the Union Intersection procedure to decompose the null hypothesis H_0. The original proposal is to consider a set of context-specific hypotheses. This type of hypothesis focuses on sub-spaces of variables. By identifying the least sparse ones, a discrete increase in power can be achieved. The work is still preliminary, but early results from simulations give promising results in terms of power. Clearly, it is necessary to extend the simulations already carried out for different levels of n, m and different scenarios among α_i, for $i = 1, \ldots, k$.

Abstract

Various processes can be modelled as quasi-reaction systems of stochastic differential equations, such as cell differentiation and disease spreading. Often the underlying interactions, such as reactions between particles or contacts between people, are unobserved, and only the state variables, such as cell type counts and number of infected individuals, are available. Statistical inference of the parameters driving these systems have been developed from concentration data over time. Whereas observing the continuous time process at a time scale as fine as possible should in theory help with parameter estimation, existing Local Linear Approximation (LLA) methods do not work well in these scenarios, due to numerical instability caused by small changes of the system at successive time points.

In this manuscript we propose a method that reconstructs the underlying unobserved interactions from the observed count data. Motivated by this, we first formalize the latent event history model underlying the observed count process. We then propose a penalized Expectation-Maximization algorithm for parameter estimation. The complete log-likelihood has the form of a LLA likelihood with a penalty term corresponding to the latent Poisson event history model. The larger this term the stronger the information about the events driving the count process. A simulation study shows the performance of the proposed method and highlights the settings where it is particularly advantageous compared to the existing LLA approaches.

1. Introduction

The measurement of many complex temporal phenomena can be described by means of stochastic differential equations (SDEs) (2), as these are able to capture both measurement uncertainty as well as the intrinsic stochasticity in the process. Their dynamics depend critically on parameters, which are often unknown. As such, various techniques have been developed to perform parameter estimation using observational data from these processes (6). Since the Markovian transition density of the underlying SDE has rarely an explicit form (5), Local Linear Approximation (LLA) methods provide an explicit but approximate formulation of the likelihood function under various assumptions (9). In stochastic kinetic systems of interacting particles, however, parameter estimation using these methods worsens if the inter-observations times are too close, as the strong correlation of the observations from one time point to the next causes computational instability. On the other hand, the state of the system at each time point can be seen as a function of an underlying counting process of the occurred events, which can be approximated by an independent non-homogeneous Poisson process (10).

Motivated by this, we propose a penalized Expectation-Maximization (EM) algorithm for parameter estimation that combines the observed counts of the state over time with a latent event history model describing the occurrence of events. A penalty term has the effect of adjusting the weight of the observed and latent components of the likelihood according to the time distance of the observations. The structure of the paper is as follows: in Section 2, we formalize the statistical modelling of quasi-reaction systems, while in Section 3, we describe the proposed penalized EM-algorithm for parameter estimation. A simulation study is shown in Section 4.

2. Probability models of dynamic processes

In this section we describe the two stochastic models that describe the interactions between the particles, and the state of the particles, respectively. They provide two dual versions of same process.

2.1 Latent history event models

Consider a closed system in which p substrates interact, with concentration levels governed by a system of reactions. Let $\mathcal{J}$ be the set of all reactions. For each time unit, consider the following multivariate counting process

$$N_j(t) = \#\{\text{Reactions of type } j \text{ occurred in time interval } [0,t]\}.$$

We assume that $N_j(0) = 0$ and that the process is adapted to the stochastic basis of a $\sigma-$algebra $\{\mathcal{F}_t\}_{t\geq 0}$ which is complete and right continuous. $N_j(t)$ is therefore a local sub martingale. Due to the Doob-Meyer decomposition, there exists a predictable increasing process $\Lambda_j(t)$ such that $\Lambda_j(0) = 0$ and $N_j(t) - \Lambda_j(t)$ is an $\mathcal{F}_t$-local martingale. Assuming that reactions cannot occur simultaneously, i.e.,

$$\Pr\big([N_j(t) - N_j(s)] \geq 1 | \mathcal{F}_s\big) = 1 - e^{-[\Lambda_j(t) - \Lambda_j(s)]},$$

one can uniquely identify the reaction that occurred at a certain instant in time. We call this reaction $r_j(t)$ and the pair $e_j(t) := (t, r_j(t))$ an *event*. If $\Lambda_j(t)$ is differentiable, it is possible to define a new predictable continuous process, $\lambda_j(t) : \mathbb{R}^p \to [0,\infty)$ such that $\dfrac{d}{dt}\Lambda_j(t) = \lambda_j(t)$, which is the instantaneous hazard rate of the jth reaction. Roughly speaking, $\mu_j(t) = \lambda_j(t)dt$ is the probability that the j-reaction occurs in the interval $[t, t+dt)$. As there is no change in the substrates concentration until a new reaction takes place, the hazard function is constant for each time interval. For all $s, t \in \mathbb{R}^+$, the waiting time for the j-reaction to occur in $[s,t)$ is distributed as an exponential random variable with cumulative density function

$$\Pr\big([N_j(t) - N_j(s)] = 1 | \mathcal{F}_s\big) = 1 - e^{-\lambda_j(t)(t-s)}.$$

From this, in a framework with discrete time steps, we conclude that the distribution of the number of events in an interval $[t_{i-1}, t_i]$ is governed by the following non-homogeneous Poisson process:

$$N_j(t_i) - N_j(t_{i-1}) | \mathcal{F}_{t_{i-1}} \sim \text{Po}(\lambda_j(t_i)(t_i - t_{i-1})), \tag{1}$$

where we assume that the hazard function remains constant on the interval $[t_{i-1}, t_i]$.

2.2 Quasi-reaction models and local linear approximation algorithm

Let $(Y_1, \ldots, Y_p)$ define the state of a reaction system. With some abuse of notation, we consider a set $\mathcal{J}$ of reactions, in which the j-th reaction is described as:

$$k_{1j}Y_1 + \ldots + k_{pj}Y_p \xrightarrow{\theta_j} s_{1j}Y_1 + \ldots + s_{pj}Y_p, \tag{2}$$

where $k_{ij}, s_{ij} \in \mathbb{Z}$ are the stoichiometric coefficients, $\theta_j \in \mathbb{R}^+$ the reaction rate, for $i = 1, \ldots, p$, and $j = 1, \ldots, |\mathcal{J}| = r$. The net change of $\mathbf{Y} = (Y_1, \ldots, Y_p)^T$ is defined by the stoichiometric matrix V with (i,j) element $v_{ij} = s_{ij} - k_{ij}$.

Considering now observations over time, and assuming that $\boldsymbol{Y}_t = (Y_{1t}, \ldots, Y_{pt}) \in \mathbb{N}_0^p$ is a continuous time counting Markov process, the hazard function described before can now be related to model (2) by

$$\lambda_j(t) = \lambda_j(\boldsymbol{Y}_t; \theta_j) = \theta_j \prod_{i=1}^{p} \binom{Y_{it-1}}{k_{ij}}, \tag{3}$$

where $\binom{Y_{it-1}}{k_{ij}} = 0, \forall Y_{it-1} < k_{ij}$. As the distribution of $\boldsymbol{Y}_t$ satisfies the stochastic differential "chemical master equations" (8), which are tractable only in few cases, discrete-event simulation algorithms, in particular the Gillespie algorithm (4), are typically used to generate samples from this distribution. Alternatively, an Euler-Maruyama approximation can be used, based on the first two moments of the jump process, given by

$$\frac{d}{dt}\mathbb{E}[\mathbf{Y}_t|t] = V\boldsymbol{\lambda}(\boldsymbol{Y_t}; \theta), \quad \frac{d}{dt}\text{Var}[\mathbf{Y}_t|t] = V\text{Diag}(\boldsymbol{\lambda}(\boldsymbol{Y_t}; \theta))V^T,$$

respectively (7), where $\boldsymbol{\lambda}(\boldsymbol{Y_t}; \theta)$ is the vector of hazard rates defined in (3). Assuming a Gaussian distribution for the jumps and constant rates on discretized time intervals, a simulation algorithm as well as a parameter estimation method can be devised based on the assumption that

$$\left(\boldsymbol{Y}_{t_i} - \boldsymbol{Y}_{t_{i-1}}\right)\left|\boldsymbol{Y}_{t_{i-1}} \sim \mathcal{N}\left(V\boldsymbol{\lambda}(\boldsymbol{Y}_{t_{i-1}}; \boldsymbol{\theta})(t_i - t_{i-1}), V\text{Diag}(\boldsymbol{\lambda}(\boldsymbol{Y}_{t_{i-1}}; \boldsymbol{\theta}))V^T(t_i - t_{i-1})\right)\right., \tag{4}$$

on the interval $[t_{i-1}, t_i]$.

2.3 Exogenous drivers of the reaction system

An intrinsic feature of stochastic reaction systems are their emergent behaviour, i.e., the occurrence of a particular reaction changes the state, which in turn changes the rates of the reactions. However, besides endogenous drivers, many dynamic systems are also subject to external forces. For example, the cell differentiation may depend on the particular characteristics of the patient. For this reason, we extend the traditional modelling frameworks with the inclusion of external covariates, which can affect the transition probabilities of the Markov process (1). In particular, we will model the direct effect of covariates on the reaction rates θ_j by

$$\theta_j = \exp(\mathbf{x}\boldsymbol{\beta_j}),$$

with $\mathbf{x} \in \mathbb{R}^q$ a vector of q covariates, which are subject specific but do not vary over time. The aim of this manuscript is to estimate the parameters $\boldsymbol{\beta} \in \mathbb{R}^{qr}$ describing all the reaction rates.

3. Penalised EM for parameter estimation

Assume that $N + 1$ observations are collected per subject, at N not necessarily equispaced time intervals. Using the modelling framework of Section 2, the complete *penalized* log-likelihood of the latent reaction events e and the observed states y for one subject is given by

$$l_{e,y}(\boldsymbol{\beta}; \alpha, \gamma) = l_y(\boldsymbol{\beta}) + \gamma l_{e|y}(\boldsymbol{\beta}) - \alpha\boldsymbol{\beta}^T\boldsymbol{\beta} \tag{5}$$

where

$$l_{e|y}(\boldsymbol{\beta}) = \sum_{i=1}^{N}\sum_{j\in\mathcal{J}}\left\{-\lambda_j(\boldsymbol{y}_{t_i}; \mathbf{x}, \boldsymbol{\beta})(t_i - t_{i-1}) + e_{ij}\log\left(\lambda_j(\boldsymbol{y}_{t_i}; \mathbf{x}, \boldsymbol{\beta})(t_i - t_{i-1})\right)\right\}$$

is the contribution of the Poisson likelihood from the latent model (1) and

$$l_y(\boldsymbol{\beta}) = -\frac{1}{2}\sum_{i=1}^{N}\left\{\log(|g_{t_i}(\boldsymbol{\beta})|) + \left[\Delta y_i - f_{t_i}(\boldsymbol{\beta})\right]^T g_{t_i}(\boldsymbol{\beta})^{-1}\left[\Delta y_i - f_{t_i}(\boldsymbol{\beta})\right]\right\} \tag{6}$$

is the contribution from the Gaussian likelihood from model (4), with $f_t(\boldsymbol{\lambda}(\mathbf{y}_t; \mathbf{x}, \boldsymbol{\beta}))$ and $g_t(\boldsymbol{\lambda}(\mathbf{y}_t; \mathbf{x}, \boldsymbol{\beta}))$ denoting the mean and variance of the process. The full log-likelihood from multiple processes (e.g. several patients) will simply be the sum of all the log-likelihoods.

Notice how some penalty terms are introduced to weigh the different components of the likelihood. In particular, increasing $\gamma \in \mathbb{R}^+$ puts more weight on the latent event information, while $\gamma = 0$ corresponds to the likelihood used by the LLA existing method. In general, we would expect that the finer the time scale, the smaller the value of γ that should be set. An additional tuning parameter $\alpha \in \mathbb{R}^+$ induces a ridge penalty term which should improve the estimation accuracy in the presence of strongly correlated responses across time, as it is often the case at finer time scales.

The complete log-likelihood in (5) depends both on the observed concentration data and on the hidden reactions. Its maximum can be found efficiently via an EM algorithm (3). The procedure iterates the following two steps:

- **E-step**: calculate the conditional expected value of the complete log-likelihood based on the current estimate $\boldsymbol{\beta}^*$ of $\boldsymbol{\beta}$. This value will be denoted by $\mu^*_{ij}(t) = \lambda^*_{ij}(t)dt$ and is obtained by evaluating Equation (3) using $\boldsymbol{\beta}^*$.
- **M-step**: Fix μ^*_{ij} from the E-step and find the optimal $\boldsymbol{\beta}$ by maximising the Q-function:

$$\max_{\boldsymbol{\beta}} Q(\boldsymbol{\beta}) = \max_{\boldsymbol{\beta}} l_y(\boldsymbol{\beta}) + \gamma \sum_{i=1}^{N} \sum_{j=1}^{r} \Big[-\boldsymbol{\mu}_{ij}(\boldsymbol{\beta}) + \boldsymbol{\mu}^*_{ij} \log\big(\boldsymbol{\mu}_{ij}(\boldsymbol{\beta})\big) \Big] - \alpha \boldsymbol{\beta}^T \boldsymbol{\beta}.$$

For the optimisation, we make use of the Broyden-Fletcher-Goldfarb-Shanno algorithm, which is an approximation of the Newton's method. The iterative process continues until no significant change is obtained between successive estimations of the parameters. The initial parameter values are sampled from a normal distribution with zero mean and unitary variance and the first estimation is conducted assuming no covariance structure.

4. Simulation Study

Inspired by (7), we set up the simulation study in the context of cell dynamics. Here, the substrates correspond to cell types and the interactions between particles to chemical reactions. Figure 1 (left) shows the specific process that we consider, involving 2 cell duplication (DP), 2 cell death (DT), and 2 cell differentiation (DF) reactions. The rates $\boldsymbol{\theta} = (\theta_1, \ldots, \theta_6)^T$ depend on 2 covariates, which vary across 4 subjects by drawing their values from a Uniform[0,1] distribution. Together with an intercept, we set the parameters $\boldsymbol{\beta} \in \mathbb{R}^{18}$ to

$$\begin{aligned} \boldsymbol{\beta}_{DP} &= (1.70, 1.02, 1.17; 1.20, 1.03, 1.24), \quad \boldsymbol{\beta}_{DT} = (-1.20, 0.03, 0.13; -2.40, 0.65, 1.80) \\ \boldsymbol{\beta}_{DF} &= (-1.89, 1.07, 0.34; -4.32, 1.26, 2.10) \end{aligned}$$

We set the initial concentration to $\mathbf{y}_0 = (200, 100, 200)$. From this, a Gillespie algorithm is used to generate the state of the process over time. Since we want to evaluate how the method performs when data are collected at a finer versus a coarser time scale, we consider the following two scenarios:

- **Scenario A**: For each subject, the process is simulated for 100 event times, but only every other observation is retained, for a total of N=49 time intervals. The LLA approach is expected to lead to inaccurate parametric estimates here due to the strong correlation of the variables from one time point to the next.

- **Scenario B**: For each subject, the process is simulated for 1500 event times, but only every other 30th observation is retained, for a total of N=49 time intervals. Observations are here much more distant in time and reconstruction of the latent event history process is more challenging.

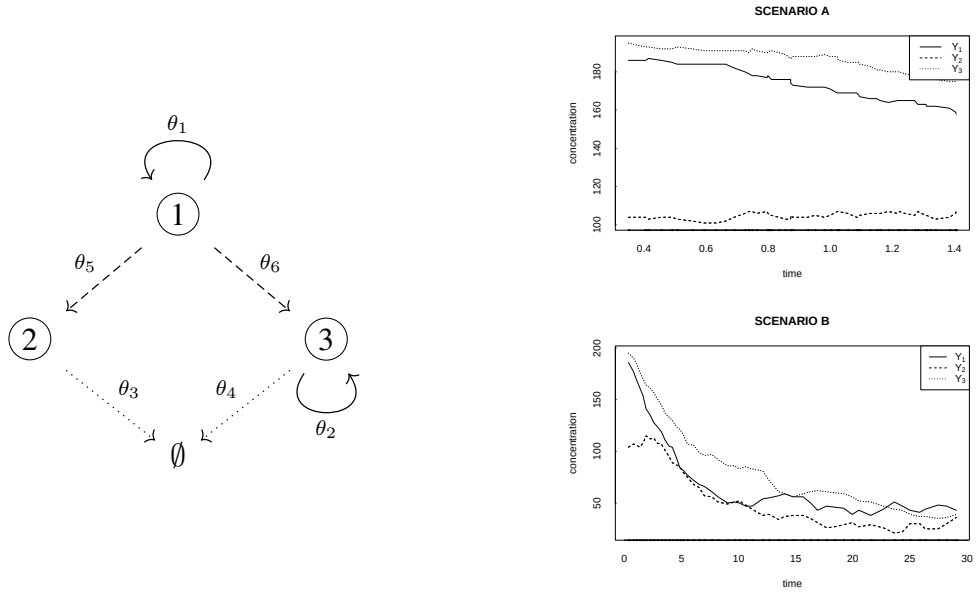

Figure 1: *Left: the stochastic cell differentiation process used in the simulation. Each of the 3 substrates is represented by a node, whereas birth, death and differentiation events are denoted by full, dotted and dashed edges, respectively. Right: the trajectories of the process for one subject, generated via a Gillespie algorithm in scenario A (top) and B (bottom).*

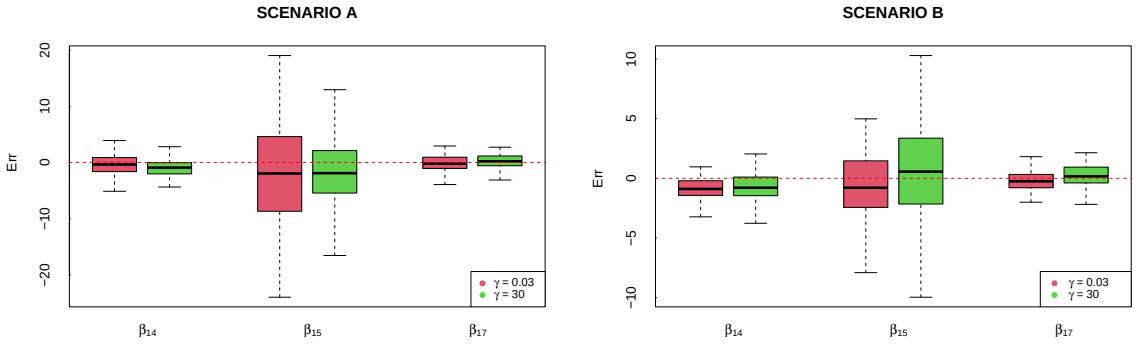

Figure 2: *Distribution of the errors for scenario A (left) and scenario B (right) and for a selection of the $\boldsymbol{\beta}$ parameters. The accuracy of the parameters is shown when using a small (red) and a large (green) value of γ, respectively.*

We repeat each scenario 100 times and report the average accuracy of the estimators by calculating $\sum_{i=1}^{100} \frac{\hat{\boldsymbol{\beta}}_i - \boldsymbol{\beta}_i}{\boldsymbol{\beta}_i}$. For parameter estimation, the tolerance in the EM algorithm is set to 0.01. The two plots in Figure 2 show the distribution of the accuracy in the two scenarios, respectively, when using a small (red) and a large (green) value of γ, respectively. Moreover, we set the ridge tuning parameter in scenario A to $\alpha = 2 \times 10^{-5}$ and in scenario B to $\alpha = 2 \times 10^{-4}$. The results show how a high value of the tuning parameter γ leads to better estimates of $\boldsymbol{\beta}$ in the first scenario, i.e., the Poisson component of the likelihood is particularly beneficial when observations are close in time, while a low value of γ, i.e., an estimation procedure close to the existing LLA methods, works well in the second scenario.

5. Conclusions

In this paper, we have proposed an innovative algorithm for the estimation of stochastic rate constants governing kinetic diffusion processes. Noting that LLA methods perform poorly when the system is observed at fine time intervals, due to numerical instability caused by the strong correlations in the observations from one time point to the next, our proposed method focusses on reconstructing the underlying process of hidden events. Using an Expectation-Maximation algorithm, we have shown, by means of simulation studies, how the new approach leads to more accurate estimates precisely in these settings.

Abstract

In this paper we develop a mixed graphical model for identifying conditional independence relations between continuous and discrete variables in a quantile framework using Parzen's definition of mid-quantile. To recover the graph structure and induce sparsity, we consider the neighborhood selection approach in which conditional mid-quantiles of each variable in the network are modeled as a sparse function of all others. Building on previous work, we propose a two-step estimation procedure where, in the first step, conditional mid-probabilities are obtained and, in the second step, the model parameters are estimated by solving an implicit equation with a LASSO penalty. The empirical application investigates the relationship between depression and inflammation on a sample of individuals from the National Health and Nutrition Examination Survey 2017-2020.

Keywords: LASSO, mixed random variables, mid-CDF, neighborhood selection, NHANES

1. Introduction

Graphical models have become a popular and effective framework for the statistical analysis of complex dependence relations among variables. Within this literature, Gaussian Graphical Models (GGMs, 11) have received considerable attention as they provide a model for the pair-wise conditional correlation structure of the variables of interest. Under the assumption of normality, the underlying conditional dependence structure is completely characterized by the inverse of the covariance matrix of the corresponding GGM. However, GGMs suffer from two limitations. First, they rely on the assumption of normally distributed data. Despite its simplicity and mathematical tractability, this assumption is hardly met in actual applications, and deviation from normality makes it harder to characterize conditional dependence structures. To overcome this issue, semi-parametric Gaussian copula models (15; 22) or power transformations of the data may be considered. Alternatively, one may forgo the normal distribution and consider more robust alternatives such as the multivariate t-distribution (7). Such proposals, however, have mainly relied on the use of symmetric distributions or on, more in general, location-shift models. In contrast, a quantile-based approach (1; 5) allows one to infer the conditional dependence structure without having to introduce assumptions on the form of the distributions.

Another, drawback of the GGMs is that they are confined to the modeling of continuous variables only. In many applications of practical relevance, however, the dataset of interest consists of mixed variables (categorical, counts, and continuous). Unfortunately, the literature regarding graphical models in which the variables are of different types is fairly limited. In parallel efforts, (23) and (3) introduced the class of Mixed Graphical Models (MGMs), which specify the conditional distribution of each variable

(continuous and discrete) given the rest as a member of the exponential family of distributions. Subsequently, in a related line of research, (14) and (4) proposed a generalization of the conditional Gaussian model of (12) for mixed data.

The aim of this paper is to introduce a quantile-based graphical model for mixed variables that tackles conditional dependency structures, without making assumptions on the functional form of the distributions. We start from the work of (8) who developed a quantile regression method for discrete responses by extending Parzen's definition of marginal mid-quantiles (19). Intuitively, mid-quantiles can be viewed as fractional order statistics and have been extensively studied by (16). In this context, using mid-quantiles comes with desirable advantages as opposed to existing approaches, based on either jittering or latent constructs. Most importantly, they offer a unifying theory for quantile estimation with discrete or continuous variables, and are well-behaved asymptotically.

In our approach, to identify conditional independence relations and induce sparsity in the network, we model the conditional mid-quantiles of each variable as a sparse function of all others and fit separate regularized regressions using the neighborhood selection method of (17). For each variable, the parameters are estimated via a two-step procedure where conditional mid-probabilities are first obtained semi-parametrically and then regression coefficients are estimated by solving a LASSO-penalized implicit equation. The proposed method allows us to embed in a common graphical framework both continuous (possibly, e.g., heavy-tailed, skewed, multimodals) and discrete (e.g., binary, ordinal, count) variables, thus offering a much richer class of conditional distribution estimates than the conditional mean.

The relevance of this methodology is shown using observations from adult participants of the National Health and Nutrition Examination Survey (NHANES) 2017-2020 to investigate the association between C-Reactive Protein (CRP) and depression symptoms.

The rest of this paper is organized as follows. Sect. 2. formally describes the proposed model while the estimation procedure is discussed in Sect. 3. Finally, the empirical application is presented in Sect. 4.

2. Methods

In this section we illustrate the proposed mid-quantile mixed graphical model. In order to introduce our methods, we extend the mid-quantile regression of (8) to the graphical modeling framework with both continuous and discrete variables. Subsequently, using the neighborhood selection approach of (17), we show how to estimate a sparse mixed graphical model characterizing conditional independence relations among variables via node-wise penalized mid-quantile regressions.

Let $\mathbf{Y} = (X_1, \dots, X_{p_1}, Z_1, \dots, Z_{p_2})'$ denote a p-dimensional random vector, where $X_1, \dots, X_{p_1}$ are p_1 continuous variables and $Z_1, \dots, Z_{p_2}$ are p_2 discrete variables. Also, let $\mathcal{G} = (V, E)$ denote an undirected graph where $V = \{1, \dots, p\}$ is the set of nodes such that each component of the random variable $\mathbf{Y}$ corresponds to a node in V, and $E \subseteq V \times V$ represents the set of undirected edges.

Following (8), we first introduce the conditional mid-cumulative distribution function (mid-CDF, 19; 20) of Y_j given all other variables as

$$G_{Y_j|\mathbf{Y}_{\neg j}}(y_j \mid \mathbf{y}_{\neg j}) = F_{Y_j|\mathbf{Y}_{\neg j}}(y_j \mid \mathbf{y}_{\neg j}) - 0.5 m_{Y_j|\mathbf{Y}_{\neg j}}(y_j \mid \mathbf{y}_{\neg j}), \tag{1}$$

where $\mathbf{Y}_{\neg j}$ denotes all variables except Y_j, $F_{Y_j|\mathbf{Y}_{\neg j}}(\cdot \mid \cdot)$ is the conditional CDF of Y_j and $m_{Y_j|\mathbf{Y}_{\neg j}}(y_j \mid \mathbf{y}_{\neg j}) = \Pr(Y_j = y_j \mid \mathbf{Y}_{\neg j} = \mathbf{y}_{\neg j})$. The definition of conditional mid-CDF in eq. (1) applies to both continuous and discrete variables. Indeed, if Y_j is discrete, $G_{Y_j|\mathbf{Y}_{\neg j}}(y_j \mid \mathbf{y}_{\neg j})$ is a step function while it reduces to $F_{Y_j|\mathbf{Y}_{\neg j}}(y_j \mid \mathbf{y}_{\neg j})$ if Y_j is continuous since $\Pr(Y_j = y_j \mid \mathbf{Y}_{\neg j} = \mathbf{y}_{\neg j}) = 0$.

Let $\mathcal{S}_{Y_j}$ be the set of s distinct values in the population that the random variable Y_j can take on. Then, the conditional mid-quantile function (mid-QF) of Y_j, $H_{Y_j|\mathbf{Y}_{\neg j}}(\tau)$, is defined as the piecewise linear function connecting the values $G^{-1}_{Y_j|\mathbf{Y}_{\neg j}}(\pi_{jh} \mid \mathbf{y}_{\neg j})$, where $\pi_{jh} = G_{Y_j|\mathbf{Y}_{\neg j}}(y_j \mid \mathbf{y}_{\neg j})$, $h = 1, \dots, s$, for a given quantile level $\tau \in (0, 1)$. We model the τ-th conditional mid-quantile of Y_j given all the other variables using the following mid-quantile regression model:

$$H_{g_j(Y_j)|\mathbf{Y}_{\neg j}}(\tau) = \beta_j^0(\tau) + \mathbf{y}'_{\neg j}\boldsymbol{\beta}_j(\tau), \quad j = 1, \dots, p, \tag{2}$$

where $g_j(\cdot)$ is a known monotone and differentiable "link" function, and $\boldsymbol{\beta}_j(\tau) = (\beta_j^1(\tau), \ldots, \beta_j^{p-1}(\tau))'$ is a vector of $p-1$ unknown regression coefficients, with $\beta_j^0(\tau)$ being an intercept term, for a given τ.

To study conditional independence relations between the components of $\mathbf{Y}$ through the graph $\mathcal{G}$, we establish a result that allows us to make inference on the edge structure E using mid-quantile regressions. Following (1) and (5), the next proposition characterizes the relationship between the conditional mid-quantile function in eq. (2) and the conditional independence between any pair of variables in $\mathbf{Y}$ given the rest.

Proposition 1. *Suppose that the conditional mid-QF of a random variable Y_j, for some $j = 1, \ldots, p$, is defined by the mid-quantile regression model in eq. (2). Then, Y_j is conditionally independent from Y_k, with $k = 1, \ldots, p$ and $k \neq j$, given all of the other variables if and only if $\beta_j^k(\tau) = 0$ for all $\tau \in (0,1)$.*

The proof of Proposition 1 follows from the relationship between the conditional mid-quantile and CDF of each node given the others. Most importantly, from Proposition 1 follows that the zero elements of the vector $\beta_j^k(\tau)$ for all $\tau \in (0,1)$ identify conditional independence relations between the components of $\mathbf{Y}$. Hence, the edge set E of the graph $\mathcal{G}$ is completely determined by the non-zero components in the regression vector $\boldsymbol{\beta}_j(\tau)$, that is, $(j,k) \in E$ if and only if $\beta_j^k(\tau) \neq 0$. Based on this result, we can build a mixed quantile graphical model to characterize conditional independence relationships between the elements of $\mathbf{Y}$ by inferring the sparsity pattern of $\boldsymbol{\beta}_j(\tau)$.

We exploit the neighborhood selection approach of (17) by running separate mid-quantile regressions of each component in $\mathbf{Y}$ on all the others. Specifically, let $\boldsymbol{\tau} = (\tau_1, \ldots, \tau_L)$ be a grid of L ordered quantile levels with $\tau_l \in (0,1)$, $l = 1, \ldots, L$. Large values of L allow us to investigate conditional independence more accurately, but they also increase the computational cost of estimating the model. To infer the graph structure, we consider the linear model in eq. (2) for the conditional mid-QF, $H_{g_j(Y_j)|\mathbf{Y}_{\neg j}}(\tau_l)$, over all variables $j = 1, \ldots, p$ and levels $l = 1, \ldots, L$. Consequently, the corresponding edge set E of conditional dependencies is defined as

$$E = \Big\{(j,k) : \max_{l=1,\ldots,L} \{\max\{|\ \beta_j^k(\tau_l)\ |, |\ \beta_k^j(\tau_l)\ |\}\} > 0, \quad \text{for} \quad 1 \leq j \neq k \leq p\Big\}. \tag{3}$$

In the next section, we describe a procedure to estimate the proposed graphical model $\mathcal{G}$ and induce sparsity in the regression coefficients.

3. Estimation

Consider a sample $\mathbf{Y}_i, i = 1, \ldots, n$, with corresponding observations $\mathbf{y}_i$. For each variable Y_j, $j = 1, \ldots, p$ and level τ_l, $l = 1, \ldots, L$, estimation of the model in eq. (2), and in turn, of the set E in eq. (3), proceeds in two steps.

Let z_{jh}, $h = 1, \ldots, k$, be the h-th distinct observation of Y_j that occurs in the sample, with $z_{jh} < z_{jh+1}$ for all $h = 1, \ldots, k-1$. In the first step we estimate the mid-CDF in eq. (1), $\widehat{G}_{Y_j|\mathbf{Y}_{\neg j}}(y_j \mid \mathbf{y}_{\neg j})$, where $\widehat{F}_{Y_j|\mathbf{Y}_{\neg j}}$ is obtained by fitting h separate logistic regressions, one for each value of z_{jh}, $h = 1, \ldots, k$. In the second step, we define $\widehat{G}^c_{Y_j|\mathbf{Y}_{\neg j}}(y_j \mid \mathbf{y}_{\neg j})$ as the function interpolating the points $(z_{jh}, \widehat{G}_{Y_j|\mathbf{Y}_{\neg j}}(z_{jh} \mid \mathbf{y}_{\neg j}))$, where the ordinates have been obtained in the first step. The goal now is to estimate $(\beta^0(\tau_l), \boldsymbol{\beta}_j(\tau_l))$ in eq. (2) by solving the implicit equation $\tau_l = \widehat{G}^c_{Y_j|\mathbf{Y}_{\neg j}}(\eta(\tau_l) \mid \mathbf{y}_{\neg j})$, where $\eta(\tau_l) = g_j^{-1}\{\beta^0(\tau_l) + \mathbf{y}'_{\neg j}\boldsymbol{\beta}_j(\tau_l)\}$, and, at the same time, capture the most relevant interconnections between the variables, which motivates us to use a sparse estimator that automatically shrink the elements of $\boldsymbol{\beta}_j(\tau_l)$. Following (8), we thus obtain an estimate of $\boldsymbol{\beta}_j(\tau_l)$, denoted $\widehat{\boldsymbol{\beta}}_j(\tau_l)$, by minimizing the following objective function

$$\arg\min_{\boldsymbol{\beta}} \frac{1}{n} \sum_{i=1}^{n} \Big(\tau_l - \widehat{G}^c_{Y_j|\mathbf{Y}_{\neg j}}(\eta_i \mid \mathbf{y}_{\neg j})\Big)^2 + \lambda \mid\mid \mathrm{diag}(\mathbf{w})\boldsymbol{\beta}_j(\tau_l) \mid\mid_1, \tag{4}$$

where we consider the linear interpolation function

$$\widehat{G}^{c}_{Y_j|\mathbf{Y}_{\neg j}}(\eta_i \mid \mathbf{y}_{\neg j}) = b_{h_i}(\eta_i - z_{jh_i}) + \widehat{\pi}_{jh_i}, \quad z_{jh_i} \leq \eta_i \leq z_{jh_i+1}, \tag{5}$$

with $b_{h_i} = \frac{\widehat{\pi}_{jh_i+1} - \widehat{\pi}_{jh_i}}{z_{jh_i+1} - z_{jh_i}}$ and $\widehat{\pi}_{jh_i} = \widehat{G}_{Y_j|\mathbf{Y}_{\neg j}}(z_{jh_i} \mid \mathbf{y}_{\neg j})$. The penalization in eq. (4) is given by a Lasso-type penalty on $\boldsymbol{\beta}_j(\tau_l)$ where we allow a different weight for each coefficient by using the vector $\mathbf{w}$ to avoid that variables of different types are on different scales, and where $\lambda \geq 0$ is the overall tuning parameter of the model. The parameter λ controls the strength of the penalization and determines the sparsity of the graph: a higher (lower) value is responsible for a lower (higher) number of edges; when $\lambda = 0$, $\widehat{\boldsymbol{\beta}}_j(\tau_l)$ reduces to the closed-form estimator in (8, see eq. 2.9). Finally, to infer the graph structure we solve the minimization problem in eq. (4) for all Y_j, $j = 1, \ldots, p$ and τ_l, $l = 1, \ldots, L$, and estimate the edge set E as follows:

$$\widehat{E} = \Big\{(j,k) : \max_{l=1,\ldots,L} \{\max\{|\, \widehat{\beta^k_j}(\tau_l)\,|, |\, \widehat{\beta^j_k}(\tau_l)\,|\}\} > 0, \quad \text{for} \quad 1 \leq j \neq k \leq p\Big\}. \tag{6}$$

To select the optimal value of the penalty parameter λ, we adopt the following BIC-type criteria (5):

$$\text{BIC}(\lambda) = \sum_{l=1}^{L}\sum_{j=1}^{p}\left[\ln\left(\sum_{i=1}^{n}\rho_\tau(y_{ij} - \beta^0_j(\tau_l) - \mathbf{y}'_{i\neg j}\boldsymbol{\beta}_j(\tau_l))\right) + \frac{\ln n \ln(p-1)}{2n}\nu_{jl}\right], \tag{7}$$

where $\rho_\tau(u) = u(\tau - I(u < 0))$ is the quantile loss function (9), with $I(\cdot)$ being the indicator function, and ν_{jl} is the number of estimated non-zero components in $\widehat{\boldsymbol{\beta}}_j(\tau_l)$ for node j at quantile level τ_l. Specifically, we fit the model for a grid of candidate values of λ and then select the optimal tuning parameter as that corresponding to the lowest BIC value in eq. (7).

4. Application

To evaluate the performance of the proposed methods, we illustrate an application to depression symptoms and inflammatory proteins from the NHANES 2017-2020. There is mounting evidence that inflammatory proteins adversely affect functional ability, quality of life, and well-being of individuals (18; 13). Among these proteins, C-Reactive Protein (CRP) is arguably the most extensively studied inflammatory index in depression research. CRP is a protein synthesized by the liver during the acute phase of an inflammatory/infectious process in response to stimulation from other pro-inflammatory proteins (e.g., elevated cytokine levels (6)). Research suggests that the presence, size, and direction of the association between CRP level and depression vary. One possible explanation for this might be the heterogeneity in the population due to, e.g., age and race/ethnicity. Another explanation may be that CRP is also associated with numerous factors (confounders), such as socio-demographic variables and the overall health status of the individual. As potential reasons for these inconsistencies, (21) also pointed out differences in population settings (e.g., inpatient, outpatient, or community), depression assessment (e.g., sum-scores or diagnoses), or adjustment for important chronic conditions.

Graphical models represent the ideal tool to help disentangling the intricate dependencies between CRP, depression symptoms and individual characteristics. Following (8), before carrying out the analysis we remove the effect of NHANES oversampling and then restrict the dataset to individuals aged 20-70 years. The final sample size for analysis is $n = 3690$, composed of about 59.4% of white persons and 50.1% females. In this network, we include the concentration of CRP (mg/L), nine depression symptoms measured via the Patient Health Questionnaire-9 (PHQ-9, 10) scored on a 4-point Likert scale and 17 socio-demographic, clinical, and lifestyle variables collected among the survey participants, resulting in a total of $p = 17$ nodes. Specifically, the PHQ-9 is a nine-item self-report questionnaire that was administered to assess the frequency of nine major depression criteria listed in the Diagnostic and Statistical Manual of Mental Disorders (2). The questionnaire is a well-established, validated tool that evaluates how often individuals had been bothered by any of the nine items in the previous 2 weeks, on a scale ranging from 0 ("not at all") to 3 ("nearly every day").

We fit the proposed model using a grid of $L = 7$ quantile levels, $\boldsymbol{\tau} = (1/8, \ldots, 7/8)$, across an equispaced sequence of 100 values of the tuning parameter λ on the log scale from 0.001 to 5. Prior to fitting, continuous variables have been centered around zero and divided by their standard deviation. For continuous and count variables, we take $g(\cdot)$ to be, respectively, the identity and the logarithmic function, while we use the logistic mid-quantile model for binary nodes. Finally, the edge set $\widehat{E}$ is estimated as described in eq. (6). To reduce model uncertainty and improve reliability of the inferred interactions, we adopt a model averaging approach. Specifically, 500 bootstrap datasets are created by resampling from the original one. Then, we fit the proposed model on the 500 bootstrap re-samples and estimate the edge structure for each bootstrap dataset. Eventually, in the final network we retain only those edges that are present in at least 85% (18) of the learned graphs.

Fig. 1 provides a graphical representation of the estimated network, where the width of the edges is proportional to the absolute value of the strength of the interaction and the edge colors specify the sign of the corresponding interaction (green = positive, red = negative, grey = undefined). The colors of the nodes map to the three different domains, Inflammation Marker, Depression Criteria, and Covariates.

Results indicate that CRP is associated with greater changes in appetite, presenting a non-zero edge in 90% of bootstrap re-samples. CRP also shows noteworthy connections with other variables: it is positively associated with BMI and gender but negatively with recent smoking and alcohol consumption. Finally, smoking and gender are proximal to several symptom criteria including fatigue, appetite problems, psychomotor changes and thoughts of death, suggesting that there may be gender differences underlying these relationships.

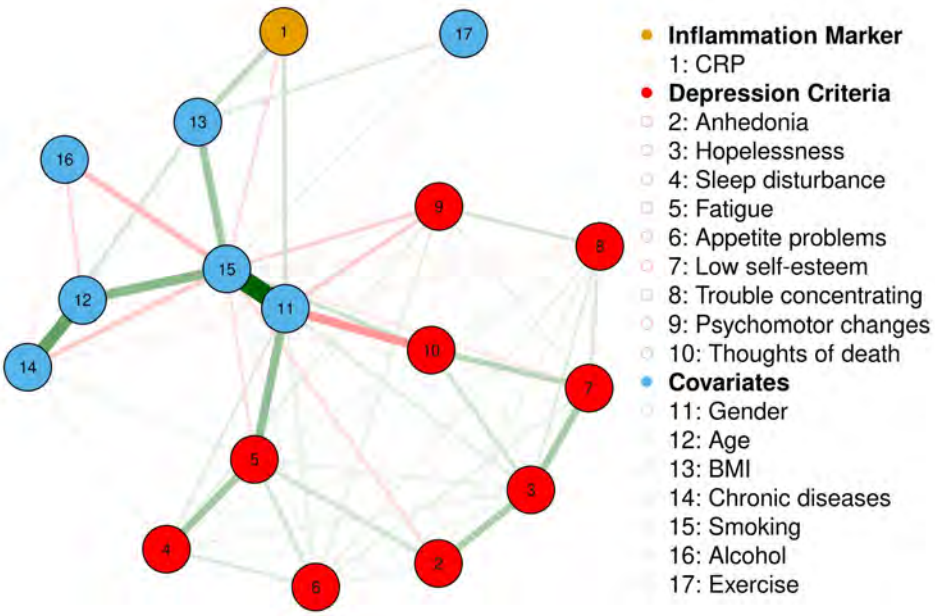

Figure 1: Estimated graph structure. Edges represent interactions that was found to be non-zero in at least 85% of the 500 bootstrap re-samples. Green edges in the networks depict positive associations, red edges represent negative associations, and grey ones signify interactions wherein no sign is defined. Thicker edges depict stronger associations.

Abstract

The main parametric families of distributions for random compositions include the Dirichlet distribution and some appropriate generalization of the Dirichlet family (7; 4), or the logratio normal family (6). In this contribution we consider as a valid alternative the logratio Student t distribution on the simplex, an extension to the additive logistic Student t distribution (2) derived from the multivariate t distribution in real space. We give its representation within the algebraic-geometric structure of the simplex compatible with the Aitchison measure. We illustrate the use of this model by a real data example, showing its usefulness in the modelling of compositional data.

Keywords: Aitchison measure, logratio normal family, coordinate representations

1. The model

Katz and King (2) proposed an Additive logistic Student t distribution to model the composition of multiparty electoral data. Then the multivariate t distribution is used to model the additive logratio transformation (alr) vector and, finally, the inverse logistic transformation is used to return to the unit simplex $\mathcal{S}^D$. The alr is a non-isometric transformation which maps a composition in the D-part simplex into $\mathbb{R}^{D-1}$, considering the last part as common denominator of the others.

The additive logistic multivariate t distribution includes the additive logistic normal as a limiting special case. Here we define a multivariate t distribution on $\mathcal{S}^D$, that can be called logratio t distribution, in analogy with the logratio normal. The model, instead of using the alr transformed vector, is obtained using orthonormal log-ratio coordinates of a random composition and defining a density with respect to the Aitchison measure λ_a, which is compatible with the inner vector space structure of the simplex defined in Pawlowsky-Glahn (8), and could be considered a natural measure for the simplex. The Euclidean vector space structure of the simplex, the principle of working on coordinates (5) and the Aitchison measure allows us to define such isometric logistic Student t distribution.

A random composition $\mathbf{X} \in \mathcal{S}^D$ has a logratio Student t distribution with location $\boldsymbol{\mu} \in \mathbb{R}^{D-1}$, scatter matrix $\boldsymbol{\Upsilon}$ and ν degrees of freedom, if it has density function

$$f_a(\mathbf{x}) = \frac{dP_a}{d\lambda_a}(\mathbf{x}) = \frac{\Gamma(\frac{\nu+d}{2})}{\Gamma(\nu/2)(\nu\pi)^{d/2}|\boldsymbol{\Upsilon}|^{1/2}} \left(1 + \frac{1}{\nu}(h(\mathbf{x}) - \boldsymbol{\mu})'\boldsymbol{\Upsilon}^{-1}(h(\mathbf{x}) - \boldsymbol{\mu})\right)^{-\left(\frac{\nu+d}{2}\right)},$$

where $d = D-1$, $h(\cdot)$ stands for the orthonormal coordinates and P_a is the logratio Student t probability measure. This distribution will be denoted by $\mathbf{X} \sim t_{\mathcal{S}}^D(\boldsymbol{\mu}, \boldsymbol{\Upsilon}, \nu)$.

Using the inverse of the Jacobian, $|d\lambda_a/d\lambda| = (\sqrt{D}x_1x_2\cdots x_D)^{-1}$, we can change the measure by the Radon-Nikodym chain rule, and express this density function with respect to the Lebesgue measure λ in $\mathbb{R}^{D-1}$. The resulting expression is

$$f(\mathbf{x}) = \frac{dP}{d\lambda}(\mathbf{x}) = \frac{\Gamma(\frac{\nu+d}{2})(\sqrt{D}x_1x_2\cdots x_D)^{-1}}{\Gamma(\nu/2)(\nu\pi)^{d/2}|\boldsymbol{\Upsilon}|^{1/2}}\left(1+\frac{1}{\nu}(h(\mathbf{x})-\boldsymbol{\mu})'\boldsymbol{\Upsilon}^{-1}(h(\mathbf{x})-\boldsymbol{\mu})\right)^{-\left(\frac{\nu+d}{2}\right)}. \quad (1)$$

The mode and the expected value of $\mathbf{X} \sim t_{\mathcal{S}}^{D}(\boldsymbol{\mu}, \boldsymbol{\Upsilon}, \nu)$, if $\nu > 1$, else is undefined, with respect to the measure λ_a coincide and are

$$\mathrm{mode}_a(\mathbf{X}) = \mathrm{E}_a(\mathbf{X}) = h^{-1}(\boldsymbol{\mu}),$$

independently of the orthonormal coordinates $h(\mathbf{x})$.

For a composition $\mathbf{X} \sim t_{\mathcal{S}}^{D}(\boldsymbol{\mu}, \boldsymbol{\Upsilon}, \nu)$ there is no closed form for $\mathrm{E}(\mathbf{X})$ with respect to the Lebesgue measure λ. Since the integral expression exists, it is not reducible to any simple form and it is necessary to use numerical integration to obtain it. Given $\mathbf{X} \sim t_{\mathcal{S}}^{D}(\boldsymbol{\mu}, \boldsymbol{\Upsilon}, \nu)$, when $\nu > 2$, then $\mathrm{Mvar}(\mathbf{X}) = \frac{\nu}{\nu-2}\mathrm{trace}\,(\boldsymbol{\Upsilon})$.

The parameter estimation is based on the maximum likelihood estimation (MLE) and the algorithm is obtained from the expectation-maximization (EM) method (3).

2. An example

The data set used is taken from Katz and King (1) related to 1979 British House of Commons electoral data. The three parties vote proportions, namely Conservative, Labour and Liberal from the British electoral system were considered. For this example the data were filtered from outliers and the missing values were removed.

After taking a suitable ilr transformation, the maximum likelihood estimates for the Normal Distribution in the Simplex are:

$$\hat{\boldsymbol{\mu}} = (-0.161, -0.268), \quad \hat{\boldsymbol{\Gamma}} = \begin{pmatrix} 0.181 & -0.359 \\ -0.359 & 0.959 \end{pmatrix}.$$

While the maximum likelihood estimates for the Student t Distribution in the Simplex, where the degrees of freedoms ν are obtained in an iterative estimation with the rest of the parameters via the EM algorithm, are:

$$\hat{\boldsymbol{\mu}} = (-0.158, -0.278), \quad \hat{\boldsymbol{\Gamma}} = \begin{pmatrix} 0.131 & -0.261 \\ -0.261 & 0.695 \end{pmatrix}, \quad \hat{\nu} = 6.364\,.$$

Figure 1 shows the sample in a ternary diagram and the isodensity curves at levels 50% and 95% of the fitted Normal Distribution in the Simplex (Left) and Student t Distributions in the Simplex (Right).

A different fit using the logratio t distribution is evident from the two ternary diagrams, in particular the outer region is slightly wider for the t than the normal as expected.

Figure 2 shows contours and sample plotted in the ilr coordinate space. The better fit of the multivariate t distribution is confirmed by the Akaike information criterion which is equal to 1145.367 and 1128.209 for the normal and the Student t model respectively (the lower, the better).

A decomposition of the changes in tourism demand in Tuscany over the 2019-2021 period

Mauro Mussini[a]

[a] Department of Economics, Management and Statistics, Piazza dell'Ateneo Nuovo, 1 – 20126, Milan
mauro.mussini1@unimib.it

Abstract

The paper examines the changes in tourism demand in the provinces of Tuscany in the 2019-2021 period, when the tourism sector was severely hit by the COVID-19 pandemic. The change in the number of overnight stays is broken down into components by using the index decomposition analysis, which separates the contributions of changes in tourist arrivals, tourist-mix and length-of-stay. The decomposition results show that a fall in tourist arrivals was the main driver in reducing the number of overnight stays whereas the length-of-stay component partially mitigated the decline in overnight stays in all provinces, except Florence. A relatively small tourist-mix component suggests that the changes in the relative composition of tourism demand had a minor role in the change in overnight stays.

Keywords: decomposition, tourism demand, tourist flows.

1. Introduction

The tourism sector in Italy was severely affected by the outbreak of the COVID-19 pandemic, with a tourism demand that started to recover in 2021 but remaining far below the pre-pandemic levels [3]. All Italian regions suffered a sharp reduction in foreign tourist flows, especially the regions having a higher proportion of foreign tourists. Tuscany is one of the most visited regions by foreign tourists, also because of a diversified tourism product including art cities, sun and beach destinations, thermal spas and traditional landscapes. After a decade of growth, tourism demand in Tuscany fell dramatically in 2020 and it was still far from a complete recovery in 2021 [5]. In such a scenario, monitoring the dynamics of tourism demand is important for decision-making in the recovery plan of the tourism sector in the region.

Tourism demand in a destination is usually examined by observing some key indicators: the number of overnight stays, the number of tourist arrivals, the average length-of-stay. The changes in these indicators can be jointly analysed by using the log mean Divisia index decomposition of the variation in tourism demand [4], which breaks down the change in overnight stays by separating the roles of changes in tourist arrivals, tourist-mix and length-of-stay.

The paper is organized as follows: section 2 describes the index decomposition technique for the analysis of changes in tourism demand; section 3 shows the results of the decomposition applied to the changes in tourism demand in the provinces of Tuscany over the 2019-2021 period; section 4 concludes and suggests some directions for future research.

2. The index decomposition analysis of changes in tourism demand

The index decomposition analysis is based on the log mean Divisia index decomposition, a technique which is widely used in the studies on energy efficiency to separate the contributions of different factors to the change in energy consumption [1, 2]. Recently, the log mean Divisia index decomposition has been used to obtain a decomposition of the change in tourism demand [4], where tourism demand in a destination is measured by the number of overnight stays in that destination. This decomposition links the change in the number of overnight stays to the changes in the number of tourist arrivals, in the average length-of-stay and in the relative composition of tourism demand.

Let D_{it} and A_{it} be respectively the number of overnight stays and the number of tourist arrivals in destination i in year t. Supposing that both D_{it} and A_{it} can be disaggregated into k segments by a segmentation variable (e.g. type of accommodation), we have that $D_{it} = \sum_{j=1}^{k} D_{ijt}$ and $A_{it} = \sum_{j=1}^{k} A_{ijt}$ where D_{ijt} is the number of overnight stays in segment j and A_{ijt} is the number of arrivals in the same segment, with $j = 1, \cdots, k$. The number of overnight stays in segment j can be written as

$$D_{ijt} = A_{it} \frac{A_{ijt}}{A_{it}} \frac{D_{ijt}}{A_{ijt}} = A_{it} M_{ijt} L_{ijt}, \tag{1}$$

where M_{ijt} is the proportion of arrivals in segment j and L_{ijt} is the average length-of-stay of tourists in that segment [4]. The total number of overnight stays in destination i in year t is expressed as

$$D_{it} = \sum_{j=1}^{k} A_{it} M_{ijt} L_{ijt} \tag{2}$$

and the change in overnight stays between two years, namely year 0 and 1, becomes

$$\Delta D_i = D_{i1} - D_{i0} = \sum_{j=1}^{k} A_{i1} M_{ij1} L_{ij1} - \sum_{j=1}^{k} A_{i0} M_{ij0} L_{ij0}. \tag{3}$$

The change in overnight stays in eq. (3) can be split into three components by using the log mean Divisia index decomposition [4]. W_{ij} being the logarithmic mean of D_{ij1} and D_{ij0}

$$W_{ij} = \begin{cases} \frac{D_{ij1} - D_{ij0}}{\ln D_{ij1} - \ln D_{ij0}} & if \;\; D_{ij1} \neq D_{ij0} \\ D_{ij1} & if \;\; D_{ij1} = D_{ij0} \end{cases}, \tag{4}$$

the change in overnight stays in eq. (3) is broken down into three components:

$$\Delta D_i = \sum_{j=1}^{k} W_{ij} \ln\left(\frac{A_{i1}}{A_{i0}}\right) + \sum_{j=1}^{k} W_{ij} \ln\left(\frac{M_{ij1}}{M_{ij0}}\right) + \sum_{j=1}^{k} W_{ij} \ln\left(\frac{L_{ij1}}{L_{ij0}}\right) = \Delta D_i^A + \Delta D_i^M + \Delta D_i^L, \tag{5}$$

where W_{ij} is the weight of segment j in terms of overnight stays. In eq. (5), ΔD_i^A is the tourist-flow component measuring the change in overnight stays due to a variation in tourist arrivals, ΔD_i^M is the tourist-mix component quantifying the change in overnight stays linked to changes in the relative distribution of arrivals among the tourist segments and ΔD_i^L is the length-of-stay component measuring the effect of changes in average length-of-stay in the segments [4].

3. An analysis of the changes in overnight stays in Tuscany

The changes in the number of overnight stays in the provinces of Tuscany are examined over the 2019-2021 period; i.e., from the year before the outbreak of the COVID-19 pandemic in Italy to the year when the tourism sector started to recover. Data on tourist arrivals, country of residence of tourists (Italy or foreign countries) and overnight stays are from the tourism database of the Tuscany Region [6]. The decomposition of the change in the number of overnight stays is obtained by considering two tourist segments, resident and non-resident tourists, in each destination.

Table 1 shows the decomposition of the changes in the number of overnight stays from 2019 to 2021 by province. The variation in the number of overnight stays was negative in each province of Tuscany, but with differences in the magnitude of the decrease. Florence had the largest reduction in overnight stays, a result that one might expect since it was the province with the largest number of overnight stays in 2019, most of which recorded for non-resident tourists. The large decreases in overnight stays occurred in the provinces of Siena, Pistoia and Pisa seem to suggest that the provinces with a tourism product based on cultural and artistic heritage were particularly affected by the COVID-19 pandemic. A graphical analysis of the tourist-flow,

tourist-mix and length-of-stay components may help to compare their respective roles in the change of overnight stays.

Table 1: Components of the change in overnight stays in the provinces of Tuscany, 2019-2021.

Provinces	**ΔD**	**Components of ΔD**		
		Tourist-flow	**Tourist-mix**	**Length-of-stay**
Florence	-10524238	-8848904.36	-552665.44	-1122668.19
Siena	-1636332	-1894697.08	-278242.79	536607.87
Pistoia	-1307427	-1451079.87	-207949.66	351602.52
Pisa	-1154175	-1771075.20	71388.56	545511.65
Lucca	-928869	-1274969.85	-29314.12	375414.97
Grosseto	-512546	-863350.72	-37955.46	388760.18
Arezzo	-359158	-524906.65	-171713.22	337461.88
Livorno	-333021	-566559.55	-100594.33	334132.88
Prato	-265244	-309929.57	244.57	44441.00
Massa-Carrara	-79761	-167747.92	10833.27	77153.65

Figure 1 (panels A and B) shows the three components of the change in overnight stays for each province. Florence, the province with the largest decrease in overnight stays, has a negative sign for each of the three components of the change in the number of overnight stays. The decline in tourist arrivals had the most important role in reducing the number of overnight stays in the province of Florence. The loss of overnight stays in the provinces of Siena, Pistoia, Pisa and Lucca (figure 1, panel A) was due to the reduction in tourist arrivals, which was only partially counterbalanced by a positive length-of-stay component while the tourist-mix component was relatively small or almost negligible (in Pisa and Lucca). This suggests that the changes in the proportions of resident and non-resident tourists had a minor impact on the variation in the number of overnight stays.

The number of overnight stays would have increased for effect of the length-of-stay component in the provinces of Grosseto, Arezzo and Livorno (figure 1, panel B), however the decrease in tourist arrivals resulted in a negative tourist-flow component which overcame, in absolute value, the positive contribution of the change in length-of-stay in such provinces. The tourist-mix component contributed to reducing the number of overnight stays in the above three provinces, especially in the province of Arezzo where the proportion of non-resident tourist arrivals had a large decrease. The changes in the number of overnight stays were smaller in the provinces of Prato and Massa-Carrara, but it is worth mentioning that overnight stays in such provinces were lower than those in other provinces at the beginning of the period under consideration.

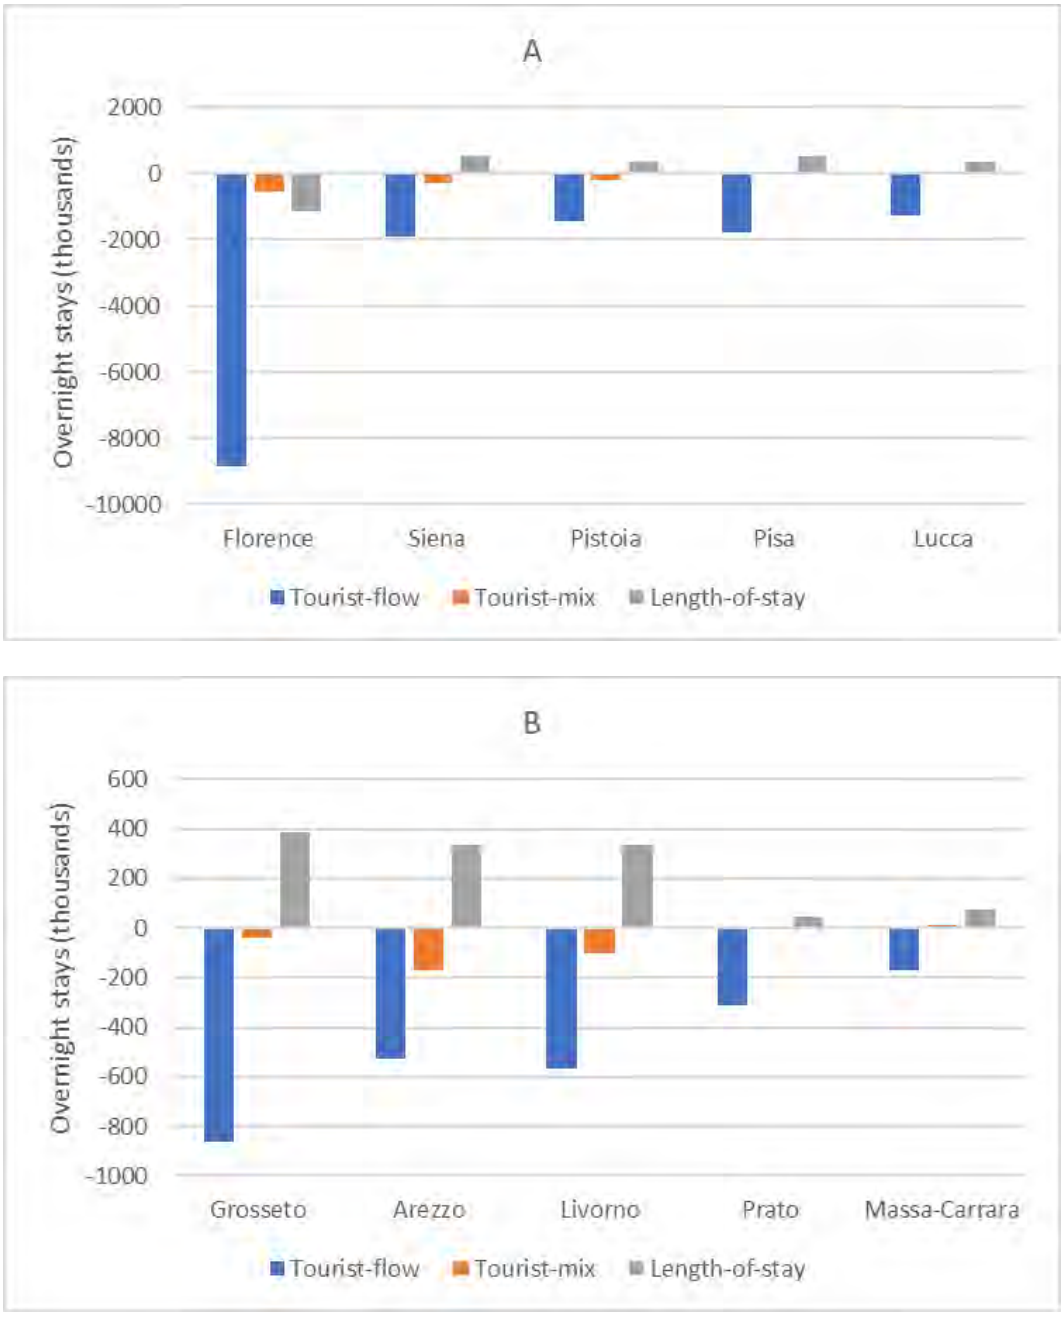

Figure 1: Decomposition of the changes in overnight stays from 2019 to 2021 by province.

4. Conclusion

The analysis of changes in tourism demand in the provinces of Tuscany points out that overnight stays were still below their pre-pandemic levels in 2021, especially where the tourism product is mainly based on cultural and artistic heritage. The decomposition of the changes in the number of overnight stays shows that a decline in the number of tourist arrivals was the main driver of the decrease in overnight stays observed in each province between 2019 and 2021. The length-of-stay component is always positive, except in the province of Florence, suggesting that an increase in the average length-of-stay mitigated to some extent the negative impact of the fall in tourist arrivals. In other words, far fewer tourists arrived in Tuscany in 2021 compared with 2019 but they stayed a little longer. The variation in the proportions of resident and non-resident tourist arrivals had a minor role in changing the number of overnight stays in Tuscany over the 2019-2021 period.

Future research might examine the drivers of the change in tourism demand by segmenting tourists according to the type of accommodation they chose and by extending the period of observation once the

2022 data are available for analysis. A further direction for future research is the development of a decomposition which can take the spatial relationships between destinations into account when breaking down the change in tourism demand of a region.

Abstract

Gender impact assessment is a process that evaluates the effect of gender policies and motivates the introduction of subsequent improvement strategies oriented at balancing out gender inequalities. Currently, one of the most employed tools to assess the effect of gender-related policies is the European Gender Equality Index, a composite indicator that summarizes several dimensions of the gender gap. In this paper, a Bayesian network-based approach is proposed as an alternative for combining dimensions of the index. Such modelling, discussed through an application, allows the construction of a network where ingredients of the index interact with socio-economic variables and the inferential engine associated to the network is employed to carry-out both *ex-ante* and *ex-post* analysis. As a result, the method can be a valuable tool for supporting the gender impact assessment.

Keywords: Bayesian Network, GEI, Impact evaluation, Province Level, Value of Information Analysis

1. The rationale

Structural gender inequalities are embedded in the society. There is a risk of being gender blind that leads to ignore the specific effects a governmental decision or policy can have on different genders. The European Commission defines gender impact assessment as a tool for detecting if policies are impacting differently between women and men and thus reinforcing or mitigating inequalities ($urly.it/3q\_q4$). The process of quantifying the impact of a policy on the gender gap is however unavoidably tied to the measure of gender gap itself. In macroeconomics, composite indicators are popular for their ease of interpretation (8). One of the most used in Europe, is the Gender Equality Index (GEI) developed by the European Institute for Gender Equality (EIGE) for monitoring and compare the gender equality at national level within EU Member States. GEI is based on 6 core domains, measured in 14 sub-domains through 31 variables, here called indicators, playing the role of ingredients of the computation. Ingredients are aggregated through arithmetic means within sub-domains and through geometric means across sub-domains to produce domain-level scores. Finally scores are linearly combined across domains according to a weighting system informed upon experts' advice.
Even though composite indicators like GEI are largely adopted and have an increasingly complex architecture of aggregation, their result is a single value, without any multivariate feature. Indeed, composite indicators do not provide any information about the dependence structure among its ingredient variables and cause-effect relations between specific sets of variables contributing to a certain level of the indicator. In this sense a clear improvement of GEI would be to complement it with a multivariate statistical

approach to holistically handle the gender gap, providing policy makers with a statistical tool to evaluate and compare scenarios of gender policies (7). An integrated approach could result in a richer set of information to orient impact assessment while, at the same time, controlling for collateral negative impact. The aim of the paper is to present a structured framework where GEI is supported by a multivariate graphical statistical model, namely a Bayesian network, and to highlight the advantages of this approach with regard to policy guidance and impact assessment. An empirical application on Italian data at province level is provided to show the functioning of the novel method. We firstly discuss the data availability for reproducing the European Gender Equality Index (GEI) at Italian provincial level (Section 2); in Section 3. we estimate the Bayesian network and we show its potential in Section 4.

2. Gender data availabilty

Gender impact assessment promotes transparent decision-making and better governance to achieve a relevant impact on the society and human well-being. A crucial point of the gender impact assessment is the availability of gender-sensitive data, i.e. data collected and analysed by accounting for sex. Moreover, to address geographical heterogeneities, gender sensitive data should be collected with territorial granularity. Undoubtedly, inclusion strategies should be rooted in a territorial specificity to be more effective (2). Nevertheless, gender micro-data may be unavailable, compromising a proper gender impact assessment. United Nations Member States (UN) shared, by an Agenda of Sustainable Development, a set of goals aiming at peace and prosperity for people and the planet but in Italy, according to Openpolis.it, in 2020, 52.5% of gender indicators proposed by UN for monitoring the achievement of the Agenda 2030 were missing.

In this work, firstly, we employ ISTAT data to reconstruct a province level GEI (PV-GEI). This step is similar to what has been made at regional level by (1). Figure 1 compares the data availability of ingredient variables of GEI at regional and provincial level, eventually also denoting proxy variables availability.

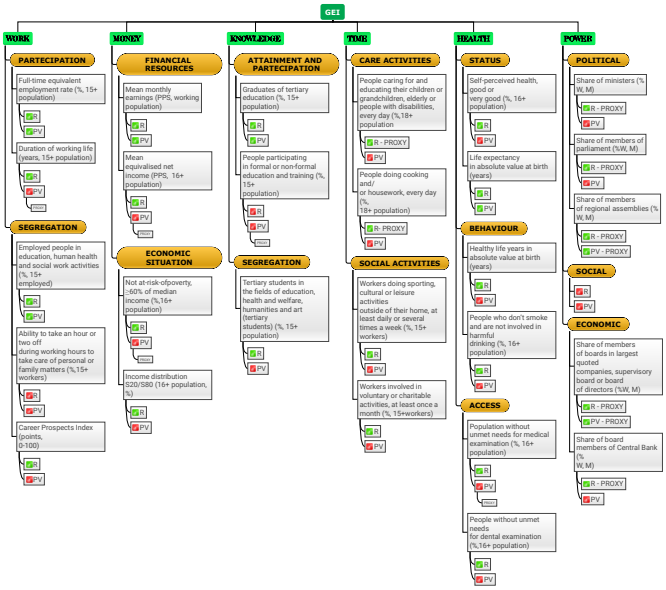

Figure 1: Ingredient variables of GEI: a comparison between data availability at regional and provincial level

The PV-GEI has been built on the basis of available data, so that, with respect to the national GEI, the Time domain is missing. The Italian PV-GEI distribution is depicted in Figure 2. The map shows that highest values of GEI belong to larger cities or northern cities.

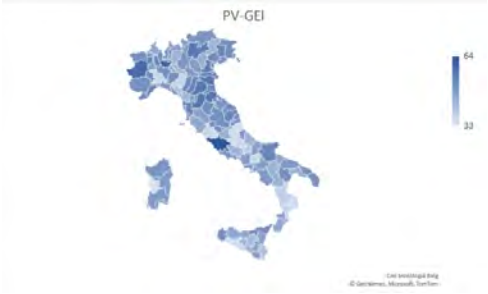

Figure 2: Map chart of GEI at provincial level

3. A Bayesian Network for the gender impact assessment

The second phase of our work consists in employing a Bayesian network to support and integrate the measured PV-GEI that, here, has been treated as a variable. The point of departure for this contribution is the model presented in (5). Bayesian networks (BNs, (9)) consist of a directed acyclic graph (DAG) and an associated joint probability distribution, that can be interpreted as a conditional independence map. A DAG is a graph $G(V, E)$ consisting of a set of nodes (or vertices) V and a set E of directed edges that cannot give rise to directed cycles, *i.e.* directed paths starting and ending with the same node following arrow direction. The vertices of the DAG represent random variables and the edges describe the relations between them. A BN is provided with an inferential engine that allows for what-if-analyses. To do so, evidence (i.e. a possible policy) is inserted in the network and then it is propagated throughout it producing the updated marginal distributions. The model can be thus interpretable as a tool for impact assessment.
The proposed model has been developed at Italian provincial level since conducting the analisys at a fine granularity level is crucial to study the determinants of inequalities and thus, for supporting effective decision-making ($urly.it/3ra09$). The statistical model we discuss has been directly learnt from data by means of structural learning (3). Specifically we have employed the PC algorithm (4), a procedure that performs multiple conditional independence tests on data and then translates the obtained independence statements into a DAG. The learning phase has been conducted using the statistical software Hugin. The variables contained in the dataset are the PV-GEI, GEI ingredients and synthetic domains (as depicted in Figure 1), as well as additional structural and socioeconomic features, called extra variables. The latter have been included in the model to obtain a BN that not only captures the relationships among gender-related variables but also investigates if and how other social and economic dimensions can affect the gender gap. Focusing on a wider picture could improve our understanding of how gender-based differences are tied to other domains of our society and provide policy makers with a deeper awareness of the systemic impact of their interventions.

In the learning process, it is assumed that extra variables are not affected by GEI ingredients; consequently, edges from GEI have been forbidden and indicators built to summarize the GEI domains have been forced to be linked to the PV-GEI. The resulting DAG is shown in Figure 3. PV-GEI has been inserted in the network as an additional node, with incoming arcs from each synthetic score domain. The presence of the PV-GEI node allows ranking provinces in terms of gender equality. The colour of the vertices denotes the variables group (orange= extra variables, light green= GEI ingredients, green=GEI domains synthesis, dark green= PV-GEI). The graph provides a clear picture of how all the variables interact under a full multivariate approach.

4. Discussion

The model in Figure 3 can be used in both *ex-ante* and *ex-post* perspectives. What-if analysis can provide policy makers with a powerful tool for an *ex-ante* analysis. The simulation of scenarios could help identifying the most effective policy to mitigate gender-related disequities and promote social and

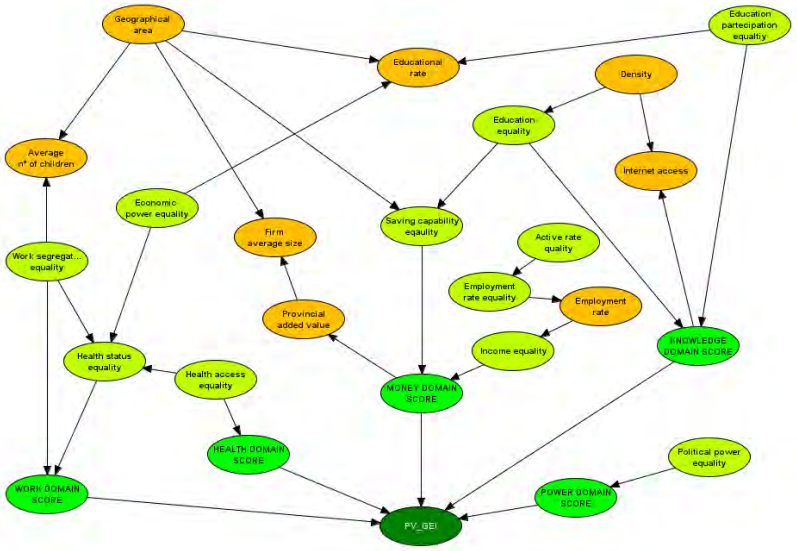

Figure 3: Bayesian network model for territorial gender impact assessment

economic well-being. Moreover, the obtained BN can be used to perform value of information analysis (VOI). VOI allows the user to quantify the mutual information between variables and, thus, to explore the most impacting variables for an area of interest. This may help in defining priorities when considering different improvement actions that target the gender gap. Taking an *ex-post* perspective, the impact of policies can be evaluated by performing a causal analysis on the network (6). A causal use of Bayesian networks requires stronger hypotheses in the structural learning phase (4). However, if the assumptions hold, it allows estimating the impact of policies even when only *ex-post* policy-related observational data are available.

An integrated use of composite indicators and BN can thus enhance the role of statistics in the analysis of gender gap, by providing a tool-set able to simultaneously measure, monitor, predict and evaluate in a unified framework.

Can statistics be helpful in detecting electoral fraud?

Massimo Attanasio[a], Vincenzo G. Genova[a], and Michele Tumminello[a]

[a] Department of Economics, Business, and Statistics. University of Palermo; massimo.attanasio@unipa.it,vincenzogiuseppe.genova@unipa.it, michele.tumminello@unipa.it

Abstract

This paper presents a case study of electoral fraud in the Italian Overseas Constituencies during the 2018 Italian Election. The study leverages publicly available electoral data obtained from the Central Office for Foreign Circumscriptions at the Rome Court of Appeal to conduct an analysis of voting preferences expressed for the party "Unione Sudamericana Emigrati Italiani" (USEI) and evaluates statistical anomalies in the preferences expressed for the candidate Cario Adriano. The study employs a comprehensive four-step methodology that includes numerical analysis, Monte Carlo simulations, validation, and outlier detection analysis. The results suggest that there is evidence of electoral fraud in the polling stations of Buenos Aires, with specific anomalies identified in the preferences expressed for Cario Adriano.

Keywords: Electoral fraud, Italian Overseas Constituencies, Southern American election

1. Introduction

The Italian Electoral Law of 2017, also known as Rosatellum Bis, is a mixed electoral system that allocates 37% of seats through a first-past-the-post system and 63% proportional allocation. The Chamber and Senate of the Republic use the largest remainder method to allocate proportional seats, and both houses are elected in a single round of voting [1]. The law replaced the 2005 Porcellum and 2015 Italicum laws, which were declared partly unconstitutional by the Italian Constitutional Court. The Chamber of Deputies has 400 members, with 147 elected in single-member districts, 245 elected through proportional representation, and 8 Overseas Constituencies elected by the Italians abroad [1]. On the other hand, the Senate has 200 elected members, with 74 elected in single member districts, 122 elected through proportional representation, and 4 Overseas [1]. The Senate election uses a single ballot system which includes the district representative elected through a simple majority. The ballot also lists the political parties and party lists that support the representative, used to determine proportional representation with a 3% minimum threshold for party representation. Finally, in the composition of the Senate, a limited number of senators-for-life are appointed for life by the President of the Republic [1]. Concerning the Overseas Constituencies' election, the Italian Parliament has established the Overseas Constituencies to guarantee representation for Italian citizens residing abroad. The right to vote by mail was introduced just for the Italian citizens residing abroad since 2001 [2]. Consular offices are responsible for sending electoral ballots to eligible voters, collecting the ballots, and sending them to the Chamber of Deputies and the Senate of the Republic in Rome. Abroad voters cast their vote by marking the symbol associated with their preferred list, and they can also express a vote of preference by writing the candidate's last name [2]. To write the candidate's name is a prerogative of the Italians residing abroad, while in Italy voters are allowed to mark just the party.

This work regards Fabio Porta, a deputy of the Democratic Party in the Italian Parliament elected in 2022. In 2018, Porta ran as a candidate in the South America constituency for a seat in the Senate of the Republic, which was instead awarded to Adriano Cario. Porta reported Cario for electoral fraud and the Senate conducted a thorough judicial investigation into the preference votes. In October 2021, Porta, on

the advice of his lawyer, requested statistical consulting from the authors of this work to support the findings of previous investigations that had revealed anomalies at the consulate of Buenos Aires. The statistical anomalies founded in this paper have been used by the lawyer to support their legal dispute. In January 2022, Porta replaced Cario as senator and won the legal dispute.

The consultation was organised according to a four-step statistical methodology to uncover anomalies. The first involved a preliminary numerical analysis. In the second step, Monte Carlo simulations were carried out on the Buenos Aires polling stations. In the third step, the results of the Monte Carlo simulations were validated by performing an indirect verification using the polling stations of another consulate as a validation set.

Finally, in the fourth step, an outlier detection analysis was performed on the polling stations in Buenos Aires to identify any preferences that were "outlier," through the Bonferroni test statistics.

The paper is organised as follows: in Section 2, we illustrate the data and aim; in Section 3, we present the four-step statistical procedure; in Section 4, we will offer some conclusions.

2. Data and aim

The present study uses electoral data of the Senate, published by the Central Office for Foreign Circumscriptions at the Rome Court of Appeal. This dataset regards the Italian election of the Southern American Overseas Constituencies held on March 4th, 2018. The dataset provides voting preferences expressed for each Overseas candidate at individual polling sections within Consular offices (Table 1 reports just some Polling Sections).

The aim of this paper is to assess statistical anomalies in the preferences expressed for the candidate Cario Adriano in the Buenos Aires consulate. Rosario Consulate is used as a validation set. This examination was carried out while controlling for the preferences expressed for other candidates within the same political party. To achieve the objectives of our analysis, we analyzed voting preferences expressed in Buenos Aires (100 polling sections) and Rosario (47 polling sections) for the candidates of the "Unione Sudamericana Emigrati Italiani" (USEI) party.

Table 1: Preferences for the USEI candidates in Buenos Aires and Rosario consulates by Polling Sections

Consulate	Polling Section	USEI candidates				**Total**
		Nardelli	Vicentini	Cario	Moya	
Buenos Aires	1	83	0	3	191	**277**
	⋮	⋮	⋮	⋮	⋮	⋮
	23	115	2	49	104	**270**
	⋮	⋮	⋮	⋮	⋮	⋮
	100	12	1	344	6	**363**
Total		**3,645**	**184**	**21,972**	**2,437**	**28,238**
Rosario	1	46	1	0	20	**67**
	⋮	⋮	⋮	⋮	⋮	⋮
	23	52	3	3	37	**95**
	⋮	⋮	⋮	⋮	⋮	⋮
	47	30	2	0	38	**70**
Total		**1,860**	**107**	**69**	**1,097**	**3,133**

3. The four-step statistical procedure

3.1 Preliminary analysis

In the first step, we built for the two consulates two contingency tables IxJ: the first table (100x2) refers to Buenos Aires, and the second (47x2) to Rosario. In these tables, the columns of the candidates Nardelli, Vicentini, and Moya are collapsed into one (Other USEI). So, we calculate the variances and coefficients of variation of preferences expressed for candidate Cario and other USEI candidates calcu-

lated over the 100 polling sections in Buenos Aires (Table 2). The results indicate that Cario's preferences variance in Buenos Aires (41,734) is higher than that of the other USEI candidates (33,175). This difference is evident in the higher coefficient of variation too: Cario's coefficient is 0.93 and the others' coefficient is 0.64.

Table 2: Variances and coefficient of variation for the USEI candidates

USEI candidates	Variances	Coefficient of Variation
Cario	41,734.7	0.93
Other USEI	33,175.6	0.64

These findings suggest that Cario's variability over the polling sections is much higher than the others.

3.2 Monte Carlo simulation

To detect any potential anomalies in the election data, we compare the real data (observed) to the data obtained via a random ballot allocation (expected). According to the rules adopted in each consulate, each polling section should collect the ballots into a precise number of boxes (100 for Buenos Aires, 47 for Rosario, etc.), just following the order of delivery.

To identify anomalies in the election results, we are conducting a Monte Carlo simulation by generating 10,000 preference tables assuming independence and proportional allocation of preferences to each cell based on fixed marginals [3], given by the collapsed contingency tables (see Section 3.1). The simulation is based on a multivariate hypergeometric distribution [4], which yields 10,000 contingency tables for each consulate. We use these tables to calculate 10,000 variances, one for each simulated table. The empirical distribution of these variances is shown in Figure 1. By comparing the observed variance of preferences expressed for Cairo, which is 41,734.7, to the range of variances [27,000 – 30,000] obtained from the Monte Carlo simulation, it is evident that the observed variance is significantly outside this range.

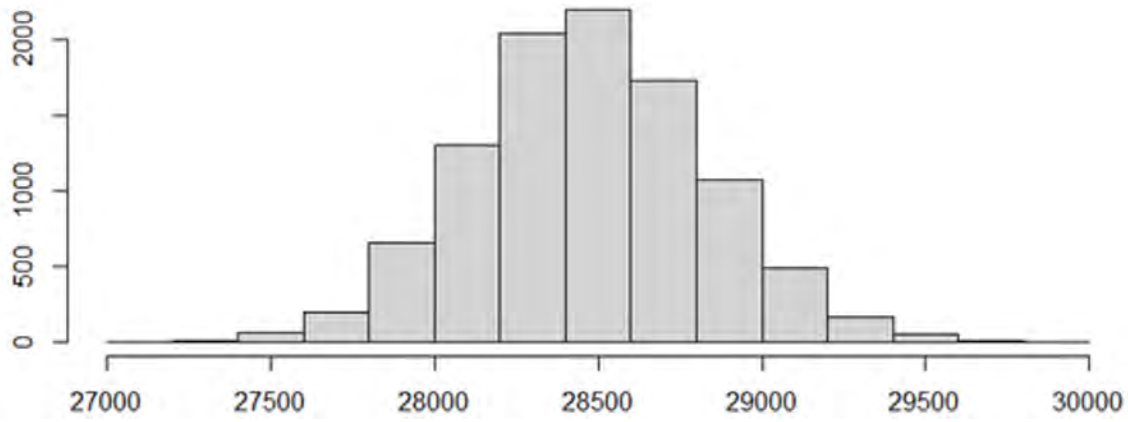

Figure 1: Variance distribution of the 10,000 simulated contingency tables for Buenos Aires

3.3 Validation set

We are validating the simulation procedure described in Section 3.2 by replicating the simulation on the validation set in Rosario, which is the second largest Argentinian consulate after Buenos Aires. As with the previous simulation, we generate 10,000 contingency tables, from which we calculate 10,000 variances – one for each simulated table. The empirical distribution of these variances is shown in Figure 2. By comparing the observed variance for Cairo, which is 2.34, to the range of variances [0.5

– 3.0] obtained from the Monte Carlo simulation, it is evident that the observed variance falls perfectly within this range. This result indirectly suggests that the simulated data closely approximate the actual case.

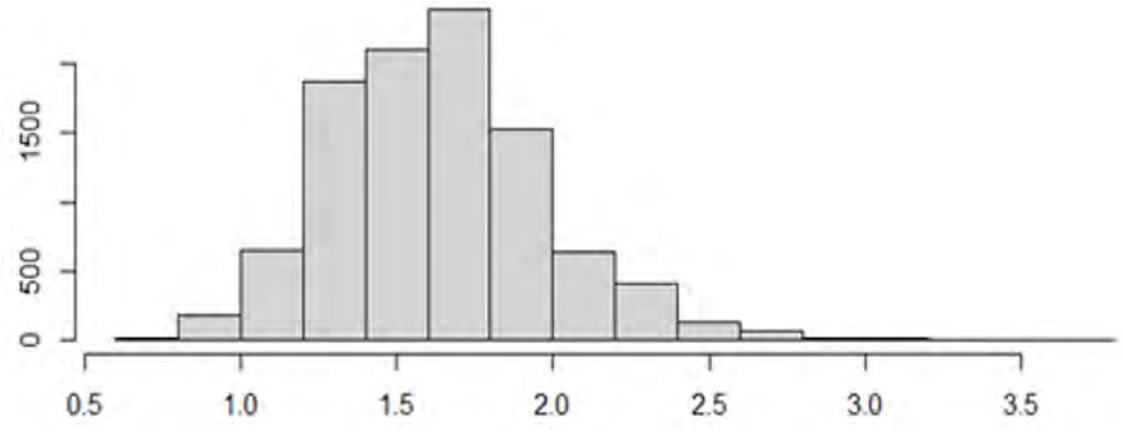

Figure 2: Variance distribution of the 10,000 simulated contingency tables for Rosario.

3.4 Outlier Polling Section detection

To identify any tampered polling sections at the Buenos Aires consulate, as suggested by the legal investigations, we have tested a null hypothesis of a random distribution of votes across the different sections. This hypothesis depends on both the total number of votes received by each candidate and the total number of preferences included in each polling section. Specifically, we use the total number of electors (N), the total number of votes received by candidate Cario (K_c), the total number of votes in the *i-th* section (n_i), and the number of votes in the *i-th* section allocated to candidate Cario (n_{ic}).

The aim is to test the hypothesis that n_{ic} follows a hypergeometric distribution of parameters n_i, K_c, and N. This means testing the hypothesis that votes are randomly distributed across the sections. A *p-value* can then be calculated to detect any overexpression of votes for the candidate Cairo in each *i-th* section, as follows:

$$P(n_{ic} \geq x_{ic}) = \sum_{n_{ic}=x_{ic}}^{\min(n_i,K_c)} \frac{\binom{n_i}{n_{ic}}\binom{N-n_i}{K_c-n_{ic}}}{\binom{N}{K_c}}, \quad (1)$$

where x_{ic} is the actual number of votes to Cairo included in the *i-th* section.

We associated a p-value with each electoral section of Buenos Aires (100 polling sections). Therefore, statistical significance has evaluated using a correction for multiple hypothesis testing. Since the analysis concerns potentially fraudulent activities, it is advisable to minimize type one errors (false positive rate). Thus, we use the most conservative correction for multiple tests, that is, the Bonferroni correction [5]. Accordingly, by setting a univariate threshold of statistical significance equal to $\alpha = 0.01$, we select all the poling section with a *p-value* lower than $\alpha/100 = 0.0001$. The *p-values* obtained from this procedure indicate the presence of 30 tampered sections. This result is in line with the calligraphic analysis conducted during the process, which identified 32 tampered sections.[1]

[1] Unfortunately, we could not check the overlapping between the 30 polling section that turned out to be suspected according our statistical test and the 32 polling sections identified by calligraphic expertise, since the list of the latter polling sections was not provided to us for privacy reasons.

4. Conclusions

The findings of this study suggest the presence of anomalies in the distribution of preferences expressed for Cario in Buenos Aires, as demonstrated by several statistical proofs: the significantly higher variance and coefficient of variation, the Monte Carlo simulation, and the "corrected" Fisher test applied to the contingency tables. These findings can be used as a straightforward application of statistical tools to detect anomalies (fraud!) in electoral data.

Companies' sustainability disclosure and contrast to hunger: the role of social inclusion

Chiara Di Maria[a] and Rodolfo Damiano[a]

[a]Department of Economics, Business and Statistics, University of Palermo;
chiara.dimaria@unipa.it, rodolfo.damiano@unipa.it

Abstract

In order to achieve the sustainable development goals (SDGs) stated in the Agenda 2030, different actors at each level of society are involved. In particular, companies play a key role and have started to disclose their contribution to SDGs through their sustainability reports. In this work, we focus on the second sustainable goal, 'Zero hunger', and analyse which factors are linked with higher sustainable nutrition scores reported by a sample of companies considered as the most influential for the achievement of SDGs. In particular, we investigate the association between nutrition scores, the presence of a corporate social responsibility committee within companies and their reported level of social inclusion, testing if the latter can play a mediating role.

Keywords: SDGs, nutrition, social inclusion, sustainability disclosure, mediation analysis

1. Introduction

In September 2015, the 193 countries members of the United Nations signed Agenda 2030 consisting of 17 sustainable development goals (SDGs) to achieve by 2030. These objectives cover several areas, ranging from contrasting poverty and hunger, achieving gender equality, promoting human rights, guaranteeing equal access to education, and protecting the environment. Every country, by means of its government, institutions and citizens, has to give its contribution to fulfilling the SDGs. Indeed, governments cannot achieve SDGs in isolation; they need the support and commitment of several social forces. In this respect, a key role is played by large companies, whose activities affect not only the economy of the countries where they operate but also have social and environmental implications.

Academia and professionals agree about the prominent role of the business community in SDGs achievement; however, research is still needed to comprehend how companies are coping with this role. Large companies have already demonstrated a proactive attitude toward SDGs (3). In recent years, several companies have started to disclose their contribution to SDGs achievement through their sustainability reporting practices. Moreover, companies claim to have integrated these goals into their business strategy to create social value by achieving optimal financial, social, and environmental performance. According to previous studies, sustainability disclosure is a booster for corporate social responsibility performance (6) and can change how organizations think and act (1). However, while companies can use these sustainability-related disclosures to enact and improve their sustainable behaviours towards the achievement of SDGs, in contrast, the accounting literature has also pointed out that these can be used to gain legitimacy, masking business as usual and destructive practices as sustainable ones (10; 8; 15). In this regard, accounting researchers have suggested that these disclosure practices have to be transparent, more inclusive and grounded on principles such as democracy and engagement to be effective

and to improve companies' contributions to sustainable development (4; 5). In this light, and focusing on the second SDG ("Zero hunger", denoted SDG2 in the following), the aim of this work is to test whether companies providing more information regarding their sustainability strategies and more evidence of inclusiveness also achieve a higher level of nutritional sustainability-related disclosure and if social inclusion can act as a mediator in the relationship.

2. Data description

We used data from the SDG2000 database, created by the World Benchmarking Alliance (WBA) and containing information about the 2000 most influential companies for the achievement of SDGs. Since our interest lies in the second SDG, contrast to hunger and nutrition improvement, we focused on a subset of SDG2000 called 'Food and Agriculture Benchmark', consisting of 350 leading companies in the nutrition sector. For each company, the data set includes information on the country of its headquarters, on its sector, and the score it obtained in 2021 over a set of indicators, either disaggregated and aggregated into four areas of performance: governance and strategy, environment, nutrition and social inclusion (16; 17). We integrated these variables with financial information retrieved from the annual reports, such as total assets, generally used as a proxy of companies' size, and the return on assets (ROA), as a proxy of profitability. Since annual reports were not available for all firms in the sample, we restricted our focus to only the public ones, moving to a sample size of 211. In addition, we considered variables related to compliance with certain Global standards connected to sustainability reporting. Finally, to account for differences at national levels, we included two variables encoding the national SDG and SDG2 scores related to the country where each company has its headquarters: they allow us to link the national performance in terms of sustainability to the companies' results (11).

In our framework, the three variables of main interest are the presence of a corporate social responsibility committee in the board of each company (PCC), the social inclusion score (SI) and the nutrition score. PCC is a discrete score ranging from 0 to 2, varying by 0.5, where 0 denotes that the company does not disclose information about its governance linked to sustainability, while 2 means that the company has a committee dealing with sustainability issues and discloses information about its remuneration. Social inclusion score ranges from 0 to 18 and is obtained by summing 18 WBA indicators assessing several areas, such as respecting human rights, engaging with potentially negatively affected stakeholders, providing and promoting decent work and acting ethically. Finally, nutrition score measures the extent to which a company contributes to sustainable nutrition; it ranges from 0 to 30 and is assessed over six indicators.

3. Data analysis

To investigate the relationship between the variables of interest we first carried out an exploratory analysis and then performed the mediation analysis, which will be discussed in turn in the next sections.

3.1 Exploratory analysis

Almost half of the companies (49.3%) show an intermediate PCC score, while the rest is approximately equally distributed between low scores (≤ 0.5) and high scores (≥ 1.5). As regards inclusion and nutrition scores, many companies present the minimum score (0 for both variables), but none the maximum, and their distributions look positively skewed.

We graphically inspected the interplay of the target variables by means of boxplots. Figures 1 and 2 show how SI and nutrition scores vary as PCC increases, while Figure 3 represents the relationship between nutrition score and inclusion score, the latter categorised through its quartiles. It can be noticed that both the inclusion and nutrition scores increase as PCC increases, moreover nutrition score shows higher medians at the last quartiles of SI. It seems then that these variables are linked and, to further investigate their associations, we moved to the modelling phase, described in the next section.

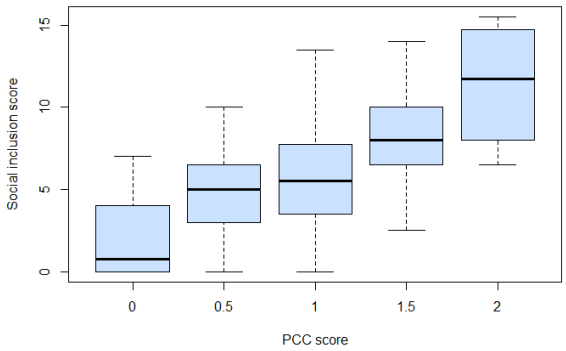

Figure 1: Boxplot of social inclusion score as a function of PCC.

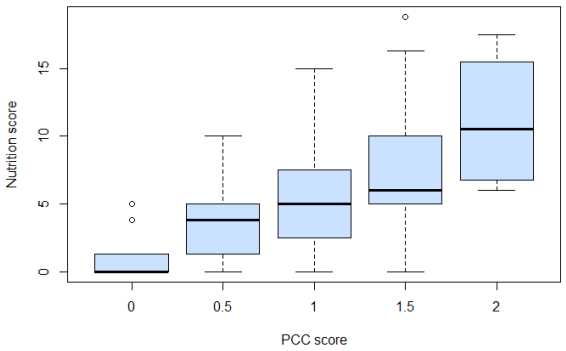

Figure 2: Boxplot of nutrition score as a function of PCC.

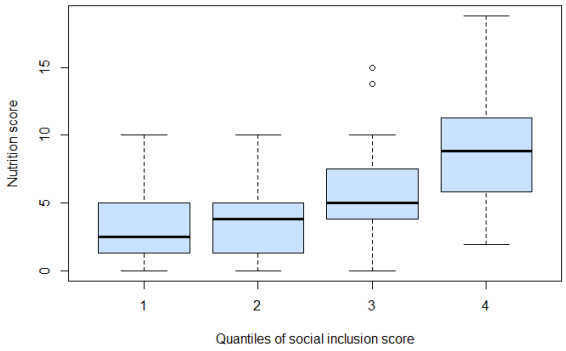

Figure 3: Boxplot of nutrition score as a function of social inclusion score quartiles.

3.2 Mediation models

Since both the response variables under investigation are scores, the Beta regression model seems an appropriate modeling option. We transformed the discrete scores into continuous variables ranging from 0 to 1 by dividing them by the maximum value they can take and then using the transformation proposed by (12) to constrain extreme values to fall in (0, 1). For each outcome, we started from a complex model including all variables listed in Table 1 and progressively reduced the number of variables through a stepwise selection procedure based on AIC. The variables included in each model are shown in the last column of Table 1. In both models we used the loglog link function. Results are shown in Table 2.

The disclosed presence of a corporate social responsibility committee is positively and significantly associated with SI, but it is only slightly significant in the outcome model. Larger companies have larger inclusion scores but lower nutrition scores, and the same pattern holds true for ROA, which is however only slightly significant in the mediator model. Adopting sustainability reporting standards is linked to higher inclusion scores, while, among the six industrial sectors only two are significantly associated to SI. The overall and the SDG2 scores at the national level have significant effects on SI, positive and negative respectively. As regards the outcome, only the national overall SDG score is slightly significant and has a negative sign. Companies' industrial sector was not included in the model, since it was not significant, while higher environmental and social inclusion scores are correlated to a higher nutrition score.

These results suggest that SI may act as a mediator in the relationship between PCC and nutrition score. In the traditional mediational setting described by (2) and (9), denoting the exposure by X, the mediator by M and the outcome by Y, the mediator and the outcome model are assumed to be linear, so that the indirect effect is the product of the regression coefficients lying on the paths from X to M and from M to Y. In our setting, both the mediator and the outcome models are characterised by a nonlinear

Table 1: For each variable we reported a short description, its type, and in which model it was included as a predictor after the model selection procedure.

Variable name	Description	Variable type	Model
PCC	Governance and accountability for sustainable development	Numeric discrete	mediator, outcome
SI	Social inclusion score	Numeric discrete	outcome
Nutrition score	Nutrition	Numeric discrete	-
Region	Geographic macro-region of the country where the company has its headquarters	Six-level factor	-
Size	Logarithm of company's total assets	Numeric continuous	mediator, outcome
ROA	Company's return on assets	Numeric continuous	mediator, outcome
SRS	Number of international standards concerning sustainable disclosure to which a company is subject to	Numeric discrete	mediator
Environmental score	Score related to environmental disclosure	Numeric discrete	outcome
National_SDG_2020	SDG score of the country where the company has its headquarters in 2020	Numeric continuous	mediator, outcome
National_SDG2_2020	Nutrition score of the country where the company has its headquarters in 2020	Numeric continuous	mediator, outcome
Industrial sector	Sector of companies among Agricultural inputs, Agricultural product and commodities, Animal proteins, Food and beverage manufacturers processors, Food retailers and Restaurant and Food service	Six dummy variables	mediator

link function, thus deriving an expression for the indirect effect is not straightforward. In the associational framework, there are not many examples of mediation analysis in nonlinear settings. (9) discusses the case of binary outcomes and how to estimate the indirect effect through the product method, by rescaling standard errors. (13) focuses on settings with a binary mediator and a binary outcome, deriving an exact formula which allows one to disentangle the direct and indirect effect of the exposure on the outcome. (14) claims that an indirect effect can be considered as a variation in the outcome corresponding to a variation in the exposure via the mediator. In other words, the response variable is a composite function of X, since Y depends on M and M is a function of X. Analytically, a variation can be expressed through derivatives and, since the expectation of Y is a composite function, using the chain rule from calculus, the indirect effect of X on Y through M can be expressed as

$$\text{Indirect effect} = \frac{\partial \hat{Y}}{\partial M}\frac{\partial \hat{M}}{\partial X}, \tag{1}$$

where $\hat{M} = \mathbb{E}[M|X, Z_M]$ and $\hat{Y} = \mathbb{E}[Y|X, M, Z_Y]$, with Z_M and Z_Y two (possibly coinciding) set of covariates for the mediator and the outcome models, respectively (7). When both models have identity link functions, the indirect effect is a product of coefficients, consistently with the path-analytic framework. In contrast, when at least one between the mediator and the outcome model is nonlinear, there is not a single indirect effect, common to all subjects in the sample, but 'conditional' indirect effects (7), which depend on the values of X and, for some combinations of link functions, on those of M. Thus, if X is continuous, it is possible to draw a curve of indirect effects or, in alternative, one can select a set of values of interest and estimate the corresponding indirect effects, where M, if present in the formula, is not chosen at random, but assumes the values predicted by the mediator model at each selected x.

When X has a discrete support, as in the current analysis, expressing a variation in terms of derivatives is pointless, thus we used finite differences instead. The discrete version of formula (1) is

$$\text{Indirect effect} = \frac{h_Y(x) - h_Y(x')}{k} \tag{2}$$

where h_Y is the inverse of the link function of the outcome model, x and x' two values in the domain of

Table 3: Indirect effects according to the values of PCC. Estimates, standard errors and confidence intervals were obtained through 1000 bootstrap replicates.

Values of PCC	0 - 0.5	0.5 -1	1 - 1.5	1.5 - 2
Indirect effect	0.041 (0.015) (0.009, 0.068)	0.049 (0.019) (0.011, 0.085)	0.055 (0.022) (0.013, 0.099)	0.059 (0.024) (0.013, 0.107)

the exposure and $k = x - x'$, assuming that $x > x'$[1]. We estimated the indirect effect for each couple of consecutive values of the exposure. Standards errors and confidence intervals were obtained through non-parametric bootstrap with $B = 1000$ resamples. Results are shown in Table 3. It can be noticed that all effects are significant and, as PCC increases, the variation between two adjacent values yields higher indirect effects; so, for example, the change from PCC = 0 to 0.5 induces an increase of 4.1% in nutrition score through the social inclusion score, while the change of PCC from 1.5 to 2 leads to a 5.9% increase in the nutrition score via SI.

4. Conclusions

Achieving goals of Agenda 2030 calls for efforts by all societal actors and companies can play an important role in the process. In this work, we focused on the second sustainable development goal, contrast to hunger and nutrition improvement, and analysed the determinants of nutrition scores using a sample of 211 companies considered as the most influential for fulfilling SDG2. Our results show that the presence of a corporate social responsibility committee within the company is slightly associated to a higher nutrition score and that this effect is mediated by the social inclusion score. Specifically, moving from a PCC score to the subsequent one leads to an increase in the nutrition score mediated by the social inclusion score, and this positive change becomes larger as the two compared values of PCC increase.

[1]The function h_Y depends also on M, but, as discussed, the mediator value depends itself on the value of the exposure.

This suggests that companies more transparent in their board commitment to sustainability and more inclusive in their reporting practices also provide evidence of achieving better nutrition conditions for everyone.

Abstract

This work exploits the possibility to combine information retrieved from network analysis and the methodology to construct a performance indicator of the team play in football. The main contribution is to propose a unique index able to summarize the passing behaviour of a football team from a network perspective. The applicability of the proposed approach is shown through an empirical application involving 192 network from 96 matches of UEFA Champions League 2016-2017.

Keywords: passing networks, performance indicator, network intensity, ball possession

1. Introduction

In the last decade, Network Analysis (NA) became a well-known and useful tool to visualize and analyse the football passes. At the team level, the seminal contribution of Grund (6) shown the existence of a relationship between some network-based variables and the football outcome, measured in terms of scored goals of two competing teams. Following this approach, a set of network summary measures has been used to model the probability of winning the match (7) or the football outcome measured in terms of scored goals or difference in goals (8). From a different perspective, a hierarchical clustering approach is also proposed to identify different tactics based on the community structure retrieved from NA (4).

Despite the availability of studies considering network indices and team strategies in football (1), the possibility to develop a comprehensive index of the passing behaviour (also viewed as the quality of team play) at the team level has not been fully explored in the literature, to the best of our knowledge. The aim of this paper is to exploit the methodology regarding composite indicators (CI's) (5) to propose an *ex post* performance indicator to compare and rank the passing behaviour of the football teams in a tournament. Nine variables at a team level are involved to construct the CI and four combinations of normalization and aggregation methods are compared using data from the Season 2016-2017 of UEFA Champions League.

The paper is organized as follows: Section 2. presents the considered network-related variables while the methodology used to construct the CI is illustrated in Section 3. Section 4. presents the main results of the empirical application concerning UEFA Champions League data. Finally, Section 5. concludes with some remarks and possible advances.

2. Passing Network Variables

The passing network distribution of a football team can be expressed as a weighted and directed network in the form of *adjacency matrix* P. The names of both columns and rows involve the football players of a team in a match. The generic cell p_{ij} contains the number of passes given by the i-th player to the j-th player and, at the same time, the cell expresses the number of passes that j-th player receives from i-th one. Starting from this P and considering passing information usually freely available at the end of the match, we consider variables capturing the complexity of network topology, also having a meaningful interpretation for football (2; 8). These variables are described in the following list

***Pass Accuracy*:** it is defined as the sum of ratios between completed and attempted passes, representing a measure of the overall technical passing skills of a football team.

***Ball Possession*:** is the ratio between the time in which a team plays the ball and the total time of a match.

***Short, medium and long passes*:** these three variables depict the raw counts of short, medium and long passes, respectively, completed by a team in each match.

***Network Intensity*:** considering T as the actual ball possession time in minutes and p_{ij} as the generic element of P, the expression: $\mathrm{T}^{-1} \sum_i \sum_j p_{ij}$, quantifying the level of passing speed of a team (6; 8).

***Network Diameter*:** it is the maximum length between two vertices of a graph, without taking into account the weights, expressing the ability to generate a variety of direct connections (7; 8).

***Reciprocity*:** it is computed as the proportion of mutual connections in a directed graph.. In football, it measures the overall ability of players to have mutual connections with each other, also evaluating the balance of a team in terms of passing directions (8).

***Median of Average Nearest Neighbors (MANN)*:** this measure is the median of an individual measure computed as follows: (2):

$$ANN_i = \frac{\sum_j (p_{ij} + p_{ji})(p_{j\cdot} + p_{\cdot j})}{2(p_{i\cdot} + p_{\cdot i})},$$

where $p_{i\cdot}$ and $p_{\cdot i}$ are, respectively, the row and column marginal sums of P. The team-level indicator MANN measures the cohesion in terms of passing behaviour (8).

3. Constructing The Performance Indicator

To construct a unique performance indicator to measure the quality of team play, four normalization (and aggregation) methods are considered. Let be $g = 1, \ldots G$ the networks (in our case the football teams in the matches) and the previously mentioned variables $k = 1, \ldots, K = 9$, the *min-max* method used to compute the normalized variables I_{gk} can be summarized as follows:

$$I_{gk} = \frac{x_{gk} - \max_g(x_{gk})}{\max_g(x_{gk}) - \min_g(x_{gk})}, \tag{1}$$

where x_{gk} is the value of the k-th variable collected in for the g network, and $\max_g(x_{gk})$ and $\min_g(x_{gk})$ are the maximum and the minimum of the k-th variable, respectively, over the G networks.

The second normalization method, i.e., the *z-score*, can be expressed as:

$$z_{gk} = \frac{x_{gk} - \overline{x}_k}{s_k}, \tag{2}$$

where $\overline{x}_k$ and s_k stand for the average and the standard deviation of the k-th variable over the G networks, respectively. For both normalization methods, the considered aggregating function to compute the CI is the arithmetic mean:

$$\mathrm{CI}_g^{mm} = \frac{1}{K} \sum_{k=1}^{K} I_{gk}; \qquad \mathrm{CI}_g^{z} = \frac{1}{K} \sum_{k=1}^{K} z_{gk}, \tag{3}$$

Table 1: Descriptive statistics of the passing network variable

Variable	Mean	Median	Min	Max	S.D.	CV (%)
Pass Accuracy (%)	84.38	85.69	65.99	96.09	5.80	6.87
Ball Possession (%)	50.00	50.00	28.00	72.00	9.94	19.89
Short Passes (n)	113.58	107.00	35.00	238.00	38.68	34.06
Medium Passes (n)	277.83	266.00	70.00	661.00	110.74	39.86
Long Passes (n)	41.03	38.00	18.00	88.00	12.85	31.32
Network Intensity (n/T)	13.80	13.73	7.65	18.78	2.13	15.41
Network Diameter (n)	5.82	6.00	4.00	10.00	1.37	23.62
Reciprocity (%)	68.56	68.93	42.59	85.00	8.44	12.31
MANN	20.28	19.74	14.22	31.06	3.07	15.13

S.D.: Standard Deviation

where CI_g^{mm} is computed using the min-max method and CI_g^z through the z-score method.

Moreover, the two illustrated methods are considered compensatory approaches (9) in the literature regarding CI's, suffering from the so called substitutability issue. Thus, we decide to apply two partially compensatory approaches that are able to take into account the possible unbalances arising between the original variables. The first method is called Mazziotta-Pareto index (MPI) (3) and the normalization step is based on a modification of the *z-score*:

$$z_{gk}^{\star} = 100 + \frac{x_{gk} - \overline{x}_k}{s_k} \cdot 10. \tag{4}$$

The last method is called Adjusted Mazziotta-Pareto index (AMPI) (9). With respect to MPI, AMPI allows proper comparison of CI's over time, and the normalization step is based on a modification of the *min-max*, as follows:

$$I_{gk}^{\star} = \frac{x_{gk} - max_k(x_g)}{max_g(x_k) - min(x_{gk})} \cdot 60 + 70. \tag{5}$$

When the composite indicator has a positive direction, i.e., it increases in the case of positive changes in the phenomenon of interest (i.e., the passing behaviour at the team level), the considered aggregating functions to compute the CI's for MPI and AMPI are:

$$\text{CI}_g^{MPI} = \frac{1}{K}\sum_{k=1}^{K} I_{gk}^{\star} - S_{I_g^{\star}} \cdot CV_{I_g^{\star}}; \qquad \text{CI}_g^{AMPI} = \frac{1}{K}\sum_{k=1}^{K} z_{gk}^{\star} - S_{z_g^{\star}} \cdot CV_{z_g^{\star}}, \tag{6}$$

where $S_{(.)_g}$ and $CV_{(.)_g}$ are the standard deviation and the Coefficient of Variation (CV) of the K normalized indicators for the network g obtained using (4) or (5). In practice, these kind of CI's penalizes each statistical unit g exploiting its horizontal variability, i.e., the variability of the K normalized indicators.

We remark that in case of negative direction ("polarity") of one or more variables involved in the CI, i.e., a negative sign in the relationship with the phenomenon of interest, the expressions (1), (2), (4) and (5) should be properly modified.

4. Empirical Application

Data for the application are collected using freely available press kits from the official UEFA website[1] and include $G = 192$ passing networks retrieved for 32 European teams. The matches come from the first phase of the tournament, named Group Stage, in the Season 2016-2017. This phase involves 8 groups composed by 4 teams, for a total of 96 matches.

Firstly, the descriptive statistics of the G networks are depicted in Table 1. The variability ranges from the 7% of the pass accuracy to the 40% of the completed passes of medium length. To confirm the positive directions of the variables with respect to the team quality of passes, an exploratory data

[1] www.uefa.com

analysis is carried out. First of all, correlation analysis using Spearman coefficients shows that all the observed correlations between variables are greater than 0. Secondly, a Principal Component Analysis (PCA) is performed to investigate the relationships between the $K = 9$ variables. The first component (or dimension) explains the 61% of the overall variability and all variables are positively correlated with them. In particular, this correlation is greater than 0.8 for both short and medium passes, network intensity, pass accuracy, and ball possession. The largest contributions to the first dimension can be registered for medium passes (16%), network intensity (15%), ball possession (14%) and accuracy (14%). Furthermore, all variables show a pairwise positive relationship with the winning of the match and a (pairwise) positive correlation with the number of scored goals. Thus, following a data-driven approach, the results of PCA confirm the positive direction of the $K = 9$ variables with respect to the phenomenon of interest.

The ranking of European Football teams in terms of passing behaviour is summarized in Table 2 that contains the best and the worst 10 networks associated to a team in a match, where the match number is depicted in brackets. All the methods identify the network of the German team Bayern Munich (in its fourth match against PSV Eindhoven with a final results 1-2 for the "Bavarians") as the best in terms of quality of passes. The same team, coached by Carlo Ancelotti (that succeeded Pep Guardiola) appears at least four times in the considered top 10 rankings. Another relevant performance is represented by the sixth match of Barcelona, against Borussia M'Gladbach, ended with the result of 4-0, followed by the performance of Borussia Dortmund in the match won 8-4 against Legia Warsaw. In addition, all the teams in the top 10 of each method, except Seville, were able to pass the Group Stage and were qualified to the Round of Sixteen. Regarding the worst team in terms of passing behaviour, the Russian team of Rostov appears at least two times in the four considered worst ten. In addition, the bad performance of the Dutch team PSV Eindhoven against Bayern Munich arises from this analysis.

Table 2: Performance indicator for the quality of passes: ranking of different CI's

Rank	Team	CI^{mm}	Team	CI^{z}	Team	CI^{MPI}	Team	CI^{AMPI}
1	Bayern Munich (4)	0.81	Bayern Munich (4)	1.84	Bayern Munich (4)	116.62	Bayern Munich (4)	116.22
2	Barcelona (6)	0.80	Barcelona (6)	1.78	Bayern Munich (1)	113.34	Bayern Munich (1)	111.26
3	Bayern Munich (1)	0.76	Bayern Munich (1)	1.62	Bayern Munich (3)	111.05	Barcelona (6)	106.94
4	Paris Saint-Germain (2)	0.74	Paris Saint-Germain (2)	1.56	Borussia Dortmund (5)	110.38	Bayern Munich (6)	106.91
5	Bayern Munich (3)	0.73	Bayern Munich (3)	1.45	Barcelona (6)	109.97	Borussia Dortmund (5)	102.65
6	Seville (3)	0.72	Barcelona (1)	1.39	Bayern Munich (6)	109.97	Bayern Munich (3)	101.91
7	Barcelona (1)	0.72	Seville (3)	1.38	Juventus (2)	108.71	Paris Saint-Germain (3)	101.88
8	Bayern Munich (6)	0.71	Bayern Munich (6)	1.34	Manchester City (5)	107.46	Real Madrid (1)	101.00
9	Paris Saint-Germain (3)	0.70	Bayern Munich (5)	1.28	Barcelona (1)	107.38	Club Atletico Madrid (3)	100.94
10	Borussia Dortmund (5)	0.70	Borussia Dortmund (5)	1.27	Bayern Munich (5)	107.17	Juventus (6)	99.97
⋮	⋮	⋮	⋮	⋮	⋮	⋮	⋮	⋮
183	Bayer Leverkusen (4)	0.20	Bayer Leverkusen (4)	-1.22	Dinamo Zagreb (4)	83.98	Celtic Glasgow (1)	72.50
184	CSKA Moskow (2)	0.19	CSKA Moskow (2)	-1.28	PSV Eindhoven (4)	83.43	PSV Eindhoven (2)	71.98
185	CSKA Moskow (6)	0.17	CSKA Moskow (6)	-1.37	Rostov (1)	82.28	Manchester City (4)	71.45
186	Dinamo Zagreb (3)	0.17	PSV Eindhoven (4)	-1.44	Bayer Leverkusen (4)	81.06	PSV Eindhoven (4)	71.35
187	PSV Eindhoven (4)	0.16	Dinamo Zagreb (3)	-1.45	Rostov (4)	79.58	Rostov (5)	70.67
188	Dinamo Zagreb (4)	0.15	Dinamo Zagreb (4)	-1.50	Rostov (3)	78.57	Borussia M'Gladbach (6)	70.55
189	Rostov (1)	0.15	Rostov (1)	-1.52	Dinamo Zagreb (2)	77.52	PSV Eindhoven (3)	70.49
190	Rostov (4)	0.13	Rostov (4)	-1.61	Rostov (6)	75.17	Dinamo Zagreb (2)	69.33
191	Rostov (3)	0.13	Rostov (3)	-1.63	Rostov (5)	71.92	Rostov (6)	67.67
192	Rostov (5)	0.03	Rostov (5)	-2.10	Dinamo Zagreb (3)	64.36	Dinamo Zagreb (3)	54.36

A comparison between the four methods is carried out through a correlation analysis using the Spearman coefficient and considering the mean absolute deviation between rankings. As expected, the correlation between compensatory methods (min-max and z-score) is practically equal to 1, while the MPI method results highly correlated with both compensatory methods exhibiting ranking correlation greater than 0.95. Moreover, the AMPI appears less correlated with the two compensatory methods, with Spearman coefficient equal to 0.88, and presents correlation equal to 0.92 with the other partially compensatory method (MPI). The mean absolute difference shows that changes in rank between min-max and z-score are equal to 1.4 position, on average. This difference increases when the compensatory methods are compared with the partially compensatory methods, reaching values approximately equal to 12 positions in both cases. The largest differences can be observed in the comparison with respect to the AMPI, with values ranging from 18 to 21 positions. Moreover, averaging the CI's by 32 teams in the sixth matches, all methods confirm the excellent performance of Bayern Munich, followed by Barcelona, Paris Saint-German, Real Madrid, Borussia Dortmund, Juventus and Naples, and the bad performance of teams such

as Rostov, Dinamo Zagreb and CSKA Moskov.

Table 3: Comparison of rankings in terms of different CI's

Spearman Correlation Coefficient				
Method	Min-Max	Z-score	MPI	AMPI
Min-Max	1.000	0.999	0.953	0.882
Z-score	0.999	1.000	0.955	0.879
MPI	0.953	0.955	1.000	0.915
AMPI	0.882	0.879	0.915	1.000
Mean absolute difference of rank				
Method	Min-Max	Z-score	MPI	AMPI
Min-Max	0.000	1.417	11.708	20.969
Z-score	1.417	0.000	11.510	21.156
MPI	11.708	11.510	0.000	18.260
AMPI	20.969	21.156	18.260	0.000

To show the usefulness of the proposed approach, a logistic regression is performed to model the probability of win the game. Four specifications of the model are compared using the four types of performance indicators. In addition, the following seven in-match variables are included in the model: a) number of shots on target b) number of corners c) number of fouls committed d) number of fouls suffered e) yellow cards f) red cards and g) distance covered in kilometres. Multicollinearity is checked through Variance Inflation Factor (VIF): all variables present values ranging between 1 and 1.3.

Coefficients of logistic regression models are depicted in Table 4. In line with previous studies (8; 7), shots on target appears the most relevant variable in terms of statistical significance. Moreover, while the other in-field covariates result not statistically different from zero in each model specification, the proposed indicator shows a statistically significant positive impact on the probability of winning the match. This relationship is weaker using the MPI ($p = 0.055$) and stronger using the AMPI ($p = 0.008$). Thus, conventional measures such as Bayesian Information Criterion (BIC), McFadden's Pseudo R^2, and in-sample accuracy show that the model including CI^{AMPI} slightly outperforms the others. We remark that it is possible to run variable selection methods, such as the *stepwise* selection, to remove redundant variables. Indeed, the method based on the AIC (Akaike Information Criterion) helps to select only three variables in all of the model specifications. These variables are shots on target, the new performance indicator and number of corners.

Table 4: Results of Logistic Regressions

	CI methods			
Variable	Min-Max	Z-score	MPI	AMPI
Intercept	-4.381	-2.713	-8.442	-8.051
Shots on Target	0.376 (***)	0.377 (***)	0.388 (***)	0.384 (***)
New Indicator	3.743 (*)	0.721 (*)	0.056 (.)	0.068 (**)
Corners	-0.100	-0.099	-0.091	-0.103
Fouls committed	-0.047	-0.047	-0.051	-0.052
Fouls suffered	0.041	0.042	0.040	0.040
Yellow cards	-0.074	-0.076	-0.087	-0.089
Red cards	-0.555	-0.548	-0.547	-0.559
Distance covered (km)	0.009	0.009	0.012	0.005
BIC	232.740	233.020	235.617	231.837
Pseudo R^2	0.253	0.252	0.242	0.257
Accuracy (%)	80.7	79.7	79.7	80.7

Statistical significance; (.): $p < 0.1$; (*): $p < 0.05$; (**): $p < 0.01$; (***): $p < 0.001$

5. Concluding Remarks

Measuring the passing behaviour of a team will be an interesting challenge for statisticians and sport scientists, even from a network perspective, to give a unique measure of the team play. Indeed, comprehensive and easily interpretable indicators such as the expected goals ("XG") are very used in football by practitioners, experts, journalists and trainers.

The present paper explored the possibility to construct a reasonable *ex post* performance indicator to measure the passing behaviour of a team also considering variables retrieved from NA. Four different normalization-aggregation methods have been considered allowing to rank teams in a tournament. Despite the differences arising between rankings obtained through compensatory (min-max and z-scores) and partially compensatory methods (MPI and AMPI), these comprehensive indicators appear to be statistically significant to model the probability of win the match in logistic regression models, even including very relevant information such as the shots on target.

Several advances will be carried out to improve the proposed approach. First of all, relevance of selected variables to measure the team play will be investigated using a larger set of matches, e.g., considering different tournaments (or championships) or several seasons of the same tournament. Secondly, other normalization methods and/o linear combinations of the variables should be implemented, e.g., fully non compensatory methods (such as the geometric mean or the Jevons index). Lastly, the assumption of equal weights for each variable can be relaxed using different weighting schemes. A first proposal can be the use of the PCA results in the aggregating function (i.e., the weighted average), considering the observed contributions of the variables (in percentage).

Topic Modeling for the travel and tourism industry: classical and innovative methods compared

Fabrizio Di Mari[a]

[a]Università degli Studi di Roma "La Sapienza"; fabrizio.dimari@uniroma1.com

Abstract

Reviews of monuments have a huge impact on the decision-making of tourists, determining whether or not those monuments will be visited. The will to analyze textually these reviews leads to performing *Sentiment Classification* on macro-level topics covered by the reviews, to provide a clear idea of what people think about all the different aspects of a site of interest. This paper tackles the problem of extracting topics from big data in the form of textual reviews employing *Topic Modeling* techniques. As an application, all the reviews of the *Colosseum* between January 2004 to mid-March 2022 have been extracted from the *TripAdvisor*'s website and analyzed.

Keywords: Topic Model, Natural Language Processing, Text Mining, Travel, Tourism

1. Introduction

People often read reviews online before visiting restaurants, hotels, or other places, and these assessments can greatly impact businesses. To remain competitive in the market, public and private organizations demand ways to translate these gigabytes of reviews into information that can help them take targeted actions to improve their business. *Text Analysis* is a whole statistical field whose aim is to provide *Statistical Models* capable of extracting relevant information from text. More recent approaches involve *Machine* and *Deep Learning* which have yielded very promising results, sometimes even better than more classical statistical approaches. A *Topic Model* is a type of statistical model for discovering the abstract topics occurring in a collection of documents. The first topic model was published by Deerwester et al. under the name of *Indexing by Latent Semantic Analysis* (1). This model extracts latent topics using a well-known matrix factorization method named *Singular Value Decomposition* applied on the term-document matrix. By retaining only the first k largest singular values, the best k rank approximation of the original matrix in terms of *Frobenius* norm is obtained. Then, the resulting decomposition provides levels of association of documents and words to the k topics. Although it is not a probabilistic model, it has laid the foundation for the development of further topic-modeling techniques. In 2001, Hofmann proposed the probabilistic version of this model named *Probabilistic Latent Semantic Analysis* (2), which is a generative latent variable model for the co-occurrences of words in documents. The reason why it is called that way is that it turns out that the expression of the joint probability model can be written, in matrix form, as a Singular Value Decomposition. A shortcoming of this model, for which it has been often criticized, is that it is not a proper generative model for new documents, namely, it does not provide a probabilistic model at the level of documents. Furthermore, the number of parameters grows linearly with the number of training documents, which can lead to over-fitting problems when the size of the training corpus grows. For these reasons, further generative models have been developed; nonetheless, it has been a useful step toward the probabilistic modeling of text. *Latent Dirichlet Allocation (LDA)* (3) is a well-defined generative model that can easily generalize to new documents, and the

model parameters do not grow linearly with the size of the training corpus.
However, The models discussed so far neglect semantic relationships among words since each document is described using the *bag-of-words* representation, failing to account for the context of words in a phrase. A possible solution relies on the field of *Natural Language Processing*, leveraging text embedding models that provide semantically meaningful vector representations of documents. Semantically similar documents are then close in the embedding vector space, and topics are built by clustering these vectors, with each cluster representing a latent concept. Each topic can be represented through the N words of the reference corpus whose embeddings are closest to each respective cluster centroid. However, this topicś representation disregard all density-based clustering methods, where clusters might not be spherical as in centroid-based methods using the *Euclidean norm*. *BERTopic* (4), published in 2022, deals with this drawback by scoring words within each cluster with a class-based *TF-IDF* procedure.
In the next sections, the problem of extracting information from text will be addressed by comparing two approaches to Topic Modeling: a classical approach involving conventional statistical tools and a modern approach involving Deep Learning techniques.

2. Methodology

To successfully apply a *Topic Model* to a corpus of text, several steps need to be taken into consideration. Firstly, the text must be pre-processed, meaning that it must be cleaned of potentially misleading words and characters that could affect the outcome of the model used. Once the text is pre-processed, the next step is to determine the optimal number of topics to provide as a hyper-parameter to the chosen model for the analysis. In this paper, the *Coherence Score* has been chosen as the evaluation metric for the topics. The Coherence Score can be calculated as shown in Paper (5) while the usual *Normalized Pointwise Mutual Information* serves as a *Confirmation Measure*. For the subsequent analyses, two models have been considered: *Latend Dirichlet Allocation* and *BERTopic*.

2.1 Latent Dirichlet Allocation

Latent Dirichlet Allocation is a hierarchical probabilistic model that aims to build a generative probabilistic model of a corpus. It represents documents as random mixtures over latent topics, where each topic is characterized by a probability distribution over words. For each document **w** in a corpus **D**, the following assumptions are made:

1. Select $N \sim$ Poisson(ξ), number of words in **w**.
2. Select $\theta \sim$ Dir(α), vector of topics' probabilities.
3. For each of the N words w_n of the document:
   (a) Select a topic $z_n \sim$ Multinomial(θ).
   (b) Select a word w_n from the multinomial distribution $p(w_n \mid z_n, \beta)$.

Although the posterior distribution of the hidden variables given a document is intractable for inference, a relatively simple convexity-based variational algorithm can be used for approximate inference. The basic idea behind this algorithm is to utilize the Jensen inequality to obtain an adjustable lower bound on the log-likelihood (6). Essentially, a family of lower bounds is considered, indexed by a set of variational parameters that are selected via an optimization procedure aiming to find the tightest possible lower bound. Then, the parameters of the original model can be found via an alternating variational *Expectation-Maximization* procedure. This procedure maximizes a lower bound with respect to the variational parameters for each document. Then, fixing the variational parameters, the overall variational lower bound is maximized with respect to the model parameters α and β. It is important to note that N is in general assumed fixed in advance.

2.2 BERTopic

BERTopic is a cutting-edge Topic Model that employs a class-based TF-IDF (Term Frequency - Inverse Document Frequency) approach to generate coherent representations of topics. This technique involves four main steps. First, each document is transformed into its embedding representation using *Sentence-BERT* (7), a pre-trained language model that fine-tunes *BERT* (8). Second, to optimize the clustering process, the dimension of the resulting embeddings is reduced using *Uniform Manifold Approximation* (10). Third, *Accelerated Hierarchical Density-Based Clustering* (9) is used for clusterization. Finally, a modified version of the traditional TF-IDF function is utilized to assign scores to words inside every cluster, which eventually leads to the depiction of each topic. The formula for this approach is as follows:

$$W_{t,c} = f_{t,c} \cdot \log\left(1 + \frac{A}{\tilde{f}_t}\right).$$

The term $f_{t,c}$ represents the relative frequency of the term t in all documents related to cluster c. Instead of using the inverse document frequency in the standard formula, this procedure uses the inverse class frequency to measure how much information a term t provides to a class c. This value is calculated by taking the logarithm of A, which is the average number of words per class, divided by the absolute frequency $\tilde{f}_t$ of term t across all classes. To ensure that only positive values are outputted, 1 is added to the division within the logarithm. Thus, by using this class-based TF-IDF procedure, the importance of words in clusters is modeled, rather than in individual documents. This approach provides each latent concept with a list of words that mostly characterizes the concept itself, which can hopefully offer a meaningful description of it.

3. Experimental analysis

This section focuses on the application of the models described in the previous section to the content of 68659 *Colosseum* reviews. These reviews were web-scraped from *TripAdvisor*'s website using *R*, within the time window from January 2004 to mid-March 2022.
Before being fed to the two models, the data underwent different pre-processing methods. This choice was made to fully exploit the potential of both models and compare them in their best possible condition.

3.1 Latent Dirichlet Allocation

The data pre-processing of Latent Dirichlet Allocation began with the utilization of the Python libraries *spaCy* and *Gensim*. Gensim was first used to perform basic pre-processing tasks such as lowercase conversion, de-accentuation, and stop-word removal from the text. After this, spaCy was applied to lemmatize the words. To illustrate the pre-processing effect, the first review of the dataset is presented both before and after pre-processing. The original review states "The Colosseum was truly remarkable. I loved walking the arena paths and imagining life during Roman times. We visited during February and the crowds werent too bad. Artifacts from the time were on display and the columns were huge.". The pre-processed version reads: "colosseum truly remarkable love walk arena path imagine life roman time visit february crowd bad artifact time display column huge".
To determine the optimal number of topics for the LDA model, we fit the model to a range of 1 to 20 topics while calculating the NPMI Coherence Score each time. The results of this analysis are presented in Figure 1, where the x-axis represents the number of topics and the y-axis represents the mean NPMI Coherence Score of the latent concepts obtained from fitting the model. It is evident from the Figure that the optimal number of topics is 4.

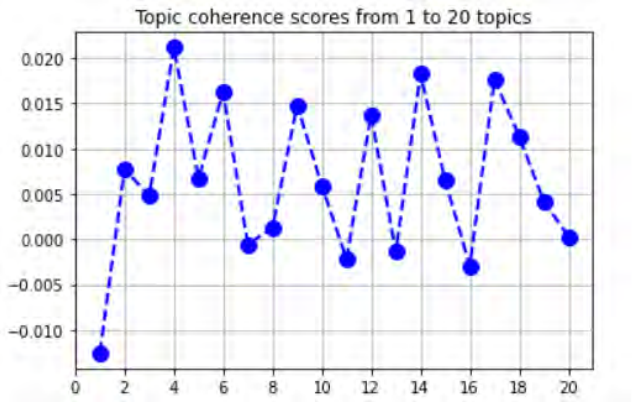

Figure 1: NPMI Coherence Score of LDA fitted from 1 topic to 20 topics.

After applying the model to the Colosseum corpus, the representations of the following topics were obtained based on four latent concepts (Table 1). It was decided to retain the ten most relevant words per topic.

LDA	Most Relevant Words			
Topics	1	2	3	4
	ticket	see	gladiator	pass
	tour	history	build	roma
	line	rome	arena	front
	guide	place	ago	watch
	forum	must	year	metro
	buy	night	wonder	bad
	queue	amazing	size	fee
	book	beautiful	animal	real
	hour	feel	probably	late
	get	historical	fight	preserve

Table 1: The 10 most relevant words for each of the 4 topics detected by LDA.

The ranking of words within latent concepts was provided using *pyLDAvis*, a powerful tool for visualizing and interpreting LDA model topics. This tool uses a formula called *relevance* which is defined as follows: for a given term w, a topic k, and a weight parameter $\lambda \in [0, 1]$, the relevance of term w within topic k is

$$r(w, k \mid \lambda) = \lambda \log(\phi_{kw}) + (1 - \lambda) \log \left(\frac{\phi_{kw}}{p_w} \right),$$

where ϕ_{kw} is the probability of term w conditioned on topic k and p_w is the marginal probability of term w in the reference corpus. Adjusting the value of λ can aid in the interpretation of topics, and in this case, $\lambda = 0.4$ was used. The latent concepts can be interpreted as follows:

1 Ticket specification and line to purchase it.
2 The beauty of the Colosseum.
3 The history of the Colosseum.
4 Complaints about the outside of the Colosseum, public transportation, and other related issues.

3.2 BERTopic

In section 2, it was described that BERTopic uses document embedding techniques to provide a semantically meaningful representation of documents in an embedding vector space. Language models that

perform this task are trained on large corpora of text with minimal to no pre-processing. Therefore, it was decided not to pre-process the text to fully exploit the power of these models. Furthermore, since each embedding is assigned to only one latent concept, each review was divided into sentences with the intuitive assumption that a single review might refer to more than one topic. Here are the results of the model for four topics, each with the top ten most important words:

BERTopic	Most Relevant Words			
Topics	1	2	3	4
	the	tickets	the	the
	we	the	palantine	underground
	in	to	hill	tour
	to	buy	forum	to
	and	you	and	and
	was	online	ticket	level
	early	your	for	you
	tickets	ticket	to	we
	queue	in	euros	floor
	line	advance	you	of

Table 2: The 10 most relevant words for each of the 4 topics detected by BERTopic.

In this case, the ranking of terms within the topic was directly provided by the application of the method with the class-based TF-IDF procedure. The latent concepts can be interpreted as follows:

1 Line to purchase the ticket.
2 Advice to buy tickets online in advance.
3 The surrounding of the Colosseum: the Palantine Hill and the Roman Forum.
4 The underground tour of the Colosseum.

Due to the choice of not pre-processing the data before feeding it to the model, the topic representation in BERTopic contains a lot of stop-words.

4. Conclusions

The results of the previous section indicate that although BERTopic's representation of latent concepts includes many stop-words, the topics generated by BERTopic are easier to interpret than those generated by the Latent Dirichlet Allocation model. This finding is supported by the NPMI Coherence Score, which is 0.05 for BERTopic compared to the 0.02 achieved by LDA. Thus, despite BERTopic's direct application potentially lacking in quantity of information due to the presence of stop-words, it produces more "coherent" topics than LDA. However, although LDA is less "coherent" than BERTopic, it generates broader latent concepts, which help clarify some specific topics.
To improve BERTopic's representation of latent concepts, it may be useful to remove the stop-words after obtaining the document embeddings. This could be accomplished by adding a text engineering block to BERTopic's pipeline, following the application of the language model Sentence-BERT to the documents in the reference corpus. Additionally, it would be interesting to investigate whether people complain or approve of the concepts that are most frequently discussed on a particular site of interest. *Text Summarization* techniques could be employed to provide a more in-depth and meaningful description of each topic. Two possible approaches to this are: a classical and more intuitive approach, which involves ranking reviews' sentences based on the number of *keywords* of the latent concept they mention and then taking the top N sentences as output; and a more recent approach, which utilizes pre-trained language models that have shown to provide excellent results on Text Summarization tasks (see for instance *bart*, trained by *Facebook AI*), to generate the topic's descriptions. Moreover, since each review comes with a

label of satisfaction ranging from 1 to 5 stars, it would be beneficial to use *BERT*-like models to perform *Sentiment Classification* on labeled reviews of one site and fine-tune the last fully connected layers on labeled reviews of another targeted site of interest to predict people's satisfaction. The objective would be to determine if knowledge of one site can aid in predicting the satisfaction of reviewers of another site. This could be accomplished by comparing the accuracy of the fine-tuned model with that of the same model *fully* trained on the targeted site's domain.

An Importance Sampling Algorithm For Bayesian Logistic Regression with Independent Gaussian Scale Mixture Prior

Paolo Onorati[a] and Brunero Liseo[a]

[a]Sapienza University of Rome; p.onorati@uniroma1.it, brunero.liseo@uniroma1.it

Abstract

We propose an importance sampling algorithm for producing a posterior sample for quantities of interest in the logit model when the prior distribution on the β coefficients follows a Student-t prior with independent components. We also show that the proposed method allows one to easily compute the marginal density of the data, which facilitates model selection procedures through the Bayes factor. The algorithm then avoids the use of Markov Chain Monte Carlo methods, at least when the sample size is less than 500.

Keywords: Unified Skew-Normal Distributions, Bayes Factor, Kolmogorov Distribution, Weakly Informative Prior.

1. Introduction

Binary regression is among the most popular and routinely used statistical methods in applied science. Standard Bayesian approaches and off-the-shelf packages are today available, see for example the R suites `brms` or `rstanarms`. However, there is no general consensus on the choice of prior distributions and on how to select among different link functions.

A remarkable contribution in this direction has been provided by Durante (6) who shows that the SUN family of densities (2) can be used as a conjugate prior for the probit regression model, that is the posterior distribution of the regression coefficients in a probit setting still belongs to the SUN family. Durante (6) himself provides methods for efficiently sampling from the SUN distribution. The above methodology is particularly useful in the case when $p >> n$.

Following this line of research, we have introduced a larger class of distributions, namely the *perturbed SUN* (pSUN hereafter) family (9), which is obtained by replacing the two Gaussian laws appearing in the SUN definition with two scale mixtures of Gaussian distributions. This double scaling produces a larger class of densities which can be particularly useful in Bayesian binary regression.

However, the use of scale mixtures leads to some increasing in computational complexity; indeed, for a SUN distribution it is possible to obtain an exact posterior sample, through Botev (5) algorithm, as long as the sample size is not too large, that is no more than few hundreds of observations, say 500: see Durante (6) and Botev (5) for more details; nonetheless for a pSUN distribution the above method cannot be used and, in general, we must introduce a Gibbs sampler step.

On the other hand, the availability of an exact posterior simulator would lead to a computational gain in efficiency with respect to the use of MCMC methods. For this reason, we have introduced an importance sampling algorithm that works for a pSUN posterior distribution in the case of a logistic regression with a Gaussian prior for the β coefficients. In (9) we present an example where the Gibbs

sampler takes 26 mins in order to get 10^4 posterior draws while the importance sampling strategy only takes 33 secs for the same number of draws.

The gist of this paper is to construct an importance sampling algorithm that works for a larger class of priors; in particular, we concentrate on a Student-t prior with independent components as suggested by Gelman et al. (8). However our approach can be easily adapted to any scale mixtures of Gaussian densities.

The rest of the paper is organized as follows: in section 2. we illustrate the construction of SUN and pSUN parametric families; then we introduce the Bayesian binary regression model with emphasis to the logit link; in section 3. we describe the importance sampling method for the Student-t with independent components prior. Section 4. is devoted to some numerical examples.

2. Conjugate Prior for Bayesian Binary Regression Model

Arellano-Valle and Azzalini (2) introduce the Unified Skew-Normal (SUN) class of densities which includes many of the several proposals appeared in the literature. It is based on the introduction of a given number m of latent variables; a d-dimensional random vector β has a SUN distribution, i.e. $\beta \sim \mathrm{SUN}_{d,m}(\Gamma, \Delta, \gamma, \xi, \Omega)$, if its density function is

$$f_\beta(\beta) = \phi_\Omega(\beta - \xi) \frac{\Phi_{\Gamma - \Delta'\bar{\Omega}^{-1}\Delta}\left(\gamma + \Delta'\bar{\Omega}^{-1}\mathrm{diag}^{-\frac{1}{2}}(\Omega)(\beta - \xi)\right)}{\Phi_\Gamma(\gamma)},$$

where Γ is a m-correlation matrix, Δ is $d \times m$ matrix, $\gamma \in \mathbb{R}^m$,, $\xi \in \mathbb{R}^d$, Ω is a d-covariance matrix, and $\bar{\Omega} = \mathrm{diag}^{-\frac{1}{2}}(\Omega)\, \Omega\, \mathrm{diag}^{-\frac{1}{2}}(\Omega)$. Here we use a slightly different parametrization, namely

$$\begin{aligned} \Theta &= \mathrm{diag}^{-\frac{1}{2}}\left(\Gamma - \Delta'\bar{\Omega}^{-1}\Delta\right)\left(\Gamma - \Delta'\bar{\Omega}^{-1}\Delta\right)\mathrm{diag}^{-\frac{1}{2}}\left(\Gamma - \Delta'\bar{\Omega}^{-1}\Delta\right), \\ A &= \mathrm{diag}^{-\frac{1}{2}}\left(\Gamma - \Delta'\bar{\Omega}^{-1}\Delta\right)\Delta'\bar{\Omega}^{-1}, \\ b &= \mathrm{diag}^{-\frac{1}{2}}\left(\Gamma - \Delta'\bar{\Omega}^{-1}\Delta\right)\gamma; \end{aligned} \tag{1}$$

in this case we denote $\beta \sim \mathrm{SUN}^*_{d,m}(\Theta, A, b, \xi, \Omega)$ and the following stochastic representation holds:

$$\beta = \xi + \mathrm{diag}^{\frac{1}{2}}(\Omega) Z \,|\, (T \leq AZ + b), \tag{2}$$

where $Z \sim N_d(0, \bar{\Omega})$ is independent of $T \sim N_m(0, \Theta)$. An extension of the above family is obtained by considering a scale mixture of Gaussian densities replacing T and Z. We will use the following notation: let Σ be a generic covariance matrix and let $Q(\cdot)$ be a CDF with positive values in the positive orthant; then we set

$$\begin{aligned} \phi_{\Sigma,Q}(u) &= \int_{\mathbb{R}^d} \prod_{i=1}^{d} \left(W_i^{-\frac{1}{2}}\right) \phi_\Sigma\left(\mathrm{diag}^{-\frac{1}{2}}(W)\, u\right) dQ(W), \\ \Phi_{\Sigma,Q}(u) &= \int_{\mathbb{R}^d} \Phi_\Sigma\left(\mathrm{diag}^{-\frac{1}{2}}(W)\, u\right) dQ(W), \\ \Psi_{Q_V,\Theta,A,Q_W,\bar{\Omega}}(b) &= \mathrm{P}(T - AZ \leq b), \\ T \sim \Phi_{\Theta,Q_V}(\cdot) &\perp\!\!\!\perp Z \sim \Phi_{\bar{\Omega},Q_W}(\cdot). \end{aligned}$$

Let V and W be a m-dimensional and a d-dimensional random vectors, respectively, both defined on their positive orthant. With a little abuse of notation, for a generic d-dimensional vector H, let $\mathrm{diag}(H)$ be the d-dimensional diagonal matrix with same entries as H. Assume that

$$\begin{aligned} T|V \sim N_m(0, \Theta_V) \quad &\perp\!\!\!\perp \quad Z|W \sim N_d(0, \bar{\Omega}_W), \\ V \sim Q_V(\cdot) \quad &\perp\!\!\!\perp \quad W \sim Q_W(\cdot); \end{aligned} \tag{3}$$

where $\Theta_V = \text{diag}^{\frac{1}{2}}(V)\Theta\,\text{diag}^{\frac{1}{2}}(V)$ and $\bar{\Omega}_W = \text{diag}^{\frac{1}{2}}(W)\bar{\Omega}\,\text{diag}^{\frac{1}{2}}(W)$. Then the pSUN class of distributions is defined by the stochastic representation of equation (2) with the assumptions introduced in formula (3) on Z and T; in this case we denote

$$\beta \sim \text{pSUN}_{d,m}\left(Q_V, \Theta, A, b, Q_W, \Omega, \xi\right)$$

and it is easy to see that the density is

$$f_\beta(\beta) = \phi_{\Omega,Q_W}(\beta-\xi)\frac{\Phi_{\Theta,Q_V}\left(A\,\text{diag}^{-\frac{1}{2}}(\Omega)(\beta-\xi)+b\right)}{\Psi_{Q_V,\Theta,A,Q_W,\bar{\Omega}}(b)}\,.$$

As we will see, the SUN and pSUN families play a central role in Bayesian inference for binary output. Consider a general version of the model as

$$\begin{aligned} Y_i|p_i &\overset{\text{ind}}{\sim} Be(p_i), \quad \forall i = 1,2,\ldots,n \\ p_i &= \Lambda(\eta(X_i))\,, \end{aligned}$$

where $\Lambda : \mathbb{R} \to [0,1]$ is a known link function, $\eta(\cdot)$ is a calibration function, and $X_i \in \mathbb{R}^p$ is the i-th row of the design matrix X. Typically $\Lambda(\cdot)$ is an univariate CDF of some random variable, symmetric about 0, and $\eta(x)$ takes the simple linear form, $x'\beta$; we refer to this case as the linear symmetric binary regression model (LSBR). Let $\Lambda_n(x) = \prod_{i=1}^n \Lambda(x_i)$, $x \in \mathbb{R}^n$ and $B_x = [2\,\text{diag}(x) - I_n]$ for $x \in \{0,1\}^n$, where I_n is the identity matrix of size n; the likelihood function of a LSBR model can be written as

$$L\left(\beta; y\right) = \Lambda_n(B_y X\beta)\,.$$

Durante (6) shows that if β has a SUN prior distribution and $\Lambda(x) = \Phi(x)$ then $\beta|Y$ is still SUN distributed; notice that the Gaussian distribution is a special case of the SUN so if β is given a Gaussian prior, then the posterior is known to be a SUN distribution.

In order to extend the result of Durante (6) to the logit model, i.e. $\Lambda(x) = \left(1+\exp(-x)\right)^{-1}$, we show that if β is given a pSUN prior and $\Lambda(x)$ is a CDF of a random variable that admits a representation in terms of scale mixture of centered Gaussian random variables, then $\beta|Y$ still belongs to the $psun$ family. The logit link satisfies this condition; see Andrews and Mallows (1) and Stefanski (11).

Here we concentrate on the case of independent Student-t distributions; if $\beta_i \overset{i.i.d.}{\sim} T(\nu, \xi_i, \Omega_{i,i})\,,\ i = 1,2,\ldots,p$ then

$$\beta|Y \sim \text{pSUN}_{p,n}(Q^n_{V^*}, I_n, B_Y X\text{diag}^{\frac{1}{2}}(\Omega), B_Y X\xi, Q^p_{W^*}, \xi, \Omega)\,, \tag{4}$$

where $Q^n_{V^*}(\cdot)$ denotes the CDF of n i.i.d. random variables distributed as 4 times the square of a Kolmogorov distribution, $Q^p_{W^*}(\cdot)$ denotes the CDF of p i.i.d. random variables with $\text{Inv.Gamma}(\nu/2, \nu/2)$ and Ω is a diagonal matrix with components $\Omega_{i,i}\,,\ i = 1,2,\ldots,p$. See Onorati and Liseo (9) for details.

3. Importance Sampling Algorithm

In this section we illustrate an importance sampling algorithm in order to compute posterior quantities of interest from distribution (4). Notice that if one sets V and W equal to some constant, say $\widetilde{V}$ and $\widetilde{W}$, then

$$\beta|Y, \widetilde{V}, \widetilde{W} \sim \text{SUN}^*_{p,n}(I_n, \text{diag}^{-\frac{1}{2}}(\widetilde{V})B_Y X\text{diag}^{\frac{1}{2}}(\Omega)\text{diag}^{\frac{1}{2}}(\widetilde{W}), \text{diag}^{-\frac{1}{2}}(\widetilde{V})B_Y X\xi, \xi, \Omega_W)\,. \tag{5}$$

Therefore, we set $\widetilde{V}_i = \text{E}(V_i) = \pi^2/3\,,\ i = 1,2,\ldots,n$; this value is chosen since it represents the variance of the centered Gaussian random variable that minimizes the Kullback-Leibler divergence from

a standard logistic distribution; for $\widetilde{W}_i\,, i = 1, 2, \ldots, p$ we choose the median of an Inverse Gamma distributed random variable with density

$$\text{Inv.Gamma}\left(\frac{\nu+1}{2}, \frac{\nu + (\widehat{\beta}_{i,MaP} - \xi_i)^2/\Omega_{i,i}}{2}\right)\,, \tag{6}$$

Expression (6) denotes the distribution of W_i when conditioned to β_i set equal to its posterior mode.

However, the ratio between densities (4) and (5) is unbounded. To circumvent this problem, we replace the distribution (5) with a scale mixtures based on an Inverse Gamma distribution. More in detail

$$\begin{aligned}
&\zeta_1 = \xi + \sqrt{S}\text{diag}^{\frac{1}{2}}(\Omega)\text{diag}^{\frac{1}{2}}(\widetilde{W})\zeta_0\,,\\
&S \sim \text{Inv.Gamma}\left(\frac{\nu_0}{2}, \frac{\nu_0}{2}\right)\,,\\
&\zeta_0 \sim \text{SUN}^*_{p,n}(I_n, \text{diag}^{-\frac{1}{2}}(\widetilde{V})B_Y X\text{diag}^{\frac{1}{2}}(\Omega)\text{diag}^{\frac{1}{2}}(\widetilde{W}), \text{diag}^{-\frac{1}{2}}(\widetilde{V})B_Y X\xi, 0, \bar{\Omega})\,,\\
&S \perp\!\!\!\perp \zeta_0\,.
\end{aligned}$$

This way it is easy to show that the density ratio between (4) and the above importance density is bounded if some mild conditions hold; in particular, the existence of the MLE is a sufficient condition. The parameter value ν_0 is set to 5; see Onorati and Liseo (9) for other details.

4. Examples

We evaluate the performance of the proposed importance algorithm; in particular we present a simulation study for evaluating the frequentist coverage of the resulting posterior sample. We also discuss a real data example, where we compare posterior means and credible intervals obtained with our method with those computed using the Polya-Gamma Gibbs sampler (10).

In all settings we use the prior described in Gelman et al. (8); i.e. $\nu = 1$, $\xi = 0$, $\Omega_{1,1} = 100$ and $\Omega_{i,i} = 6.25\,,\ i = 2, 3, \ldots, p$; in this case β_1 is the intercept and all the other covariates are centered and scaled in order to have a standard deviation equals to 0.5. In all settings we produce 10^5 draws both in the Gibbs sampler and in the importance sampling set up.

4.1 Simulation Study

We first show the simulation study to evaluate the finite sample performance of the algorithm. Let $G = 3000$ be the number of iterations. We implement the following procedure:

for $g = 1, 2, \ldots, G$;
- set the first column of X equals to a vector of ones; sample the other covariate values independently, i.e. $X_{ij}^{(g)} \overset{i.i.d.}{\sim} N(0,1)\,,\ i = 1, 2, \ldots, n\,,\ j = 2, 3, \ldots, p$;
- center and scale each column, but the first, of $X^{(g)}$ in order to have a standard deviation equal to 0.5;
- sample $\beta^*_{(1,g)} \sim Ca(0, 10)$ and $\beta^*_{(i,g)} \overset{i.i.d.}{\sim} Ca(0, 2.5)\,,\ i = 2, 3, \ldots, p$;
- sample $Y_i^{(g)} \overset{ind}{\sim} Be\big(\Lambda(X_i'^{(g)}\beta^*_{(g)})\big)$;
- draw 10^5 values through importance sampling;
- compute the empirical quantiles of level $\gamma \in \{1/10 \times j, j = 1, 2, \ldots, 9\}$;

$\Longrightarrow$ evaluate the frequentist coverage comparing the quantiles with $\beta^*_{(g)}$.

We set the sample size $n = 100$ and $p = 10$. Table 1 reports the results.

4.2 Iris Dataset

We consider a real data analysis on the Iris dataset, (7). There are $n = 150$ observations with 4 covariates, i.e. length and width for sepal and petal of 3 species, namely "setosa", "versicolor" and "virginica". We

Table 1: Average Frequentist Coverage of the 10 Parameters

Theoretical	10%	20%	30%	40%	50%	60%	70%	80%	90%
Empirical	10.93%	21.05%	30.94%	40.41%	49.84%	59.2%	68.76%	78.44%	88.52%

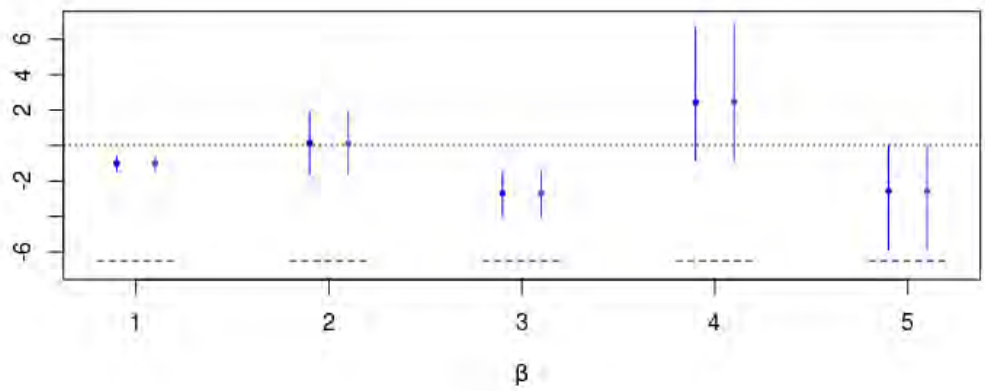

Figure 1: Iris dataset, logit model with independent Cauchy priors: Posterior means and 95% credible sets of the coefficients for the 4 covariates and the intercept β_1: Polya-Gamma (blue); importance sampling (purple)

set $y_i = 1$ if the output is "versicolor" and $y_i = 0$ otherwise. As before, we center and scale the covariates in order to have a standard deviation equal to 0.5; we also add the intercept so that the total number of parameters is $p = 5$.

We compute the posterior means and 95% credible intervals using both the proposed importance sampling and the Gibbs sampler of (10). Figure 1 compares the results of the two methods. One can notice that they are essentially similar.

We have also implemented a variable selection procedure based on the posterior probabilities of all possible subsets of covariates, adopting a uniform prior over the model space and compatible independent Cauchy priors within each model. Using the importance sampling algorithm, one is able to quickly compute, for each model, the normalizing constant of the posterior distribution. Assuming, as it is customary (4), that the intercept is included in all models, there are $2^{p-1} = 2^4 = 16$ possible combinations of covariates. See Onorati and Liseo (9) for more details about the implemented procedure for Bayes factor and computation of posterior inclusion probabilities.

Table 2 reports the results for each covariate; if a covariate is selected when its posterior inclusion probability is larger than 0.5 (3), we only select the predictor "Sepal Width", i.e. the third one.

Table 2: Posterior Probabilities

Sepal Length	Sepal Width	Petal Length	Petal Width
0.1549	> 0.9999	0.2575	0.2710

5. Conclusions

We have proposed a new method for computing quantities of interest of the posterior distribution in a Bayesian logistic regression model using independent Student-t prior. We have also shown how to compute the marginal density of data, opening the way to perform variable selection and model choice using Bayes factor.

Furthermore, when the sample size is not too large, one can completely avoid the use of Markov Chain simulations. Indeed, in logistic regression, MCMC techniques show a poor performance when the number of parameters is very large. On the other hand, with some refinements of the proposed algorithm, the importance sampling strategy can adequately manage this case. Here we have only discussed a specific Student t prior. However, the algorithm can be easily adapted to any prior that can be expressed as a scale mixture of Gaussian densities, for instance in the case of a LASSO prior. Also, all the results can be easily adapted to other link functions, including the probit case.

Bayesian analysis of Amazon's best-selling books via finite nested mixture models

Laura D'Angelo[a] and Francesco Denti[b]

[a]Department of Economics, Management and Statistics, Università di Milano-Bicocca; laura.dangelo@unimib.it
[b]Department of Statistics, Università Cattolica del Sacro Cuore; francesco.denti@unicatt.it

Abstract

Online shopping has become increasingly common in recent years and has influenced how we form our preferences and choose the items to buy. This influence also applies to the books we read: other readers' online reviews are one of the most used tools to determine the next book we will buy. The increasing use of e-commerce websites has also led to a large availability of data to study how the users' ratings interact with other variables. Here, we consider a dataset of Amazon's best-selling books in the period 2009-2019. In particular, we study the similarities of the distributions of ratings and prices across different years. To fully capture the complexity of the observed data, we make use of flexible Bayesian nested mixture models to simultaneously avoid strict parametric assumptions and study the clustering structure of observations and years.

Keywords: Common atoms model; Grouped data; Model-based clustering; Finite Mixtures; Nested models.

1. Introduction

Amazon is an American multinational company that provides several technological services and is one of the largest e-commerce companies in the world. One of the distinctive features of its marketplace is the possibility for customers to grade and review the quality of the purchased goods. In particular, the customer rating system attached to each item is particularly famous and recognizable with its one-to-five-star scale.

It is interesting to study how this rating interacts with other variables as, for example, the items' price and the sold quantity. In this paper, we analyze a public dataset (Saalu, 2020) available on Kaggle [1] containing Amazon's 50 best-selling books over the years between 2009 and 2019. Quantitative analyses of data measuring the characteristics of Amazon's best-seller have received increasing attention over the last few years. For example, researchers have focused on understanding the dynamics behind a literature success, assessing the effect of online reviews on online book sales, and developing enhanced recommendation systems (Kaur and Singh, 2021; Maity et al., 2017; Maity et al., 2019). The dataset we consider contains the title and author of Amazon's most sold books of each year, its price (as of 13/10/2020), the number of reviews, and the overall users' rating.

In particular, we are interested in modeling the distributions of the users' ratings and the books' prices over the years. Note that by *rating*, we mean the index computed by Amazon to summarize all the users' grades. Figure 1 shows the boxplots summarizing the distributions of the two quantities for

[1]https://www.kaggle.com/datasets/sootersaalu/amazon-top-50-bestselling-books-2009-2019

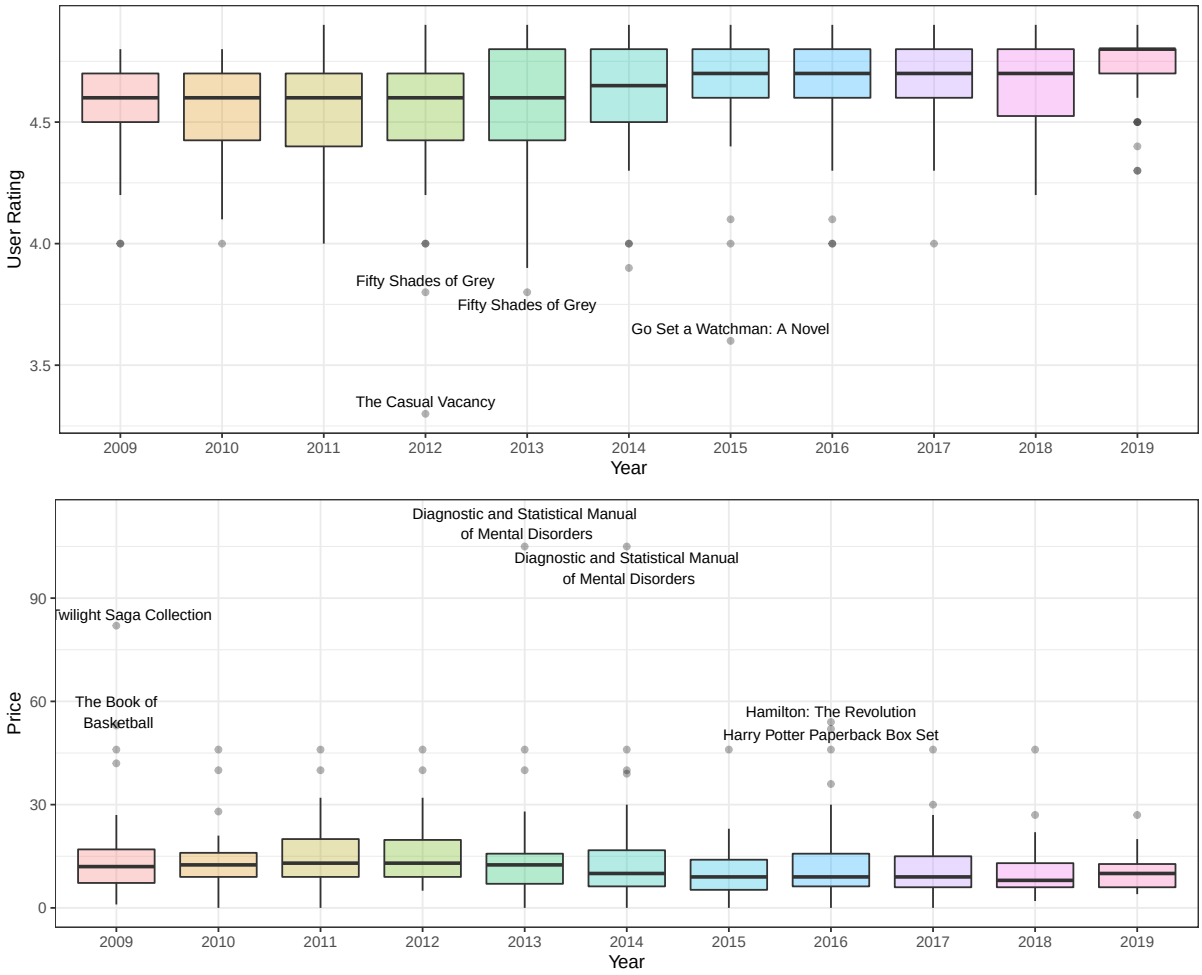

Figure 1: Distribution of the user ratings (top) and the books' prices (bottom) over the years. Some of the outliers are annotated with their titles.

each considered year. The top panel shows the distributions of the ratings. Each customer's rating goes from a minimum of one star to a maximum of five stars: the "overall rating" is a continuous value that ranges between one and five. In this case, however, since the best-selling books are likely to receive a high appreciation, the minimum observed index is 3.30, while the maximum is 4.90. In the plot, we also highlighted some outliers with the corresponding book title: it is noticeable how *"Fifty Shades of Gray"* reached the top of the best-seller books chart for two years in a row (2012 and 2013) while also having the lowest rating. The bottom panel shows the distribution of the books' prices over the years. All distributions are skewed because of the presence of some outliers in the right tail, which are particular books with an exceptionally high price. A quick analysis reveals how these outliers are often non-fiction books (e.g., the technical manual about mental disorders in 2013 and 2014) or collections of books (e.g., the *"Twilight Saga Collection"* in 2009).

What is evident for both variables is that their distribution is highly skewed, with heavy tails and the presence of many outliers. Hence, an analysis based on standard parametric densities is likely inadequate. A possible strategy could be pre-processing the data to remove the outliers and "force" the observations into fitting a pre-specified parametric model. However, this comes at the expense of flexibility, potentially losing some characteristics of the real phenomenon of interest. A different, more adequate strategy consists in abandoning the assumption of a simple parametric form and using a more flexible statistical model. The following section outlines an analysis based on Bayesian nonparametric nested mixture models.

2. Bayesian analysis of best-seller books

Bayesian nonparametric mixtures have emerged in recent years thanks to their ability to approximate very complex and non-standard distributions in a coherent and relatively simple way. Moreover, observations associated with the same mixture components can be seen as belonging to the same cluster, leading to a straightforward interpretation of the results.

In particular, to model data that are organized in different but related groups, as in our case, one can rely on nonparametric nested mixtures. These models exploit a two-level mixture structure to cluster both the observations and the groups. Notable examples are the nested Dirichlet Process (Rodríguez et al., 2008) and the common atoms models (CAM, Denti et al., 2021), among others. Recently we have also assisted in a renewed interest in finite mixtures, and indeed the finite counterpart of the CAM has been proposed (fCAM, D'Angelo et al., 2022). In the literature, we can find several applications of these classes of models to a broad range of fields, including neuroimaging (D'Angelo et al., 2021; Denti et al., 2022b), microbiome analysis (Denti et al., 2021), segmentation of functions of hormone profiles from multiple menstrual cycle (Rodriguez and Dunson, 2014) or music artists according to their songs' energy (Denti et al., 2022a).

In the following, we will employ the fCAM model to separately estimate the distributions of prices and ratings where the groups are indicated by the different years. By doing so, the model can cluster years characterized by similar distributions.

For each variable, we run the Gibbs sampler for the fCAM model for 20,000 iterations. After discarding the first half of the sample as burn-in period, we estimated the two-layer clustering solution via the minimization of the variation of information (Wade and Ghahramani, 2018; Dahl et al., 2022), a loss function over the space of the partitions. For the sake of conciseness, here we only report the results of the distributional partition.

The results are reported in Figure 2, which displays the kernel density estimates of the variables of interest colored by the their cluster allocation. In both cases, we recover two distributional clusters: for the ratings, the years between 2009 and 2011 are separated from the others. Similarly, for the prices, the years from 2010 to 2012 are grouped together. Being the main bodies of the distributions all similar, we believe that this clustering is mostly driven by the tails and outliers. It is interesting to observe how recent years have been characterized by higher dispersion in the ratings.

3. Discussion

In this contribution, we applied the fCAM method to a real dataset containing data of Amazon's bestsellers divided into 10 different years. The results allowed us to observe, for both variables, some kind of separation between the most recent years and the past. The presence of such structure in the data suggests some modeling extensions to research in the near future. First, in this analysis we used the years to define groups of variables. Nested models could be extended to account for potential temporal correlation across neighboring years in order to model the distributional evolution over time. Second, we can extend fCAM to handle multivariate data, so to perform a joint analysis of price and ratings.

Binomial Extended Stochastic Block Model for Brain Networks

Valentina Ghidini, Sirio Legramanti, Raffaele Argiento

Abstract One of the main goals in the statistical analysis of brain networks is clustering nodes, which represent brain regions, based on their connectivity patterns. This can be assisted by node covariates, such as lobe memberships. In the present paper, we cluster the nodes of a weighted brain network through a binomial extension of the extended stochastic block model by Legramanti et al. (2022b), which was originally designed for binary networks.

Key words: Bayesian nonparametrics, Gibbs-type priors, Weighted networks

1 Introduction

One of the main goals when analyzing brain networks, in which each node corresponds to a brain region, is obtaining clusters of nodes that are homogeneous with respect to their connectivity patterns. Since each brain region belongs to a lobe (macro-area) and brain regions in the same lobe typically exhibit similar connectivity, lobe memberships can be leveraged to assist the above-mentioned clustering.

Clustering nodes is not limited to brain networks, and several algorithms are available for this task (e.g. Newman, 2004; Von Luxburg, 2007; Blondel et al., 2008), including some that exploit node covariates (e.g. Combe et al., 2015; Binkiewicz et al., 2017). However, algorithmic techniques have major drawbacks, such as the need to choose the number of clusters in advance, instead of learning it from data, and the absence of uncertainty quantification around the estimated partition. For

Raffaele Argiento
University of Bergamo, e-mail: raffaele.argiento@unibg.it

these reasons, in this work we consider a model-based approach. In particular, we build on the extended stochastic block model (ESBM) by Legramanti et al. (2022b), which already proved effective on brain data (Legramanti et al., 2022a) but was originally implemented for binary networks. To fully exploit the information in the considered brain network, instead of dichotomizing its integer edge weights, we extend the ESBM by introducing a binomial likelihood, as detailed in the next section.

2 Binomial Extended Stochastic Block Model

Consider an undirected integer-weighted network with V nodes and its $V \times V$ symmetric adjacency matrix Y. Each element Y_{uv} of Y is such that $Y_{uv} = Y_{vu} \in \{0, 1, \ldots, K\}$, and contains the weight of the edge linking nodes u and v. Since here the goal is clustering, self-loops are neglected and, consequently, Y_{vv} is set to 0 for each $v = 1, \ldots, V$. Moreover, let $\mathbf{x}_v = (x_{v1}, \ldots, x_{vp})$ be the p-dimensional row vector of the covariates associated to node v, and let X be the $V \times p$ matrix obtained by stacking all the $\mathbf{x}_v$'s. Finally, let $\mathbf{z} = (z_1, \ldots, z_V) \in \{1, \ldots, H\}^V$ be the vector containing the node memberships associated to a partition of the V nodes into H mutually-exclusive clusters, such that $z_v = h$ if and only if node v belongs to cluster h. We are now ready to define our binomial extended stochastic block model (bESBM):

$$\begin{aligned} (Y_{uv} | z_u = h, z_v = k, \phi_{hk}) &\overset{ind.}{\sim} \text{Binomial}(K, \phi_{hk}) && \text{for } 1 \leq u < v \leq V, \\ (\phi_{hk} | \mathbf{z}) &\overset{i.i.d.}{\sim} \text{Beta}(a, b) && \text{for } h, k = 1, \ldots, H, \\ (\mathbf{z} | X) &\sim \text{supervised Gibbs-type}(\sigma, X). \end{aligned} \tag{1}$$

In words, each edge weight is modeled with a conditionally independent binomial whose probability depends solely on the cluster memberships of the involved nodes. Independent Beta priors with common positive hyperparameters a and b are placed on such binomial probabilities. Finally, cluster memberships are given a Gibbs-type prior with (discount) parameter $\sigma < 1$ and supervised by node covariates, i.e.

$$p(\mathbf{z} | X) \propto \mathscr{W}_{V,H} \prod_{h=1}^{H} (1 - \sigma)_{n_h - 1} g(X_h^*)^{\beta}, \tag{2}$$

where n_h is the cardinality of cluster h, $g(\cdot)$ is the so-called cohesion function, and X_h^* is the $n_h \times p$ matrix obtained by stacking the covariates of the nodes in cluster h, while $\{\mathscr{W}_{V,H} : 1 \leq H \leq V\}$ is a collection of non-negative weights such that $\mathscr{W}_{V,H} = (V - H\sigma)\mathscr{W}_{V+1,H} + \mathscr{W}_{V+1,H+1}$ and $\mathscr{W}_{1,1} = 1$. The parameter $\beta \geq 0$ allows to adjust the impact of the covariates on the partition process.

Several specifications of the cohesion $g(\cdot)$ have been proposed (e.g. Dahl, 2008; Müller et al., 2011; Page and Quintana, 2016); among these, we follow the recipe for categorical settings in Müller et al. (2011), motivated by the application in Section 4. In particular, considering the case in which each node attribute is a single categorical variable with C levels, we choose a cohesion function that is proportional to the

marginal likelihood of a Dirichlet-multinomial model on the covariates:

$$g(X_h^*) = \frac{1}{\Gamma(n_h + \alpha_0)} \prod_{c=1}^{C} \Gamma(n_{hc} + \alpha_c), \tag{3}$$

where n_{hc} is the number of nodes in cluster h with covariate c, while $\alpha_c > 0$ ($c = 1, \ldots, C$) are the Dirichlet concentration parameters, and $\alpha_0 = \sum_{c=1}^{C} \alpha_c$ is their sum.

3 Posterior Inference

In this section, we outline a collapsed Gibbs sampler for the posterior distribution $p(\mathbf{z}|Y,X)$ of the bESBM in (1). First of all, the cluster-specific probabilities ϕ_{hk}, which are not of direct interest here, are marginalized out from (1), yielding

$$\begin{aligned} p(Y|\mathbf{z}) = \prod_{h=1}^{H} \prod_{k=1}^{h-1} \Bigg\{ \prod_{u,v: z_u=h;\, z_v=k} \binom{K}{y_{uv}} \Bigg\} \frac{B(m_{hk} + a, K n_h n_k - m_{hk} + b)}{B(a,b)} \cdot \\ \cdot \Bigg\{ \prod_{u<v:\, z_u=z_v=h} \binom{K}{y_{uv}} \Bigg\} \frac{B(m_{hh} + a, (K/2)(n_h - 1) n_h - m_{hh} + b)}{B(a,b)}, \end{aligned} \tag{4}$$

where m_{hk} is the sum of the weights of the edges connecting nodes in cluster h and nodes in cluster k, while m_{hh} is the sum of edge weights within cluster h. From (4), we derive a collapsed Gibbs sampler that, at every iteration, updates the cluster membership of each node according to its full-conditional distribution

$$p(z_v = h|\mathbf{z}^{(-v)}, X, Y) \propto p(z_v = h|\mathbf{z}^{(-v)}, X) \frac{p(Y|\mathbf{z}^{(-v)}, z_v = h)}{p(Y^{(-v)}|\mathbf{z}^{(-v)})}, \tag{5}$$

where the superscript $(-v)$ denotes quantities computed excluding node v. The final ratio in (5) is computed from (4) while, for a bESBM with the cohesion in (3),

$$p(z_v = h|\mathbf{z}^{(-v)}, X) \propto \begin{cases} [(n_{hx_v}^{(-v)} + \alpha_{x_v})/(n_h^{(-v)} + \alpha_0)]^{\beta} \mathscr{W}_{V,H^{(-v)}}(n_h^{(-v)} - \sigma), & \text{for } h = 1, \ldots, H^{(-v)}, \\ (\alpha_{x_v}/\alpha_0)^{\beta} \mathscr{W}_{V,H^{(-v)}+1}, & \text{for } h = H^{(-v)} + 1, \end{cases}$$

where $\mathscr{W}_{V,H}$ and σ are determined by the Gibbs-type prior of choice; see, e.g., Legramanti et al. (2022b). In particular, for the application in Section 4, we will employ a Gnedin prior (Gnedin and Pitman, 2004), which corresponds to $\sigma = -1$ and $\mathscr{W}_{V,H} = (\gamma)_{V-H} \prod_{h=1}^{H} (h^2 - \gamma h) / \prod_{v=1}^{V} (v^2 + \gamma v)$.

4 Brain Network Application

The motivating dataset is the result of the `NKI1` pilot study of the Enhanced Nathan Kline Institute-Rockland Sample project[1], and contains brain imaging data for 20 patients. From this data, we obtain a binary network for each subject, with nodes representing the 68 brain regions in the Desikan atlas (Desikan et al., 2006) and binary edges denoting the presence of white matter fibers between two regions. Since we are not interested in subject-specific structures, we sum the 20 individual binary adjacency matrices obtaining a single integer-valued adjacency matrix Y, whose entries $Y_{uv} \in \{0,1,\dots,20\}$ count how many out of the 20 considered subjects show a connection between brain regions u and v. The resulting matrix corresponds to a single integer-weighted network, and clearly motivates our binomial extension of the ESBM. Finally, the lobe membership of each brain region is leveraged as a node covariate. Figure 1 shows the resulting integer-weighted network and the corresponding adjacency matrix, with nodes colored according to lobe memberships.

We sample from the posterior distribution of $\mathbf{z}$ by running the Gibbs sampler described in Section 3 for 10'000 iterations, with a burn-in of 1'000. Within the bESBM in (1), we employ a Gnedin prior with $\gamma = 0.3$, corresponding to a prior expectation of 17 clusters, while for the cohesion function in (3) we set $\alpha_c = 1$ for $c = 1,\dots 6$ (the six lobes in the human brain). In Figure 2 we represent the posterior

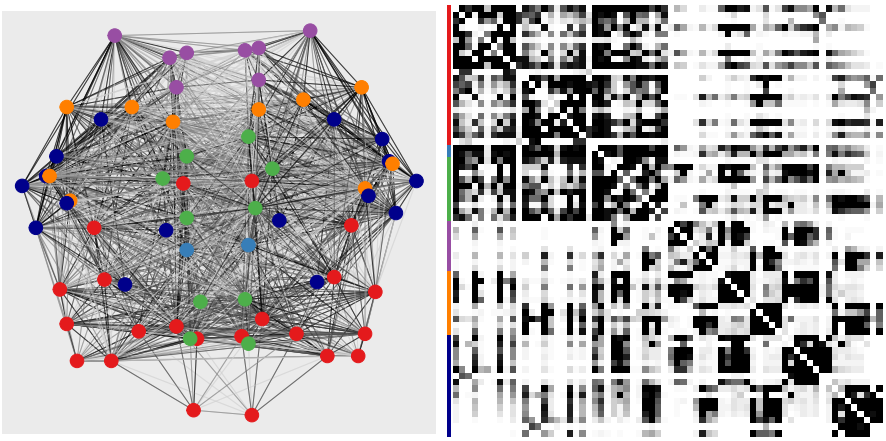

Fig. 1: Graphical representation (left) and adjacency matrix (right) of the considered integer-weighted brain network. Each node represents a brain region and is placed in its anatomical location. Node and side colors correspond to the human brain lobes: frontal (red), inter-hemispheric (light blue), limbic (green), occipital (purple), parietal (orange), or temporal (blue). The darkness of network edges and adjacency-matrix cells represents edge weights (the darker, the higher).

[1] `http://fcon_1000.projects.nitrc.org/indi/enhanced/`

point estimate of the node clustering (see Wade and Ghahramani, 2018) for $\beta = 0$ (no supervision), $\beta = 10$ (mild supervision) and $\beta = 1000$ (strong supervision). As expected, by increasing β, we obtain a partition that is more and more coherent with the node covariates, i.e. with the lobes illustrated in Figure 1.

Abstract

Mass spectrometry methods can record biomolecule abundance for a broad set of molecular masses given a sample of a specific biological tissue. In particular, the MALDI-MSI technique produces imaging data where, for each pixel, a mass spectrum is recorded. There is the urge to rely on suited statistical methods to model these data, fully addressing their morphological characteristics. Here, we investigate the use of Bayesian mixture models to segment these real biomedical images. We aim to detect groups of pixels that present similar patterns to extract interesting insights, such as anomalies that one cannot capture from the original pictures. This task is particularly challenging given the high dimensionality of the data and the spatial correlation among pixels. To account for the spatial nature of the dataset, we rely on Hidden Markov Random Fields.

Keywords: Mass spectrometry, Bayesian mixture models, Potts model, Brain imaging.

1. Introduction

Mass spectrometry imaging (MSI) is an emerging technology capable of mapping various biomolecules within their native spatial context. In this work, we describe an application to spatial multi-omics data obtained via the state-of-the-art MALDI-MSI technology. MALDI-MSI uses a laser energy-absorbing matrix to create ions from large molecules with minimal fragmentation. In other words, this technology visualizes the distribution of molecules such as peptides, lipids, and glycans in a biological sample [10]. Here, we focus on the sequential MALDI-MSI of lipids on a single mouse brain formalin-fixed paraffin-embedded (FFPE) tissue section. A slice of this brain is partitioned into a grid of pixels: see panel (a) of Figure 1 for a low-resolution depiction of the biological sample we consider. Then, MALDI-MSI acquires a mass spectrum for each pixel. In particular, MALDI-MSI creates pixel-by-pixel spectra by measuring the mass-to-charge (m/z) values representing analytes of interest along the x-axis and the corresponding abundance along the y-axis [3]. Finally, a three-dimensional MSI dataset is obtained by arranging the mass spectra and the grid of coordinates for each pixel to be investigated in further analyses. Due to experimental limitations, the MALDI-MSI spectra can contain noise affecting subsequent statistical analyses. To mitigate this issue, a well-established biological preprocessing step has to be performed. In this contribution, we aim to segment the pixels of images obtained with the MALDI-MSI

technique into biologically meaningful clusters employing Bayesian mixture models. Our article proceeds as follows. In the next subsection, we introduce the dataset we analyze. In Section 2, we describe our modeling approach, while in Section 3, our results are presented and discussed. Finally, in Section 4, we discuss future directions and conclude.

1.1 Data description and statistical preprocessing

As we already mentioned, the raw dataset produced by the MALDI-MSI technology undergoes some initial preprocessing steps to filter out the noise. These steps are baseline correction, smoothing, normalization, spectra alignment, peak detection and extraction. In addition, the preprocessing needs to reduce the intra-sample variability and correct for analytical and instrumental variability following sample preparation to ensure accurate *m/z* localization. For more details, see, for example, [4]. The resulting dataset for our statistical analysis has the following characteristics. The lipid image of the biological tissue is analyzed with a raster of 50 μm resulting in a total of about 18,000 laser shots (defining the pixels). In other words, we obtain thousands of spectra, each with its pixel coordinates (s_1,s_2). Recall that, for each pixel, the abundance of the lipids as a function of different values of molecular masses (*m/z*) is recorded, resulting in potentially hundreds of variables. Therefore, given the large dimensionality of the data, as the first step, we perform pixel-wise functional principal component analysis [9]. We then consider only the first functional principal component scores (fPCs) value for each pixel. We report the distributions of fPCs in panel (b) of Figure 1. The shape of the distribution suggests using Gaussian mixtures to segment the pixels of the image.

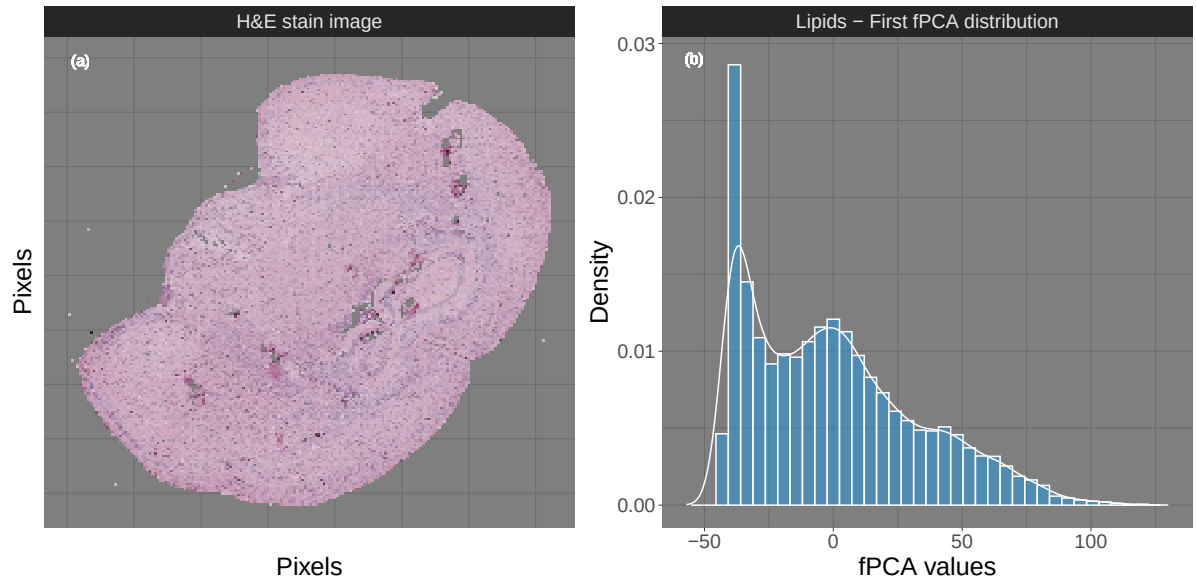

Figure 1: Panel (a): Hematoxylin and Eosin (H&E) staining image (low resolution). The reported mouse brain slice underwent digital scanning. Panel (b): The distribution of the first fPCs scores considered for our analysis. The shape suggests using a mixture of normal distributions to model the data.

2. Gaussian Mixtures and Potts Models

Here, we describe the model-based clustering approach we adopt for the preprocessed data presented in the previous section. We estimate clustering solutions via mixture models. Consider the vector $\boldsymbol{y} = (y_1, \ldots, y_n)$, where $y_i \in \mathbb{R}$ denotes the value of the first fPCs assumed by i-th pixel. Moreover, denote with $\mathcal{N}_i$ the set of all the neighboring (adjacent) pixels to the i-th one. Assuming the different pixels are

fully exchangeable (i.e., ignoring any spatial relation), one can specify the following basic, univariate Gaussian mixture likelihood with a fixed number of components K:

$$p(y_i \mid \boldsymbol{w}, \boldsymbol{\mu}, \boldsymbol{\sigma}^2) = \sum_{k=1}^{K} w_k \phi(\mu_k, \sigma_k^2), \qquad i = 1, \ldots, n, \tag{1}$$

where $\phi(\mu_k, \sigma_k^2)$ denotes a Normal density with mean μ_k and variance σ_k^2 and $\boldsymbol{w} = (w_1, \ldots, w_K)$ is the collection of mixture weights. To complete our model specification in a Bayesian setting, exploiting conjugacy, we adopt a Dirichlet prior for the mixture weights and Normal and Inverse Gamma priors for the mixture components' means and variances, respectively. In formulas, $\boldsymbol{w} \sim Dir_K(\boldsymbol{\lambda})$ and for $1, \ldots, K$, we assume $\mu_k \sim Normal(m, s^2)$ and $\sigma_k^2 \sim InvGamma(a, b)$. As customary with mixtures, we can augment the likelihood specification (1) by adding a set of n latent membership labels $\{z_i\}_{i=1}^n$. Each membership label has a discrete distribution with support over $1, \ldots, K$, and $z_i = k$ implies that the i-th observation has been assigned to the k-th cluster. The augmented likelihood can be expressed as, for $i = 1, \ldots, n$:

$$y_i \mid z_i, \boldsymbol{\mu}, \boldsymbol{\sigma}^2 \sim Normal(\mu_{z_i}, \sigma_{z_i}^2), \qquad p(z_i|\boldsymbol{w}) = \sum_{k=1}^{K} w_k \, \delta_k(z_i), \tag{2}$$

where $\delta_i(j)$ is the delta function, equal to 1 when $i = j$ and 0 otherwise. Note how y_i only depends on its correspondent latent membership z_i. It becomes evident how the addition of the latent variables considerably simplifies inference, usually carried out via MCMC techniques. We apply model (2) to set a benchmarking result.

Although the Bayesian Gaussian mixture model (GMM) presents a fully probabilistic extension to the classical K-means algorithm, the above specification disregards the available spatial information. Intuitively, especially when performing image segmentation, we expect neighboring pixels to have a higher probability of belonging to the same cluster. To introduce such spatial structure in the model, we can rely on Hidden Markov Random Fields. In particular, following [1; 2], we can defined a Potts model by modifying the distribution of the membership labels, introducing dependence of each pixel i on the sets of its neighbors $\mathcal{N}_i$. We assume a Gibbs distribution for the vector $\boldsymbol{z}$, which can be specified via the following conditional probability statement:

$$p(z_i|\boldsymbol{z}_{-i}, \beta) \propto \exp(\beta \sum_{j \in \mathcal{N}_i} \delta_{z_i}(z_l)), \tag{3}$$

where $\boldsymbol{z}_{-i}$ denotes all the variables in $\boldsymbol{z}$ without the i-th, and β is the *inverse temperature parameter*, which defines the strength of the spatial connection. Tuning and simulating the β parameter is challenging due to the doubly-intractable nature of its full conditional distributions. More importantly, the Potts model undergoes a phase transition, switching from a disordered to an ordered state. The phase transition happens as β exceeds a threshold β^*, also called *critical value*. The critical value for a regular 2D lattice is given by $\beta = \log(1 + \sqrt{K})$ [5; 8]. For simplicity, in this application, we assume a fixed value of inverse temperature, setting $\beta = \beta^*$. To fit both the GMM and the Hidden Potts model (HPM), we rely on the R package `bayesImageS` [6].

3. MALDI-MSI Bayesian Segmentation Results

All the results described in this section are summarized in Figure 2. Panel (a) shows the fPCs values across the pixels. Spatial patterns are apparent, highlighting the hippocampal formation (light blue pixels), the white matter (high-intensity blue pixels), and a combination of gray matter and cerebral cortex (white pixels). Moreover, from a biological perspective, we expect to distinguish the Thalamus and Hypothalamus within the hippocampal formation. Led by this biological information, we set the number of mixture components K equal to 5.

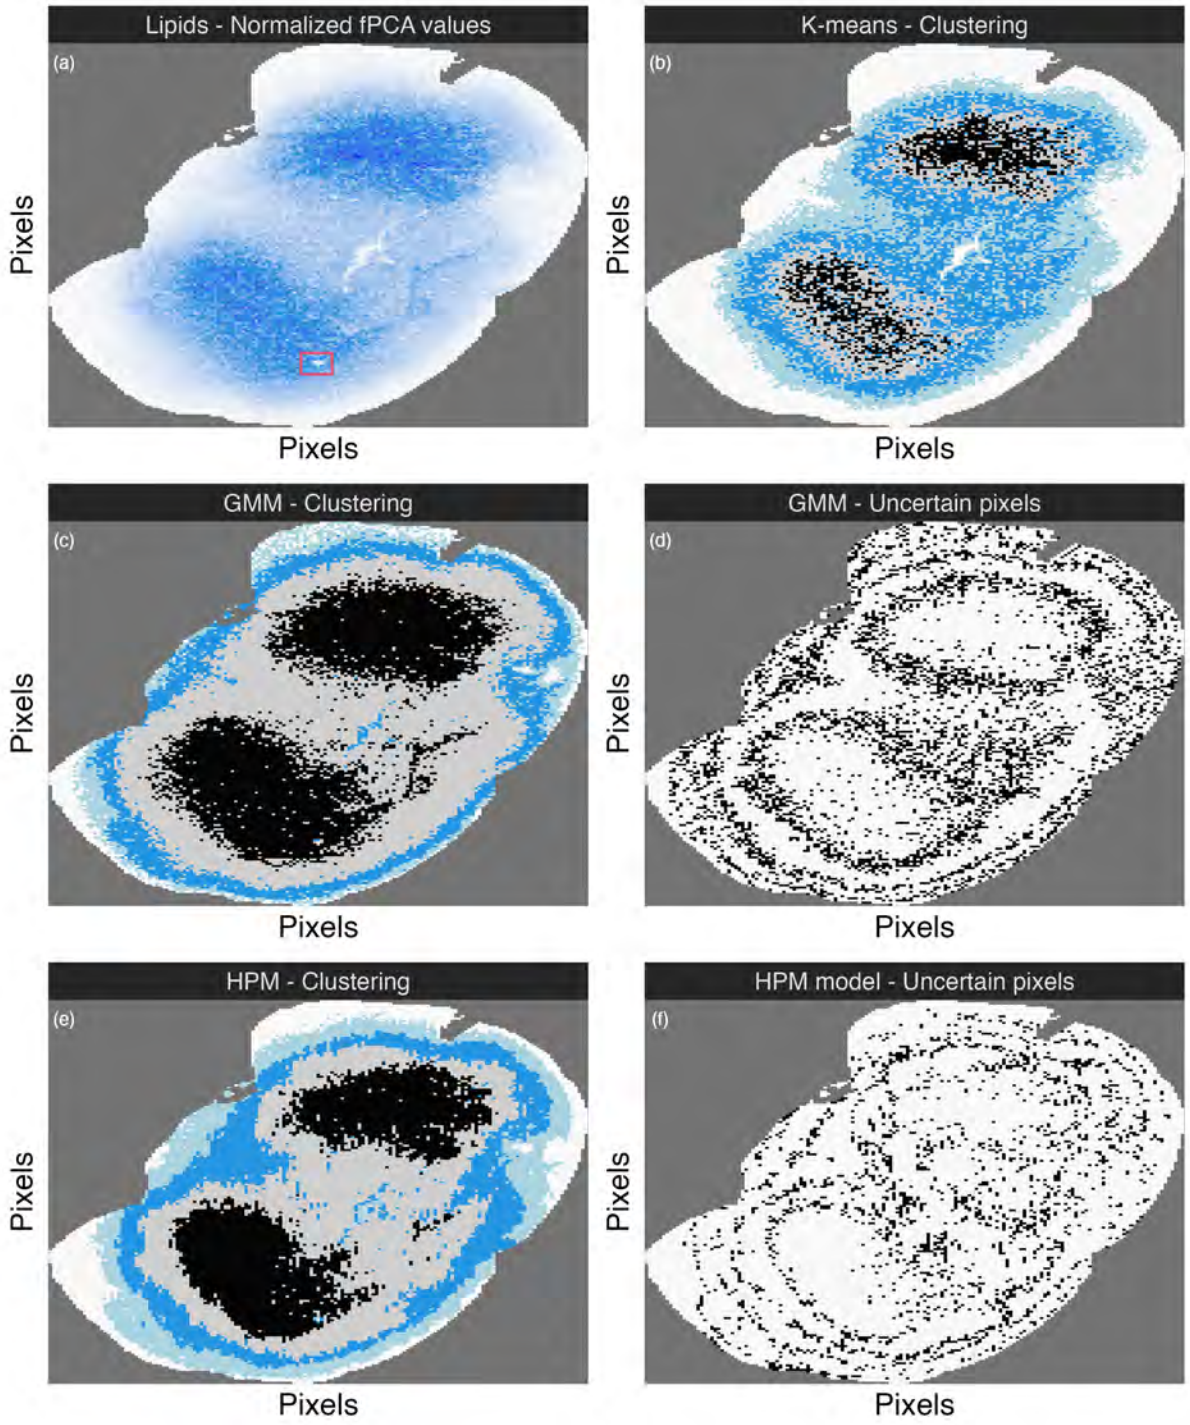

Figure 2: Each panel presents a pixelated image of the considered brain slice colored according to different results. (a) Distribution of the (normalized) first fPCs; (b) K-means clustering results; (c) GMM modal clustering results and (d) corresponding most uncertain pixels (e) HPM modal clustering results and (f) corresponding most uncertain pixels.

To benchmark our mixture models' results, we also fit a K-means algorithm on the first fPCs values. The resulting partition is reported in panel (b). The partition is fuzzy in the central parts of the slices, and no clear pattern is evident. We then fit both the GMM and the HPM. No label switching problem was detected: therefore, we estimate the clustering membership for each pixel as $\hat{c}_i = \arg\max_k f_{i,k}$, where $f_{i,k}$ is the proportion of iterations in which the MCMC allocated pixel i in cluster k. In panels (c) and

(e), we report the results of the GMM and the HPM, respectively. The addition of spatial information helps the model detect clearer boundaries across the different regions of the picture.

Moreover, we compute a Gini-Simpson index for each pixel as $g_i = 1 - \sum_{k=1}^{K} f_{i,k}^2$, summarizing the uncertainty of the model in the allocation of a specific pixel. Indeed, a large value of g_i implies that, across all the MCMC iterations, the pixels have been assigned to multiple clusters with similar probability, making $\hat{c}_i$ an unreliable estimate. In panels (d) and (f), we flag as uncertain (in black) all the pixels for which $g_i > 0.4$. These last two panels showed a discrete separation between the inter-brain formations (hippocampal white matter regions) and the external ones (gray matter). Since uncertain pixels correspond to cells that fall in the separation border between clusters, the separation enhances as we add spatial information. In fact, the number of pixels flagged as uncertain decreases from panels (d) to (f). The presence of uncertain pixels has a biological explanation. The laser diameter used by the MALDI-MSI in this analysis was 50 μm, while the average dimension of a single cell is $\approx 10\mu m$. Therefore, pixels at the border between two brain regions may contain cells of multiple natures that hinder their classifications.

Finally, the histological sample shows some anomalies (see, for example, the pixels highlighted by the red rectangle in panel (a) of Figure 2). These pixels correspond to pieces of tissue that detached from their original position and moved during sample preparation and analysis. Both the GMM and the HPM correctly classify these pixels exploiting their histological information. While retaining these anomalies, we can appreciate how the two Bayesian models eliminate sampling impurities better than the K-means.

4. Conclusions

The results presented in this contribution are promising and pave the way for many future directions to pursue. First, one can enhance the modeling aspect by allowing the estimation of a stochastic β using, for example, the pseudo-likelihood approach or the exchange algorithm [7]. Second, one could extend the likelihood specification to handle multivariate measurements. This extension would allow the joint modeling of multiple functional principal components, increasing the amount of information preserved after our dimensionality reduction step. Alternatively, these findings also encourage the development of statistical methods that can be used to jointly model lipids, peptides, and glycans, uncovering hidden molecular patterns resulting from the relationship between these multiple molecular levels. Integrating the three molecular data sets could improve the separation across distinct histopathological regions of interest of the mouse brain sections. Lastly, one could focus on the original image of the biological tissue, modeling its RGB encoding to detect anomalies in its morphological characteristics patterns. We plan to explore these research avenues in the future.

Abstract

Bayesian binary regression is a prosperous area of research due to the computational challenges encountered by currently available methods either for high-dimensional settings or large datasets, or both. In the present work, we focus on the expectation propagation (EP) approximation of the posterior distribution in Bayesian probit regression under a multivariate Gaussian prior distribution. Adapting more general derivations in Anceschi et al. (2023), we show how to leverage results on the extended multivariate skew-normal distribution to derive an efficient implementation of the EP routine having a per-iteration cost that scales linearly in the number of covariates. This makes EP computationally feasible also in challenging high-dimensional settings, as shown in a detailed simulation study.

Keywords: Probit Model, Expectation Propagation, Bayesian Inference, Extended Multivariate Skew-Normal Distribution

1. Introduction and literature review

The past few years have seen florid research in Bayesian inference for the probit model [4; 8] as well as its extensions to dynamic [7; 6] and multinomial [5; 9; 10] settings and beyond [1; 11]. This has been driven, among others, by computational challenges that may arise in high-dimensional settings. See [3] for an excellent review of Bayesian computations for binary regression. Here, we focus on the expectation propagation (EP) approximation of the posterior of the Bayesian probit model

$$\begin{aligned} y_i \mid \boldsymbol{\beta} &\overset{ind}{\sim} \text{BERN}\left(\Phi\left(\mathbf{x}_i^\intercal \boldsymbol{\beta}\right)\right), \quad i = 1, \dots, n, \\ \boldsymbol{\beta} &\sim \text{N}_p(\mathbf{0}, \nu^2 \mathbf{I}_p), \end{aligned} \tag{1}$$

where $\boldsymbol{\beta} \in \mathbb{R}^p$ is the unknown vector of parameters, $\mathbf{x}_i \in \mathbb{R}^p$ is the covariate vector associated with observation i and $\mathbf{I}_p$ denotes the identity matrix of dimension p. $\Phi(t)$ denotes instead the cumulative distribution function of a standard Gaussian random variable evaluated at t. Similarly, $\phi_p(\mathbf{t}, \mathbf{S})$ will denote the density of a p-variate Gaussian random variable with mean $\mathbf{0}$ and covariance matrix $\mathbf{S}$, evaluated at $\mathbf{t}$. [4] showed that the posterior distribution for model (1) is a unified skew-normal (SUN) and that, thanks to characterization properties of the SUN family, one can obtain i.i.d. samples from it via a linear combination of p-variate Gaussian samples and n-variate truncated Gaussian samples. As the computational bottleneck is represented by the truncated normal component, such i.i.d. sampler is well-suited for high-dimensional problems with small-to-moderate sample sizes but may become computationally hard for larger sample sizes. To overcome such limitation, [8] developed a partially-factorized variational (PFM-VB) approximation of the posterior distribution which, for any fixed n, converges to the true posterior distribution as p diverges. Crucially, PFM-VB does not require dealing with any multivariate truncated Gaussian since the corresponding density component is replaced with a product of univariate truncated Gaussian densities, which do not represent a computational problem. This approximation has a pre-processing cost of $\mathcal{O}(pn \cdot \min\{p, n\})$ and cost-per-iteration of $\mathcal{O}(n \cdot \min\{p, n\})$, making it computationally tractable also in large p and large n settings. Empirically, the approximate posterior moments closely match the ones obtained via i.i.d. sampling for $p \geq 2n$. The possible over-shrinkage of the posterior moments towards zero for smaller p motivates the investigation of efficient implementations of other approximation techniques that may be more accurate in those settings, like EP, at the price of a higher computational cost. Adapting more general results obtained for a broad class of models in [1], we show how the EP routine for posterior inference under the multivariate Gaussian prior in (1) can be implemented at per-iteration-cost of $\mathcal{O}(pn \cdot \min\{p, n\})$, which, although higher than the one of PFM-VB, improves over the cost $\mathcal{O}(p^2 n)$ reported in [3], leading to sensible computational advantages and making EP computationally feasible also in settings with p of the order of tens of thousands. Considering the goodness of the EP approximation [1; 3], the possibility to extend the number of scenarios where it can be effectively implemented represents a major contribution to Bayesian binary regression computations.

2. Expectation propagation for the probit model

In this section, we present an implementation of EP for the probit model (1) which leverages results on multivariate extended skew-normal (SN) random variables (see [2]). Calling $\mathbf{y} = (y_1, \dots, y_n)$, in EP we approximate $p(\boldsymbol{\beta} \mid \mathbf{y})$ with $q(\boldsymbol{\beta}) \propto \prod_{i=0}^n q_i(\boldsymbol{\beta})$, where $q_0(\boldsymbol{\beta}), \dots, q_n(\boldsymbol{\beta})$ are probability density functions and, in particular, $q_0(\boldsymbol{\beta}) = p(\boldsymbol{\beta})$ and $q_i(\boldsymbol{\beta}) \propto \exp\{-\frac{1}{2}\boldsymbol{\beta}^\intercal \mathbf{Q}_i \boldsymbol{\beta} + \boldsymbol{\beta}^\intercal \mathbf{r}_i\}$ for $i = 1, \dots, n$. Hence, writing $q_0(\boldsymbol{\beta}) \propto \exp\{-\frac{1}{2}\boldsymbol{\beta}^\intercal \mathbf{Q}_0 \boldsymbol{\beta} + \boldsymbol{\beta}^\intercal \mathbf{r}_0\}$, with $\mathbf{r}_0 = \mathbf{0}$ and $\mathbf{Q}_0 = \nu^{-2}\mathbf{I}_p$, we immediately note that $q(\boldsymbol{\beta}) = \phi_p(\boldsymbol{\beta} - \mathbf{Q}^{-1}\mathbf{r}, \mathbf{Q}^{-1})$, where $\mathbf{r} = \sum_{i=0}^n \mathbf{r}_i$, $\mathbf{Q} = \sum_{i=0}^n \mathbf{Q}_i$.

EP proceeds by updating each site $i = 1, \dots, n$ (we do not update the site of the prior), by iteratively matching the first two moments of the global approximation $q(\boldsymbol{\beta})$ and the hybrid distribution

$$h_i(\boldsymbol{\beta}) \propto p(y_i \mid \boldsymbol{\beta}) \prod_{j \neq i} q_j(\boldsymbol{\beta}) = \Phi((2y_i - 1)\mathbf{x}_i^\intercal \boldsymbol{\beta}) \prod_{j \neq i} q_j(\boldsymbol{\beta}). \tag{2}$$

To compute the moments of (2), instead of proceeding as [3], we can exploit the fact that some easy algebraic manipulations show that (2) is the kernel of a multivariate extended skew-normal distribution

$\text{SN}_p(\boldsymbol{\xi}_i, \boldsymbol{\Omega}_i, \boldsymbol{\alpha}_i, \tau_i)$ (see [2]), with

$$\boldsymbol{\xi}_i = \mathbf{Q}_{-i}^{-1}\mathbf{r}_{-i}, \quad \boldsymbol{\Omega}_i = \mathbf{Q}_{-i}^{-1},$$
$$\boldsymbol{\alpha}_i = (2y_i - 1)\boldsymbol{\omega}_i\mathbf{x}_i, \quad \tau_i = (2y_i - 1)(1 + \mathbf{x}_i^\intercal\boldsymbol{\Omega}_i\mathbf{x}_i)^{-1/2}\mathbf{x}_i^\intercal\boldsymbol{\xi}_i,$$

where $\mathbf{Q}_{-i} = \sum_{j\neq i}\mathbf{Q}_j$, $\mathbf{r}_{-i} = \sum_{j\neq i}\mathbf{r}_j$ and $\boldsymbol{\omega}_i = [\text{diag}\,(\boldsymbol{\Omega}_i)]^{1/2}$.

After noticing this, exploiting formulae (5.71) and (5.72) in [2], we can immediately obtain the first two moments of $h_i(\boldsymbol{\beta})$:

$$\boldsymbol{\mu}_{h_i} = \mathbb{E}_{h_i(\boldsymbol{\beta})}[\boldsymbol{\beta}] = \boldsymbol{\xi}_i + \zeta_1(\tau_i)s_i\boldsymbol{\Omega}_i\mathbf{x}_i$$
$$\boldsymbol{\Sigma}_{h_i} = \text{var}_{h_i(\boldsymbol{\beta})}[\boldsymbol{\beta}] = \boldsymbol{\Omega}_i + \zeta_2(\tau_i)s_i^2(\boldsymbol{\Omega}_i\mathbf{x}_i)(\boldsymbol{\Omega}_i\mathbf{x}_i)^\intercal,$$

where $s_i = (2y_i - 1)(1 + \mathbf{x}_i^\intercal\boldsymbol{\Omega}_i\mathbf{x}_i)^{-1/2}$, $\zeta_1(x) = \phi(x)/\Phi(x)$ and $\zeta_2(x) = -\zeta_1(x)^2 - x\zeta_1(x)$. Hence, when updating site i, the EP moment-matching condition implies that the updated quantities $\mathbf{r}_i^{\text{NEW}}$ and $\mathbf{Q}_i^{\text{NEW}}$ must be such that

$$\begin{cases} (\mathbf{Q}_{-i} + \mathbf{Q}_i^{\text{NEW}})^{-1}(\mathbf{r}_{-i} + \mathbf{r}_i^{\text{NEW}}) = \boldsymbol{\mu}_{h_i} \\ (\mathbf{Q}_{-i} + \mathbf{Q}_i^{\text{NEW}})^{-1} = \boldsymbol{\Sigma}_{h_i}, \end{cases}$$

from which it immediately follows

$$\begin{cases} \mathbf{r}_i^{\text{NEW}} = (\mathbf{Q}_{-i} + \mathbf{Q}_i^{\text{NEW}})\,\boldsymbol{\mu}_{h_i} - \mathbf{r}_{-i} \\ \mathbf{Q}_i^{\text{NEW}} = \boldsymbol{\Sigma}_{h_i}^{-1} - \mathbf{Q}_{-i}. \end{cases}$$

The direct computation of $\boldsymbol{\Sigma}_{h_i}^{-1}$ can be avoided since, by Woodbury's identity

$$\begin{aligned} \mathbf{Q}_i^{\text{NEW}} &= \boldsymbol{\Omega}_i^{-1} - \zeta_2(\tau_i)s_i^2(1 + \zeta_2(\tau_i)s_i^2\mathbf{x}_i^\intercal\boldsymbol{\Omega}_i\boldsymbol{\Omega}_i^{-1}\boldsymbol{\Omega}_i\mathbf{x}_i)^{-1}\boldsymbol{\Omega}_i^{-1}\boldsymbol{\Omega}_i\mathbf{x}_i\mathbf{x}_i^\intercal\boldsymbol{\Omega}_i\boldsymbol{\Omega}_i^{-1} - \mathbf{Q}_{-i} \\ &= -\zeta_2(\tau_i)s_i^2(1 + \zeta_2(\tau_i)s_i^2\mathbf{x}_i^\intercal\boldsymbol{\Omega}_i\mathbf{x}_i)^{-1}\mathbf{x}_i\mathbf{x}_i^\intercal = -(\zeta_2(\tau_i)^{-1}s_i^{-2} + \mathbf{x}_i^\intercal\boldsymbol{\Omega}_i\mathbf{x}_i)^{-1}\mathbf{x}_i\mathbf{x}_i^\intercal \\ &= -\frac{\zeta_2(\tau_i)}{1 + \mathbf{x}_i^\intercal\boldsymbol{\Omega}_i\mathbf{x}_i + \zeta_2(\tau_i)\mathbf{x}_i^\intercal\boldsymbol{\Omega}_i\mathbf{x}_i}\mathbf{x}_i\mathbf{x}_i^\intercal = k_i^{\text{NEW}}\mathbf{x}_i\mathbf{x}_i^\intercal, \end{aligned}$$

with $k_i^{\text{NEW}} = -\zeta_2(\tau_i)/\,(1 + \mathbf{x}_i^\intercal\boldsymbol{\Omega}_i\mathbf{x}_i + \zeta_2(\tau_i)\mathbf{x}_i^\intercal\boldsymbol{\Omega}_i\mathbf{x}_i)$. Moreover,

$$\begin{aligned} \mathbf{r}_i^{\text{NEW}} &= \mathbf{Q}_{-i}\boldsymbol{\mu}_{h_i} + \mathbf{Q}_i^{\text{NEW}}\boldsymbol{\mu}_{h_i} - \mathbf{r}_{-i} = \mathbf{Q}_{-i}\mathbf{Q}_{-i}^{-1}\mathbf{r}_{-i} + \zeta_1(\tau_i)s_i\mathbf{Q}_{-i}\boldsymbol{\Omega}_i\mathbf{x}_i + \mathbf{Q}_i^{\text{NEW}}\boldsymbol{\mu}_{h_i} - \mathbf{r}_{-i} \\ &= \zeta_1(\tau_i)s_i\mathbf{x}_i + \mathbf{Q}_i^{\text{NEW}}\boldsymbol{\mu}_{h_i} = \zeta_1(\tau_i)s_i\mathbf{x}_i + k_i^{\text{NEW}}\mathbf{x}_i\mathbf{x}_i^\intercal\boldsymbol{\Omega}_i\mathbf{r}_{-i} + k_i^{\text{NEW}}\zeta_1(\tau_i)s_i\mathbf{x}_i\mathbf{x}_i^\intercal\boldsymbol{\Omega}_i\mathbf{x}_i \\ &= [\zeta_1(\tau_i)s_i + k_i^{\text{NEW}}(\boldsymbol{\Omega}_i\mathbf{x}_i)^\intercal\mathbf{r}_{-i} + k_i^{\text{NEW}}\zeta_1(\tau_i)s_i\mathbf{x}_i^\intercal\boldsymbol{\Omega}_i\mathbf{x}_i]\mathbf{x}_i = m_i^{\text{NEW}}\mathbf{x}_i, \end{aligned}$$

Algorithm 1: Probit EP - $\mathcal{O}(p^2n)$ cost per iteration

---

Initialization: $\mathbf{Q} = \nu^{-2}\mathbf{I}_p$; $\mathbf{Q}^{-1} = \nu^2\mathbf{I}_p$; $\mathbf{r} = \mathbf{0}$; $k_i = 0$ and $m_i = 0$ for $i = 1, \ldots, n$.

for *t from 1 until convergence* **do**

  for *i from 1 to n* **do**

    $\mathbf{Q}_{-i} = \mathbf{Q} - k_i\mathbf{x}_i\mathbf{x}_i^\intercal$

    $\mathbf{r}_{-i} = \mathbf{r} - m_i\mathbf{x}_i$

    $\boldsymbol{\Omega}_i = \mathbf{Q}^{-1} + k_i/\,(1 - k_i\mathbf{x}_i^\intercal\mathbf{Q}^{-1}\mathbf{x}_i)\,(\mathbf{Q}^{-1}\mathbf{x}_i)\,(\mathbf{Q}^{-1}\mathbf{x}_i)^\intercal$

    $s_i = (2y_i - 1)(1 + \mathbf{x}_i^\intercal\boldsymbol{\Omega}_i\mathbf{x}_i)^{-1/2}$

    $\tau_i = s_i\mathbf{x}_i^\intercal\boldsymbol{\Omega}_i\,\mathbf{r}_{-i}$

    $k_i = -\zeta_2(\tau_i)/\,(1 + \mathbf{x}_i^\intercal\boldsymbol{\Omega}_i\mathbf{x}_i + \zeta_2(\tau_i)\mathbf{x}_i^\intercal\boldsymbol{\Omega}_i\mathbf{x}_i)$

    $m_i = \zeta_1(\tau_i)s_i + k_i(\boldsymbol{\Omega}_i\mathbf{x}_i)^\intercal\mathbf{r}_{-i} + k_i\zeta_1(\tau_i)s_i\mathbf{x}_i^\intercal\boldsymbol{\Omega}_i\mathbf{x}_i$

    $\mathbf{Q} = \mathbf{Q}_{-i} + k_i\mathbf{x}_i\mathbf{x}_i^\intercal$

    $\mathbf{r} = \mathbf{r}_{-i} + m_i\mathbf{x}_i$

    $\mathbf{Q}^{-1} = \boldsymbol{\Omega}_i + \zeta_2(\tau_i)s_i^2(\boldsymbol{\Omega}_i\mathbf{x}_i)(\boldsymbol{\Omega}_i\mathbf{x}_i)^\intercal$

Output: $q(\boldsymbol{\beta}) = \phi_p(\boldsymbol{\beta} - \mathbf{Q}^{-1}\mathbf{r}; \mathbf{Q}^{-1})$

---

where $m_i^{\text{NEW}} = \zeta_1(\tau_i)s_i + k_i^{\text{NEW}}(\boldsymbol{\Omega}_i\mathbf{x}_i)^\intercal\mathbf{r}_{-i} + k_i^{\text{NEW}}\zeta_1(\tau_i)s_i\mathbf{x}_i^\intercal\boldsymbol{\Omega}_i\mathbf{x}_i$. Hence, we can implement EP by storing only the scalar quantities k_i and m_i, $i = 1, \ldots, n$. In practice, they are initialized to zero, so that the initial global approximation is the prior distribution. Combining the above results with Woodbury's identity, we obtain

$$\boldsymbol{\Omega}_i = \mathbf{Q}_{-i}^{-1} = (\mathbf{Q} - k_i\mathbf{x}_i\mathbf{x}_i^\intercal)^{-1} = \mathbf{Q}^{-1} + \frac{k_i}{1 - k_i\mathbf{x}_i^\intercal\mathbf{Q}^{-1}\mathbf{x}_i}\left(\mathbf{Q}^{-1}\mathbf{x}_i\right)\left(\mathbf{Q}^{-1}\mathbf{x}_i\right)^\intercal,$$

which can be computed avoiding explicit matrix inversions, since $\mathbf{Q}^{-1}$ is known from the beginning. Finally, the update of the inverse of the EP precision matrix is immediate as $(\mathbf{Q}^{\text{NEW}})^{-1} = (\mathbf{Q}_{-i} + \mathbf{Q}_i^{\text{NEW}})^{-1} = \boldsymbol{\Sigma}_{h_i}$.

Putting it all together, we obtain the EP implementation in Algorithm 1. Its core part coincides with the EP derivations presented in [3], and implemented in the `EPprobit` function in the `R` package `EPGLM`. However, we arrived at it by exploiting results on SNs that leverage more general derivations for a broader class of models presented in [1]. We also avoided the computation of the normalizing constants for the unnormalized densities, Z_i, $i = 1, \ldots, n$, which can be used for the computation of the approximate marginal likelihood, since the approximated posterior moments can be computed also without them. Algorithm 1 has per-iteration cost $\mathcal{O}(p^2n)$, which, although avoiding explicit $p \times p$ matrix inversions, might be impractical in high-dimensional settings. Adapting more general results presented in [1], we thus derive in Section in full detail an implementation of EP for the Bayesian probit model having per-iteration cost $\mathcal{O}(pn^2)$.

3. Efficient expectation propagation for large p settings

The crucial part to obtain a per-iteration-cost that is linear in p is to note that we can avoid handling $p \times p$ matrices, as, by close inspection of Algorithm 1, the whole EP routine can be written by working out directly the updates of the p-dimensional vectors $\mathbf{w}_i = \boldsymbol{\Omega}_i\mathbf{x}_i = \mathbf{Q}_{-i}^{-1}\mathbf{x}_i$ and $\mathbf{v}_i = \mathbf{Q}^{-1}\mathbf{x}_i$, $i = 1, \ldots, n$. As for the former, we have

$$\begin{aligned}\mathbf{w}_i = \mathbf{Q}_{-i}^{-1}\mathbf{x}_i = (\mathbf{Q} - \mathbf{Q}_i)^{-1}\mathbf{x}_i &= \mathbf{Q}^{-1}\mathbf{x}_i + (1 - k_i\mathbf{x}_i^\intercal\mathbf{Q}^{-1}\mathbf{x}_i)^{-1}k_i(\mathbf{Q}^{-1}\mathbf{x}_i)(\mathbf{Q}^{-1}\mathbf{x}_i)^\intercal\mathbf{x}_i \\ &= \mathbf{v}_i + k_i(1 - k_i\mathbf{x}_i^\intercal\mathbf{v}_i)^{-1}\mathbf{v}_i\mathbf{v}_i^\intercal\mathbf{x}_i = \left[1 + (1 - k_i\mathbf{x}_i^\intercal\mathbf{v}_i)^{-1}(k_i\mathbf{x}_i^\intercal\mathbf{v}_i)\right]\mathbf{v}_i = d_i\mathbf{v}_i,\end{aligned}$$

where $d_i = (1 - k_i\mathbf{x}_i^\intercal\mathbf{v}_i)^{-1}$. As for the $\mathbf{v}_i$'s, each time a site i is updated $\mathbf{Q}$ changes and thus all the $\mathbf{v}_j$'s, $j = 1, \ldots, n$, should be modified accordingly as

$$\begin{aligned}\mathbf{v}_j^{\text{NEW}} = (\mathbf{Q}^{\text{NEW}})^{-1}\mathbf{x}_j &= (\mathbf{Q} - \mathbf{Q}_i + \mathbf{Q}_i^{\text{NEW}})^{-1}\mathbf{x}_j = [\mathbf{Q} + (k_i^{\text{NEW}} - k_i)\mathbf{x}_i\mathbf{x}_i^\intercal]^{-1}\mathbf{x}_j \\ &= [\mathbf{Q}^{-1} - (k_i^{\text{NEW}} - k_i)[1 + (k_i^{\text{NEW}} - k_i)\mathbf{x}_i^\intercal\mathbf{Q}^{-1}\mathbf{x}_i]^{-1}\mathbf{Q}^{-1}\mathbf{x}_i\mathbf{x}_i^\intercal\mathbf{Q}^{-1}]\mathbf{x}_j \\ &= \mathbf{Q}^{-1}\mathbf{x}_j - [(k_i^{\text{NEW}} - k_i)^{-1} + \mathbf{x}_i^\intercal\mathbf{v}_i]^{-1}\mathbf{v}_i\mathbf{x}_i^\intercal\mathbf{v}_j = \mathbf{v}_j - c_i(\mathbf{x}_i^\intercal\mathbf{v}_j)\mathbf{v}_i,\end{aligned}$$

where $c_i = (k_i^{\text{NEW}} - k_i)/(1 + (k_i^{\text{NEW}} - k_i)\mathbf{x}_i^\intercal\mathbf{v}_i)$. Instead of cycling over j, these updates can be performed in block by defining a $p \times n$ matrix $\mathbf{V} = [\mathbf{v}_1, \mathbf{v}_2, \ldots, \mathbf{v}_n]$. Accordingly, $\mathbf{V}^{\text{NEW}} = \mathbf{V} - c_i\mathbf{v}_i\mathbf{x}_i^\intercal\mathbf{V}$. This operation is the most expensive per site update, being of order $\mathcal{O}(pn)$. Accordingly, each EP iteration has cost $\mathcal{O}(pn^2)$. Contrarily to Algorithm 1, once the procedure has reached convergence we still need to calculate the inverse of the global precision matrix $\mathbf{Q}^{-1}$. The explicit calculation can be avoided as follows, obtaining a post-processing cost of $\mathcal{O}(p^2n)$. First, $\mathbf{Q} = \mathbf{Q}_0 + \sum_{i=1}^n k_i\mathbf{x}_i\mathbf{x}_i^\intercal = \nu^{-2}\mathbf{I}_p + \mathbf{X}^\intercal\mathbf{K}\mathbf{X}$ with $\mathbf{X} = (\mathbf{x}_1, \ldots, \mathbf{x}_n)^\intercal$ $\mathbf{K} = \text{diag}(k_1, \ldots, k_n)$. Calling $\boldsymbol{\Lambda} = (\mathbf{I}_n + \nu^2\mathbf{K}\mathbf{X}\mathbf{X}^\intercal)^{-1}$, so that, by Woodbury's identity, $\mathbf{Q}^{-1} = \nu^2\mathbf{I}_p - \nu^4\mathbf{X}^\intercal\boldsymbol{\Lambda}\mathbf{K}\mathbf{X}$, one obtains that $\mathbf{V} = \mathbf{Q}^{-1}\mathbf{X}^\intercal = \nu^2\mathbf{X}^\intercal\left[\mathbf{I}_n - \nu^2\boldsymbol{\Lambda}\mathbf{K}\mathbf{X}\mathbf{X}^\intercal\right] = \nu^2\mathbf{X}^\intercal\boldsymbol{\Lambda}\left[\boldsymbol{\Lambda}^{-1} - \nu^2\mathbf{K}\mathbf{X}\mathbf{X}^\intercal\right] = \nu^2\mathbf{X}^\intercal\boldsymbol{\Lambda}$ and thus $\mathbf{Q}^{-1} = \nu^2\mathbf{I}_p - \nu^2\mathbf{V}\mathbf{K}\mathbf{X}$. Notice that, if the interest is only in approximate posterior means and variances, this expression for $\mathbf{Q}^{-1}$ allows doing it at reduced post-processing cost of $\mathcal{O}(pn)$. The whole routine is summarized in Algorithm 2.

Algorithm 2: Efficient probit EP for large p - $\mathcal{O}(p \cdot n^2)$ cost per iteration

Initialization: $\mathbf{r} = \mathbf{0}$; $k_i = 0$ and $m_i = 0$ for $i = 1, \dots, n$; $\mathbf{V} = [\mathbf{v}_1, \dots, \mathbf{v}_n] = \nu^2 \mathbf{X}^\intercal$.

for t *from* 1 *until convergence* **do**

  for i *from* 1 *to* n **do**

    $\mathbf{w}_i = (1 - k_i \mathbf{x}_i^\intercal \mathbf{v}_i)^{-1} \mathbf{v}_i$

    $\mathbf{r}_{-i} = \mathbf{r} - m_i \mathbf{x}_i$

    $s_i = (2y_i - 1)(1 + \mathbf{x}_i^\intercal \mathbf{w}_i)^{-1/2}$

    $\tau_i = s_i \mathbf{w}_i^\intercal \, \mathbf{r}_{-i}$

    $k_i^{\text{NEW}} = -\zeta_2(\tau_i) / \left(1 + \mathbf{x}_i^\intercal \mathbf{w}_i + \zeta_2(\tau_i) \mathbf{x}_i^\intercal \mathbf{w}_i\right)$

    $m_i = \zeta_1(\tau_i) s_i + k_i^{\text{NEW}} \mathbf{w}_i^\intercal \mathbf{r}_{-i} + k_i^{\text{NEW}} \zeta_1(\tau_i) s_i \mathbf{x}_i^\intercal \mathbf{w}_i$

    $k_i = k_i^{\text{new}}$

    $\mathbf{r} = \mathbf{r}_{-i} + m_i \mathbf{x}_i$

    $\mathbf{V} = \mathbf{V} - \mathbf{v}_i \left[(k_i^{\text{NEW}} - k_i) / \left(1 + (k_i^{\text{NEW}} - k_i) \mathbf{x}_i^\intercal \mathbf{v}_i\right)\right] \mathbf{x}_i^\intercal \mathbf{V}$

$\mathbf{Q}^{-1} = \nu^2 \mathbf{I}_p - \nu^2 \mathbf{V} \mathbf{K} \mathbf{X}$

Output: $q(\boldsymbol{\beta}) = \phi_p(\boldsymbol{\beta} - \mathbf{Q}^{-1}\mathbf{r}; \mathbf{Q}^{-1})$

4. Simulation study

We conclude with a simulation study where probit regression is applied to multiple simulated datasets, with $n = 100$ and $p = 50, 100, 200, 400$ and 800. We investigate the performances of EP when the efficient implementations presented in Algorithm 1 and Algorithm 2 are used when $p < n$ and $p \geq n$, respectively. Such implementation, denoted EP-EFF in the following, is compared with PFM-VB in terms of running time and quality of the approximation. The latter is measured by the median absolute difference between the approximate posterior means and standard deviations and the ones computed via 2000 i.i.d. samples, for $\nu^2 = 25$. The moderate sample size is taken so that the i.i.d. sampler is computationally efficient, but the approximate methods could be used in more challenging settings, as in all scenarios they both give almost immediate outputs. To show the computational gains with respect to standard EP implementations, we also compare the running time needed to obtain the EP approximation with the `R` function `EPprobit` from the package `EPGLM`, which implements the EP derivations reported in [3]. As it emerges from Table 1, EP-EFF leads to a dramatic reduction of the computational effort with respect to the standard `EPprobit` in high dimensions. This results in a drop of the running time by more than three orders of magnitude in the setting $p = 800$, with a computational gain increasing with p, as expected. The EP-EFF running times, although generally much lower than the ones of `EPprobit`, are still higher than the ones of PFM-VB in most cases. Nevertheless, if one looks at the quality of the approximation of the two posterior moments in Figure 1, EP-EFF gives consistently accurate approximations across different dimensions of p, while PFM-VB gets similar accuracy for $p \gtrsim 2n$. This shows the importance of developing efficient implementations for EP like the ones in this paper, so make it computationally feasible in challenging high-dimensional settings where routine implementations are impractical. Code can be found at https://github.com/augustofasano/EPprobit-SN.

Table 1: Running time, in seconds, to compute posterior means and standard deviations with the EP approximation as in Algorithms 1 and 2 (EP-EFF), with the EP approximation computed via the `R` function `EPprobit` (`EPprobit`) and with the PFM-VB approximation (PFM-VB) for probit regression with $n = 100$ and $\nu^2 = 25$.

Abstract

In this work we propose a way to cluster time series in which we assume as unique commonality that two time series belong to the same group if structural changes in their behaviour happen at the same times. Our object of interest is then a latent random partition of the time series generated by a discrete distribution whose weights are distributed as a Dirichlet distribution. To obtain a posterior estimate of the partition we propose a collapsed Gibbs sampler on which we implement an acceleration step based on the split-and-merge scheme that improves the mixing performances of the algorithm. We show with a simulation on synthetic data that the model is capable of detecting correctly the clustering structure.

Keywords: Bayesian Statistics, Change Points, Model Based Clustering, Time Series Analysis

1. Introduction

In statistics an important role is played by methods for time series analysis. Since many phenomena evolve through time, it is crucial to take into account the temporal dependence of data. In this context an important and recently popular class of methods consists of detecting structural changes in the dynamic of the time series. This class of methods is called change points analysis. A change point corresponds to a time instant in which the data-generating distribution changes. If we assume that observations are generated by the same general law, then a change point will occur when the parameters of this law mutate. In literature methods for change points detection can be found both with frequentist and Bayesian frameworks.

Another important class of methods in statistics are those for clustering analysis. Grouping together observations allows us to find possible latent structures in the data. One of the main approaches to perform clustering consists in assuming that data within each cluster are generated by the same model, and then we can define to which group an observation belongs by studying its generating model.

In this work we propose a model based clustering method for time series based on the time occurrence of their change points. That is, two time series belong to the same group if they have changes that occur approximately in the same moment. To motivate our proposal, consider two time series that measure the profit of two companies, one that sells energy and another one whose production system relies on a significant amount of energy. A potential crisis in the energy supplies will influence both of them, but

in opposite terms - one negatively and the other positively. Therefore we can state that both companies have some sort of similarity since they both experience a shock from the same event at the same time, even though with opposite consequences.

The rest of the short paper is organized as follows. In Sect. 2. we present the model specification. Sect. 3. gives a glimpse on the computational aspects and the key quantities needed to perform posterior inference on the clustering structure. Finally, in Sect. 4. we show an application on synthetic data. Future directions with a possible applications on real data are deferred to Sect. 5.

2. Model

We denote with $\boldsymbol{y}_i = \{y_{i,1}, \dots y_{i,T}\}$ the generic ith observation that takes values in the discrete time range $1, \dots, T$. Then our sample is a vector of time series denoted by $\{\boldsymbol{y}_1, \dots \boldsymbol{y}_n\}$ where $\boldsymbol{y}_i = \{y_{i,l}\}_{l=1}^{T}$ and the generic $y_{i,l}$ takes values on $(\mathbb{Y}, \mathcal{Y})$, a Polish space endowed with its σ-algebra. We assume that each time series is indexed by a sequence of parameters $\theta_{i,1}, \dots, \theta_{i,T}$ associated to each observation. We further assume that two observations, say $y_{i,j}$ and $y_{i,l}$, belong to the same group h if they share the same value of the parameter, i.e. $\theta_{i,j} = \theta_{i,l} = \theta^*_{i,h}$. A change point occurs whenever two subsequent observations belong to different groups. The sequence $\theta^*_{i,1} \dots \theta^*_{i,h} \dots \theta^*_{i,k_i}$ denotes the unique values of the parameters associated to the k_i different regimes of the generic time series $\boldsymbol{y}_i$. We consider as distribution to model the sequence of parameters the product of two independent terms

$$\mathcal{L}(\theta_{i,1}, \dots, \theta_{i,T}) = \mathcal{L}(\rho_i)\mathcal{L}(\theta^*_{i,1}, \dots, \theta^*_{i,k_i}), \tag{1}$$

where $\mathcal{L}(\theta^*_{i,1}, \dots, \theta^*_{i,k_i})$ is the distribution of the sequence of unique values and $\mathcal{L}(\rho_i)$ is the distribution of the random order ρ_i. The random order ρ_i is defined as a sequence of disjoint subsets of the observational time indices with an ordering constant and it is fully characterizing the change points. Specifically, we have that $\rho_i = \{A_{i,1}, \dots, A_{i,k_i}\}$ with $A_{i,j} \cap A_{i,l} = \emptyset$ for any $j \neq l$ and $\bigcup_{j=1}^{k_i} A_{i,j} = \{1, \dots, T\}$ and $i < s$ for any $i \in A_{i,j}$ and $s \in A_{i,l}$ with $j < l$. In other words, $A_{i,1}$ is a set containing all the time indices t ranging from the first observational time 1 to the time $t^*_{i,1}$, corresponding to the first change point for the ith time series, i.e. $A_{i,1} = \{1, 2, \dots, t^*_{i,1}\}$. The generic block $A_{i,j}$ contains the observational times ranging from the $(j-1)$th to the jth change points, with $A_{i,j} = \{t^*_{i,j-1} + 1, t^*_{i,j-1} + 2, \dots, t^*_{i,j}\}$. A graphical representation of a single time series with corresponding latent parameters and blocks is given in Figure 1.

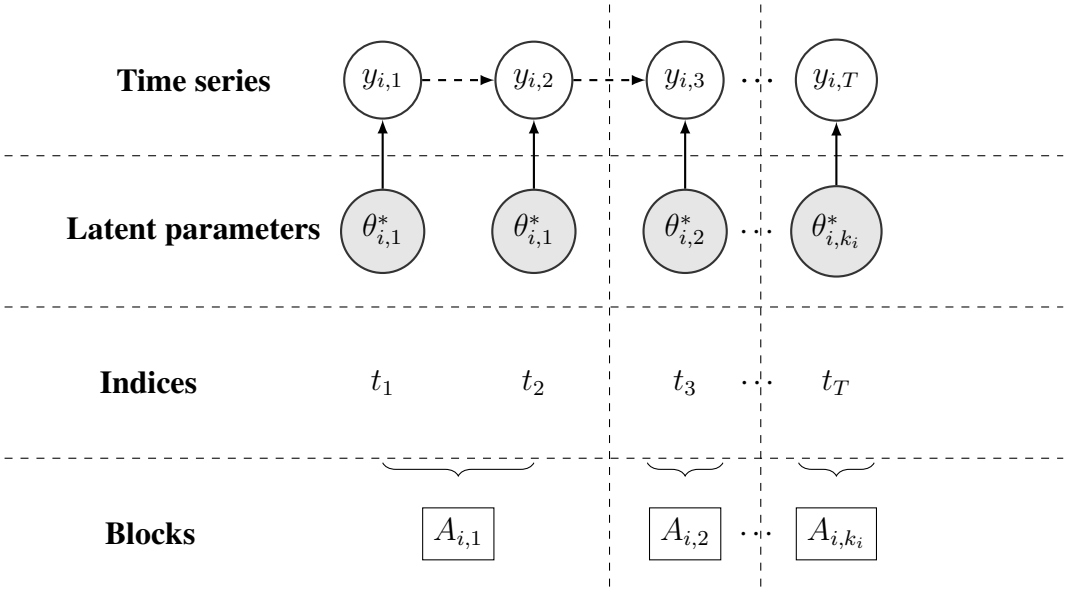

Figure 1: graphical representation of a time series $\boldsymbol{y}_i$ divided into k_i blocks $A_{i,1}, A_{i,2}, \dots, A_{i,k_i}$

This way of defining the distribution of a random order for change points detection problems was proposed for the first time in (1) considering general product partition models. For a more recent non-parametric approach see (3), where the authors defined a probability distribution for random orders by considering the restriction of an exchangeable partition probability function from the partitions' space to the orders' space. Recent extensions also investigated the multivariate setting, see (2), and the multiple parameter case in (5).

Our goal is to perform model-based clustering of time series with respect to their latent random orders. In other words if two time series $\boldsymbol{y}_i$ and $\boldsymbol{y}_j$ have the same latent random order, i.e $\rho_i = \rho_j$, they belong to the same jth cluster with corresponding order ρ_j^*. The generic ith observation is also characterised by a unique sequence of parameters $\theta_{i,1}^*, \dots, \theta_{i,k}^*$. However our interest is not in such sequence of parameters, but only in the clustering structure, namely the sequence of blocks $A_1, \dots, A_k$ that characterises each cluster ρ_j^*.

We consider $\rho_1, \dots, \rho_n$ as a sequence of exchangeable realisations from a discrete distribution that we denote with $\tilde{p}$. The atoms of $\tilde{p}$ are the possible latent orders for the time series. Since we do not want to make assumptions on the parametric form of this distribution we consider $\tilde{p}$ as a realisation from a random discrete probability measure. Then we have that, according to De Finetti's theorem, the exchangeable sequence $\rho_1, \dots, \rho_n$ conditioned on $\tilde{p}$ can be represented as an iid sequence precisely from $\tilde{p}$, i.e. $\rho_i \mid \tilde{p} \overset{iid}{\sim} \tilde{p}$, where $\tilde{p}$ is a discrete distribution of the form

$$\tilde{p} = \sum_{r=1}^{2^{T-1}} \pi_r \delta_{\rho_r^*}(\cdot), \tag{2}$$

with $\rho_1^*, \dots, \rho_{2^{T-1}}^*$ denoting all the possible orders of T elements. The distribution of $\tilde{p}$ is then fully specified by letting the weights $\pi_1, \dots, \pi_{2^{T-1}}$ distributed a priori as a Dirichlet distribution. The discrete structure of (2) implies the possible presence of ties among the orders, that means that there is a positive probability of having groups with more than one time series sharing the same structure of change points. We assume a Markovian dependence structure within each block of the ith time series and the likelihood term then can be factorised in the product of sub-sequential time instants. The final model is given by

$$\begin{aligned}
\boldsymbol{y}_i \mid \rho_i, \boldsymbol{\theta}_i^* &\sim \prod_{j=1}^{|\rho_i|} \prod_{t \in A_{i,j}} \mathcal{L}(y_{i,t} \mid y_{i,t-1}, \theta_{i,j}^*) \\
\theta_{i,j}^* &\overset{iid}{\sim} Q_0(d\theta) \\
\rho_1, \dots, \rho_n \mid \tilde{p} = p &\overset{iid}{\sim} \tilde{p} \\
\tilde{p} &= \sum_{r=1}^{2^{T-1}} \pi_r \delta_{\rho_r^*}(\cdot) \\
(\pi_1, \dots \pi_R) &\sim \text{Dir}(\alpha_1, \dots, \alpha_R),
\end{aligned} \tag{3}$$

with the proviso that if $t' = \min(A_{i,j})$ then $\mathcal{L}(y_{i,t'} \mid y_{i,t'-1}, \theta_{i,j}^*) = \mathcal{L}(y_{i,t'} \mid \theta_{i,j}^*)$.

3. Computational details

We denote with $\boldsymbol{Y} = \{\boldsymbol{y}_1, \dots, \boldsymbol{y}_n\}$ the observed data, with $\boldsymbol{\theta} = \{\theta_{1,1}, \dots \theta_{t,n}\}$ the whole latent parameters, with $\boldsymbol{\rho} = \{\rho_1, \dots, \rho_n\}$ the latent random orders and with $\boldsymbol{\pi} = \{\pi_1, \dots \pi_{2^{T-1}}\}$ the weights of (2). The joint distribution of the model can be obtained by exploiting the conditional distributions,

$$\mathcal{L}(\boldsymbol{Y}, \boldsymbol{\theta}, \boldsymbol{\rho}, \boldsymbol{\pi}) = \prod_{i=1}^{n} \prod_{j=1}^{|\rho_i|} \prod_{l \in A_{i,j}} \mathcal{L}(y_{i,l} \mid y_{i,l-1}, \theta_{i,j}^*) \prod_{i=1}^{n} \prod_{j=1}^{|\rho_i|} Q_0(\theta_{i,j}^*) \prod_{i=1}^{n} \tilde{p}(\rho_i) \frac{1}{B(\boldsymbol{\alpha})} \prod_{r=1}^{2^{T-1}} \pi_r^{\alpha_r - 1}, \tag{4}$$

where $B(\boldsymbol{\alpha})$ is the multivariate beta function with parameter $\boldsymbol{\alpha}$ and Q_0 is a non-atomic probability measure whose support coincides with the support of the latent parameters. Since we are not interested both in the specific values of $\boldsymbol{\theta}$ and $\boldsymbol{\pi}$ we integrate them out obtaining

$$\mathcal{L}(\boldsymbol{Y}, \boldsymbol{\rho}) = \frac{\Gamma(\alpha^+)}{\Gamma(\alpha^+ + n)} \prod_{r=1}^{2^{T-1}} \frac{\Gamma(\alpha_r + n_r)}{\Gamma(\alpha_r)} \prod_{\{i:\rho_i=\rho_r^*\}} \prod_{j=1}^{|\rho_r^*|} \mathcal{M}(\{y_{i,l} \mid l \in A_{i,j}\}), \tag{5}$$

with $\alpha^+ = \sum_{r=1}^{2^{T-1}} \alpha_r$, $n_r = |\{i : \rho_i = \rho_r^*\}|$ and where $\mathcal{M}(\{y_{i,l} \mid l \in A_{i,j}\})$ is the marginal distribution of the ith time series in the jth block. In equation (5) we have the convolution of the block specific marginal distributions, through the marginal distribution of a Dirichlet-Multinomial model, and the marginal distribution for each specific block of each observed time series. We exploit the distribution of $\rho_i \mid \boldsymbol{\rho_{(i)}}$, where $\boldsymbol{\rho}_{(i)} = \{\rho_1 \dots \rho_{i-1}, \rho_{i+1}, \dots, \rho_n\}$ denotes the random orders associated to the observed time series without the ith element, to update the allocation of the time series to different components of $\tilde{p}$. That corresponds to a Pólya-Urn scheme of a Dirichlet-Multinomial process, and we have that

$$\begin{aligned} P(\rho_i = \rho_r^* \mid \boldsymbol{y}_i, \boldsymbol{\rho}_{(i)}) \propto & \sum_{r \in \mathcal{S}_{(i)}^c} \frac{\alpha_r}{\alpha^+ + n - 1} \prod_{j=1}^{|\rho_r^*|} \mathcal{M}\left(\{y_{i,l} \mid l \in A_{r,j}^*\}\right) \\ & + \sum_{r \in \mathcal{S}_{(i)}} \frac{\alpha_r + n_{(i),r}}{\alpha + n - 1} \prod_{j=1}^{|\rho_r^*|} \mathcal{M}\left(\{y_{i,l} \mid l \in A_{r,j}^*\}\right), \end{aligned} \tag{6}$$

where $A_{r,j}^*$ is the jth block of ρ_r^*, $\mathcal{S}_{(i)}$ denotes the indices in $\{1, \dots, 2^{T-1}\}$ whose clusters are non-empty after removing the ith element, i.e. $r \in \mathcal{S}_{(i)}$ if $|\{\ell \neq i : \rho_\ell = \rho_r^*\}| > 0$, $\mathcal{S}_{(i)}^c = \{1, \dots, 2^{T-1}\} \setminus S_{(i)}$ and $n_{(i),r}$ the number of time series (except $\boldsymbol{y}_i$) that belong to ρ_r^*.

In order to sample from equation (6) we resort to a collapsed Gibbs sampler in which we add an acceleration step to improve the mixing ability of the sampler. The acceleration step updates at each iteration the unique values ρ_j^* and it is based on a split-and-merge strategy fully inspired by the work (3).

4. Illustration

We perform a simulation on synthetic data to verify if the model correctly identifies groups of time series generated by the same underlying distribution. We consider a scenario of normally distributed time series, each one with $T = 300$ time instants, grouped in $k = 3$ clusters respectively with size $n_1 = 3$, $n_2 = 4$ and $n_3 = 3$. We include a markovian dependency by considering each time observation dependent on the previous one. The jth time series at time i is defined as

$$y_{ij} = \begin{cases} \mu_{ij} + N(0, 0.25) & \text{if } i = 1 \\ \gamma\, y_{i-1,j} + (1-\gamma)\, \mu_{ij} + N(0, 0.25) & \text{otherwise.} \end{cases}$$

We fix $\gamma = 0.5$ and set μ_{ij} according to the scheme

$$\textbf{Group 1} \quad (j = 1, \dots, 3) \quad \begin{cases} \mu_{ij} = 2 & \text{if } i = 1, \dots, 100 \\ \mu_{ij} = 1 & \text{if } i = 101, \dots, 200 \\ \mu_{ij} = 2 & \text{if } i = 201, \dots, 300 \end{cases}$$

$$\textbf{Group 2} \quad (j = 4, \dots, 7) \qquad \begin{cases} \mu_{ij} = 0 & \text{if } i = 1, \dots, 25 \\ \mu_{ij} = 1 & \text{if } i = 26, \dots, 50 \\ \mu_{ij} = 0 & \text{if } i = 51, \dots, 70 \\ \mu_{ij} = -1 & \text{if } i = 71, \dots, 160 \\ \mu_{ij} = -2 & \text{if } i = 161, \dots, 300 \end{cases}$$

$$\textbf{Group 3} \quad (j = 8, \dots, 10) \qquad \begin{cases} \mu_{ij} = -1 & \text{if } i = 1, \dots, 30 \\ \mu_{ij} = -2 & \text{if } i = 31, \dots, 150 \\ \mu_{ij} = 0 & \text{if } i = 151, \dots, 300. \end{cases}$$

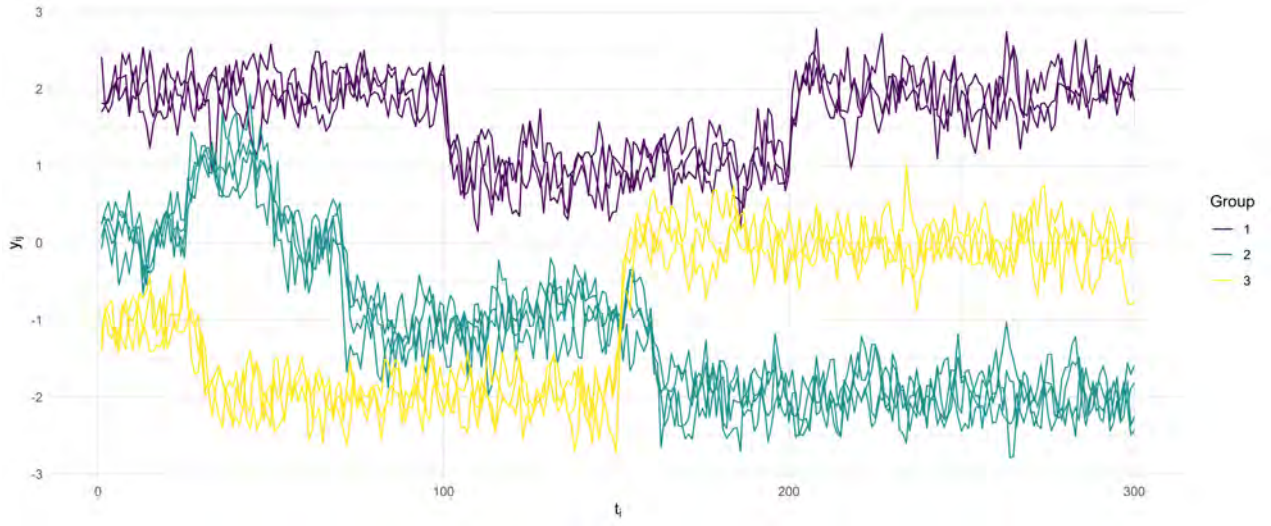

Figure 2: Posterior clustering of the synthetic time series.

Figure 2 shows a realisation from this model. We run the algorithm for 1000 iterations preceded by 500 burn-in iterations. Since sampling from all the potential 2^{T-1} partitions is infeasible, especially when T is large, we sample from a b-dimensional subset of $S_{(i)}$. The dimension b of this subset from which we sample the proposals of new unique values for ρ_i is definitely a parameter that determines the quality of the approximation. We choose $b = 25$ so we can gain a good trade-off between approximation consistency and computational time. According to the *Variation of Information* loss function (4) the algorithm selects as optimal partition $\{\{\boldsymbol{y}_1, \boldsymbol{y}_2, \boldsymbol{y}_3\}, \{\boldsymbol{y}_4, \boldsymbol{y}_5, \boldsymbol{y}_6, \boldsymbol{y}_7\}, \{\boldsymbol{y}_8, \boldsymbol{y}_9, \boldsymbol{y}_{10}\}\}$ which corresponds to the real one.

5. Future directions

In this work we presented a way to effectively perform a clustering of time series according to their changes over time. Future directions consist in applying this model to real data in different contexts. As mentioned in the introduction a first possible application might be in analyzing the effect of gas prices on different companies, or in general how the prices of raw materials affect the economies. Another interesting usage might be in studying real estate market, especially how it reacts to the global market changes and to inflation. Finally a notable application is in the field of infectious disease epidemiology, specifically for grouping survival functions for the time of infection of patients affected by a particular disease.

Abstract

In the context of modelling earthquake-induced ground motion for the Italian territory, we consider the response of a Ground Motion Model as an element of a functional space. We propose to reconstruct the missing trajectories of the functional response, and to adopt a routine which estimates the functional coefficients of the Ground Motion Model by taking into account that some values of the functional responses have been directly observed, and other values have been reconstructed. To this end, we present a novel methodology that introduces a system of weights giving full weight to estimation errors made on originally observed values, and less weight to errors made on reconstructed values.

Keywords: Functional data, weighted analysis, partially observed data, ground motion model

1. Introduction

Securing buildings from seismic damage is an issue of great importance all over the world, and especially in the Italian context, characterised by a medium-high seismic hazard level. To optimize the action of the institutions in terms of civil protection planning and seismic adaptation, it is pivotal to quantify the impact that the occurrence of a prospective earthquake would have on the territory. Ground Motion Models (GMMs) are regression models that estimate the expected value of some ground motion intensity measure, conditionally on seismic parameters that describe a given seismic scenario. Spectral acceleration is an intensity measure commonly used as response variable in GMMs, which describes the maximum acceleration that a damped harmonic oscillator (*i.e.*, a building) is subjected to during a seismic sequence. By construction, spectral acceleration is defined over a domain of natural vibration periods. This implies that the response variable of a GMM can be embedded in three alternative analytical frameworks: scalar, multivariate, or functional. The scalar GMM proposed in (3), which we refer to as ITA18, is a highly interpretable benchmark for the italian context, but necessarely suffers from the two main drawbacks of a scalar approach: *(i)* it provides only discrete estimates at some specific periods of interest, and *(ii)* no correlation between periods is included in the model. In this communication, we report the main methodological idea and results discussed by (1), which considers spectral acceleration as a function defined over the domain of vibration periods, and in this framework provides estimates of the regression coefficients of the ITA18 model.

Embedding spectral acceleration in a functional space implies coping with the fact that a non-negligible fraction of SA profiles are only partially observed over the domain of vibration periods, and need to be reconstructed. In the framework of functional data analysis, we propose a methodology that

produces estimates of the functional regression coefficients of the GMM, by accounting for the varying degrees of confidence that we have on different parts of the reconstructed curves of spectral acceleration. This is done by defining curve-specific weighting functions which enter the estimation routine by giving full weight to the errors made on the parts of the curves which are directly observed, and less weight to the errors made on parts of the curves that are reconstructed and thus more uncertain. The routine consists of two cascading steps – smoothing and concurrent linear regression – whose classical formulation and use (2; 5) are generalized in (1), in order to include observation-specific weighting functions.

2. Data and Model

Most of the data is provided by the ITalian ACcelerometric Archive (ITACA; (6)), which collects the manually-revised waveforms recorded by the main seismic networks in Italy. The dataset collects 5607 records of 146 earthquakes registered at 1657 stations (4), also including recordings of high-magnitude worldwide earthquakes, characterized by strike-slip and thrust faulting mechanisms.

The analysis considers 37 discrete intensity measures, namely the peak ground acceleration (PGA) and the spectral acceleration (SA) recorded at 36 vibration periods T_j in the interval $[0.04\ s, 10\ s]$. By convention, we refer to PGA as the spectral acceleration corresponding to $T_1 = 0\ s$, and to the set of longitudinal observations of spectral acceleration as SA profile. The manual processing of the intensity measures records at the sites results in some cases in incomplete SA profiles over the domain of periods. In the dataset under analysis, the fraction of observed values is close to 1 up to $5\ s$, and then quickly falls to about 0.75 at longer periods. The idea that we propose is to reconstruct the partially observed SA profiles from their last valid record up to $10\ s$ (see Section 4.1 and Section 5.1 of (1) for an overview of alternative reconstruction strategies), and to account later in the analysis for the presence of reconstructed and thus more uncertain values. This prevents the great loss of information that would occur if one discarded from the dataset the profiles with at least one missing value.

The ground motion model proposed in (3), and hereafter referred to as ITA18, estimates the median spectral acceleration separately at the 37 periods, by fitting a scalar linear regression model at every period. At each T_j, the model reads

$$\log_{10} \mathrm{SA}_j = a_j + F_M(M_w(T_j), SoF) + F_D(M_w(T_j), R(T_j)) + F_S(V_{S30}) + \epsilon_j, \tag{1}$$

where a_j is the offset, F_M, F_D, F_S are the source-, path- and site-related terms respectively, and ϵ_j is the remaining error. Variable M_w denotes the magnitude, SoF the style-of-faulting, R the source-to-site distance corrected by the pseudodepth at the site, and V_{S30} the shear-wave velocity. Notice that parameters M_h, M_{ref} and h in equation (1) are dependent on the periods, implying that we are given with longitudinal observations of the terms F_M and F_D. As the aim is to give a fully functional formulation of equation (1), i.e. functional response, coefficients and covariates, we embed this period-dependent terms in a suitable functional space with domain $\mathcal{T}$. The functional covariates are obtained resorting to penalized smoothing (5). Following some *ad hoc* considerations, the functional source term $\mathcal{F}_M$ is defined on a quadratic B-spline basis via a smoothing that penalizes its first derivative. The functional path term $\mathcal{F}_D$, on the other hand, is a cubic B-spline with knots at the sampling points.

Eventually, the embedding of the scalar model into a fully functional framework reads

$$\log_{10} \mathcal{SA} = \alpha + \mathcal{F}_M(M_w, \mathrm{SoF}, \mathcal{M}_h) + \mathcal{F}_D(M_w, d_{JB}, \mathcal{M}_{\text{ref}}, h) + \mathcal{F}_S(V_{S30}) + \mathcal{E}. \tag{2}$$

In (2), $\mathcal{SA}$ is a functional random variable with values in a suitable infinite dimensional space, α is the offset, and $\mathcal{F}_M$, $\mathcal{F}_D$ and $\mathcal{F}_S$ are known functions with domain $\mathcal{T}$. We are assuming $\mathcal{E}$ to be a realization of a zero mean stochastic process.

3. Method

Let $y_1, \ldots, y_n$ be the reconstructed curves belonging to the space $L^2(\mathcal{T})$, where $\mathcal{T}$ is an open subset of $\mathbb{R}$. Each reconstructed curve y_i is coupled with a weighting function $w_i : \mathcal{T} \to [0, 1]$. Denote by

$\boldsymbol{y}_i = (y_{i1}, \ldots, y_{iN})$ the vector of discrete observations, either directly registered or reconstructed, of curve y_i at the sampling instants $t_1, \ldots, t_N$.

The smoothing of each $\boldsymbol{y}_i$ is done by relying on a weighted penalized least square criterion (5), where the weights at the sampling instants are defined as $v_{ij} = w_i(t_j)$ for $j = 1, \ldots, N$. The penalty is imposed on the squared L^2-norm of the second derivative of the smoothed function, and the minimum is searched in the space $H^2(\mathcal{T})$ to guarantee the finiteness of this norm. The penalization parameter for each curve is tuned via generalized cross-validation. The resulting smoothed curve is a cubic spline with knots at the sampling points. Differently from the classical weighted penalized smoothing, we propose to make use of weights that vary not only along the sampling instants, but also on a data-by-data basis. This has an impact on the form of the overall smoothing map, that links the matrix of raw observations to the matrix collecting the smoothing coefficients. The overall smoothing map plays a crucial role in the assessment of the uncertainty related to the point coefficients estimates, and is thus relevant to provide an accurate representation of it (refer to Section 3 of (1) for a more detailed discussion on this).

In the second step of the routine, the smoothed functional observations z_i are assumed to be generated by a concurrent regression model, namely

$$z_i = \sum_{j=1}^{q} \beta_j x_{ij} + \epsilon_i, \qquad i = 1, \ldots, n, \tag{3}$$

where $x_{i1}, \ldots, x_{iq}$ are independent functional covariates, and $\beta_1, \ldots, \beta_q$ are the functional coefficients defined on $\mathcal{T}$. Errors $\epsilon_1, \ldots, \epsilon_n$ are assumed to be realizations of a zero-mean stochastic process.
We define a penalized fitting criterion which minimizes

$$\sum_{i=1}^{n} \int_{\mathcal{T}} w_i \left(z_i - \beta_j x_{ij}\right)^2 + \sum_{j=1}^{q} \int_{\mathcal{T}} \lambda_j \left(D^2 \beta_j\right)^2. \tag{4}$$

The second sum in (4) is a roughness penalty that regularizes the estimates, and $\lambda_1, \ldots, \lambda_q$ are penalization parameters which are tuned via generalized cross-validation. Each coefficient is associated to a specific penalization parameter, meaning that the estimates of the coefficients are allowed to have diverse levels of smoothness.

The dimensionality of problem (4) is reduced by assuming that each β_j belongs to a finite dimensional space spanned by suitable basis functions, and that it is uniquely identified by the coefficients of a specific linear combination of the basis functions. Section 3 in (1) shows that problem (4) is well posed in this setting, and that the explicit solution for $\beta_1, \ldots, \beta_q$ is found by exploiting the dimensionality reduction argument and some algebraic manipulations of the finite dimensional counterpart of (4).

4. Results

We refer to Section 5 of (1) for an extensive discussion on the choice of the weights, the calibration of the model, and a full description of the results of analysis.

In this communication we only call attention to the effect that the weighted functional methodology has on the estimates of the regression coefficients, by considering a specific coefficient of ITA18 as paradigmatic example. The site term in equation (1) reads $F_S(V_{S30}) = k \log\left(\frac{V_0}{800}\right)$, where $V_0 = V_{S30}$ if $V_{S30} \leq 1500\ m/s$, $V_0 = 1500\ m/s$ otherwise. Coefficient k accounts for the linear scaling of the shear-wave velocity for values of V_{S30} lower than $1500\ m/s$. The estimate of k resulting from the use of the scalar and functional models is displayed in Figure 1. The fences of the functional boxplot are to be interpreted as a reliable quantification of the variability associated to the functional coefficients point estimates, simultaneously over the entire domain of definition of the reconstructed SA profiles. The argument that legitimizes the adoption of a bootstrap methodology in this context is reported in Section 3.3 of (1). The functional estimate follows the trend of the scalar estimate while displaying a smoother behavior. The main deviation is observed in the right half of the domain, where the weighted analysis impacts the estimates. The fitting of the scalar model at large periods neglects all the information given

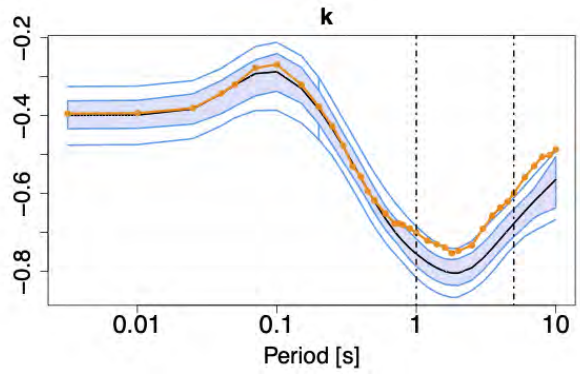

Figure 1: Comparison of the estimates of coefficient k, made with the scalar (orange) and the functional (black) models. The light blue bands are the fences of the functional boxplot built for k. The vertical lines mark the points of the last instants where 100% and $> 90\%$ of the curves are observed.

by the partially observed SA profiles, and the estimates are built by relying only on the 75% of the data used to get the functional estimates. By exploiting the correlation between the SA ordinates to reconstruct the profiles, and by adopting a weighted functional approach, the proposed method overcomes the loss of information, while providing reliable estimates continuously over the interval of relevant oscillation periods.

Conditional Gaussian Graphical Models for Functional Variables with Partially Separable Operators

Rita Fici[a], Gianluca Sottile[a], and Luigi Augugliaro[a]

[a]Department SEAS, University of Palermo, Italy; rita.fici@unipa.it, gianluca.sottile@unipa.it, luigi.augugliaro@unipa.it

Abstract

Functional graphical modeling is gaining increasing attention in recent years. In this paper, we contribute to the literature by extending the notion of conditional Gaussian graphical model to a functional setting. We propose a double-penalized estimator and an efficient algorithm to recover the edge-set encoding both the conditional covariance structure of the response functions and the effects of the predictor functions on the conditional distribution.

Keywords: Graphical models, multivariate functional data, multivariate Gaussian process, partial separability, sparse inference.

1. Introduction

In recent years, functional data has become a commonly encountered data type. The first approach aimed to extend graphical models to the functional setting was proposed in (6), where, under the assumption that the random functions follow a multivariate Gaussian process (MGP), the authors introduce the notion of functional Gaussian graphical model (fGGM) and an extension of the graphical lasso (glasso) (9) to estimate the edge-set encoding the conditional dependence structure. A notion of conditional functional graphical model, where the graph links are allowed to vary with the external variables, is introduced in (5). In this paper, we are not interested in constructing a random graph; rather, we are interested in the effect of the explanatory variables on the expected value of the multivariate response process. Recently, in (10) is addressed the general problem of covariance modelling for multivariate functional data, particularly fGGMs. The authors introduce the notion of partial separability for the covariance operator and show that this is particularly useful in functional graphical modelling (FGM) since it allows us to overcome the theoretical problems related to the covariance operator, which is compact and thus not invertible.

In this paper, we contribute to the literature on FGM by extending the notion of conditional Gaussian graphical model (cGGM) (8) and proposing a double-penalized estimator by which to recover the edge-set of the corresponding graph. We complete this section by providing a brief description of the cGGM models.

Let $\boldsymbol{X} = (X_1, \ldots, X_q)^\top$ and $\boldsymbol{Y} = (Y_1, \ldots, Y_p)^\top$ be two random vectors. cGGMs are based on the assumption that $\boldsymbol{Y} \mid \boldsymbol{x} \sim N(\boldsymbol{B}\boldsymbol{x}, \Sigma)$, where $\boldsymbol{B}\boldsymbol{x} = \mathrm{E}(\boldsymbol{Y} \mid \boldsymbol{x})$ and $\Sigma = \mathrm{V}(\boldsymbol{Y} \mid \boldsymbol{x})$, and that exists a graph $\mathscr{G} = (\mathscr{V}, \mathscr{E} = \mathscr{E}_\mu \cup \mathscr{E}_\Theta)$ encoding the effects of $\boldsymbol{X}$ onto the conditional distribution of $\boldsymbol{Y}$. The edge-set $\mathscr{E}$ is defined as the union of two specific sets. The set $\mathscr{E}_\mu$ contains the directed links representing the effects

of $\boldsymbol{X}$ on $\mathrm{E}(\boldsymbol{Y} \mid \boldsymbol{x})$, i.e., the directed link (m,h) belongs to $\mathscr{E}_\mu$ iff X_m has an effect on the conditional expected value of Y_h, i.e., $\beta_{hm} \neq 0$. The set $\mathscr{E}_\Theta$ contains the undirected links depicting the conditional dependence structure among the response variables, consequently, according to the standard theory on the factorization of the multivariate Gaussian distribution (see (4) for more details), the undirected link (h,k) belongs to $\mathscr{E}_\Theta$ iff the corresponding element of the precision matrix $\Theta = \Sigma^{-1}$ is different from zero. In this class of graphical models, our final goal is to estimate $\boldsymbol{B}$ and Θ and recover the information encoded in $\mathscr{E}$.

2. The functional conditional Gaussian graphical model

Notation We use the term multivariate functional data to refer to the realization of a multivariate process. Specifically, we denote the multivariate processes corresponding to the response and predictor functions as $\mathscr{P}_Y = \{\boldsymbol{\mathscr{Y}}(t) \in \mathbb{R}^p : t \in \mathscr{T}\}$ and $\mathscr{P}_X = \{\boldsymbol{\mathscr{X}}(s) \in \mathbb{R}^q : s \in \mathscr{S}\}$, where $\mathscr{T}$ and $\mathscr{S}$ are closed subsets of $\mathbb{R}$. It is assumed that $\mathscr{P}_Y$ and $\mathscr{P}_X$ are MGPs and that $\mathscr{Y}_h$ and $\mathscr{X}_m$ are elements of $\mathscr{L}_2(\mathscr{T})$ and $\mathscr{L}_2(\mathscr{S})$, where $\mathscr{L}_2(\cdot)$ denotes the Hilbert space of square-integrable functions endowed with the standard inner product $\langle g_1, g_2 \rangle = \int_{\mathscr{S}} g_1(s) g_2(s) ds$ and norm $\|\cdot\| = \langle \cdot, \cdot \rangle^{1/2}$. We also assume that $\boldsymbol{\mathscr{X}}$ has zero mean and a smooth covariance function $G^X(s_1,s_2) = \{G^X_{mn}(s_1,s_2)\}$, where $G^X_{mn}(s_1,s_2) = \mathrm{cov}(\mathscr{X}_m(s_1), \mathscr{X}_n(s_2))$. Similarly, $\boldsymbol{\mathscr{Y}}$ has zero mean and smooth covariance function $G^Y(t_1,t_2) = \{G^Y_{hk}(t_1,t_2)\}$. Finally, for each bivariate function $f \in \mathscr{L}_2(\mathscr{T} \times \mathscr{S})$, by $\|f\| = \{\int\int f(t,s) dt ds\}^{1/2}$ we denote the Hilbert-Schimdt norm.

The functional conditional Gaussian graphical model We are interesting in inferring how the predictor process affects the distribution of the conditional process $\mathscr{P}_{Y|X} = \{\boldsymbol{\mathscr{Y}}(t) \mid \boldsymbol{\mathscr{X}} : t \in \mathscr{T}\}$, which is Gaussian and uniquely specified by:

$$\mathrm{E}(\mathscr{Y}_h(t) \mid \boldsymbol{\mathscr{X}}) = \sum_{m=1}^{q} \int_{\mathscr{S}} \beta_{hm}(t,s) \mathscr{X}_m(s) ds, \quad G^{Y|X}(t_1,t_2) = \left\{ G^{Y|X}_{hk}(t_1,t_2) \right\}, \tag{1}$$

where $\beta_{hm}(t,s) \in \mathscr{L}_2(\mathscr{T} \times \mathscr{S})$ are the bivariate regression coefficient functions, and $G^{Y|X}_{hk}(t_1,t_2) = \mathrm{cov}(\mathscr{Y}_h(t_1), \mathscr{Y}_k(t_2) \mid \boldsymbol{\mathscr{X}})$ is the conditional covariance function. To provide a coherent extension of the cGGM, we must define the edge-sets $\mathscr{E}_\mu$ and $\mathscr{E}_\Theta$. While the first set can be easily defined using the left-hand-side in (1), i.e., $\mathscr{E}_\mu = \{(m,h) : \|\beta_{hm}\| \neq 0\}$, a proper definition of $\mathscr{E}_\Theta$ can be obtained only through the notion of conditional cross-covariance function (6):

$$C^{Y|X}_{hk}(t_1,t_2) = \mathrm{cov}(\mathscr{Y}_h(t_1), \mathscr{Y}_k(t_2) \mid \boldsymbol{\mathscr{Y}}_{-(hk)}, \boldsymbol{\mathscr{X}}), \tag{2}$$

which represents the covariance between $\mathscr{Y}_h$ and $\mathscr{Y}_k$ given the processes $\boldsymbol{\mathscr{Y}}_{-(hk)}$ and $\boldsymbol{\mathscr{X}}$. Using (2), we define $\mathscr{E}_\Theta = \{(h,k) : \|C^{Y|X}_{hk}\| \neq 0\}$. In the remaining part of this paper, by functional conditional Gaussian graphical model (fcGGM) we mean the set $\{\mathscr{P}_{Y|X}, \mathscr{G} = \{\mathscr{V}, \mathscr{E} = \mathscr{E}_\mu \cup \mathscr{E}_\Theta\}\}$, and our goal is to recover the edge-set $\mathscr{E}$.

Partial separability and fcGGM In principle, we could recover $\mathscr{E}$ using the approach presented in (6), representing each random function by the coefficients of a truncated basis expansion and then estimating $\mathscr{E}$ using a modified glasso estimator. Although this method is an intuitive approach to FGM estimation, the authors show the existence of a theoretical link between precision matrix and true FGM, only under the assumption that each random function takes values in a finite-dimensional space. As elucidated in (10), in an infinite-dimensional setting, the relationship between precision matrix and conditional independence structure is lost because the covariance operator is compact and thus not invertible; therefore, to estimate $\mathscr{E}$ in an fcGGM, we enforce our assumptions by assuming that the covariance operators G^X and G^Y are partially separable. As a consequence, by Theorem 1 in (10), we have the following

multivariate expansions:

$$\mathscr{Y}_h(t) = \sum_{l=1}^{+\infty} Y_{hl}\varphi_l(t), \quad \text{and} \quad \mathscr{X}_m(s) = \sum_{l=1}^{+\infty} X_{ml}\psi_l(s), \tag{3}$$

where $\{\varphi_l\}_{l=1}^{+\infty}$, $\{\psi_l\}_{l=1}^{+\infty}$ are orthonormal bases of $\mathscr{L}_2(\mathscr{T})$ and $\mathscr{L}_2(\mathscr{S})$, whereas $Y_{hl} = \langle \mathscr{Y}_h, \varphi_l \rangle$, $X_{ml} = \langle \mathscr{X}_m, \phi_l \rangle$ are random variables. Since $\mathscr{P}_Y$ and $\mathscr{P}_X$ are Gaussian, the vector $\boldsymbol{Z}_l = (X_{1l}, \ldots, X_{ql}, Y_{1l}, \ldots, Y_{pl})^\top$ is also Gaussian with parameters, $\mathrm{E}(\boldsymbol{Z}_l) = \boldsymbol{0}$ and $V(\boldsymbol{Z}_l) = \Sigma_l$. Moreover, $\boldsymbol{Z}_l \perp\!\!\!\perp \boldsymbol{Z}_{l'}$. Using (3), it is possible to show that:

$$\mathrm{E}(\mathscr{Y}_h(t) \mid \boldsymbol{\mathscr{X}}) = \sum_{m=1}^{q} \sum_{l=1}^{+\infty} \beta_{hml} x_{ml} \varphi_l(t), \tag{4}$$

where x_{ml} denotes a realization of X_{ml} and $\sum_{m=1}^{q} \beta_{hml} x_{ml} = \mathrm{E}(Y_{hl} \mid \boldsymbol{X}_l)$. A direct consequence of the expansion (4) is that $\mathscr{E}_\mu$ can be defined in terms of β_{hml}, i.e., $(m,h) \in \mathscr{E}_\mu$ iff exists at least an index $l \in \mathbb{N}$ such that $\beta_{hml} \neq 0$.

The main advantage of the expansion (4) is that it allows us to express the conditional cross-covariance function (2) in terms of conditional covariance between Y_{hl} and Y_{kl}. First, note that expansion (4) also implies that the residual process admits a multivariate expansion of type (3), thus, according to Theorem 1 of (10), the covariance operator in (1) is also partially separable, consequently, using Theorem 3 in (10) and the standard results on the conditional Gaussian distribution, we have:

$$C_{hk}^{Y|X}(t_1,t_2) = \sum_{l=1}^{+\infty} \mathrm{cov}(Y_{hl}, Y_{kl} \mid \boldsymbol{Y}_{-(hk)}, \boldsymbol{X}_l)\varphi_l(t_1)\varphi_l(t_2) = -\sum_{l=1}^{+\infty} \frac{\theta_{hkl}\varphi_l(t_1)\varphi_l(t_2)}{\theta_{hhl}\theta_{kkl} - \theta_{hkl}^2}, \tag{5}$$

where θ_{hkl} are the entries of $\Theta_l = \mathrm{V}(\boldsymbol{Y}_l \mid \boldsymbol{X}_l)^{-1}$. Using (5) it follows that an undirected link, say (h,k), belongs to $\mathscr{E}_\Theta$ iff exists at least an index $l \in \mathbb{N}$ such that $\theta_{hkl} \neq 0$.

The functional joint conditional graphical lasso estimator In the previous section, we have shown that all the necessary information needed to recover the edge set associated with an fcGGM is contained in the conditional distribution of $\boldsymbol{Y}_l$ given $\boldsymbol{X}_l$. Below, we propose a two-step procedure to estimate $\mathscr{E}$.

Step 1. Suppose we observe N independent realizations from $\mathscr{P}_Y$ and $\mathscr{P}_X$, denoted by $\boldsymbol{\mathscr{Y}}_i = (\mathscr{Y}_{i1}, \ldots, \mathscr{Y}_{ip})^\top$ and $\boldsymbol{\mathscr{X}}_i = (\mathscr{X}_{i1}, \ldots, \mathscr{X}_{ip})^\top$, with $i = 1, \ldots, N$, over T time instants. Expansions (3) allow us to represent each random function as an infinite-dimensional object; thus, it is necessary for some form of dimensionality reduction. First, the mean functions are calculated over the observed time instants as $\bar{\mathscr{Y}}_h(t) = \sum_{i=1}^{N} \mathscr{Y}_{ih}(t)/N$. Then p autocovariance matrices are estimated and each entry is given by $[\widehat{G}_h^Y]_{1,2} = \sum_{i=1}^{N} \{\mathscr{Y}_{ih}(t_1) - \bar{\mathscr{Y}}_h(t_1)\}\{\mathscr{Y}_{ih}(t_2) - \bar{\mathscr{Y}}_h(t_2)\}/N$. All those $T \times T$ matrices are summed and divided by p in order to have $\hat{H}^Y$, which indicates the mean-variance over the responses variables for each couple of time instants. According to Theorem 2 in (10), the basis functions $\varphi_l(t)$ can be estimated performing the eigen-decomposition on $\widehat{H}^Y$. Each $\mathscr{Y}_{ih}$ can be approximated using the first L leading terms, i.e., the function $\mathscr{Y}_{ih}^L(t) = \sum_{l=1}^{L} y_{ihl}\widehat{\varphi}_l(t)$, where the estimated principal component scores are $y_{ihl} = \langle \mathscr{Y}_{ih}, \widehat{\varphi}_l \rangle$. The procedure described above is used to estimate the quantities related to $\mathscr{X}_{im}(s)$, i.e., $\widehat{\psi}_l(s)$ and the corresponding scores $x_{iml} = \langle \mathscr{X}_{im}, \widehat{\psi}_l \rangle$. For ease of notation, we suppose again to use the first L leading terms to approximate the random predictor functions, i.e., $\mathscr{X}_{im}^L(s) = \sum_{l=1}^{L} x_{iml}\widehat{\psi}_l(s)$.

Step 2. Let $\mathbf{Y}_l = (y_{ihl})$ and $\mathbf{X}_l = (x_{iml})$, with $l = 1, \ldots, L$, be the matrices of the estimated scores. Given the assumption underlying the fcGGM, the rows of these matrices are independent realizations from a multiple cGGM, i.e., a collection of cGGMs; therefore, the sets $\mathscr{E}_\mu$ and $\mathscr{E}_\Theta$ can be estimated using a proper extension of the joint glasso (2), such as the one proposed in (3) or, in the context of censored data, in (1) and (7).

Let us denote by $\boldsymbol{B}_l$ and Θ_l the parameters associated to the lth cGGM and let $\{\boldsymbol{B}\} = \{\boldsymbol{B}_1, \ldots, \boldsymbol{B}_L\}$ and $\{\Theta\} = \{\Theta_1, \ldots, \Theta_L\}$. As the assumption of partial separability implies that $\boldsymbol{Z}_l \perp\!\!\!\perp \boldsymbol{Z}_{l'}$, for each $l \neq l'$, we

propose to recover $\mathscr{E}$ using the following double-penalized estimator, named functional joint conditional glasso estimator:

$$\{\widehat{\boldsymbol{B}}\},\{\widehat{\Theta}\} = \arg\max \sum_{l=1}^{L} \{\log\det\Theta_l - \mathrm{tr}(\mathbf{S}(\boldsymbol{B}_l)\Theta_l)\} - \lambda P_1(\{\boldsymbol{B}\}) - \rho P_2(\{\Theta\}), \tag{6}$$

where $\mathbf{S}(\boldsymbol{B}_l) = (\mathbf{Y}_l - \mathbf{X}_l\boldsymbol{B}_l)^\top(\mathbf{Y}_l - \mathbf{X}_l\boldsymbol{B}_l)/N$. The penalty functions in (6) selects convex functions that encourage sparsity in each matrix and specific forms of similarity across the regression coefficient matrices and the precision matrices. In this paper, we propose to use the group lasso penalty functions: $P_1(\{\boldsymbol{B}\}) = \sum_{h=1}^{p}\sum_{m=1}^{q}\left(\sum_{l=1}^{L}\beta_{hml}^2\right)^{1/2}$ and $P_2(\{\Theta\}) = \sum_{h\neq k}\left(\sum_{l=1}^{L}\theta_{hkl}^2\right)^{1/2}$, thus, the desired edge-sets can be estimated by $\widehat{\mathscr{E}}_\mu = \left\{(m,h) : \sum_{l=1}^{L}\hat{\beta}_{hml}^2 > 0\right\}$ and $\widehat{\mathscr{E}}_\Theta = \left\{(h,k) : \sum_{l=1}^{L}\hat{\theta}_{hkl}^2 > 0\right\}$.

3. A simulation study

To simulate a sample of $N = 600$ independent observations from an fcGGM, we use the following model:

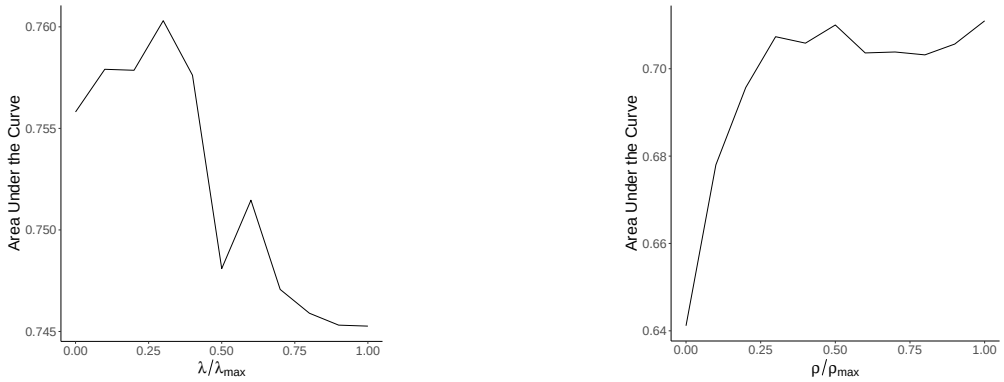
$$y_{ihr}^L = \sum_{l=1}^{L} y_{ihl}\varphi_l(t_r) + \varepsilon_{ihr}, \qquad x_{imr}^L = \sum_{l=1}^{L} x_{iml}\psi_l(s_r) + \varepsilon_{imr},$$

where ε_{ihr} and ε_{imr} are independent random errors drawn from $N(0,10)$, $\{t_r\}_{r=1}^{30}$ and $\{s_r\}_{r=1}^{30}$ are evenly spaced sequences with $t_1 = s_1 = 0$ and $t_{30} = s_{30} = 1$, and $\{\varphi_l\},\{\psi_l\}$ are Fourier bases. In our study, we set $L = 3$, $p = 24$ and $q = 7$. According to the assumptions underlying the proposed fcGGM, for each l, the vectors $\boldsymbol{z}_{il} = (\boldsymbol{x}_{il}^\top, \boldsymbol{y}_{il}^\top)^\top$ are independent realizations from a multivariate Gaussian distribution with zero expected value and covariance matrix Σ_l^z structured as follows:

$$\Sigma_l^z = 3l^{-1.8} \times \begin{bmatrix} \sigma_x^2\boldsymbol{I} + \boldsymbol{B}_l\Theta_l\boldsymbol{B}_l^\top & -\boldsymbol{B}_l\Theta_l \\ -\Theta_l\boldsymbol{B}_l^\top & \Theta_l \end{bmatrix}^{-1}. \tag{7}$$

where, as in (10), the decreasing factor $3l^{1.8}$ guarantees that $\mathrm{tr}(\Sigma_l^z)$ decreases monotonically in l, whereas the quantities in the matrix in (7) are related to the marginal distribution of $\boldsymbol{X}_{il}$ and to the conditional distribution of $\boldsymbol{Y}_{il}$ given $\boldsymbol{x}_{il}$ be the identities: $\mathrm{V}(\boldsymbol{X}_{il}) = \sigma_x^2\boldsymbol{I}$, with $\sigma_x^2 = 20$, $\mathrm{E}(\boldsymbol{Y}_{il} \mid \boldsymbol{x}_{il}) = \boldsymbol{B}_l\boldsymbol{x}_{il}$ and, finally, $\{\mathrm{V}(\boldsymbol{Y}_{il} \mid \boldsymbol{x}_{il})\}^{-1} = \Theta_l$. To generate a sparse fcGGM, for each l, each row of $\boldsymbol{B}_l$ has only two non-zero regression coefficients sampled from $U([-0.8,-0.5]\cup[+0.5,+0.8])$ whereas the conditional precision matrix Θ_l is structured in such a way that the associated graph is the union of a common and a specific star. Formally, the non-zero entries of each Θ_l are sampled by the model: $\theta_{hkl} \sim U([-0.15,-0.10]\cup[+0.10,+0.15])$, with $h \in \{1, 6l+1\}$ and $k = (h+1),\ldots,(h+5)$.

To compute the estimator (6), we use the algorithm proposed in (7). The behaviours of $\mathscr{E}_{\hat{\Theta}}$ and $\mathscr{E}_{\hat{\mu}}$ are studied under different combinations of λ and ρ; to analyze the coefficient path for $\{\widehat{\Theta}\}$, we first control the amount of shrinkage on $\{\widehat{\boldsymbol{B}}\}$ by keeping fixed the ratio λ/λ_{max}, and then, for this fixed λ value, the path for $\{\widehat{\Theta}\}$ is computed across a decreasing sequence of eleven evenly spaced values of ρ, from ρ_{max} to 0 with steps equal to $0.1\times\rho_{max}$. We use the median area under ROC curves to evaluate the resulting path in network recovery. Figure 1 shows the results. The left side of figure 1 shows the values of the AUC given by the eleven values of ρ when λ is fixed. On the $X-$axes, there is the value of λ expressed in percentage of its maximum value; the first value, $0\times\lambda_{max}$, corresponds to the case in which $\{\widehat{\boldsymbol{B}}\}$ is not penalized, the last value corresponds to the case where the predictor variables do not affect the conditional expected value of the response variables. On the $Y-$axes, the AUC median value over 50 simulations with λ fixed is reported. The left side of figure 1 shows that the level of shrinkage of $\{\widehat{\boldsymbol{B}}\}$ affects the ratio between TPR and FPR of $\mathscr{E}_{\hat{\Theta}}$, indeed, when the penalization for $\{\widehat{\boldsymbol{B}}\}$ is small, the resulting AUC of the network recovery for $\{\widehat{\Theta}\}$ is high. The higher the penalization parameter for $\{\widehat{\boldsymbol{B}}\}$, the more difficult for the model to detect the correct set of edges, suggesting that the explanatory variables are needed for an accurate evaluation of $\mathscr{E}_{\hat{\Theta}}$ and that the regression model is working well. The comparison of $\{\widehat{\boldsymbol{B}}\}$ paths is made using the same strategy as for $\{\widehat{\Theta}\}$, but inverting the role. Unlike the



(a) AUC of $\{\widehat{\Theta}\}$ (b) AUC of $\{\widehat{\boldsymbol{B}}\}$

Figure 1: AUC for different percentages of λ_{max} and ρ_{max}, and different values of $\sigma_{\boldsymbol{x}}$.

plot on the left of figure 1, the plot on the right shows a light effect of ρ on the ROC curve for $\{\widehat{\boldsymbol{B}}\}$, which confirms what is known in the literature.

4. Conclusion

Our model employs the multivariate expansion proposed by (10), to decompose the variables into two components: the stochastic component, which does not depend on the continuous domain, and the deterministic component, which depends on the domain of the variables. To the best of our knowledge, the proposed model is the first in which the analysis of the stochastic component is used to infer the structure of the dependencies among variables on both the side of the conditional independence relations of the variables of a functional response process and their dependencies on the functional covariates. The simulation study shows good performance of the cfGGM in terms of adjacency regression and precision matrices.

Abstract

The detection of outliers in functional data analysis (FDA) is crucial as unusual curves can lead to incorrect inference and biased parameters estimation. However, the identification of such anomalous samples may prove difficult in the infinite-dimensional space containing such data. To address this issue, we propose a simulation-based adjustment of the fence inflation factor in the functional boxplot, a widely employed tool in FDA. The adjustment is performed by controlling the proportion of observations considered anomalous in a purified population based on the original one. To do so, robust estimators of location and scatter are required: we compare the performance of multivariate procedures, suitable for the *small N, large P* problems, and functional operators for implementing the tuning. A simulation study highlights the benefit of the proposed method.

Keywords: Functional data analysis, Functional boxplot, Outlier detection, Robust estimation

1. Introduction and motivation

Functional data analysis (FDA) has become increasingly popular in recent years. The infinite-dimensional nature of these observations makes traditional multivariate techniques inappropriate for this complex data objects. Particularly, one field affected by this limitation is functional outlier detection, which is a crucial step in data exploration for ensuring the correctness of any subsequent statistical analysis. Outliers are recognized as curves that diverge from the common pattern of the data and should therefore be examined to determine if they are the result of errors or noise, or if they contain important information about the phenomenon under study. In this context, a variety of outlying behaviors can be observed: a comprehensive taxonomy of functional outliers is provided in (3).

The main focus of the present paper will be *amplitude outliers*, i.e., the direct generalization of multivariate outliers to the functional setting. The functional boxplot, introduced in (10), is a powerful tool for identifying and visualizing amplitude outliers: it is based on the classical boxplot, in which the central region of the data is represented by a box, while the fences are determined by

$$[Q1 - F \cdot IQR, Q3 + F \cdot IQR],$$

where F is a factor that inflates the range, $Q1$ and $Q3$ are the first and third quartiles, respectively, and IQR represents the interquartile range. To calculate quantiles, a center-outward ranking must be

defined: we make use of modified band depths (MBD, 6), which provides a method for determining the centrality of a functional signal within its sample. Observations whose paths cross the fences are flagged as outliers. Likewise for univariate data, an inflation factor $F = 1.5$ is generally employed for the purpose. The reason for this is due to the fact that probability of standing above the fences for a univariate Gaussian population can be computed as $2P(Z > Q3 + F \times IQR) = 2\Phi(4z_{0.25})$ which equals to a probability of 0.7%. Nonetheless, the presence of spatio-temporal dependence within curves may impact the performance of outlier detection. Specifically, using a constant factor of 1.5 may be too high when correlation exists, as, typically, spatially correlated curves are more concentrated than those that are independent. To overcome this issue, we extend the original simulation-based adjustment for the inflation factor, initially developed in (11), considering state-of-the-art robust multivariate estimators and functional operators. In details, we leverage the contribution of recent literature in robust statistics for both high-dimensional and infinite-dimensional objects, adopting novel methods for the generation of clean synthetic populations via Gaussian processes.

The remainder of the paper is organized as follows. In Section 2.the tuning procedure for the inflation factor is described, and the considered robust estimators briefly presented. Section 3. reports the result of a simulation study, in which the beneficial effect of the proposed procedure is emphasized. Section 4. concludes the paper.

2. Tuning F^* via robust estimators

As discussed in the previous section, a constant value of the inflation factor $F = 1.5$ is too restrictive when it comes to outlier detection in a functional setting. To make the functional boxplot sample-specific and data-driven, a simulation-based adjustment of F is proposed. Building upon the original idea of (11), we aim at generating outlier-free samples possessing the main characteristics of the original dataset at hand. Clearly, in order to do so the parameters of the process must not be impacted by extreme curves, and thus robust procedures are needed. In details, the algorithmic pipeline can be summarized as follows:

1. Given a dataset of N curves, estimate the mean function via a *robust* estimation of location and the covariance function by means of a *robust* estimate of dispersion,
2. Simulate a new dataset $\tilde{X}_b$ of dimension N sampling from a Gaussian process having as mean and covariance functions the estimates computed in step 1,
3. Compute $C_{0.5}$ - the 50% deepest region - and the adjusted inflation factor for the current replication b, referred to as F_b, given by the value F_b minimizing the probability of spotting no outliers in $\tilde{X}_b$, that is
$$F_b = argmin_F P\left(\tilde{X}_b \notin F \cdot C_{0.5}\right) - 2\Phi\left(4z_{0.25}\right)$$
4. Repeat 2. and 3. B times, collecting F_b, $b = 1, \ldots, B$,
5. Build the functional boxplot for the original data, using as inflation factor
$$F^* = \frac{1}{B}\sum_{b=1}^{B} F_b.$$

Undoubtedly, the most delicate task is performed in step 1, where suitable robust estimators must be selected. While for the mean function the median curve (i.e., the sample with highest MBD) can readily be adopted, for the covariance structure several options are at our disposal. We distinguish between robust multivariate estimators and functional operators. Within the former class of approaches, we consider Ledoit-Wolf (as a non robust benckmark, 5), OGK (7), Minimum Regularized Covariance Determinant (MRCD, 1) and Kernel MRCD (9) estimators. For the latter, we include Spherical Covariance Operator (2), Median Covariation operator (4) and Kendall's τ function (12).

The simulation phase outlined in step 2 slightly differs when either multivariate estimators or functional operators are considered. For the first set of estimators, we employ a finite-dimensional approximation and we directly sample from a multivariate Gaussian distribution with robustly estimated parameters.

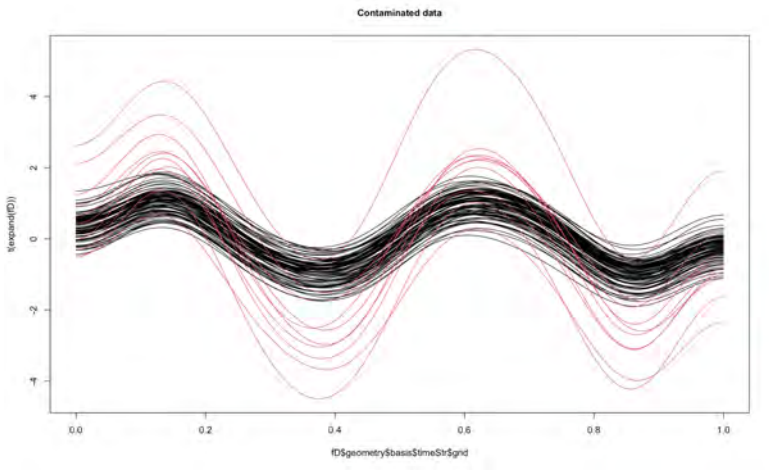

Figure 1: Example of simulated dataset according to the DGP outlined in Section 3. Uncontaminated curves are depicted in black, while red samples identify magnitude outliers.

When functional operators are considered, synthetic samples are built exploiting the Karhunen-Loève decomposition

$$X = \mu + \sum_{i=1}^{\infty} \sqrt{\lambda_i}\zeta_i\phi_i,$$

where $\zeta_i \sim \mathcal{N}(0,1)$, $\{\lambda_i, \phi i\}_{i=1,\ldots,\infty}$ are the eigencouples of the covariance function, and the eigenvalues $\{\lambda_i\}_{i=1,\ldots,\infty}$ are in decreasing order of magnitude. This expansion can be truncated at L components capturing most of the data variability: in our analysis, L is set equal to 10.

A promising simulation study, showcasing the effectiveness of both approaches for tuning F in the functional boxplot for outlier detection is presented in the next section.

3. Simulation study

The considered data-generating process (DGP) for the uncontaminated data is

$$X_i(t) = \sin(4\pi t) + \epsilon_i(t),$$

where $\epsilon_i(t)$ denotes a centered Gaussian process with Exponential Covariance function

$$C(s,t) = \alpha e^{-\beta|s-t|},$$

with s and t elements of the interval $I = [0,1]$. The parameters α and β are set to 0.12 and 0.4, respectively, which results in a low level of variability and high degree of autocorrelation. For the purpose of contamination, a portion of the observations in the dataset is replaced with outliers. The fraction of corrupted data is set to 15%: the contamination process involves inflating such a proportion of curves by multiplying the mean function by a randomly generated number $u \sim U(2,3)$, that is, for a contaminated curve the mean function is equal to $u \times \sin(4\pi t)$, $t \in I = [0,1]$. A sample obtained by the considered DGP is displayed in Figure 1. The adjustment procedure based on the estimators listed in the previous section are compared in terms of False Positive (FPR) and True Positive (TPR) outlier detection rate. A no-adjustment option, with F kept fixed at 1.5 is also included in the comparison.

The empirical distribution of the F^* values obtained by tuning the functional boxplot over 100 repetitions of the simulated experiment is displayed in Figure 2. All estimators but $kMRCD$ induce F^*s that are lower than the default value of 1.5, corroborating the need of an adjustment procedure. For the functional estimators, the resulting distribution of F^* is similar and they seem to have the most stable and robust behavior. Among the multivariate alternatives, the MRCD estimator (with hyper-parameter α set equal to either 0.5 or 0.75) appears to agree with the performance of the functional ones, whilst

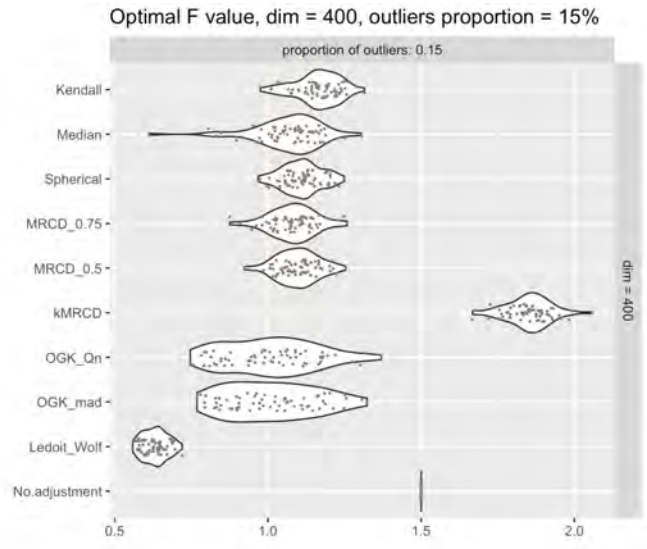

Figure 2: Violin plots of the optimal F values tuned with the adjustment procedures listed in Section 2. over 100 repetitions of the simulated experiment.

Ledoit-Wolf is biased towards smaller values of F^* being it sensitive to the presence of outliers. This behavior will lead to many False Positives, i.e., curves wrongly flagged as outliers. On the other hand, kMRCD is very conservative, resulting in very few False Positives but missing many truly outlying curves. This behavior is apparent when looking at Figure 3, where a scatterplot of average TPR against average FPR for each estimator is showcased. OGK results (obtained considered both Q_n and MAD estimates of scale) display slightly lower TPR and higher FPR with respect to MRCD, Spherical, Median, and Kendall's τ estimates. Overall, the Median Covariation brings the best trade-off between identifying the true anomalous curves whilst not producing too many false positives for this data contamination scenario.

All in all, given the poor performance of the no-adjustment setting, it is clear that tuning procedures are needed in order to improve the functional boxplot as an effective tool for outlier detection.

4. Conclusion and discussion

The paper has shown the importance of developing ad-hoc procedures when dealing with outliers in infinite-dimensional spaces. Specifically, being the functional boxplot one of the most-widely employed tools for the purpose, the importance of adjusting its inflation factor F in a distribution-free manner has been discussed. To improve the robustness of the methodology, the focus has been on using either multivariate or functional estimators for the covariance function. A taxonomy of the up-to-date choices for performing the tuning has been described and subseqeuntly employed in a simulated setting, showcasing better results than keeping F fixed.

Future research may involve extending the proposed procedure to the multivariate functional scenario. Although functional boxplots for multivariate curves have recently been introduced in the literature (8), the adaptation of the tuning procedure to this context remains a challenge that requires attention. Future effort will focus on exploring multiple possibilities that are currently under consideration.

Abstract

In recent years a literature on multivariate functional graph models has been developed. The graphical representation of the conditional dependence among a finite number of random variables is indeed appealing in different applications, such as e.g. the analysis of the brain connectivity. We want to investigate a novel extension of this methodology, considering random functions spatially and temporally correlated. A motivating case study is the analysis of the semantic network that tracks the change of the Brexit debate on Twitter across UK during a particular time frame. By considering the change in time of a word usage as a functional realization, a semantic network on the topic of interest is defined by a graphical representation of the conditional dependence among functional variables.

Keywords: Functional graphical models, Functional data analysis, Kernel Smoothing, Semantic network

1. Introduction

In recent years, literature on graphical models for functional data has been developed (6; 4). Indeed visualizing an estimated graph representing relationships between functional variables can be very effective to represent conditional dependence among them. In this framework, we contribute to extend this methodology by considering functional graphs that are spatially and temporally correlated; in particular they are supposed to vary on a spatio-temporal lattice, and for their estimation only limited measurements are available. This setting is motivated by data representing daily word usage on the Brexit debate on Twitter during 13 months (temporal units) and 41 districts in UK (spatial units) without replicates. Our main goal is to estimate a semantic network representing the connections of words used in such a debate. By means of functional graphical models it is possible to represent the connection between words from their monthly usage trends in Twitter. So doing, we offer a different insight on a public debate, moving beyond classical semantic networks built from co-occurrences of words in a sentence/tweet.

2. Motivating case study: Twitter conversations about Brexit

We dispose of data extracted from Twitter regarding the Brexit debate, as collected and pre-processed by del Gobbo et al. (1), by combining around one million of tweets with hashtag *Brexit* spanning in

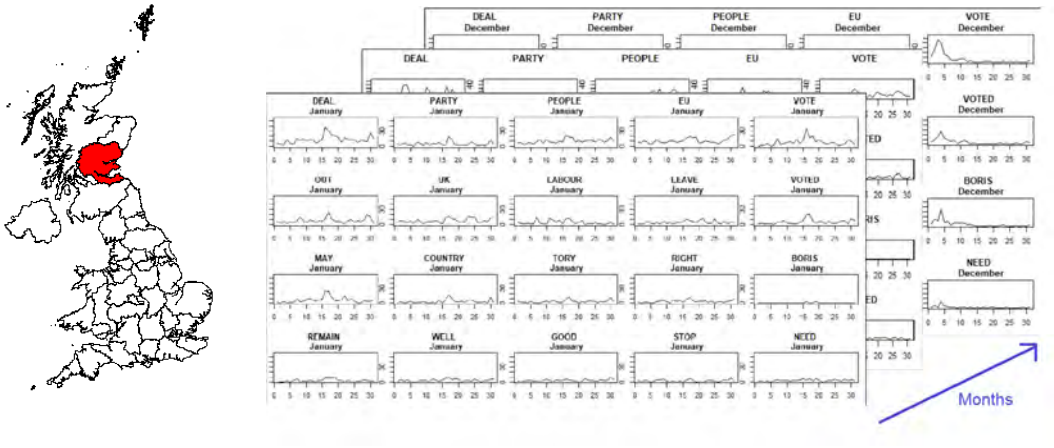

Figure 1: Example for a specific district (Eastern Scotland)

a range of 13 months (from 31 December 2018 to 9 February 2020) and geolocalized in the United Kingdom territory with 41 NUTS-2 (Nomenclature of territorial units for statistics) districts. We consider the daily usage of the first p most common words in each district in a time window of a month. Thus we have p daily time series (one for the daily usage of each word) for each month in each district, as shown in Figure 1 for the particular case of Eastern Scotland, and each time series can be seen as a noisy realization of a functional random variable. Hence the domain of the considered multiple functional data is a spatio-temporal irregular lattice $\mathcal{L} = \mathcal{S} \times \mathcal{M}$ where $\mathcal{S}$ represents the set of 41 districts and $\mathcal{M}$ the set of 13 months.

3. Functional graphical models

Let us consider a spatio-temporal irregular lattice $\mathcal{L} = \mathcal{S} \times \mathcal{M}$ where $\mathcal{S}$ represents a set of spatial units (districts) and $\mathcal{M}$ a set of time frames. Let us denote with $\mathbf{c} = (s, t)$ the spatio-temporal coordinate of a generic element of $\mathcal{L}$ and let $\mathbf{Y^c} = \{Y_1^{\mathbf{c}}, ..., Y_p^{\mathbf{c}}\}$ be a p-dimensional functional random variable taking values in $(L_2(\mathcal{T}))^p$, with $\mathcal{T} = [a, b]$, defined at a specific site (district) and time frame (month). The vector of mean functions is $E[\mathbf{Y^c}(\tau)] = \mu^{\mathbf{c}}(\tau) = \{\mu_j^{\mathbf{c}}(\tau)\}_{j=1,..,p}$, while the matrix of functional covariances is written as $\mathbf{C}(\mathbf{Y^c}(\tau), \mathbf{Y^c}(\tau')) = \mathbf{C}_{\mathbf{Y}}^{\mathbf{c}}(\tau, \tau') = \{C_{j,r}^{\mathbf{c}}(\tau, \tau')\}_{(j,r)=1,..,p}$.

By considering a continuous orthonormal basis functions, $\phi_{j,1}, \phi_{j,2}, \ldots$, the well-known Karhunen-Loéve expansion (KLE, see e.g. (2)) allows us to represent each functional variable $Y_j(\tau)^{\mathbf{c}}$ as

$$Y_j^{\mathbf{c}}(\tau) = \sum_{d=1}^{\infty} a_{j,d}^{\mathbf{c}} \phi_{j,d}(\tau),$$

where the expansion coefficients $a_{j,d}^{\mathbf{c}} = \int_{\mathcal{T}} Y_j^{\mathbf{c}}(\tau)\phi_{j,d}(\tau)d\tau$ are uncorrelated random variables, and then we consider with $D < \infty$ its truncated version

$$\tilde{Y}_j^{\mathbf{c}}(\tau) = \sum_{d=1}^{D} a_{j,d}^{\mathbf{c}} \phi_{j,d}(\tau).$$

Let $\mathbf{A^c} = \{\mathbf{a}_1^{\mathbf{c}}, ..., \mathbf{a}_p^{\mathbf{c}}\} \in \mathcal{R}^{pD}$ be the $(D \times p)$ matrix collecting the expansion coefficients associated with the p functions and let

$$\Sigma^{\mathbf{c}} = \{Cov(\mathbf{a}_j^{\mathbf{c}}, \mathbf{a}_r^{\mathbf{c}})\}_{(j,r)=1,...,p} = \{\Sigma_{j,r}^{\mathbf{c}}\}_{(j,r)=1,...,p}$$

be the $(Dp \times Dp)$ matrix collecting all covariances between expansion coefficients of all p functional variables. For the functional covariances we have the approximation:

$$C_{j,r}^{\mathbf{c}}(\tau, \tau') = C(Y_j^{\mathbf{c}}(\tau), Y_r^{\mathbf{c}}(\tau')) \approx C(\tilde{Y}_j^{\mathbf{c}}(\tau), \tilde{Y}_r^{\mathbf{c}}(\tau')),$$

and since vectors $\mathbf{a}_j^{\mathbf{c}}$ share the same information with $\tilde{Y}_j^{\mathbf{c}}(\tau)$ we can work with $\Sigma_{j,r}^{\mathbf{c}}$ and the matrix of partial correlations $\Theta^{\mathbf{c}} = (\Sigma^{\mathbf{c}})^{-1} = \{\Theta_{j,r}^{\mathbf{c}}\}_{(j,r)=1,\dots,p}$.

The matrix of partial correlation just defined is a key ingredient to evaluate relationships among functional variables in the framework of the graphical models. To this goal, for each coordinate $\mathbf{c}$, let $G^{\mathbf{c}} = \{V, E^{\mathbf{c}}\}$ be a undirected graph where $V = \{1, ..., p\}$ represents the set of vertices corresponding to the p random functions and $E^{\mathbf{c}} \subseteq \{(j,r) \ \in V \times V, \ j \neq r\}$ represents the set of edges specified by means of

$$(j,r) \notin E^{\mathbf{c}} \ \text{ if } \ ||\Theta_{j,r}^{\mathbf{c}}||_F = 0$$

where $||\cdot||_F$ denotes the Frobenius norm. The condition below is equivalent to conditional independence between the j-th and r-th variables in the Gaussian case and, in analogy with Qiao et al. (2019, (6)), by considering the p functional random variables as vertices of the graph $G^{\mathbf{c}}$ we can say that $\mathbf{Y}^{\mathbf{c}}$ follows a *Functional Graphical Model (FGM)*.

To retrieve a network, for every $\mathbf{c}$, among p functional random variables in a *FGM* we need to estimate $\Theta^{\mathbf{c}}$. Moreover, since we are interested in underlying just the most important connections among words, we consider a sparse estimator for $\Theta^{\mathbf{c}}$. To this goal, we consider the Functional graphical lasso criterion (`fglasso`) introduced by (6) as a block extension of the classical `glasso` algorithm (8; 3). The sparsity in the precision matrix is achieved by imposing a group lasso penalty, so that the estimated $\widehat{\Theta}^{\mathbf{c}}$ at each $\mathbf{c}$ is obtained by solving an optimization problem:

$$\widehat{\Theta}^{\mathbf{c}} = \underset{\Theta^{\mathbf{c}}}{\operatorname{argmax}} \left(\log\det \Theta^{\mathbf{c}} - \operatorname{trace}(\hat{\Sigma}^{\mathbf{c}}\Theta^{\mathbf{c}}) - \lambda \sum_{j \neq r} ||\Theta_{j,r}^{\mathbf{c}}||_F \right), \tag{1}$$

where $\hat{\Sigma}^{\mathbf{c}}$ is an estimate of $\Sigma^{\mathbf{c}}$ (that needs to be obtained) and λ is a nonnegative tuning parameter. The group lasso penalty $\lambda \sum_{j \neq r} ||\Theta_{j,r}^{\mathbf{c}}||_F$ shrinks all the elements in $\Theta_{j,r}^{\mathbf{c}}$ towards zero (or all nonzero, that is the case of an estimate edge between $Y_j^{\mathbf{c}}$ and $Y_r^{\mathbf{c}}$) leading to a sparser $\widehat{\Theta}^{\mathbf{c}}$ in a blockwise way, and consequently to a sparser graph $\hat{G}^{\mathbf{c}}$, when λ increases. Obviously, if $\lambda = 0$ there is no penalty and the choice of this regularization parameter is crucial: there exist suitable AIC indexes used in (6), but instead we adopt an heuristic choice to ease the interpretability of the resulting semantic network by considering an overall percentage of nonzero links below 10%.

4. Nonparametric estimator of $\Sigma^{\mathbf{c}}$

The reconstruction of sparse network structures by means of Equation 1 is possible if we have an estimation of $\Sigma^{\mathbf{c}}$ varying on the lattice $\mathcal{L}$, that is one for spatio-temporal coordinate $\mathbf{c} = (s,t)$ (indicating district and month in our case study). However, constructing an estimator of $\Sigma^{\mathbf{c}}$ represents a challenge because we deal with the case of extremely sparse data since in each $\mathbf{c}$ we observe only one realization of $\mathbf{Y}^{\mathbf{c}}$. By considering mean-corrected functional data for the sake of simplicity, a naive estimate of $\Sigma^{\mathbf{c}}$ is given by the raw covariance

$$\Sigma^{*\mathbf{c}} = \left\{\mathbf{\Sigma}_{j,r}^{*\mathbf{c}}\right\}_{j,r=1,\dots,p} = \left\{\mathbf{a}^{\mathbf{c}}{}_j \mathbf{a}^{\mathbf{c}T}_r\right\}_{j,r=1,\dots,p},$$

that exploits only the information in one datum and is not full rank since by construction it holds $\operatorname{rank}(\Sigma_{j,r}^{*\mathbf{c}}) = 1, \forall j, r$. Then to obtain a reliable estimator of $\Sigma^{\mathbf{c}}$ we propose to borrow information from the neighbours of the unit with coordinate $\mathbf{c}$ in the lattice by means of linear smoothing.

Given n units in the spatio-temporal irregular lattice $\mathcal{L}$ with coordinates $\mathbf{c}_i$, with $i = 1, \dots, n$, we consider the class of linear smoother estimators defined by

$$\widehat{\Sigma}^{\mathbf{c}} = \sum_{i=1}^{n} \omega_i(\mathbf{c}) \Sigma^{*\mathbf{c}_i}$$

where the coefficients $\omega_i(\mathbf{c})$ of the linear combination need to be determined; this class includes the Gaussian process regression estimator as well as the Kernel smoother and local polynomial estimator.

Finding $\omega(\mathbf{c}) = (\omega_1(\mathbf{c}), ..., \omega_n(\mathbf{c}))$ is equivalent to solve an optimization problem:

$$\widehat{\Sigma}^{\mathbf{c}} = \text{argmin}_{\Sigma^{\mathbf{c}}} \sum_{i=1}^{n} K(\mathbf{c}_i, \mathbf{c}) d(\Sigma^{\mathbf{c}}, \Sigma^{*\mathbf{c}_i}),$$

where and $K(\cdot, \cdot) : \mathcal{L} \times \mathcal{L} \to R$ is a kernel function and $d(\cdot, \cdot)$ is a suitable distance between covariance matrices. The choice of the distance d is not uniquely identified and different choices may or may not incorporate the constraints of the space of the positive definite matrices.

Determining K from space-time contiguity In this work, we propose to construct kernel weights that are suitable for a spatio-temporal lattice domain as in our case study. Usually a Kernel function is defined as a function of distances, and so in a spatial lattice distances among areas would be among their barycenters while in a temporal lattice distances would be lags.

To consider properly the nature of the spatio-temporal domain where graphs live, we instead take a contiguity point of view both in space and time and define the kernel by means of a Laplacian $\mathbf{L}$. Let $\mathbf{W}^{\text{Space}}$ be the adjacency matrix for the areal units such that entries are equal to 1 if two areal units are neighbours (contiguous regions), and 0 otherwise; and let $\mathbf{W}^{\text{Time}}$ be the adjacency matrix for the time frames (months) with element equal to 1 when a month before or after is considered (like a 3 months moving average window). In order to have a global adjacency matrix for the units in the spatio-temporal lattice $\mathcal{L}$ we take the Kronecker product and define

$$\mathbf{W} = \mathbf{W}^{\text{Space}} \otimes \mathbf{W}^{\text{Time}},$$

and then we consider the Laplacian

$$\mathbf{L} = \mathbf{D} - \mathbf{W}$$

with $\mathbf{D} = diag\{\mathbf{W}\mathbf{1}_n\}$.

Finally, as kernel values in the vector $\omega(\mathbf{c})$ for the linear smoother we use the elements of the matrix

$$\mathbf{K} = (\mathbf{I} + \gamma\mathbf{L})^{-1},$$

where γ is a smoothing parameter (to be fixed) that behaves as a kernel bandwidth. In fact, γ tunes the values of the weights and the extension of the neighborhood of each unit in $\mathcal{L}$ and for $\gamma \to \infty$ one has $\omega_i \to 1/n$.

5. Results about Brexit

The proposed methodology allows to estimate semantic networks, tracking the change of the Brexit debate on Twitter, for each of the 41 districts in UK along months from January 2019 to January 2020, having borrowed information by a spatio-temporal neighborhood. We take the first $p = 20$ most common words in the dataset and consider the daily usage of each word for each month in each district as (spatially and temporally correlated) functional data. Looking at the sequence of estimated semantic networks in a specific district along time (as e.g. those in Figure 2) we can detect which word is really central in the debate month by month. The estimated networks show an interesting pattern: during the first months of 2019 the word `MAY` (the former prime minister surname) is connected with other words in the debate; this holds until the summer when she resigned in favor of Boris Johnson, and then the word `BORIS` becomes connected with others in August and October. Figure 2 shows the estimated networks in Inner West London for the months January, February and March 2019, with two different values of γ, namely $\gamma = 0.2$ and $\gamma = 2$. Even with only three months we can note that the estimated network changes enough with a smaller value of γ (first row in Figure 2) while it persists with a larger value (second row in Figure 2): γ controls the 'width' of the kernel used in the smoothing process, i.e. the magnitude of elements of the matrix $\mathbf{K}$. In the first case, with smaller γ, the only weights different from zero are those related to the spatial neighbours in the same month; while a larger value acts as a large kernel bandwidth and leads to an estimate close to an average.

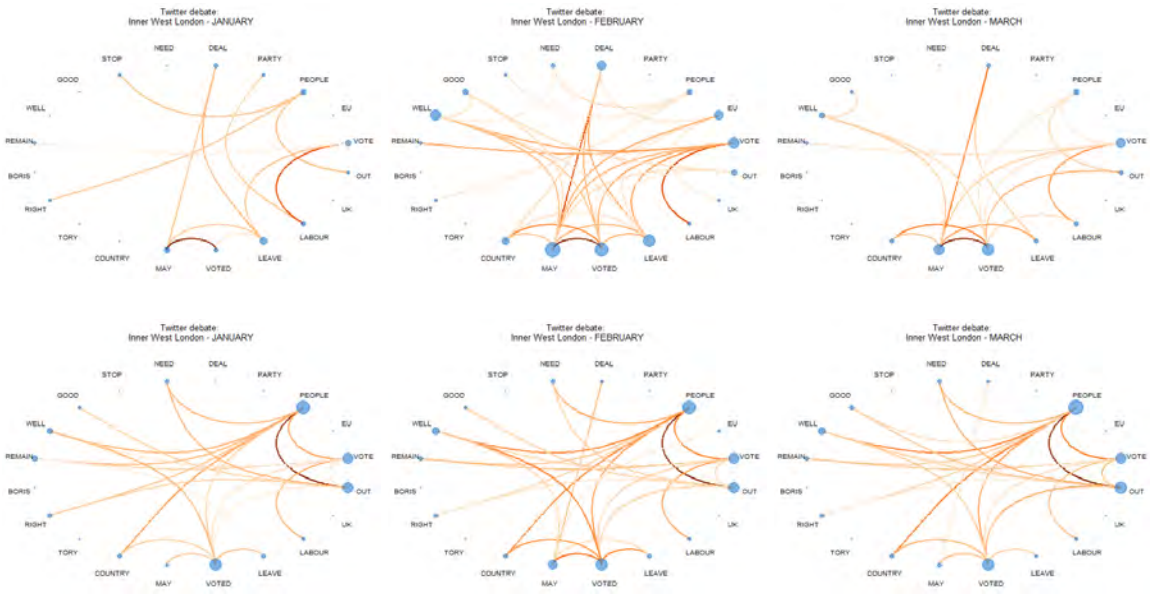

Figure 2: Estimated networks in Inner West London for the months January, February and March 2019, with $\gamma = 0.2$ (*first row*) and with $\gamma = 2$ (*second row*). Each vertex corresponds to a functional variable representing the usage of a word, the area of the blue dots is proportional to how many times that word is connected to the other words. The color and the thickness of the estimated edge change with the norm of $\hat{\Theta}_{j,r}$ for two words j and r.

6. Discussion

By considering the change in time of a word usage as a functional realization, we investigate how to estimate semantic networks via functional graphical models. Actually, by penalizing, we obtain sparse solutions that uncover interesting connections among variables/words.
In future developments, the choice of the smoothing parameter γ needs to be addressed and new strategies to preserve positive definitiveness in the estimates investigated. As for the Brexit debate analysis, the number of words p considered will be substantially increased.

Abstract

We generalize the notion of Spearman correlation coefficient to situations where the observations are curves generated by a stochastic processes. In particular, we propose a consistent estimator of the Spearman index and we use this notion to define the Spearman matrix, a mathematical object expressing the pattern of dependence among the components of a multivariate functional dataset. Finally, the notion of Spearman matrix is exploit to analyze two different populations of multivariate curves (specifically, Electrocardiographic signals of healthy and unhealthy people), in order to test if the pattern of dependence between the components is statistically different in the two cases.

Keywords: Spearman correlation coefficient, multivariate functional data, ECG signals.

1. Methods

The Spearman index is initially presented in a multivariate framework as a non-parametric measure of association between two random variables X and Y defined as the Pearson correlation coefficient ρ_p between the ranks of X and Y without requiring any assumptions on the distribution of the variables.
Let X_i and Y_i be i.i.d from the law of X and Y, respectively. Through the notion of grades, interpreted as the relative position of the observation x_i (resp. y_i) in the set **x** (resp. **y**), the sample version of the Spearman index is defined as the sample Pearson correlation coefficient of **u** and **v**:

$$\hat{\rho}_s(\mathbf{x},\mathbf{y}) = \hat{\rho}_p(\mathbf{u},\mathbf{v}) = \frac{\sum_{i=1}^{n}(u_i-\bar{u})(v_i-\bar{v})}{(\sum_{i=1}^{n}(u_i-\bar{u})^2\sum_{i=1}^{n}(v_i-\bar{v})^2)^{\frac{1}{2}}},$$

where **u** and **v** are the estimated grades defined evaluating each observation in the empirical cumulative distribution function of the corresponding sample and $\bar{u}$, $\bar{v}$ stand for the sample means of **u** and **v**.
After defining grades for functional data the Spearman index ρ_s defined for random variables has be extended to the case of two stochastic processes X_t and Y_t, generalizing to the infinite dimensional framework.
To define the notion of grade for functions two concepts called the Inferior Length and Superior Length of a curve are defined as the foundation of a depth, where the sample version of both *IL-grade* and *SL-grade* of any fixed curve $x = x(t)$ quantify the relative position of x with respect to the other curves of the

sample (see (5)).
The Spearman index for (X_t,Y_t) is defined as

$$\rho_s(X_t, Y_t) = \rho_p((IL - grade(X_t), IL - grade(Y_t)),$$

where ρ_p denotes the Pearson correlation coefficient and *IL-grade*($\cdot$) is the grade associated to a stochastic process. The corresponding sample version is denoted by $\hat{\rho}_s$(**x**, **y**) and it is defined as

$$\hat{\rho}_s(\mathbf{x}, \mathbf{y}) = \hat{\rho}_p(IL_n - grade(\mathbf{x}), IL_n - grade(\mathbf{y})).$$

Subsequently the consistency of the sample version of the Spearman coefficient is proved using the fact that it can be expressed as a U-statistic. From the definition of UB-statistic (1) and the definition of a preorder between functions (*functional order based on grades* $\prec$) the Spearman correlation coefficient $\hat{\rho}_s$ can be extended to the functional case and it can be expressed as a UB-statistic,

$$U_n = \binom{n}{3}^{-1} \sum_{1 \le i_1 < i_2 < i_3 \le n} \Phi\{(X_{i_1}, Y_{i_1}), (X_{i_2}, Y_{i_2}), (X_{i_3}, Y_{i_3})\},$$

where

$$\Phi[(x_i, y_i), (x_j, y_j), (x_z, y_z)] = 6I(x_i \prec x_j, y_i \prec y_z) + 6I(x_j \prec x_i, y_z \prec y_i) - 3,$$

where *I* denotes the indicator function.
In analogy with Kendall's τ correlation coefficient, expressing the functional $\hat{\rho}_s$ as a UB-statistic, the consistency of functional $\hat{\rho}_s$ is proved applying Theorem 2 in (7), obtaining an important asymptotic result in the functional field also for the Spearman's coefficient.
Theorem (*Consistency of* $\hat{\rho}_s$) Let $(x_1, y_1), ..., (x_n, y_n)$ be a sample of independent and identical functional observations from (X,Y). Then,

$$\hat{\rho}_s \to \rho_s \text{ a.s. as } n \to \infty.$$

We construct a new mathematical object, the Spearman Matrix, in order to express the pattern of dependence among the components of a multivariate functional dataset. The sample Spearman Matrix $\widehat{SM}(\mathbf{X})$ is given by

$$\begin{bmatrix} \hat{\rho}_s(\mathbf{x}_1, \mathbf{x}_1) & \hat{\rho}_s(\mathbf{x}_1, \mathbf{x}_2) & \dots & \hat{\rho}_s(\mathbf{x}_1, \mathbf{x}_h) \\ \hat{\rho}_s(\mathbf{x}_2, \mathbf{x}_1) & \hat{\rho}_s(\mathbf{x}_2, \mathbf{x}_2) & \dots & \hat{\rho}_s(\mathbf{x}_2, \mathbf{x}_h) \\ \vdots & \vdots & \ddots & \vdots \\ \hat{\rho}_s(\mathbf{x}_h, \mathbf{x}_1) & \hat{\rho}_s(\mathbf{x}_h, \mathbf{x}_2) & \dots & \hat{\rho}_s(\mathbf{x}_h, \mathbf{x}_h) \end{bmatrix}_{t \in I},$$

where $\hat{\rho}_s(\mathbf{x}_i, \mathbf{x}_j)$ is the sample Spearman index computed on the bivariate functional dataset [$\mathbf{x}_i$,$\mathbf{x}_j$]. The great advantage with respect to the variance-covariance operator is the fact that the dependence among components is described through scalar indexes that may be tested in a suitable inferential context.
In (6) some simulation studies are presented with different functional bivariate datasets built ad hoc in order to test the performance of the Spearman index in correctly detecting the pattern of dependence.

2. Case study

Our data consist in a multivariate functional dataset containing the ECG traces of a population of healthy people and one composed by individuals affected by an heart disease called Left Bundle Brunch Block (LBBB). Each statistical unit (patient) is characterized by the 8-variate functional datum of his/her electrocardiogram, which describes his/her heart dynamics on the eight leads I, II, V1, V2, V3, V4, V5 and V6. The data are from PROMETEO (PROgetto sull'area Milanese Elettrocardiogrammi Teletrasferiti dall'Extra Ospedaliero) database. PROMETEO project has been started in 2008 with the aim of spreading the intensive use of ECGs as prehospital diagnostic tool. Each file contained in PROMETEO

database can be associated to three sub-files, called *Details*, *Rhythm* and *Median*. For the aims of the analysis, only the last one is necessary. The *Median* file depicts a reference beat (obtained throught an authomatic filtering procedure applied to the Rhythm file) lasting 1.2 seconds on a grid of 1200 points. It provides, among others, 8 curves (one for each ECG lead) for each patient, representing patient's *Median* beat for that lead. This representative heartbeat is a trace of a single cardiac cycle (heartbeat), i.e., of a P wave, a QRS complex, a T wave, and a U wave. Actually PROMETEO database contains 6734 curves; among these, 1633 are healthy (i.e., not affected by cardiovascular diseases detectable through the ECG), whereas 5101 are affected by different heart diseases. See (2; 3; 4) for further details on the dataset and its use for statistical applications. In what follows we will focus just on one of the most common disease, that is easily detectable observing the ECG signal. It is a kind of Myocardial Infarction named Left Bundle Brunch Block (LBBB). In the PROMETEO dataset, 314 people are affected by this pathology. After suitable preprocessing and robustification (see (4) for more details) of the dataset, the final sample available for the analyses is composed by 1564 Physiological curves and 205 LBBB curves, discretized on a uniformly time grid T of 1024 points. Each patient is represented by his/her discretized multivariate signal, i.e., for $i = 1, ..., n$, $\Phi_i(t)$: $T \subset R \rightarrow R^8$. All the curves of the available sample are registered and denoised (see (2) for further details on wavelet denoising and landmarks registration adopted for preprocessing data). To fix the notation, we assume that the ECG signals of physiological and pathological patients are realizations of two different multivariate stochastic processes, $X_t = (X_t^1, X_t^2, ..., X_t^8)$ and $Y_t = (Y_t^1, Y_t^2, ..., Y_t^8)$, respectively. For the analysis, we construct two different multivariate functional dataset from the available samples: the first is denoted with $\mathbf{X}$ and collects $n_x = 200$ randomly chosen ECG signals from the population of the physiological (healthy) patients. In other words, $\mathbf{X}$ is a dataset 200×8 discretized functions, where the *i-th* row contains the multivariate curve (ECG) associated to the *i-th* selected patient. The second functional dataset is denoted with $\mathbf{Y}$ and contains the multivariate curves of $n_y = 200$ randomly chosen patients affected by LBBB. Notice that, without loss of generality, we are considering in order to ease the computations two populations of data with the same number of realizations. Figures 1 and 2 show the ECG signals selected in the datasets $\mathbf{X}$ and $\mathbf{Y}$, respectively. The first step of our analysis is to calculate the Spearman matrices for physiological ($\widehat{SM}(\mathbf{X})$) and pathological ($\widehat{SM}(\mathbf{Y})$) ECGs, respectively. The entries coloured in yellow represent those for which there isn't statistical evidence of being different from zero indicating that the corresponding pairs of leads can be assumed independent. Their detection is performed observing the confidence intervals computed using 1000 bootstrap iterations: if an interval contains zero, the hypothesis of independence between the corresponding pair of leads is not rejected and so the component of the Spearman Matrix is highlighted to indicate a non significant dependence. The two matrices provide an effective insight on the way in which the leads of the ECG signals depend on each other and give us the possibility to compare the pattern of

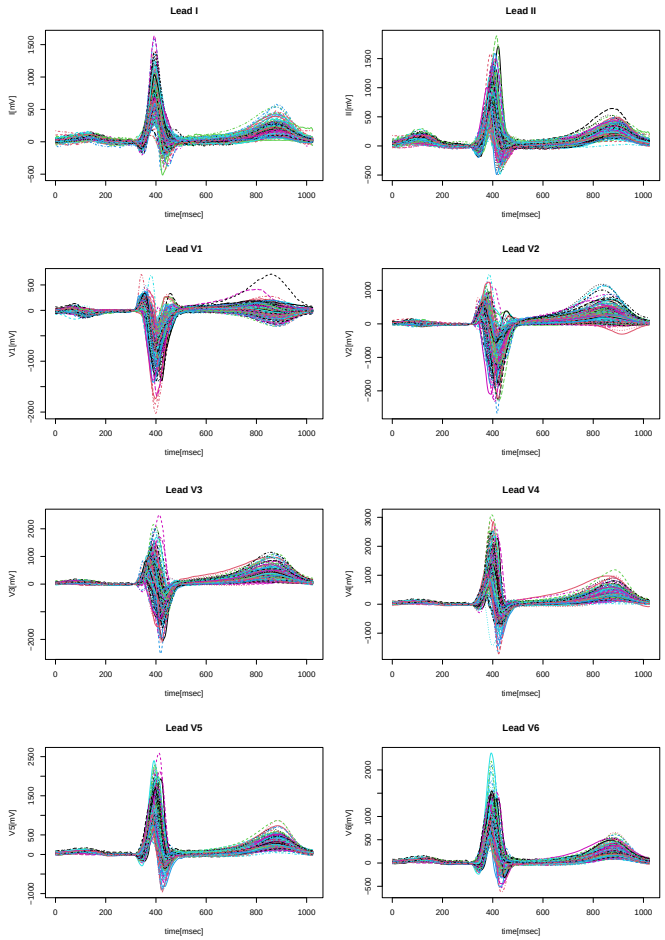

Figure 1: Registered and denoised ECG signals of the $n_x = 200$ physiological patients used for the analysis.

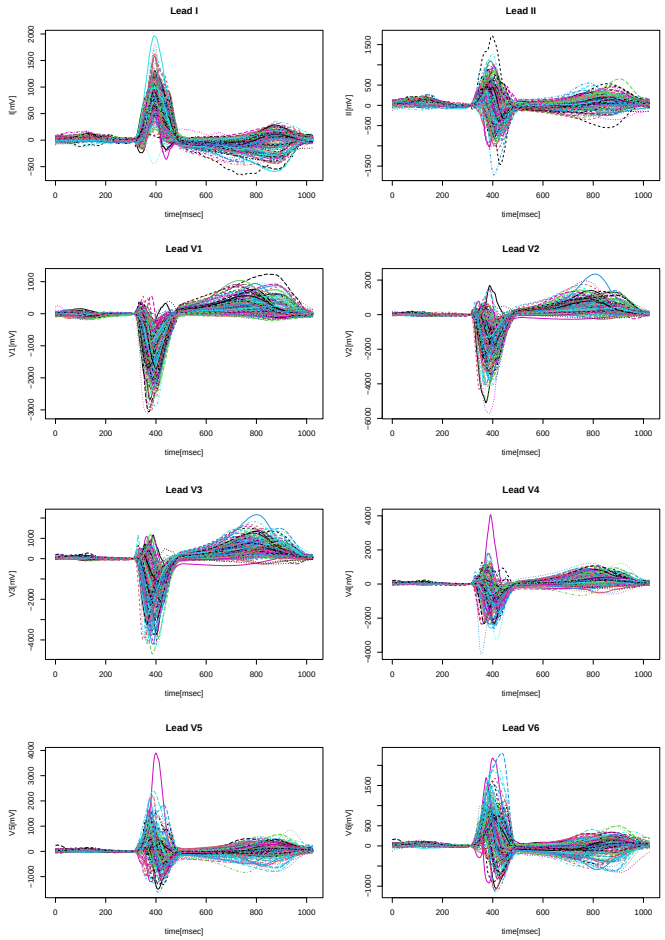

Figure 2: Registered and denoised ECG signals of the $n_y = 200$ LBBB patients used for the analysis.

dependence in the two populations. We can notice a similarity in the upper diagonals of the matrices, a part from one case, with high and significantly different from zero entries. We also notice remarkable differences: the pattern of dependence of physiological signals is more connected, whereas the one of LBBBs is more sparse, due to the presence of several pairs of independent leads. Moreover, it seems that V2 is particularly affected by the disease and in the case of physiological signals, the entries that are significatively different from zero are positive, indicating that there is agreement between the grades of the leads, while the same does not happen for the LBBB signals where we notice some negative entries. What we observe can be interpreted in terms of heart dynamics: in physiological patients, the heart dynamics is more regular and expresses coordinated behaviours in all the components of the ECGs, whereas it becomes more chaotic and characterized by independent behaviours when the pathology is present. Hence, it seems that the disease is able to change the natural relation of dependence among some leads of the ECG. In order to have a statistical evidence of our statement we introduce a test of hypothesis verifying the equality between the two matrices. We want to perform the test:

$$H_0 : SM(\mathbf{X}_t) = SM(\mathbf{Y}_t) \quad vs$$
$$H_1 : SM(\mathbf{X}_t) \neq SM(\mathbf{Y}_t).$$

with a non parametric approach presenting a permutation-based testing procedure that it does not require any distributional assumption on data that may restrict its application. This test is called K-sample Anderson-Darling test ($K \geq 2$) and the test statistic associated is based on the notion of the generalized cosine measure between two symmetric matrices (8). In our application we have $K = 2$ and the test statistic for the equality of the two Spearman matrices is $1 - cos(\mathbf{M}_1, \mathbf{M}_2)$, where the cosine is computed according to

$$cos(\mathbf{M}_1, \mathbf{M}_2) = \frac{vech^*(\mathbf{M}_1)^T vech^*(\mathbf{M}_2)}{\|vech^*(\mathbf{M}_1)\| \|vech^*(\mathbf{M}_2)\|}.$$

The modified half-vectorization operator $vech^*(\cdot)$ completely remove the redundancy in symmetric matrices and are very easy to compute. This newly proposed test statistic exploits a simple geometric property of symmetric matrices and require no distributional assumptions of data. We further adopt a permutation approach to obtain the distribution under the null hypothesis of the test statistic and compute p-values of the test. Applying the two-sample Anderson-Darling test to the case of the Spearman matrices of physiological and LBBB patients and computing 1000 permutational replication of our test statistic T under H_0 we observe that the observed value of T_0 is not likely under the null hypothesis (the p-value of the test is close to 0). Hence, the test gives strong evidence to reject H_0 and to state that the Spearman matrices of physiological and pathological signals are statistically different.

3. Conclusion

In this work, we presented the notion of Spearman index in the infinite dimensional framework to quantify the dependence among two families of functional data. Starting from this definition, we built the Spearman Matrix, a new mathematical object that mimics the covariance matrix of multivariate statistics and that provides an effective insight of the pattern of dependence among the components of a multivariate functional dataset. In the applicative part of our work, we moved to the analysis of a real dataset. We compared the Spearman Matrix arising from the 8-variate electrocardiographic signals of a population of healthy people with the one arising from signals of people affected by Left Bundle Brunch Block (LBBB). The aim was to verify if the pattern of dependence in the two cases are different due to the presence of the disease. We tested the hypothesis that physiological and pathological signals have the same Spearman Matrix, adapting to our framework a non-parametric test which check the equality of Spearman correlation matrices arising from different populations of multivariate data.

Abstract

Modern data sets are often contaminated with anomalous observations that can seriously decrease the performance of control charting procedures, especially in complex and high dimensional settings. To mitigate this issue, this paper presents a new control chart for multivariate functional data that is robust to functional casewise and cellwise outliers.

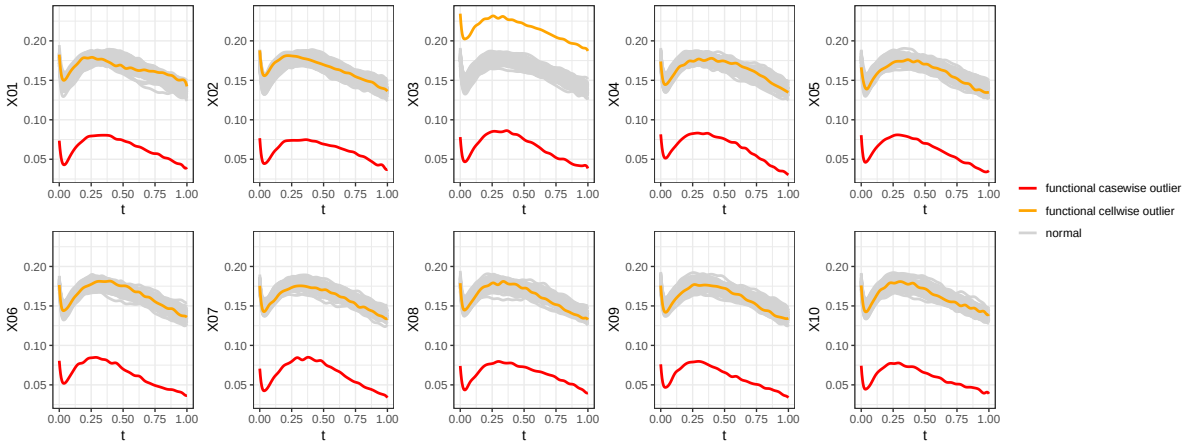
Keywords: Statistical Process Monitoring, Profile Monitoring, Casewise and Cellwise Outliers

1. Introduction

In modern industrial processes, data acquisition systems allow the collection of massive amounts of high-frequency data. In statistical process monitoring (SPM) applications, the experimental measurements of the quality characteristics, i.e., the features that can be used to assess the quality of the process, are often characterized by complex and high dimensional formats that can be well represented as functional data, also referred to as profiles (17; 12). This justifies the growing interest in *profile monitoring* (16), which is the monitoring of a process through quality characteristic in the form of one or multiple profiles. Control charts are known as the main tools for SPM and are commonly implemented in two phases. Phase I is concerned with the identification of a clean data set to be assumed as representative of the in-control state of the process. This data set is then used to quantify the expected variation of a future observation to be used for the prospective process monitoring in Phase II. However, the identification of Phase I observations in high-dimensional contexts is not an easy task due to the presence of several outliers in one or more components of the quality characteristic observations. Indeed, control charts are very sensitive to the presence of outlying observations in the Phase I sample that can lead to inflated control limits and reduced power to detect process changes in Phase II.

Several robust approaches, i.e., able to deal with outliers, have been proposed in the literature for the multivariate SPM of scalar quality characteristics (2; 4). However, to the best of the authors' knowledge, a robust approach able to successfully capture the functional nature of a multivariate functional quality characteristic has not been devised so far. Traditional multivariate robust estimators assume a contamination model with a mixture distribution where a large fraction $(1-\varepsilon)$ of the data is generated from a distribution that is free of contamination, while a small fraction ε of the data, denoted as *casewise* outliers, comes from an unspecified outlier generating distribution that may affect all the variables. In presence of many variables, a more plausible contamination model considers outlying observations where only a small fraction of the functional variables may be contaminated, hereinafter denoted as functional *cellwise* outliers. An toy example that graphically highlights the difference between casewise and

Figure 1: Example of functional casewise and cellwise outliers.



cellwise outliers is shown in Figure 1, where 100 simulated observations from a vector of 10 functional variables are plotted. Note that big shifts have been applied to clearly show the two types of outliers. The uncontaminated observations are plotted in gray, then a casewise functional outlier is added as a vector of ten red curves, while a cellwise functional outlier is plotted in orange. It is evident that functional casewise outliers come from a different distribution that affects all functional variables, which has been obtained by applying the same mean shift to the ten profiles, and may be relatively easy to identify with appropriate outlier detection methods. Whereas, in the functional cellwise outlying observation, only the third functional variable is independently contaminated, while the remaining nine ones seem to come from the same distribution as the uncontaminated data. Moreover, instead of discarding the entire observation because of only one anomalous variable, the information from the other nine components could still be useful to better estimate the distribution of the data. The main problem with cellwise outliers is that, if contamination is assumed to independently arise in each functional variable, then the fraction of perfectly observed cases can be rather small, therefore traditional multivariate robust estimators are known to fail and to be affected by the outlier propagation problem (3). Nonetheless, as pointed out by Agostinelli et al. (1), both types of data contamination, casewise and cellwise, may occur together.

In the face of these problems, we propose a new framework, referred to as robust multivariate functional control chart (RoMFCC), for the SPM of multivariate functional data in presence of both casewise and cellwise outliers. By means of a Monte Carlo simulation study, the ability of the RoMFCC in identifying mean shifts in the functional variables in presence of casewise and cellwise outliers is compared with other control charts already appeared in the literature. Finally, the proposed framework is demonstrated through a real-case study.

2. The Robust Multivariate Functional Control Chart Framework

The RoMFCC is proposed as a new general framework for the SPM of multivariate functional data and relies on the following four main elements. For additional methodological details, the reader is referred to (6).

(I) The functional univariate filter, referred to as FUF, identifies functional cellwise outliers and is an extension of the filtering proposed in (1). Specifically, the proposed FUF replaces with a missing component each component observation of the multivariate functional quality characteristic that achieves an overly large functional distance measure from the center of the data, which is specifically chosen to be robust to the presence of outliers. The corresponding multivariate functional quality characteristic observations (i.e., those achieving a large functional distance in at least one component) are then denoted as a functional cellwise outlier.

(II) The robust functional data imputation (RoFDI) method extends the robust imputation approach (4) to the functional setting. Summarily, the RoFDI method replaces the missing components of each functional cellwise outlier by sequentially imputing the observation that achieves the minimum distance

from the space generated by the complete realization, obtained through the RoMFPCA."

(III) Robust multivariate functional principal component analysis (RoMFPCA) is then used in place of the well-known standard multivariate functional principal component analysis (14) to reduce the infinite dimensionality of the multivariate functional data while taking into account the casewise outliers. The RoMFPCA extends the approach (18) to multivariate functional data by applying the ROBPCA to a specific transformation of the coefficients obtained through the basis function expansion method (17).

(IV) The consolidated monitoring strategy is performed on a multivariate functional quality characteristic based on the Hotelling's T^2 and *SPE* control charts (16; 11; 8; 7).

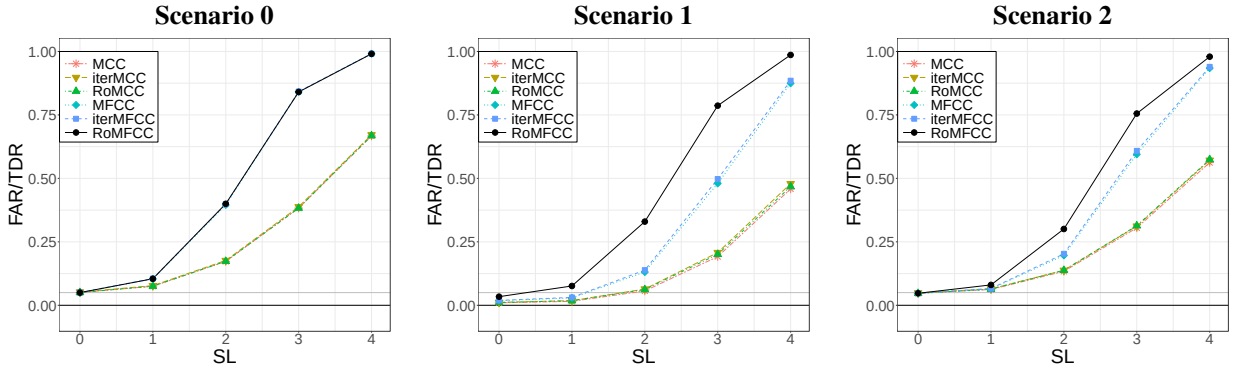
The proposed RoMFCC framework collects the elements I-IV in a Phase II monitoring strategy where the Phase I sample can be contaminated with functional casewise and cellwise outliers.

3. Simulation Study

The performance of the RoMFCC in identifying mean shifts of the multivariate functional quality characteristic is assessed through a Monte Carlo simulation of two scenarios with different Phase I sample contamination and data generated to mimic typical behaviours of the dynamic resistance curves (DRCs) shown in the real-case study of Section 4. Specifically, in Scenario 1 and Scenario 2, the Phase I sample is contaminated by functional cellwise and casewise outliers, respectively. For each scenario, the contamination model mimics typical anomalous DRCs observed in presence of splash welds, caused by excessive welding current (19). In addition, Scenario 0 simulates a Phase I sample that is not contaminated by any type of outliers. The Phase II sample is generated analogously to the contamination model at 4 different severity levels $SL = \{1,2,3,4\}$.

The proposed RoMFCC framework is compared with several natural competing approaches grouped as follows into control charts for multivariate non-functional and functional data, respectively. Specifically, the first group consists of control charts for multivariate data built on the vectors of time average (scalar) values of each component of multivariate functional data observations. In this group, we consider (*i*) the classical *multivariate* classical Hotelling's T^2 control chart, referred to as MCC; (*ii*) its *iterative* variant, referred to as iterMCC, where outliers detected by the control chart in Phase I are iteratively removed and control limits are revised until all data are assumed to be in control (IC); (*iii*) the *multivariate robust* control chart proposed in (9), referred to as RoMCC. In the second group, we consider two approaches recently appeared in the profile monitoring literature, namely (*iv*) the *multivariate functional control charts* and referred to as MFCC, proposed in (7); (*v*) its *iterative* variant, referred to as iterMFCC, where, as before, outliers detected in Phase I are iteratively removed until all data are assumed to be IC. For each scenario and severity level, 50 simulation runs are performed. The RoMFCC and the competing methods performance is assessed by means of the true detection rate (TDR) and the false alarm rate (FAR), which are defined as the proportion of points that fall outside the control limits whilst the process is, respectively out of control (OC) or IC. Figure 2 displays the mean FAR ($SL = 0$) and TDR ($SL \neq 0$) as a function of the severity level *SL* for Scenario 0, Scenario 1 and Scenario 2. When the Phase I sample is not contaminated by outliers (Scenario 0) Figure 2 shows that all the approaches able to account for the functional nature of the data (namely, MFCC, iterMFCC, RoMFCC) achieve the same performance. Although this scenario should be not favourable for robust approaches, the iterMFCC and RoMFCC perform equal to the MFCC. The non-functional approaches (namely MCC, iterMCC, RoMCC) show worse performance than the functional counterparts, and there is no significant performance difference among them as well. In Scenario 1, where the Phase I sample is contaminated by cellwise outliers, the proposed RoMFCC largely outperforms the competing methods. The iterMFCC, which is representative of the baseline method in this setting, does not greatly improve the MFCC performance. This is probably due to the masking effect that prevents the iterMFCC from iteratively identifying functional cellwise outliers in the Phase I sample. The performance of the non-functional methods is very unsatisfactory because they are not able to both capture the functional nature of the data and successfully deal with outliers. Overall, the MCC is the worst method, readily followed by iterMCC and RoMCC. Scenario 2 shows similar results as in Scenario 1, where the non-robust approaches perform slightly better than in Scenario 1 because cellwise contamination is more difficult to manage with respect to casewise outliers.

Figure 2: Mean FAR ($SL = 0$) or TDR ($SL \neq 0$) achieved by MCC, iterMCC, RoMCC, MFCC, iterMFCC and RoMFCC as a function of the severity level SL in Scenario 0, Scenario 1 and Scenario 2.



4. Real-Case Study

To demonstrate the potential of the proposed RoMFCC in practical situations, a real-case study in the automotive industry is presented hereafter. It addresses the issue of monitoring the quality of the resistance spot-welding process, which guarantees the structural integrity and solidity of welded assemblies in each vehicle (15). The modern automotive Industry 4.0 framework allows the automatic acquisition of a large volume of RSW process parameters, and, in particular, of the DRC, which is considered the most informative proxy of the RSW process quality and a low-cost relative to the alternative destructive tests. Further details on how the typical behaviour of a DRC is related to the physical and metallurgical development of a spot weld are provided in (5).

Data analyzed in this study are courtesy of Centro Ricerche Fiat (Italy) and are recorded at the Mirafiori Factory during lab tests on the body of the Fiat 500BEV. An automobile body-in-white stage is in general characterized by a large number of spot welds with different characteristics, e.g, the thickness and material of the sheets to be joined together and the welding time. To be specific, in this real-case study, we focus on the monitoring of spot welds made by only one of the welding machines. In particular, we consider the multivariate functional quality characteristic represented by the vector of ten DRCs corresponding to the same ten spot weld locations on each sub-assembly normalized on the time domain $[0, 1]$. The data set contains a total number of 1839 sub-assemblies.

The RSW process quality is directly affected by electrode wear that leads to changes in electrical, thermal and mechanical contact conditions at electrode and metal sheet interfaces (13). Thus, to take into account the wear issue, electrodes go through periodical renovations. In this setting, a paramount issue refers to the swift identification of DRCs mean shifts caused by electrode wear, which could be considered as a criterion for electrode life termination and guide the electrode renovation strategy.

In the light of this, the 919 multivariate profiles corresponding to spot welds made immediately before electrode renewal are used to form the Phase I sample, whereas, the remaining 920 observations are used in Phase II to evaluate the in-line monitoring performance in detecting the mean shift of the Phase II DRCs caused by electrode wear. The RoMFCC is implemented as in Section 3. In Phase II, the RoMFCC signals 72.3% of the observations as OC, which reflects the proposed method performance in tracking mean shifts caused by large electrode wear. The proposed method is compared with the competing methods presented in the simulation study of Section 3. through the estimated TDR, denoted as $\widehat{TDR}$, on the Phase II sample, as shown in Table 1. Similarly to (8), the uncertainty of $\widehat{TDR}$ is quantified through a bootstrap analysis (10). Table 1 reports the mean of the empirical bootstrap distribution of $\widehat{TDR}$, denoted by $\overline{TDR}$, and the corresponding bootstrap 95% confidence interval (CI) for each monitoring method. Bootstrap 95% confidence intervals achieved by the RoMFCC are strictly above those of all considered monitoring approaches. In general, as in Section 3, the considered non-functional approaches (namely, MCC, iterMCC, RoMCC) show worse performance than the functional counterparts because they are not able to satisfactorily capture the functional nature of the data and robust approaches always improve the non-robust ones on this study. Therefore, the proposed RoMFCC stands out as the best

	$\widehat{TDR}$	$\overline{TDR}$	CI
MCC	0.336	0.335	[0.305,0.368]
iterMCC	0.462	0.461	[0.428,0.496]
RoMCC	0.513	0.512	[0.481,0.547]
MFCC	0.541	0.541	[0.511,0.574]
iterMFCC	0.632	0.632	[0.595,0.664]
RoMFCC	0.723	0.723	[0.695,0.753]

method to promptly identify OC conditions in the considered RSW process characterized by a Phase I sample contaminated by functional outliers.

5. Conclusions

In this paper, we propose the RoMFCC framework for the statistical process monitoring of multivariate functional data that is robust to functional casewise and cellwise outliers. The proposed framework is suitable to monitor industrial processes as the RSW one that motivated this research where multivariate functional quality characteristics such as DRCs are available and occasionally contaminated by outliers.

The performance of the RoMFCC framework is assessed through a Monte Carlo simulation study where it is compared with several competing monitoring methods. The ability of the proposed method to estimate the distribution of the data without removing observations while being robust to functional casewise and cellwise outliers allows the RoMFCC to outperform the competitors in all the considered scenarios and to be the only alternative in high-dimensional scenarios where the most competing methods may even fail.

Acknowledgments

This work has been done in the framework of the R&D project of the multiregional investment programme "REINForce: REsearch to INspire the Future" (CDS000609) with Hitachi Rail STS, supported by the Italian Ministry for Economic Development (MISE) through the Invitalia agency.

Abstract

In response to the COVID-19 pandemic, Italy adopted restrictive mobility measures to contain the spread of the coronavirus. In this study we develop novel strategies for assessing the relationship between mobility and overall mortality. In particular, we first identify diversified behaviors over different geographical areas in terms of mobility, then evaluate the relationship between restrictions and mortality through a functional approach combined with a Spearman correlation analysis. This allows for a stratified assessment, from a precision policy perspective. Specifically, we analysed mobility data provided by Facebook between Italian provinces from March 2020 to December 2021. Measuring the Spearman's correlation coefficient between epidemiological and mobility curves, we developed two criteria for quantifying the effect of policies restrictions stratified over different areas.

1. Introduction

The year 2020 will be remembered worldwide for the sanitary emergency of COVID-19 pandemic. Despite the numerous interventions adopted by the country to cope with the situation and limit infections (8), the virus spread fast. Two cases of coronavirus were identified in Rome at the end of January, but only on February 21 the first case of SARS-CoV-2 infection was diagnosed in Italy. Soon, the epidemic spread across Northern regions, as well as in other states. On March 9, Italy was the first European country to apply a national lockdown. As of May 1, 2020, the Italian health authorities reported 28.238 deaths nationally (14). The Italian Government responded with Non-Pharmaceutical Interventions (NPI), such as school and university closures, social distancing and full lockdown, aimed at reducing the mobility of citizens to decrease the rate of contagion. Among NPIs, mobility restrictions resulted to play a central role in decreasing social contacts (4). In particular, travel restrictions proved to be particularly useful in the early stage of the outbreak, when contagion was confined to certain areas (8), but they were less effective once the virus became more widespread during the so-called second wave of infections. In October 2020, new restrictive measures were adopted to contain the emergency COVID-19. On November

6, 2020, the Italian government adopted new restrictive measures to contain the COVID-19 emergency, dividing the country into three colored areas according to the severity of contagion at the local level (7). The countrywide curfew, introduced during this period, was abolished only in June 2021.

In order to characterize the effect of mobility restrictions, we analyzed a large-scale collection of near real time data provided by the Facebook platform (6). We first identified clusters of areas with similar mobility density behaviors, applying a functional K-means informed by a Wasserstein distance. We then spotted areas with peculiar mortality density behavior with respect to the surroundings with LISA maps, exploiting the Local Moran's I statistics whose weights account for spatial correlations. Then the Spearman correlation of mortality and mobility data is computed to assess the lag of significant association between the two phenomena.

2. Data

We analyzed mobility between municipalities based on *Disease Prevention Maps* provided by Facebook through its *Data for Good* program[1]. Measurements are collected with an 8-h frequency by aggregating individual trips of Facebook users that have agreed to share their location. Mobility flows are constructed to ensure privacy and anonymity (4), and are related to movements between Italian municipalities from March 1, 2020 to December 31, 2021.
Such data may be represented as weighted networks (2), with provinces acting as nodes. For this reason, the strength node centrality may be used as an indicator of mobility. Indeed, we decided to consider as an indicator of mobility for each province the weekly strength node centrality. Thus, for each province, we calculated 96 strength values, one for each week within the period March 2020 - December 2021, meaning by strength not only the sum of people who have left or entered a given province, but also considering those who have moved internally within the province. Smoothing such curves through natural cubic splines, we end up with functional data representing the mobility of all the Italian provinces over the period of interest.

Figure 1: Total flow of the Italy mobility network. Restriction periods related to the first (in red) and second (in orange) epidemic waves are highlighted.

In Fig. 1 the weekly total flow of the Italy mobility network in the period March 2020 - December 2021 is reported, obtained by considering each province as a node. A pronounced decrease in mobility corresponding to lockdown restrictions can be noticed, confirming results already found in the literature (3) (4), and a weaker but prolonged effect of the second wave on mobility in late 2020 and early 2021.

In order to correctly interpret this functional data, we normalized them as in (12), therefore not studying directly the mobility strengths, but rather the corresponding mobility densities.

[1]For what concerns Facebook human mobility, all data are provided under an academic license agreement with Facebook through its *Data for Good* program. Facebook releases data upon request to nonprofit organization and academics.

Regarding the epidemiological data, we analyzed the daily number of deaths for all causes in each municipality provided by Istat (9), aggregating them both at the temporal level (on a weekly basis) and at the spatial level (by province). Following the same normalization procedure performed on mobility data, we studied the provincial mortality densities. We considered the same time interval analyzed for mobility, i.e., from March 2020 to December 2021.

3. Methods and Results

The variability structure of the mobility densities was explored by decomposing them in their main modes of variability through the Functional Principal Component Analysis (FPCA) (11).

In Fig. 2 the first and second functional principal components of mobility density functions retrieved by mobility networks are reported. We observe that Italian provinces may be characterized mainly in terms of the concentration of mobility they experienced in the summer periods and, secondly, for the mobility they recorded in periods of lockdown compared to that in the so-called recovery periods. Indeed, the first FPC represents a contrast between provinces that, with respect to the mean, had a higher or lower concentration of mobility in the summer, while the second principal component captures the concentration of mobility during lockdown, restrictions and recovery periods.

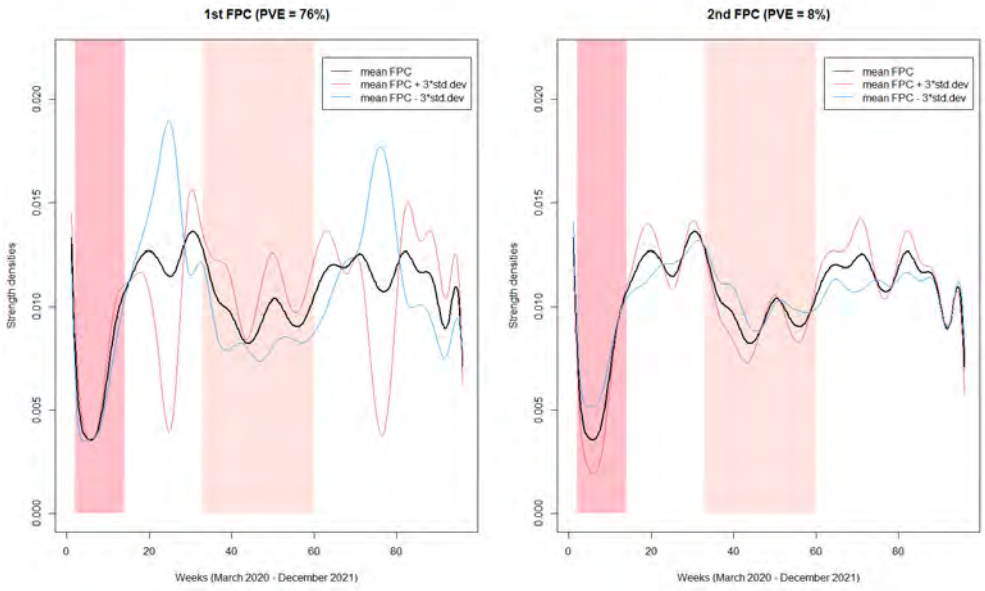

Figure 2: First and second functional principal components of mobility density functions retrieved by mobility networks. The mean of the mobility densities d (black curve) is perturbed in the direction of the principal components. Specifically, the blue curve is $d - 3\sqrt{\lambda_j}\phi_j$ and the red curve is $d + 3\sqrt{\lambda_j}\phi_j$ for $j = 1, 2$, with λ_j being the eigenvalue associated to the j-th FPC and ϕ_j the eigenfunction.

To keep also spatial dependency into account, spotting provinces with very high (low) scores on the two first FPCs which are also surrounded by provinces characterized by the same kind of mobility, we computed the Local Moran's I statistic (1) for the FPC scores. Figure 3 shows the LISA maps obtained with this procedure, which enables the identification of provinces acting as hot-spot with respect to the categorization induced by the FPCs.

To better investigate (spatial) patterns in the mobility density functions through a single clustering procedure, we then decided to cluster the mobility density functions using a Wasserstein distance based functional K-means. This approach returned the provincial mobility clusters reported in Fig. 4.

It is possible to characterize them as follows: Cluster 1 (blue) contains provinces strongly affected by the pandemic in both waves, and especially during the first one. Cluster 2 (green) contains provinces

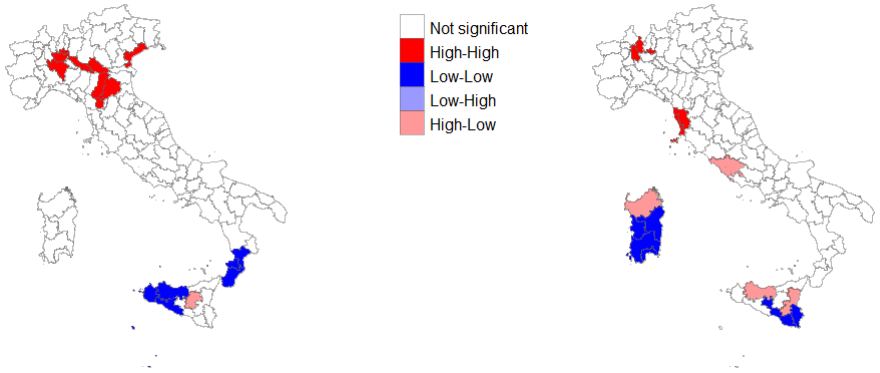

Figure 3: LISA maps on the scores of the first (left) and of the second (right) FPC according to the Local Moran's I statistic.

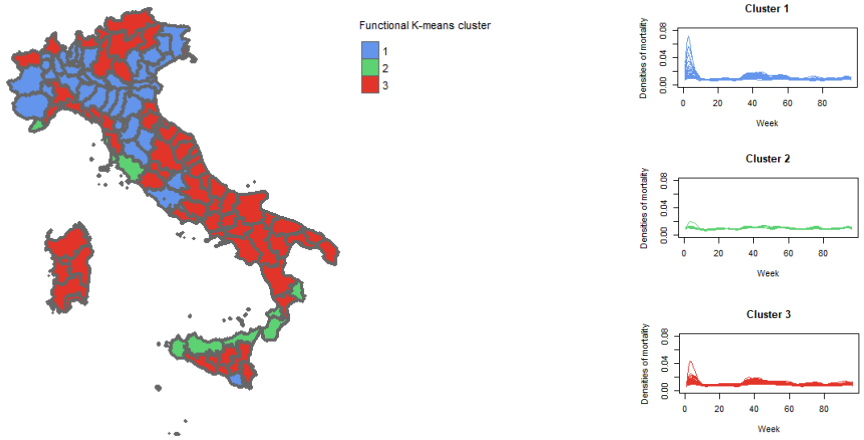

Figure 4: Clusters of provinces (left panel) deriving from the application of a Wasserstein distance based functional K-means to mobility densities, and corresponding mortality densities (right panel).

not deeply affected by the pandemic. Finally, cluster 3 (red) contains provinces affected by the pandemic in both waves, but mainly in the second.

The curves belonging to the groups defined by the Wasserstein-based functional K-means have been then related with the epidemiological curves described in Sect. 2. through a quantitative procedure. Specifically, we calculated the correlation between epidemiological and mobility curves through the Spearman's index (13). Notice that, in doing so, despite the groups being defined using the entire time domain, it is possible to set two different criteria, to be applied to time domain subset of interest, for determining the time required by mobility restriction measures to mitigate the effects of the epidemic. The first criterion relies on the point estimates of the Spearman's index: the mitigation of the epidemic induced by mobility measures ends when the correlation between mobility at the beginning of the restrictions and mortality in the following weeks changes in sign. The second concerns the p-value associated with the Spearman's estimates: when it indicates that correlation between mortality and mobility densities is no longer significant, the mobility restriction measures are no longer necessary.

Notice that we decided to take as a reference the mobility densities recorded during the first week in which the restrictive measures were activated and to calculate the Spearman's correlation between these set values and the mortality densities of that week and the following ones.

In Table 1 the Spearman's Index between mobility and mortality densities during the first and second waves, along with the corresponding p-values, are reported.

The greatest (negative) correlation is at lag=0, i.e., during the first week of restrictions, then it grad-

Table 1: Spearman's correlations (and associated p-values) between the mobility densities in the first week of restriction of the first wave and second wave, and the mortality densities of the corresponding and following weeks, for the Italian provinces belonging to cluster 1.

Lag	First wave	Second wave
0	-0.64 (< 0.0001)	-0.47 (< 0.01)
1	-0.70 (< 0.0001)	-0.48 (< 0.01)
2	-0.69 (< 0.0001)	-0.45 (< 0.01)
3	-0.70 (< 0.0001)	-0.35 (< 0.05)
4	-0.67 (< 0.0001)	-0.21 (0.22)
5	-0.59 (< 0.0001)	-0.06 (0.73)
6	-0.37 (< 0.05)	0.08 (0.63)
7	-0.30 (0.08)	-
8	-0.25 (0.13)	-
9	-0.14 (0.40)	-
10	0.009 (0.09)	-

ually rises to zero. This means that when the first lockdown was imposed and mobility suffered a sharp reduction, deaths within Italian provinces were still numerous. Then the correlation decreases in absolute value, becoming almost null between the sixth and the seventh week after the beginning of restrictions. This may be intended as a suggestion for the mobility measures to become effective in about 6 weeks in reducing the mortality densities. This result is coherent with those found at regional level in Boschi et al. (5), where a lag of about 30 days between mobility and mortality was discovered for the first wave of COVID-19.

Concerning the second wave, we obtained shorter time lags probably due to the fact that other precautionary measures, such as extensive testing, contact tracing and social distancing, were in action after the first phase of the pandemic (10; 14), weakening the relationship between epidemic and mobility.

4. Conclusions

This work was motivated by the interest in analysing mobility data and in providing decision makers with actionable tools for assessing mobility restriction policies. We exploited Facebook data to measure mobility in the country, with province granularity, over the weeks, and defined two criteria to determine when mobility restriction measures can be considered effective in containing the COVID-19 spread in terms of overall mortality. Both criteria are based on Spearman's correlation. Although correlation does not imply causation, we believe that these dynamic criteria can quantify the effects of mobility restrictions induced by the spread of COVID-19, in mitigating the epidemic.

In general, we found negative correlations between mortality and mobility densities, consistent with the fact that when high mortality concentrations were detected, the Italian Government adopted more restrictive measures and therefore allowed less in terms of mobility, and vice versa. This is particularly evident for the provinces most affected by the epidemic, especially concerning the first wave, and in cases where also the spatial component during clustering was considered. Moreover, the time lags between mobility reduction and actual results in limiting and controlling the epidemic were found to be longer in the provinces that suffered most from the COVID-19 pandemic in the period under consideration.

Acknowledgments The work is motivated as a part of the *CHANCE project*, specifically of the working group devoted to the evaluation of the effects of health strategies for the reduction of SARS-CoV-2 risk, with the aim of predicting the implications on possible future epidemics.

Abstract

A text-mining approach is proposed to identify inconsistencies between the textual description of a public contract object and its pre-assigned classification using the Common Procurement Vocabulary (CPV). After the construction of suitable vocabularies for each macro CPV class (MCPV), two tests are proposed for (i.) detecting contracts whose object description contains terms/elements incoherent with their MCPV classification and (ii.) accordingly, red flagging them as at-risk contracts. The tests are applied to short textual annotations of the object of public contracts awarded within the Italian procurement system. It is demonstrated that in the adopted sample, one test performs much better than the other. This result is commented and explained. As a future development, it is discussed how vocabulary methods can be expanded for model-based classification. Si dimostra che nel campione adottato un test performa molto meglio dell'altro. Questo risultato è commentato e spiegato. Tra gli sviluppi futuri, si discute come i metodi basati sui vocabolari possono essere espansi per classificazioni dei contratti che siano basate su modelli statistici.

Keywords: Text mining, Outlier detection, Public procurement, Short texts, TF-IDF

1. Introduction

This study aims at identifying inconsistencies between the textual description of contracts of public procurement and their classification through the Common Procurement Vocabulary (CPV), an international convention that codifies the object of the contract through a standard and internationally recognised ontology (5). The implicit assumption underlying the proposed procedure is that contract at-risk of corruption are associated with discrepancies between the textual elements enclosed in the object description and the contract CPV codification. The rationale of the proposed procedure is to provide tools to further support the process of corruption risk assessment in public procurement by informing policymakers and public authorities in charge of control activities. Moreover, as the best potentials of the proposed procedure are for prior screening of high volumes of contracts in public procurement, it can be conveniently employed to reduce the number of contracts to scrutinise in procedures of qualitative *audit*.

There are relatively few other attempts in the international literature to identify potentially risky circumstances in the public procurement process by the means of text mining (3; 4; 1; 2). This gap in the literature may be due to the semantic complexity of detecting outliers across relatively short textual strings, which brings computational burdens when applied to big data and high statistical uncertainty. Specifically, the identification of incoherent elements in the textual description of a contract object with

respect to its CPV codification implies content-specific knowledge and a sound understanding of text-mining techniques, whose application requires high calculation efforts due to sparse matrices.

Using text-mining techniques, this work proposes two basic tests for identifying inconsistencies between the object description of a public contract and its CPV classification. The procedures are tested on a sample of the Italian National Database of Public Contracts (BDNCP, *Banca Dati Nazionale dei Contratti Pubblici*), an open-access database about Italian public procurement. The proposed tests, when positive, identify contracts at risk of corruption, which are then red-flagged. Therefore, the procedure fits in that part of the scientific literature proposing red flag indicators for detecting corruption risk in public procurement (6; 9; 8).

The paper is organised as follows. Section 2, together with its subsections, describes the materials and methods employed for this work, while comments to preliminary results are reported in Section 3. Finally, concluding remarks are drawn in Section 4, by also highlighting limitations of the presented approach and proposing some future developments.

2. Materials and methods

This section is devoted to a description of the data at hand (Sect. 2.1), the proposed procedure for constructing a vocabulary (Sect. 2.2) and the tests for identifying inconsistencies between contract textual descriptions and contract objects, as identified by their CPV codes (Sect. 2.3).

2.1 Data

We consider data about the Italian public procurement process drawn from the BDNCP, a huge database handled by the Italian Anticorruption Authority, and containing detailed information of every public contract (around 61 million of contracts since 2007) managed by Italian contracting authorities (around 39 thousand).

Textual descriptions of the contract object are available in the BDNCP, as well as a CPV code assigned to any contract during the preparation of the call for tenders. The person in charge for the procurement phases within the contracting authority should select a CPV code, which should be as close as possible to the actual contract object.

We work on a sample drawn from the BDNCP, which contains 64,279 contracts issued from 2016 to 2022 by 9,811 contracting authorities. For this work, we consider the first two digits of the CPV, namely the CPV division (45 different codes), which corresponds to a macro-category of the contract object (MCPV in the following, standing for Macro CPV).

Contracts do not distribute uniformly across MCPV. MCPV 33 ("Medicine, drugs and personal care products") and MCPV 45 ("Construction works") are the most represented macro-categories of contract objects (18,241 and 17,405 contracts, respectively, corresponding to around 55% overall). The third most frequent is the MCPV 71 ("Architecture and engineering services"), with only $2,820$ contracts (4.4%), while the least frequent is the MCPV 76 ("Gas and oil services") with only 20 contracts. Moreover, 11 out of 45 MCPVs collect more than $1,000$ contracts, and 9 out of 45 include less than 100.

2.2 Costruction of a vocabulary

A *toy* vocabulary is constructed from the sample with software `tidytext` in R language (10). The command `unnest_tokens` converts the textual description of the contract object into a list of "tokens" (or terms), which consist of strings of lowercase alphanumerical symbols located between two blank spaces. In addition, using the SnowballC vocabularies dedicated to Italian language (11), tokens are reduced to their thematic roots ("stemming") and stopwords (e.g., articles, connectives, etc.) are removed.

The lists of all tokens (with associated MCPV) extracted from the sample are then recomposed into a dataframe and summarised as counts of the occurrence of each token in each MCPV. This is a tidy approach that falls under the methodology known as "Bag-of-words", since it does not account for the order of the words (7).

Let f_{ik} be the (conditional) relative frequency of token i given MCPV k, with $i = 1, \ldots, n_k$ and $k = 1, \ldots, K$ ($K = 45$ in our case study). These frequencies are weighted through a weighting scheme analogue to the Term Frequency - Inverse Document Frequency metric, or TF-IDF (10; 7). Specifically, the weighted version of f_{ik} is obtained as follows:

$$f_{ik}^{w} = f_{ik} \times \log_{10} \frac{K}{K_i}, \tag{1}$$

where $K_i = \mid \{k : i \in k\} \mid$ and represents the cardinality of the set including all the MCPVs that contain token i at least once. As such, f_{ik}^{w} is a measure of the relevance of the token i for MCPV k, so the token with a higher value is more semantically salient for that MCPV. Of course, this value exists for each token that is counted at least once for that MCPV ($f_{ik} \neq 0$).

In order to extract a vocabulary $\mathcal{V}_k$ of relevant tokens for each MCPV, the use of a fixed number of tokens (i.e., the first ten with the greatest f_{ik}^{w}) is not advisable, since the number of contracts is unbalanced across MCPVs and the most frequent ones (i.e., MCPV 33 and MCPV 45 in our case) would have the same number of tokens as the least frequent. In order to let variate the cardinality of $\mathcal{V}_k$, we propose to consider a cut-off value between 0 and 1, denoted by ϑ, and to build the vocabulary for each MCPV by including only those tokens whose cumulative weighted frequencies exceed this threshold, excluding the tokens that appear only once in that MCPV. In a formula, we have:

$$\mathcal{V}_k = \{i : F_{ik|c_{ik}>1}^{w} > \vartheta\}, \tag{2}$$

where $F_{ik|c_{ik}>1}^{w}$ is the cumulative sum of ordered f_{ik}^{w} (in descending way), after considering the tokens with $c_{ik} > 1$ (more than one occurrence in MCPV k).

In this way, the number of tokens in each $\mathcal{V}_k$ depends on the frequencies of contracts in the MCPV. Furthermore, independently from ϑ, in our case study the vocabulary of MCPV 33 and MCPV 45 will always contain a wide list of tokens, whereas those of the least frequent MCPVs (i.e., MCPV 76 or MCPV 16) will consist in very short lists.

2.3 Tests for risk detection

Two tests are proposed for identifying inconsistencies between contract textual descriptions and their MCPVs and, consequently, for red-flagging risky contracts. Given a generic contract j assigned to a specific MCPV (say, k^*), let us denote its tokenised object by $\mathbf{x} = [x_1, \ldots, x_m]^\top$ (reference to contract j is removed for ease of notation), which is the vector of the m tokens extracted from the textual description of the contract object (after stemming and stopwords removal).

Test I is positive for the contract at issue (hence, a red flag is raised for that contract) if in vector $\mathbf{x}$ there is not even one token contained in the list of relevant tokens for the MCPV assigned to that contract (k^*), that is,

$$x_z \notin \mathcal{V}_{k^*}, \ \forall z = 1, \ldots, m. \tag{3}$$

Alternatively, Test II detects as contracts at risk those contracts whose object description contains at least one token not included in the list of relevant tokens for its MCPV, but contained in the list of relevant tokens of a different MCPV:

$$\exists \ z : x_z \notin \mathcal{V}_{k^*} \text{ and } x_z \in \mathcal{V}_{\bar{k}}, \bar{k} \neq k^*. \tag{4}$$

3. Preliminary results

The two proposed tests are applied to the data at hand. Figure 1 shows that Test II is very uninformative, independently of ϑ, as it would label almost all contracts with a red flag. On the other hand, Test I is sensitive to the choice of ϑ[1], although not monotonically. The marginal reduction of "positive" contracts by conjoining the two Tests is abysmal, especially for higher ϑ.

[1] $\vartheta = 0.3$ has been elicited as the minimum value for the parameter because all relevant tokens for MCPV 16 would be filtered out under this value.

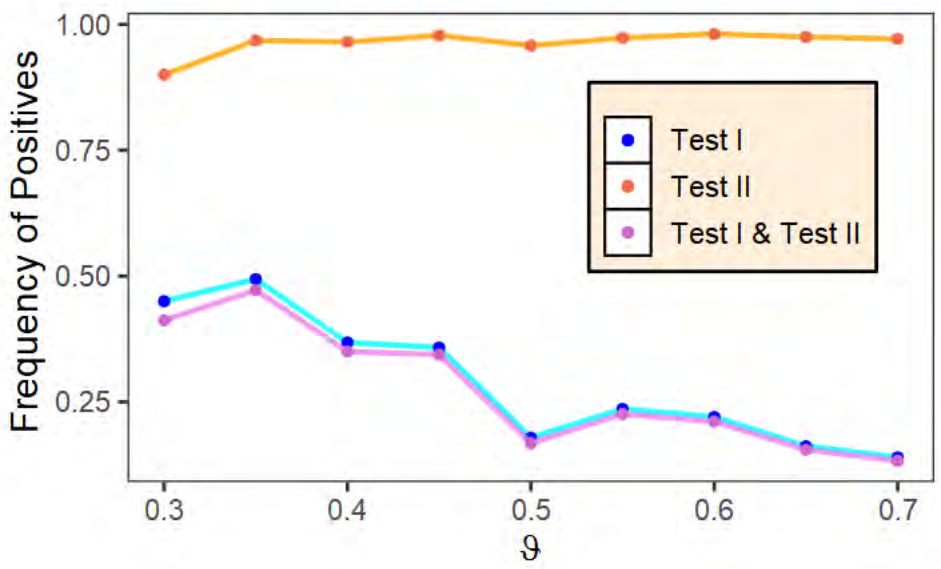

Figure 1: Relative frequency of contracts with a raised red flag according to the two proposed tests (or both).

These results are very dependent on the vocabulary, built on a relatively small sample. This affects f_{ik}^{w} since Eq. 1 considers the MCPV where token i occurs at least once, and the probability of a token i to be counted at least once depends positively on the number of contracts. Moreover, in Eq. 2 tokens that are counted only once in the MCPV are excluded from the cumulative frequency; again, the probability to occur more than once depends positively on the number of contracts in the sample.

Furthermore, the reason for Test II being so uninformative is that the probability that vector $\mathbf{x}$ includes a token associated with a MCPV different from that assigned to the contract is higher when the vocabularies contains many terms. In fact, when ϑ is small, the frequency of red flags for Test II is slightly lower (although still high).

The parametric tuning of ϑ shows that Test II must be avoided in absence of a proper large vocabulary. On the other hand, Test I is a more solid pick and its output can be optimised through the parameterisation of ϑ. Given the nature of the data at hand, it is expected that the effective number of risky contracts should be small, so Test I with $\vartheta > 0.7$ is still expected to be a powerful but not very specific test to detect contracts at risk. Especially with a larger and better vocabulary, the conjunction of Test I and Test II (i.e., red flags activated when both tests are positive) could be a better device to detect potentially suspicious contracts.

The best employment of these tests is for prior screening of high volumes of contracts in public procurement. Correctly parameterised, Test I can reduce up to 1/6 the number of contracts to scrutinise in procedures of qualitative *audit*. This performance is expected to improve with a complete vocabulary from all the contracts from the BDNCP.

4. Future developments

In this work we present a text-mining approach for identifying dissimilarities between the textual description of a public contract object and its pre-assigned classification using CPV. After the construction of suitable vocabularies for each macro class (MCPV), two tests are proposed for detecting contracts whose object description contains terms/elements incoherent with their classification.

Results are strongly conditioned for the vocabulary built on a relatively small sample, but also from the heterogeneity in the population of public contracts. Heterogeneity is problematic because it induces tokens to join vocabularies of several MCPVs, despite the use of a particularly robust weighting method

for the relative frequency of each token (see Eq. 1). In fact, some MCPVs are associated with subject categories that can be clustered according to semantic affinities. These semantic clusters are not caught by CPV classification. Moreover, weighting schemes cannot correctly assign each token to one and only one MCPV, because all the MCPVs in the cluster are too semantically close. For example, for $\vartheta = .3$, the token "server" joins the vocabulary of two MCPVs, that is, MCPV 48 ("Software and information technologies") and MCPV 72 ("Software consultancy and development"). While the objects of the contracts associated with these two MCPVs may differ in the phenomenology (e.g., selling a license, then a good, against giving a service of consultancy), the semantics may basically be the same, e.g. the act of "installing a server" could fall within both the MCPVs.

In practice, the presence of tokens belonging to different MCPVs reduces the specificity of the test and induces a high quota of false positives of the red flag. However, the low specificity offers a high power of the test to detect anomalies. Considering the previous example, an *auditor* could be interested in checking if there were reasons for the installation of a server to fall in MCPV 48 or MCPV 72, so in general, even in the current state, the method has clearly usability as a filter for a qualitative inquire of a set of contracts.

To overcome this issue, the proposal can be improved in two ways. The first is to adopt an advanced system of object classification, minimising heterogeneity in the number of contracts and merging classes that are semantically clustered.

The second approach considers the adoption of a model-based classification instead of a logical one. It is still based on vocabularies and "bag-of-words" structures, but also adopts a system of large parametric equations on a unique vocabulary of non-trivial tokens instead of listing relevant terms for each MCPV. For example, assuming K classes (MCPVs), there exists a matrix that assigns a coefficient, β_{ik}, for each pair of token (i) and MCPV (k), so that the greater the coefficient, the higher the pertinence of token i with MCPV k. Given vector $\mathbf{x}$ of tokens from a contract object, an overall coefficient, say β_k, scores the pertinence of the contract to the class k and can be derived from the coefficients related to the tokens in $\mathbf{x}$, for example, by taking their arithmetic mean.

Then, for each contract we have a distribution of β_k, with $k = 1, \ldots, K$. As outlined above, the contract has a pre-assigned MCPV (k^*), so the method would check if the assigned class is "coherent" with the distribution of β_k; for example, in the best scenario, the assigned MCPV coincides with the class associated with the highest classification score:

$$k^{(p)} = \underset{k}{\operatorname{argmax}}(\beta_k).$$

This procedure is technically analogous to "topic modelling", with classes as fixed topics (12; 13). As a detection method, it is flexible because it allows for setting richer and more complex rules for the activation of the red flag, accounting for expected semantic similarities between classes and the β_{k^*}, compared to other β_k.

Abstract

Artificial intelligence (AI) is now widely diffused in everyday life, and it is quite often based on machine learning (ML) techniques. ML, in spite of being quite effective in many applications, is very often lacking of transparency. Here we propose a methodology for explainable ML, based on a geometric approach and we apply it to the case study of protein pocket detection. Indeed our approach may lead to a faster and more sustainable process for drug design.

Keywords: XAI, XML, GENEOs, pocket detection.

1. Introduction

Equivariant operators are proving to be increasingly important in deep learning, in order to make neural networks more transparent and interpretable (2; 7). The use of such operators corresponds to the rising interest in the so called "explainable artificial intelligence" (6; 14), which looks for methods and techniques whose functioning can be understood by humans. In accordance with this line of research, Group Equivariant Non-Expansive Operators (GENEOs) have been recently proposed as elementary components for building new kinds of networks (3; 4; 8). Their use is grounded in Topological Data Analysis (TDA) and guarantees good mathematical properties to the involved spaces, such as compactness, convexity, and finite approximability, under suitable assumptions on the space of data and by choosing appropriate topologies.

A GENEO is a functional operator that transforms data into other data. By definition, it is assumed to commute with the action of given groups of transformations (equivariance) and to make the distance between data decrease (non-expansivity). The groups contain the transformations that preserve the "meaning" of our data, while the non-expansivity condition ensures that the operator simplifies the data metric structure. Both equivariance and non-expansivity are important: while equivariance reduces the

computational complexity by exploiting symmetries of data, non-expansivity guarantees that the space of GENEOs can be finitely approximated.

In this paper we will introduce GENEOs and we will show promising results obtained in an industrial application, namely protein pocket detection.

2. Basic definitions and properties of GENEO spaces

Let us now formalize the concept of GENEO, as was introduced in (3). We assume that a space Φ of functions from a set X to $\mathbb{R}^k$ is given, together with a group G of transformations of X, such that if $\varphi \in \Phi$ and $g \in G$ then $\varphi \circ g \in \Phi$. We call the couple (Φ, G) *perception pair*. We also assume that Φ is endowed with the topology induced by the L_∞-norm $D_\Phi(\varphi_1, \varphi_2) = ||\varphi_1 - \varphi_2||_\infty,\ \varphi_1, \varphi_2 \in \Phi$. Let us assume that another perception pair (Ψ, H) is given, with Ψ endowed with the topology induced by the analogous L_∞-norm distance D_Ψ, and let's fix a homomorphism $T : G \to H$.

Definition 1. *A map $F : \Phi \to \Psi$ is called a* group equivariant non-expansive operator (GENEO) *if the following conditions hold:*

1. $F(\varphi \circ g) = F(\varphi) \circ T(g)$ *for every $\varphi \in \Phi$, $g \in G$ (equivariance);*
2. $\|F(\varphi) - F(\varphi')\|_\infty \leq \|\varphi - \varphi'\|_\infty$ *for every $\varphi, \varphi' \in \Phi$ (non-expansivity).*

If we denote by F_{all} the space of all GENEOs between (Φ, G) and (Ψ, H) and we introduce the metric

$$D_{\text{GENEO}}(F_1, F_2) = \sup_{\varphi \in \Phi} ||F_1(\varphi) - F_2(\varphi)||_\infty, \qquad \forall\, F_1, F_2 \in F_{all}$$

the following main properties of F_{all} can be proven (see (3) for the proofs).

Theorem 1. *If Φ and Ψ are compact, then F_{all} is compact with respect to the topology induced by D_{GENEO}.*

Theorem 2. *If Ψ is convex, then F_{all} is convex.*

Theorem 1 guarantees that if the spaces of data are compact, then also the space of GENEOs is compact, thus it can be well approximated by a finite number of representatives, reducing thus the complexity of the problem. Theorem 2 implies that if the space of data is also convex, then any convex combination of GENEOs is still a GENEO. Thus when both properties hold we have an easy instrument to obtain new GENEOs starting from a finite number of them.

3. GENEOnet

We used GENEOs to build *GENEOnet* (5), a geometrical explainable machine learning method to detect pockets on the surface of proteins which are likely to host ligands (where ligands are usually drugs). Protein pockets detection is a core problem in the context of drug development, since the ability to restrict the search only to a finite number of good sites, allows a scientist to speed up virtual screening procedures, saving both computational resources and time.

This problem is particularly suitable to be treated with GENEOs. In fact there is some important empirical chemical-physical knowledge that can not be directly embedded in the usual machine learning techniques, but can be injected in a GENEO architecture. Additionally the problem shows a natural equivariance property, since, if we rotate or translate a protein, its pockets will be coherently transformed in the same way. This suggests that pocket detection is equivariant with respect to the group of spatial isometries.

To use GENEOs, input data have been processed by surrounding each protein with a bounded region divided into a 3D grid of voxels. In this way we could represent the data as bounded functions from the

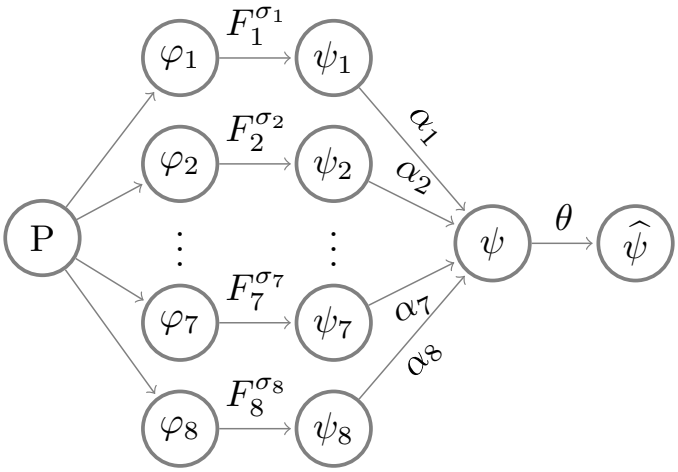

Figure 1: Model workflow: input channels $\varphi_1, \ldots, \varphi_8$ are fed to the GENEOs $F_1, \ldots, F_8$ dependent on the shape parameters $\sigma_1, \ldots, \sigma_8$. The intermediate outputs $\psi_1, \ldots, \psi_8$ are combined through convex combination with weights $\alpha_1, \ldots, \alpha_8$ to get the final result ψ. To get predictions a thresholding operation with a parameter θ is applied obtaining the binary function $\widehat{\psi}$

Euclidean space $\mathbb{R}^3$ to $\mathbb{R}^d$. Indeed, we considered $d = 8$ distinct geometrical, chemical and physical potential fields, called *channels*, that were computed for each molecule [1].

Such functions are fed to a layer of GENEOs chosen from a set of parametric families of operators, each one parametrized by a shape parameter $\sigma_i, i = 1, \ldots, d$. These families were designed in order to include the a priori knowledge of the experts of medicinal chemistry. We opted for convolutional operators with L^1 normalized kernels: if φ is one of the considered channel measured on a molecule, we compute

$$F_k(\varphi) = \int_{\mathbb{R}^3} \varphi(x) k(x - y)\, dy,$$

where k is a kernel. The behavior of such operators is determined by their kernels, thus by making the i-th kernel dependent only on one shape parameter σ_i, we have direct control on the action of each operator. We mainly used Gaussian kernels[2], or kernels having shapes of spheres, or of spherical crowns, assuming alternatively positive and negative values in different parts of the interior of the sphere or crown, and zero outside (see (5) for further details about the kernels). Nonetheless all the kernels are rotationally invariant functions. This fact, together with the properties of convolution, guarantees that the corresponding operators satisfy the key requirement to be equivariant with respect to the group of isometries of $\mathbb{R}^3$.

In the second layer the d operators are combined through a convex combination, with weights $\alpha_1, \ldots, \alpha_d$, with $\alpha_i \in [0, 1], \forall i$ and $\sum_{i=1}^{d} \alpha_i = 1$. The output of the convex combination is normalized to a function ψ from $\mathbb{R}^3$ to $[0, 1]$. Here $\psi(x)$ can be read as the probability that a point $x \in \mathbb{R}^3$ belongs to a pocket. Finally, considered a probability threshold $\theta \in [0, 1]$, we obtain the different predicted pockets by taking the connected components of the superlevel set $\{\psi \geq \theta\} \subseteq \mathbb{R}^3$. The entire model pipeline is depicted in Figure 1.

The model described until now relies just on 17 free parameters. The fact that the model only employs convolutional operators, and their linear combinations, allowed to set up a training pipeline quite similar to that of a 3D Convolutional Neural Network (CNN), but with two fundamental differences. First of all GENEOnet has a really tiny set of parameters[3]. Additionally the convolutional kernels of the GENEOs are not learned entry by entry as in classical CNNs (in this way equivariance would not be

[1] See (5) for further details on the specific channels.

[2] that is with general expression $k(x) = C \exp\left(-\frac{||x||^2}{2\sigma_i}\right)$

[3] For comparison DeepPocket (1), a recent approach that uses a 3D CNN, has 665 122 parameters.

preserved), instead the kernels are continuously generated from the values of the shape parameters that are updated during the optimization.

4. Model training and comparison with other methods

In order to identify the unknown parameters, we chose to optimize a cost function that evaluates the goodness of our predictions, in terms of volume fraction of the cavity which contains the ligand that has been correctly identified. Eventually, after training, pockets are found as the connected components of the thresholded output of the model, resulting in a set of unordered pockets. Actually this representation is not much informative, since it is usually desirable to compute also the "druggability" of the identified cavities, that is a ranking score for the pockets, on the basis of their fitness to host a ligand. Thus we used the 'not thresholded' output ψ of the model to score the pockets, so that the final output consists in a list of pockets, ranked by their corresponding scores (5).

In order to identify the optimal model, we opted for a two-step optimization procedure: in the first step we generated $m = 200$ models $(\mathcal{M})_{k=1}^{m}$ optimized from $(T_k, IC_k)_{k=1}^{m}$, where T_k is a training set of size 200, subsampled from the whole dataset and IC_k are the randomly generated initial values of the parameters. In the second step each model was evaluated for its scoring capabilities, by computing H_1 (see (1) for the definition) on a validation set in order to select the model maximizing H_1. This final model was evaluated on an independent (both from the training and the validation sets) test set to produce the results of next paragraph.[4]

We compared the results of GENEOnet with other recent methods for protein pocket detection, some of which based on ML techniques. We based our comparison on the scores assigned by the different methods to the pockets. In this way we compared the models in the assignment of highest scores to pockets matching the true ones. Given a dataset of proteins having only one ligand, and thus one "true pocket" each, we computed the following quantities

$$H_j = \frac{\#(\text{proteins whose true pocket is hit by the jth top ranked})}{\#(\text{proteins})} \tag{1}$$

and the corresponding cumulative quantities

$$T_j = \frac{\#(\text{proteins whose true pocket is hit within the jth top ranked})}{\#(\text{proteins})} = \sum_{i=1}^{j} H_j.$$

In this way different methods can be compared directly: if a model provides T_j greater than all the others for all j, then that model is definitely better.

The results reported in Table 1 show that GENEOnet is better than all the other considered methods in detecting the true pocket within the first 4 top ranked pockets, and is only slightly less performing than DeepPocket and Fpocket in the general detection of the true pockets, whatever the ranking provided by the methods. Anyway in virtual screening procedures, only the first few top ranked pockets on each protein are considered for testing their ability to host a ligand (druggability), in order to speed up the process, that usually is applied to tens of thousands of different molecules. Thus the performance of a method must be judged on the ability of the first few top ranked pockets to detect the true one. Furthermore the computational efficiency and transparency of GENEOnet are much better than the other methods, since it depends only on 17 parameters, which can be trained very rapidly even with a small training set.

Additionally, the values of the estimated parameters $\sigma_i, \alpha_i,\ i = 1, \dots, d$ can be used to provide further interpretation to the results, and thus to increase the explainability of GENEOnet: the relative magnitude of the shape parameters σ_i reflects their influence on the convolution kernels, while the values of the convex combination parameters α_j can be regarded as the corresponding channel's importance.

[4]Dataset size: 12995, Training set size: 200, Validation set size 3073 (48 proteins in the intersection with the training set), Test set size: 9070 (totally disjoint from the other sets). Protein data retrieved from PDBbind v2020 dataset (11)

Method	T_1	T_2	T_3	T_4	$\sum_{j\geq 1} H_j$

5. Discussion

We presented GENEOnet, a geometric machine learning model based on a new explainable artificial intelligence paradigm provided by the theory of GENEOs. As described, a GENEO-based approach needs some prior knowledge to be set up, but, if available, such prior knowledge can be effectively combined with the equivariance property of GENEOs in order to reduce the number of learnable parameters and the hunger for training examples of deep learning models.

A GENEO-based model possesses multiple sources of explainability: equivariance allows the model to embed in itself prior knowledge about specific geometric transformations of the data, so that this knowledge must not be learned from the training set; the low number of free parameters gives the possibility of assigning clear and understandable meaning to them; and, finally, the non-expansiveness property ensures that a GENEO-based model is stable, in the sense that close data will be mapped to close outputs.

The application to the detection of druggable pockets on the surface of proteins considered here, allowed us to show many of the stated properties of GENEOs architectures; moreover, in this case study, the use of GENEOs did not cause a reduction in model performance. On the contrary, GENEOnet achieves better or comparable results than all other models in use, but with huge advantages in terms of training time and transparency. For this reason, GENEOnet may help to improve the efficiency and speed of biochemical virtual screening procedures and lead to faster more reliable processes for drug design.

Abstract

We propose a dynamic method to hedge foreign exchange risk of international equity portfolios. The method is based on the currency returns predictions obtained from a set of alternative machine learning models, built on the main factorial components of the time series currency returns. The analysis of several model performance indicators allows to conclude that accurate predictions of global factor returns, such as those obtained with non linear machine learning models, can improve currency risk hedging.

Keywords: Currency returns, Currency risk factors, Mean-variance optimization, Time series machine learning.

1. Introduction

Global investment positions are nowadays substantial and have grown quickly in recent decades. When redenominated in the investors' home currency, the currency exposure resulting from international investments can significantly alter the underlying assets' overall risk-return profile, highlighting the key question of how investors should manage their foreign exchange exposure.

The main strategy for controlling foreign exchange (FX) exposure is mean-variance optimization, which establishes the best currency hedging positions. The strategy is theoretically interesting and includes requirements for both speculative hedging and risk management naturally. However, due to the well-known difficulties in forecasting exchange rates, this strategy, when used out-of-sample, suffers from severe estimating error in currency returns - see (3) -, leading to poor overall currency hedging performance - see (1; 2).

To solve the problem, in the paper we propose a novel methodology to dynamically determine currency hedge positions, that we denominate dynamic currency factor (DCF) hedging. The approach exploits the predictability of currency returns desumed from the predictability of the corresponding risk factors. Recent breakthroughs in international macro-finance by Lustig et al. (2011) and Verdelhan (2018) have found that the cross-section of currency returns can be explained as compensation for risk in a linear factor model that includes two global currency risk factors: dollar and carry. The dollar factor corresponds to the average return of a basket of currencies against the US dollar, while the carry factor reflects the returns from currency carry trade. These factors also account for a large proportion of the time-series exchange rate behavior in contemporaneous regressions, and thus, if their returns are predictable, currency returns are also partially predictable. We show that exploiting a predictable component in both global factors helps to mitigate the estimation error that typically hinders traditional mean-variance currency hedging, thereby delivering important investment gains.

Specifically, we build time series machine learning models to accurately forecast factor returns and improve the predictability of single currency returns.

To illustrate our proposed methodology from an empirical viewpoint, in the empirical part of the paper we take the perspective of a US investor who invests in a portfolio of G10 developed economies. The investor is assumed to have a predetermined long position in either foreign equities or bonds and desires to manage the Foreign Exchange exposure by forming optimal hedge positions within a mean-variance optimisation framework. To construct optimal hedge positions, monthly estimates of currency returns are initially formed by estimating currenciesâ exposures to dollar and carry factors (that is, factor betas). Factor returns are then forecasted using variables that have been theoretically motivated to drive either one or both factor returns, including Foreign exchange volatility (Merton, 1973; Menkhoff et al., 2012a; Cenedese et al., 2014), the average forward discount (Lustig et al., 2014), the TED spread (Brunnermeier and Pedersen, 2009; Brunnermeier et al.,2009), and commodity returns (Ready et al., 2017). These predicted global factor returns are combined with the estimated factor betas to form out-of-sample (OOS) forecasts of currency returns. The predicted currency returns are finally incorporated within the mean-variance optimizer to produce optimal, currency-specific, hedge positions.

Our empirical results show that the estimation error which frequently affects mean-variance currency hedging can be reduced and that significant economic investment gains can be achieved by taking advantage of a non-linear forecasting of components in both global factors.

2. Methodology

2.1 Framework for deriving optimal currency hedge positions

The main goal is to dynamically create the best currency hedge positions, from the viewpoint of a US investor. FX forward contracts are added to an existing portfolio of reference international equity indices in order to hedge FX exposure. Currency hedges are chosen to optimize a mean-variance investor's utility, whose objective function is used to determine hedge positions, and is specified as

$$\mu_{p,t} - \frac{\gamma}{2}\sigma^2_{p,t} \tag{1}$$

where $\mu_{p,t} = w_t'\mu_t$ represents the expected portfolio return for the following period, $\sigma^2_{p,t} = w_t'\Sigma_t w_t$ represents the portfolio risk, μ_t is the vector of expected excess returns in US dollars with variance-covariance matrix Σ_t. The vector w_t encompasses portfolio weights, and γ is the investor's level of risk aversion.

Portfolio weights in an unconstrained setting are given by $w_t^* = \frac{1}{\gamma}\Sigma_t^{-1}\mu_t$. In our setup, it is adequate to assume the underlying asset weights are predetermined by the portfolio manager, therefore determining the weights given to FX forward contracts is the ultimate goal (i.e., the optimal currency hedge positions). By first partitioning the expected return vector and related covariance matrix across the underlying equity indices and FX future contracts, the optimization issue can be rephrased as

$$\mu_t = \begin{pmatrix} \mu_{x,t} \\ \mu_{f,t} \end{pmatrix}, \quad \Sigma_t = \begin{pmatrix} \Sigma_{xx,t} & \Sigma_{xf,t} \\ \Sigma_{fx,t} & \Sigma_{ff,t} \end{pmatrix} \tag{2}$$

where the underlying indices and FX forwards are represented by x and f, respectively. Hence, the optimal weights in foreign exchange forwards are then given by

$$w^*_{f,t}(f \mid x) = \frac{1}{\gamma}\left(\Sigma^{-1}_{ff,t}\mu_{f,t}\right) - \delta_t w_{x,t} \tag{3}$$

where $w_{x,t}$ is the vector of weights and δ_t is the regression coefficient obtained from regressing underlying indices returns on long FX forward contracts returns, namely $\delta_t = \Sigma^{-1}_{ff,t}\Sigma_{fx,t}$.

Each element of $w^*_{f,t}$ is constrained to be between $-w_{x,t}$ (fully hedged) and zero (unhedged). This restriction mirrors the practice in currency overlay management that prohibits managers from taking speculative FX forward holdings above the position in the underlying security - i.e., a position cannot

be overhedged or leveraged by FX forwards. We estimate δ_t and Σ_t each month using a 5-year rolling window and set the underlying portfolio weights to be equally weighted across indices.

2.2 Building currency factors

We firstly define the currency excess return. We use the symbols S and f to represent the log of the spot exchange rate and the forward exchange rate, respectively, both expressed in terms of foreign currencies per US dollars. The value of the domestic currency rises when the dollar value does. Simply put, the net log currency excess return for an investor who goes long in foreign currency i is

$$r^l_{i,t+1} = f_{i,t} - s_{i,t+1} \tag{4}$$

The investor purchases foreign currency or, equivalently, sells the dollar forward at the price (f_t) at time t and purchases dollars at the price (s_{t+1}) in the spot market in $t+1$. Similarly, for an investor who is short the foreign currency - and therefore long in the dollar - the net log currency excess return is given by:

$$r^s_{i,t+1} = -f_{i,t} + s_{i,t+1} \tag{5}$$

We divide the sample of currencies into four portfolios at the end of each period t based on the forward discounts

$$d_{i,t} = f_{i,t} - s_{i,t} \tag{6}$$

that observed at that time. Portfolio 1 comprises the currencies with the lowest interest rates or smallest forward discounts, and portfolio 4 contains the currencies with the highest interest rates or largest future discounts. They are ranked from low to high interest rates. By averaging the log currency excess returns for each portfolio j, we can get the log currency excess return $r^j_{i,t+1}$ for portfolio j. We make the assumption that investors will short all of the foreign currencies in the first portfolio in order to calculate returns.

According to predictions made by linear factor models, the average returns on a variety of assets can be attributed to risk premia related to their exposure to a limited number of risk factors. Our currency portfolios' principal component analyses show that two factors account for more than 65% of the difference in returns across these four portfolios. Since all portfolios load equally on the first principal component, which we labeled λ^{dol}, it can be said that it acts as a level factor and accounts for more than 65% of the common variation in portfolio returns. Given that portfolio loadings rise monotonically across portfolios, the second primary component, denoted λ^{car}, which accounts for about 22% of common variance, can be seen as a slope factor. The systematic component of the dollar factor appears to correlate with low frequency global business cycle conditions and can therefore be interpreted as capturing the level of global macroeconomic risk - see (4). The carry factor is a zero-cost portfolio, constructed by investing in high-yielding currencies while funding the position in low yielding currencies.

2.3 Expected currency returns and common risk factors

The expected currency return vector $\mu_{f,t}$ is a key input in eq. (3), given that the return at time $t+1$, to a US investor who enters a long forward contract on foreign currency i at time t is defined by eq. (4).

We model the cross-section of expected currency returns as function of two common risk factors, named the dollar and carry factors:

$$Er_{i,t} = \zeta(\lambda_t^{dol,car}) \tag{7}$$

Factor return predictability is then exploited for forecasting expected returns. In particular, we run predictive models of factor returns on a set of time $t-1$ predictor variables X_{t-1} described by:

$$\lambda^j_t = \psi_j(X_{t-1}); \quad j = \{dol, car\} \tag{8}$$

to derive multi-step-ahead conditional expected factor returns $E_t\lambda^j_{t+h} = \hat{\psi}_j X_t$ where $h = t+1, ..., t+H$ where H is the forecast horizon.

Given the estimated factor betas from eq. (7) and the expected factor returns (premiums) from eq. (8), conditional expected currency return over the following H periods for each currency pair i can be found as:

$$E_t R_{i,t+h} = \hat{\zeta}(E_t \lambda^j_{t+h}) \tag{9}$$

In our setting, we propose to estimate the relationships between Er_i and $\lambda^{dol,car}$, which we label as ζ, and those among $\lambda^{dol,car}$ and X (ψ_j) by means of time series machine learning models. Many of the machine learning algorithms are well known for delivering good forecasting performances and can be exploited to accurately forecast the dollar and carry factors and the conditional expected currency returns. In particular, we test different families of machine learning forecasting models for time series, namely Discriminant Analysis for time series (DA), Regression Trees (RT) and Support Vector Machine (SVM).

2.4 Currency factor predictors

As currency factor predictors we first exploit the forward currency discount $d_{i,t}$ represented in eq. (6). Secondly, since the carry factor returns exhibit a strong negative relationship with FX volatility we make use of exchange rates volatility measured as the daily squared returns currency pairs i against the US dollar. Namely, we exploit the change in FX volatility:

$$\Delta\sigma^i_t = \log\left(\frac{\sigma^i_t}{\sigma^i_{t-1}}\right)$$

where $\sigma^i_t = r^2_{i,t}$. Thirdly, given that tighter funding liquidity, as proxied by increases in the spread among the LIBOR and the Tbills, can also forecast carry returns, we employ changes in the LIBOR ($LIBOR_t$) and in the Tbills ($Tbill_t$) as exogenous predictors:

$$\Delta LIBOR_t = \log\left(\frac{LIBOR_t}{LIBOR_{t-1}}\right)$$

$$\Delta Tbill_t = \log\left(\frac{Tbill_t}{Tbill_{t-1}}\right)$$

Fourthly, it is established that higher commodity prices predict higher carry trade returns. Therefore, we employ two commodity price indices as currency factor predictors. The first one is the Invesco DB Commodity Index Tracking (CI^1) which tracks changes in the level of the DBIQ Optimum Yield Diversified Commodity Index Excess Return plus the interest income from the Fund's holdings of primarily US Treasury securities and money market income. The second one is the iShares S&P GSCI Commodity-Indexed Trust (CI^2) which tracks a set of futures contracts on an index composed of a diversified group of commodities futures. Also in this case, we use changes in the commodity price indices as currency factor predictors, namely

$$\Delta CI^1_t = \log\left(\frac{CI^1_t}{CI^1_{t-1}}\right)$$

$$\Delta CI^2_t = \log\left(\frac{CI^2_t}{CI^2_{t-1}}\right)$$

3. Data

For the purpose of illustrating our method, collect and analyze three main types of time series data: a) currency spot and future returns; b) international reference equity market indices; c) a set of currency factor predictors. Firstly, we consider the following countries and their respective foreign exchange rates: Australia (AUD), Canada (CAD), Switzerland (CHF), Europe (EUR), Great Britain (GBP), Hong

Kong (HKD), Japan (JPY), Norway (NOC), New Zealand (NZD), Poland (PLN), Sweden (SEK), and South Africa (ZAR). For each currency, we collect spot and future closing prices. Secondly, we retrieve the equity prices of the reference stock market of each country[1]. Thirdly, we retreive daily time series observations related to the exogenous predictors discussed in Subsection 2.4. The analyzed time period ranges from 27 October 2008 to 30 December 2022.

4. Empirical results

In this Section we present the results of our methodology. The model is back-tested using a dynamic approach. For the in-sample estimation, we choose a 5-year rolling window, each one shifted by 22 working days, i.e. a trading month. For each of them, we produce out-of-sample predictions for the following month. Predictions are obtained by the selecting, for each rolling window, the best performing model across DA, RT and SVM in terms of cross-validation error. To ease computational burden, we use Bayesian optimization for training the set of different models and tuning their hyperparameters. Bayesian optimization finds an optimal set of hyperparameters for a given model by minimizing the objective function of the model, strategically selecting new hyperparameters for each iteration and tipically outperforming parameter grid search.

Figure 1 (upper panel) shows the cumulative payoff to investing in global equity portfolios, and specifically the cumulative payoff to a USD 1 invested in equally weighted global equity portfolios under different currency hedging frameworks from the perspective of a US investor. The payoffs to the linear DCF hedged portfolio, our proposed DCF hedged portfolio and the unhedged portfolio are highlighted. The profit and loss metric is complemented with two performance measures as highlighted in the central and lower panels of Figure 1, which illustrate the Sharpe and the Maximum Drawdown, respectively. Both measures are obtained with a rolling window of two years. Finally, we also report the empirical distribution of returns for the unhedged and hedged portfolio, along with the Kolmogorov-Smirnov test statistics and associated p-value.

We notice that hedged portfolios, on average, outperform the unhedged alternative. This suggests that hedging for global currency risk factors is determinant to the profitability of international equity porfolios. This is further confirmed by the sistematically superior values of the Sharpe ratios and Maximum Drawdown. Moreover, our proposed ML-hedging produces superior performances with respect to the linear hedged portfolio. The Kolmogorov-Smirnov test provides evidence against the null hypothesis that the returns of the two portfolios come from the same continuous probability distribution at all conventional significance levels ($p = 0.00073$).

5. Conclusion

In this paper we have provided a dynamic method to hedge exposure of international equity portfolios against foreign exchange risk via predictive ML models for global factor and currency returns. The method is based on the currency returns predictions that have been produced by training several ML models constructed using the principal factor components of the currency return time series. The comparison of various model performance metrics leads us to draw the conclusion that a significant currency risk hedging of global stock portfolios can be achieved by making accurate predictions of global factor returns, such as those derived with non linear machine learning models. Automated portfolio management via ML does not only offer a better hedge against currency risk, but also enhanced portfolio returns with respect to linear forecasting models.

[1]For the EURO area, we select the DAX as reference stock market index.

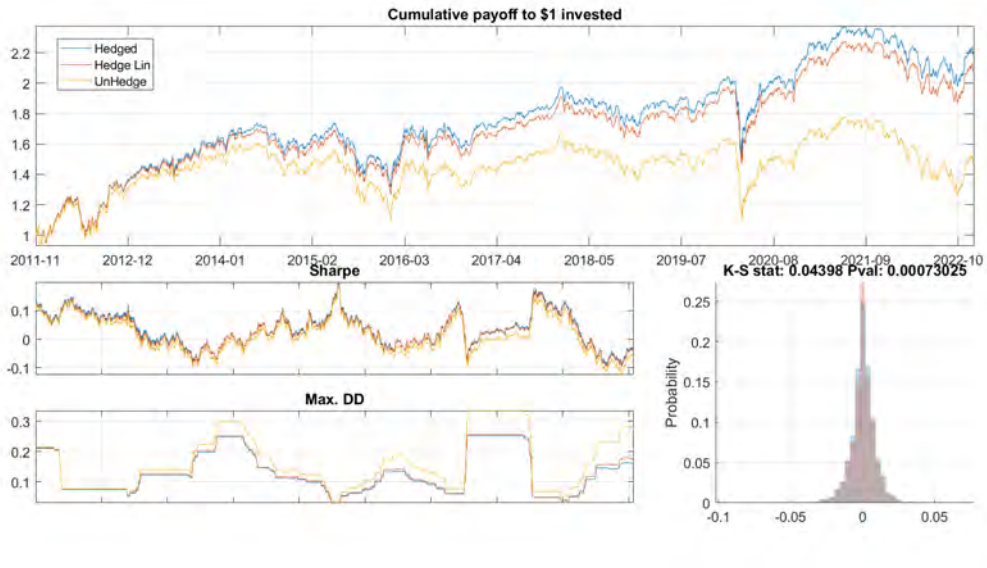

Figure 1: **Performance of ML-hedged, linear hedge and unhedged portfolios**. The upper panel shows the cumulative payoff to a USD 1 invested in equally weighted global equity portfolios under different currency hedging frameworks (ML-hedged, linear hedge and unhedged) from the perspective of a US investor. The central and lower panels of show the Sharpe and the Maximum Drawdown, both measures are obtained with a two-year rolling window. The right lower panel reports the empirical distribution of returns for the unhedged and hedged portfolio, along with the Kolmogorov-Smirnov test statistics and associated p-value.

Abstract

Explanations are necessary objects of a decision-making problem. However, complex Machine learning (ML) models that are usually used to provide decisions lack explanations. Model-agnostic explanation methods are the solutions for this problem and can find the contribution of each variable to the prediction of any ML model. Among these methods, SHapley Additive exPlanations (SHAP) is the most commonly used explanation approach which is based on game theory and requires a background dataset when interpreting an ML model. In this study we evaluate the effect of the background dataset on the explanations. In particular, we propose a variant of SHAP, InstanceSHAP, that use instance-based learning to produce a background dataset for the Shapley value framework. More precisely, we focus on Peer-to-Peer (P2P) lending credit risk assessment and design an instance-based explanation model, which uses a more similar background distribution. Experimental results reveal that the proposed model can effectively improve the ordinary shapley values and provide more robust explanations.

Keywords: Feature attribution; Shapley values; Machine Learning; Explainability.

1. Introduction

The field of credit risk management has grown rapidly in the last decades. This growth has led to a significant improvement in the performance, specifically accuracy, of prediction models, usually ML models. The trade-off between model complexity and interpretability makes it difficult to understand why sophisticated ML models perform so well. This problem prevents final users of decision-making models from trusting the predictions (10).

A key solution to this issue is the recent introduction of model-agnostic explanation approaches to understand the contribution of each predictor towards the overall prediction (2). (7) proposed a model-agnostic attribution method, SHapley Additive exPlanations (SHAP), based on the Shapley value from game theory. The Shapley value, quantifies the average contribution of a feature when it is added to all possible coalitions without the feature of interest. SHAP has been a popular method in the feature attribution literature (5) and many efforts have been devoted to improve it. For example, (1) address the problem of dependent variables in the SHAP algorithm. (3) mentions the heavy computational costs of calculating the Shapley values. Also in another study by (6), a rigorous analysis is performed to find where Shapley values are mathematically suboptimal. As computation of shapley values is based on the coalitions of the features, when dimension of the data increases, SHAP becomes computationally expensive. To reduce this complexity, SHAP (7) includes various explainers (e.g. TreeExplainer) for different ML models. A prerequisite of these explainers is a background dataset that is usually randomly

sampled from the training dataset. More precisely, when a feature is removed from a coalition, it is not clear how to have it inside the model. However, Background data is the solution for this issue by estimating the missing feature as an expectation over a background distribution (9). In this paper, we try to improve SHAP explanations by focusing on the background data. In particular, despite other studies that search for the correlation between variables and use conditional sampling for dependent features, we study the similarities among observations to improve estimation of the shapley values. For this purpose, we use an instance-based approach to provide a conditional selection for the background data.

The rest of this paper is organized as follows. Section 2 represents the methods we use in this paper. Experimental study, including description of the selected data to validate the proposed model and the results are presented in Section 3. Finally, Section 4 concludes the study and contains some remarks for future study.

2. Methodology

2.1 SHAP

SHAP values are based on the definition of Shapley values (7), which finds the marginal contribution of each variable towards the predictions. From the game theory point of view, features of an instance in the data set behave as players in a coalition, and Shapley values represent the distribution of the prediction among the features according to their contribution. In this paper we use the approximation of the Shapley values proposed in (7) that simulates the absence of a feature using the marginal expectation over a background distribution D. The Shapley value of variable i for $i = 1, \ldots, m$, is calculated as follows:

$$\phi_i = \sum_{S \subseteq \mathcal{F} \setminus i} \frac{|S|!(n-1-|S|)!}{n!}[v(S \cup i) - v(S)], \tag{1}$$

Here, $v(S)$ is equal to $= E_{x' \sim D[f(x_S, x^i)]}$. $E_{x' \sim D}$ denotes the expected value under the distribution D and $f(x_S, x_F^{'} \setminus S)$ represents prediction of the model with feature values included in S and values $x^{\hat{a}^2}$ for feature values not in S. Also, n is the total number of variables, S is a subset of predictors.

When there are n variables, we will have these calculations for 2^n coalitions so number of coalitions increases exponentially. This is the main disadvantage of shapley values that has led to approximations such as Kernel SHAP (7). In our application, as we employ random forest for the credit scoring model, we utilize a non-conditional version of TreeExplainer (8).

2.2 Instance-based Learning

The instance-based method has the ability to find some train observations that are the most similar instances to the test data that we pass through the explainers to calculate shapley values. Therefore, instead of random sampling from train data using the instance-based method we can find the similar samples and provide a more similar distribution for estimation of shapley values.

The weights for an instance-based model can be calculated using the distance between train and test instances. In this paper, we have a loan assessment problem so can define the default likelihood distance between loans i (train data) and j (test data), as follows

$$d_{ij} = |PD_i - PD_j| \tag{2}$$

Here PD_i and PD_j are the probabilities of default for loans i and j, respectively. It is obvious that we expect a higher amount of weight when observations are more near to each other. However, this is not an optimal weighing approach so as suggested by (4) we use kernel regression and follow their method to find the weights between train and test data. As the authors mention, kernel weights for instance-based modeling Kernel regression is a statistical technique to find non-linear relation between a pair of random variables. Similar to their scenario, we evaluate each observation (loan) based on risk and return but

Table 1: Summary statistics for the LendingClub data[a].

Type	Variable	Mean	STD	Min	Max
Numerical	Loan Amount	14588.273	8970.4714	500	40000
	Annual Income	77369.565	117821.8	0	110000000
	Debt To Income (DTI)	18.567739	13.08763	-1	999
	Open Accounts	11.60594	5.5755073	0	90
	Inquiries In The Last 6months	0.6125763	0.9018182	0	8
	Delinquencies In 2Years	0.312875	0.8754565	0	42
	Public Records	0.2083065	0.5901983	0	86
	Interest Rate	13.170133	4.8283	5.31	30.99
Categorical	LC Grade	7 Grades, From A(Safest) to G(Riskiest)			
	Loan Purpose	8 Categories, medical, car and etc.			
	Home Ownership	4 categories, Rent, Own, Rent and Any			
Binary	Loan Status	1=Failed Loans, 0=Fully Paid Loans			

[a]See https://www.kaggle.com/datasets/jonchan2003/lending-club-data-dictionary

since the focus of our paper is proposing an explainable model and improve the explainability we utilize interest rate, already available in data, as the return indicator and we do not calculate another measure to evaluate the return of loans. Kernel weights as supposed by (4) between the i^{th} train observation ($i = (1, \ldots, n)$) and the j^{th} test observation ($j = (1, \ldots, m)$) are calculated using the following equation:

$$W_{ij} = \frac{K(\frac{d_{ij}}{h})}{\sum_{j=1}^{n} K(\frac{d_{ij}}{h})} \tag{3}$$

Here, h (h¿0) is the bandwidth which follows the definition given by (4). After finding the optimal h, the weights between train and test observations are calculated. These weights are then used to find the similar background distribution for estimation of Shapley values.

3. Application

3.1 Data Description

We use the most common dataset in the P2P Lending Credit Scoring literature. This dataset includes information of individuals applied for a loan on the Lending Club P2P lending platform. The time horizon we consider for our paper is from 2007 to 2019. In general all observations are grouped into two categories: Class=zero, including borrowers who paid their loans and Class=one, representing borrowers who failed to pay the loan.

LC dataset is a big dataset which includes more than 100 variables. However, we select only mostly common used variables in the literature. After preprocessing the data, including dealing with missing values and encoding, explanatory analysis of the selected variables are as presented in Table 1. Loan status (a binary variable) is used as the target variable in our model.

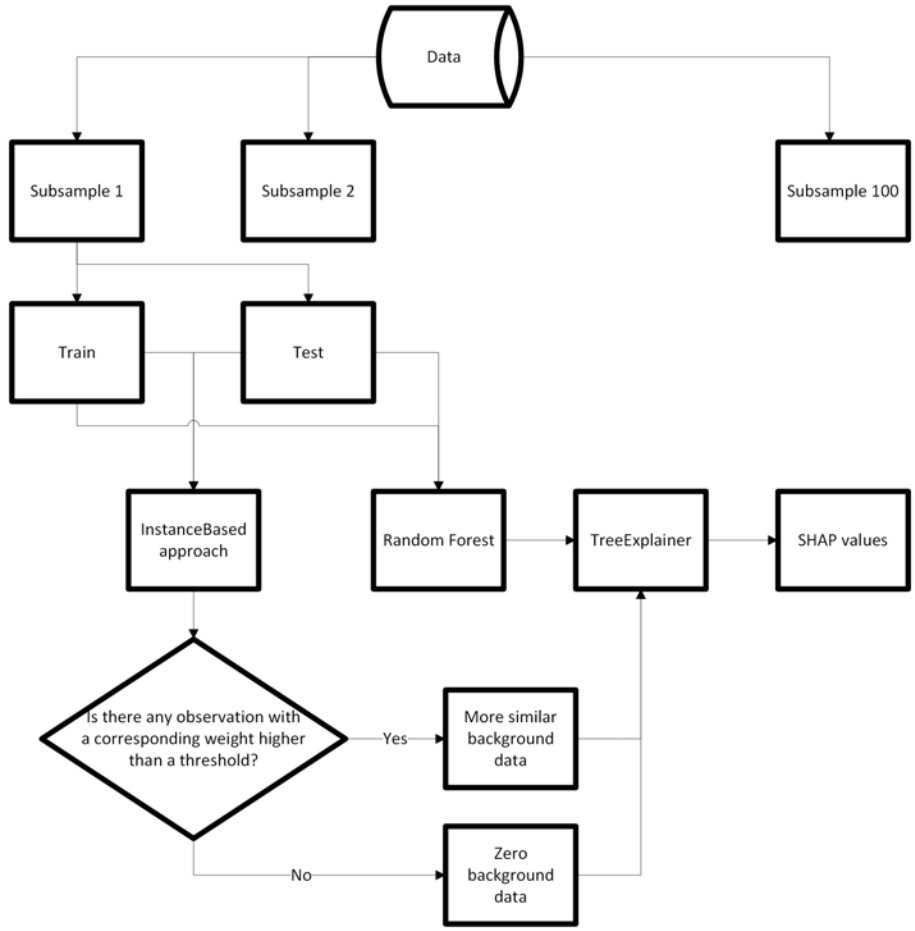

Figure 1: InstanceSHAP Flowchart

3.2 Empirical Approach Setting

Our proposed algorithm, InstanceSHAP, is illustrated in Figure 1.

As shown in Figure 1, we sample the processed data to a set of subsamples while the probability of default is being kept. Then to start the ML model that in our case is a random forest, we split subsamples to train and test data. We repeat the following operations for each set of train and test data generated by each sub sample and finally we take the mean of the results among the subsamples. The first step to find the weights between train and test observations is finding the distance among them which is calculated using Equation 2. After that, kernel weights using the calculated distance values and the optimal bandwidth are found based on Equation 3 and the description in (4). It should be mentioned that for optimizing the bandwidth we consider [0.25,1.5) with a step equal to 0.1.

Having the similarities between train and test data, we select the observations from train data for which the corresponding weight values are higher than a threshold that is set to be equal to the average of the calculated weights. In this case if no observations meet this condition, zero values are considered as the background data to estimate the missing features.

Finally, the instance-based background distribution is used in a Tree explainer. We note that we used the interventional (a.k.a., non-conditional) version of SHAP (default setting). Imagine we have 10 samples, after finding the shapley values on the explanation set for each of ten samples, we obtain 100 SHAP values for each variable in a single observation. To present the superiority of our proposed InstanceSHAP to an ordinary SHAP method in which whole train data is considered as the background distribution, we also find shapley values for each variable in each observation for each subsample and finaly to compare the InstanceSHAP with the ordinary SHAP, we consider the fluctuation of SHAP values using the concentration measure, Gini index.

Table 2: Comparison of the explanation models

Method	InstanceSHAP	OrdinarySHAP
Gini Index	0.54	0.53

Empirically, the original data is a huge dataset and contains over 1 million rows. To decrease computational time, we sample 1000 observations from the original data. Then, we set 70% of the dataset for training, and use the remaining, 30%, for testing. According to our proposed algorithm, we find the most similar train observations to the test data based on two variables. Later, in the explanation step of the algorithm, we use the retrieved observations which have a more similar distribution to the explanation data (test data) as the background data in the Tree explainer. In addition, for the purpose of comparison and validation of InstanceSHAP, we find the ordinary Shapley values. Here, ordinary shapley values mean the contribution values that are found using the whole train data as the background data in the explainer. After finding shapley values in the considered sample we go to the first step and repeat all steps for another sample. we repeat the process 100 times. In each round of the calculation, we find the Gini index of shapley values given by both explanation methods we consider in our application, InstanceSHAP and OrdinarySHAP. After finding all 100 Gini indices, we find the mean of Gini for each method. The results are presented in Table 2.

It can be seen that the value of Gini in InstanceSHAP is slightly higher than that of for OrdinarySHAP that shows, even for a relatively simple Random Forest model as the one we employ.

We should mention that since the main focus of our paper is to improve explanations provided by Shapley values, we use a simple Random Forest model with the default setting on Python. Analyzing the effect of hyperparameter optimization and machine learning models on explanation methods could be a direction for future study, which will likely lead to an even higher superiority of our proposed model.

4. Conclusion

Through an empirical study, we have shown that SHAP explanations fluctuate when background data changes. In particular, we showed that providing a background data with more similar distribution to the test data leads to better explanations. Using Gini index and comparing the indices of our proposed InstanceSHAP and OrdinarySHAP (using train data as the background data), we observe higher values for InstanceSHAP, even with a simple model. In general, our results suggest that the robustness of explanations caused by the choice of the background dataset should not be ignored. Future work should include: (i) extending to background data selection; and (ii) robustness of explanations.

Networks & Nature Based Solutions: an application for Milan hydric resources

Alessia Forciniti[a] and Emma Zavarrone[a]

[a]IULM University; alessia.forciniti@iulm.it, emma.zavarrone@iulm.it

Abstract

This paper proposes an innovative model to study the process of co-creation of stakeholders in the definition of *Nature-Based Solutions (NBS)*. Thematic groups of NBS with a focus on water well-being in Milan are identified. A random sample of oral interviews has been converted into textual corpus, combined text analytics and network analysis to detect latent thematic groups. The corpus has been divided into two gender-based sub-corpora to identify demo-diversity in building of sustainable innovation.The results revealed gender-based differences. Male stakeholders see NBS as a linear process based on circular economy and intermediation of the territorial authorities. Female stakeholders identify them as a progressive transformative process based on science, culture and citizen co-operation.

Keywords: nature based solutions, natural language processing, network analysis

1. Introduction

In 2019, the European Commission acquired through an innovative research project the concept of *Nature-Based Solutions-NBS* such as replicable models of strategies, actions, and adaptive interventions in nature aimed at increasing the sustainability of urban systems and performing the recovery of degraded ecosystems.

The perspective is oriented to foster socio-economic well-being of cities, by increasing inclusivity, re-generation of the disadvantages urban areas characterised by dilapidated infrastructures, pollution, high unemployment rates and poverty (e.g., Frantzeskaki *et al.*, 2017), by reducing violence and social tensions. This transformative potential is based on research and innovation and it is addressed to both citizens and other stakeholders in a perspective at several levels: ecological balance, creation of cultural, social, and economic advantages. However, the framework concerning the development of NBS highlights operational and technical criticalities that see solutions and approaches incompatible with local communities (e.g.; European Commission, 2020). The literature suggests to solve this limitation through cooperative governance models (Zingraff-Hamed *et al.*, 2020) based on the citizen engagement in the planning of nature-based adaptations (e.g.; Wamsler, 2020). Some authors as Burton & Mustelin (2013) and Mees *et al.*, (2015) propose a model of 'inclusive urban regeneration' which takes shape through the transdisciplinarity of different stakeholders, from residents to local authorities, from companies to academics, for a better fairness, relevance, acceptance, and co-creation of solutions oriented to management of public assets. One of the current management of public resources concerns the ongoing climate crisis that impacts the hydrogeological cycle and reflects itself in the supply of drinking water, health. In Italy, in compliance with L.R. 15 March 2016, n. 4 and the R.R. 7/2017, have been introduced the principles of hydraulic and hydrological invariance for reducing the hydrological impact of the transformation activities of the territory, and different organisations have developed to support municipalities in sustainable urban drainage systems.

The objective of this study is to investigate the process of co-creation through the dialogue with local stakeholders, by detecting the key categories characterising the NBS on water which can improve the quality of life in the metropolitan city of Milan. We explored two research questions (RQs):
RQ_1: What are the thematic groups of NBS on water that propose the stakeholders in Milan?
RQ_2: Are there gender differences in the definition of thematic groups?

To answer these RQs, in this paper we present an innovative protocol which moves itself from a sample of oral interviews of stakeholders, to the identification of the latent topics on emerging needs and intervention areas to improve the hydrological systems in Milan. After we operated a conversion of video-audio interviews in a textual corpus, we combined text analytics to network analysis as our best performing approach for detecting subgroups of words interpreted as thematic groups of NBS. In addition, we split the corpus in two sub-corpora based on stakeholders gender for detecting demo-diversities in building of sustainable innovation.

In the following, section 2 introduces the data; section 3 describe the methods; section 4 presents the results; section 5 shows the conclusion and future developments.

2. Data collection

Data collection is a population of 101 oral interviews (57.42 % male and 42.57 % female) conducted on corporate managers engaged in ecological regeneration in Milan. The selection was based on four macro-categories of topics proposed by CAP Group, the main company - founded in 1928 - that manages the integrated water service of Milan and some municipalities in Monza and Brianza. The fundamental pillars proposed are: *a) innovation; b) ecological transition; c) people; d) environment*.

To answer RQ_1, we used the population of interviews, while to satisfy RQ_2 we filtered the interviews by gender, obtaining two sub-groups. The textual transcription of the all oral interviews presents 1,957 types, 3,866 tokens, and a lexical richness by the *type-token ratio (TTR)* equal to 50.62 %, suggesting a language little diversified in describing the sustainable well-being of 'water'. The TTR within each pillars (Figure 1) ranges between 81% and 83%, denoting a little greater variability about the environment.

Additional details on corpus and sub-corpora are available in Table 1.

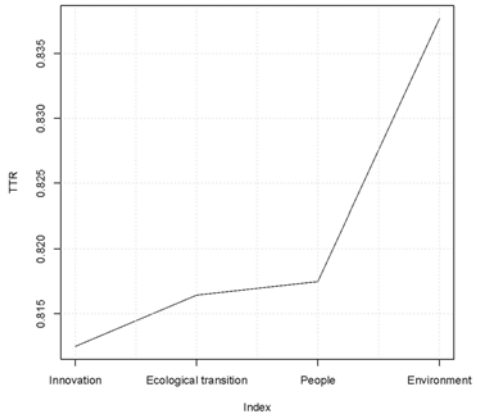

Figure 1: Lexical diversity plot

3. Methods

Our methodology is based on a 3-step model (Figure 2) which combines textual analysis to Network Analysis for detecting thematic groups. The model is based on a less conventional strategy compared to the most common methods (e.g., Hofmann, 1999; Blei *et al.*, 2003), but very effective in several studies (e.g.; Paolillo & Forciniti, 2021).

Table 1: Statistics on corpus and sub-corpora

Textual collection	Types	Tokens	TTR	DTM[a]	Sparsity
Total corpus	1,957	3,866	50.6%	$\mathbf{DTM}_{T101x915}$	72.85%
Male sub-corpora	722	1,393	51.8%	$\mathbf{DTM}_{M58x329}$	66.30%
Female sub-corpora	1,235	2,473	49.9%	$\mathbf{DTM}_{F43x586}$	57.29%

[a]**DTM**: *Document Term Matrix or Lexical Table. For details concerning the interpretation of data in Table 1 refers to paragraph 3.*

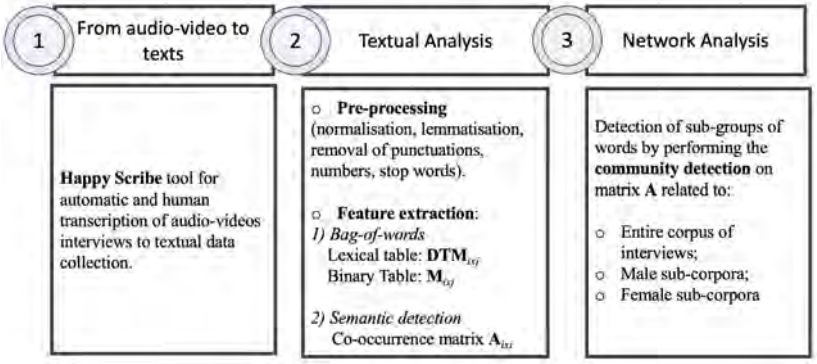

Figure 2: Flowchart of model

1. **STEP 1:** *Transformation of video-audios in textual data collection*
   We converted audio-video interviews to texts with 85-99% of accuracy using *Happy Scribe*, an automatic and human transcription tool for more than 120 languages.
2. **STEP 2:** *Textual Analysis*
   The corpus of the interviews was pre-treated through: a) normalisation; b) the removal of punctuation, numbers, stop word list for the Italian language based on standardised nomenclature of languages ISO 639 and c) lemmatisation. For feature extraction, the pre-processed texts were analysed at first by using a *bag-of-words* approach, and then by studying the relationship among the words to detect the semantic. We built the lexical table **DTM** (Document Term Matrix) based on a weighting scheme of frequency n_{ij} which measures the occurrence of the term i^{th} *(i = 1, ..., p)* in the document j^{th} *(j = 1, ..., q)*. The **DTM** was converted into a binary matrix **M** where m_{ij} is equal to 1 if the i^{th} terms occurs in the j^{th} document, and 0 otherwise.
   To keep tracks of each couple of terms side by side in a certain order, the matrix **M** was transformed into a *terms x terms* co-occurrence table **A**, multiplying $\mathbf{MM}^T$.
3. **STEP 3:** *Network Analysis*
   The matrix **A** may be interpreted such as an adjacency matrix (Wasserman & Faust, 1994) formally represented by a graph G (V, E) where V is a finite set of nodes of words and E a finite set of linkages (co-occurrences). To identify sub-groups of words densely interconnected to one another and poorly connected to other parts of the network (Newman & Girvan, 2004), we adopted the community detection. We used *fast-greedy* algorithm (Clauset *al.*, 2004), an agglomerative hierarchical clustering method for very large network, whose main advantage is the stopping criteria for choosing the number of groups based on optimisation of modularity *(Q)* (Newman & Girvan, 2004). The empirical range of its maximisation is between [0.3;0.7].

In our model, we performed the fast-greedy algorithm on matrices **A** related to both entire corpus of interviews and to gender sub-corpora in order to detect the thematic groups of NBS on water .

4. Results

To answer RQ_1, the findings on the entire corpus of interviews will be described to determine the thematic groups of NBS on water proposed by stakeholders in Milan. Later, to reply to RQ_2, the networks concerning the sub-corpora of male and female stakeholders will be showed in order to highlight gender differences in the definition of thematic groups.

Table 2: Summary of community detection

Textual collection	Co-occurrence Matrix **A**	Modularity Q
Total corpus	$\mathbf{A}_{T915x915}$	0.71
Male sub-corpora	$\mathbf{A}_{M329x329}$	0.40
Female sub-corpora	$\mathbf{A}_{F586x586}$	0.34

4.1 RQ_1: thematic groups of NBS detected on the entire corpus

For a better graphic intelligibility, we present the first four communities of NBS obtained on the most frequent 75 terms (Figure 3).

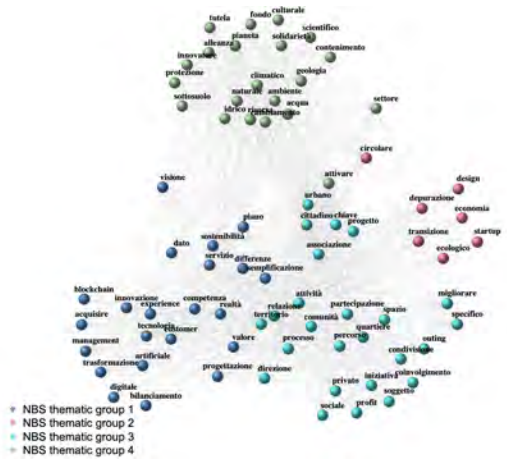

Figure 3: Thematic groups of entire corpus (RQ_1)

The first thematic group (blue cluster) is based on simplification of the processes, where innovation and digitalisation have key role. The second group (pink cluster) sees the overcoming of the linear economies through the ecological transition of start-ups, sewage treatment plants.The third group (turquoise cluster) is oriented to sustainable design and cooperation. The last group (green group) is the most specific of network, in which water, safety and the climate change emerge. Reading from bottom to top, we see the shift from the transformation of systems to the value of sharing and geological issues.

4.2 RQ_2: gender differences in the definition of thematic groups

The Figure 4 shows the network of male sub-corpora through two communities detected on the most frequent 50 terms.

The first group (turquoise cluster) describes the hydric resource with references to pollution of plastic, to depuration systems and circular economy. The second group (green cluster) is based on mediation of the local authorities (municipalities or other stakeholders).

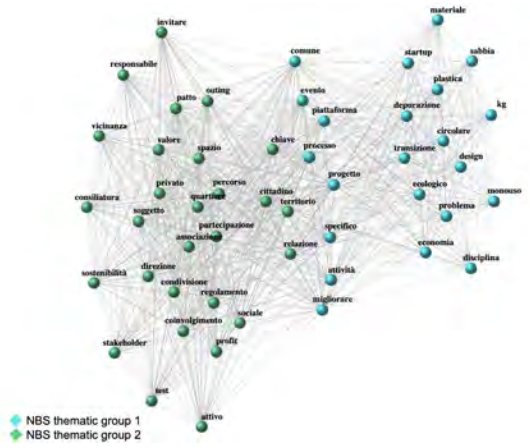

Figure 4: Thematic groups of male sub-corpora (RQ_2)

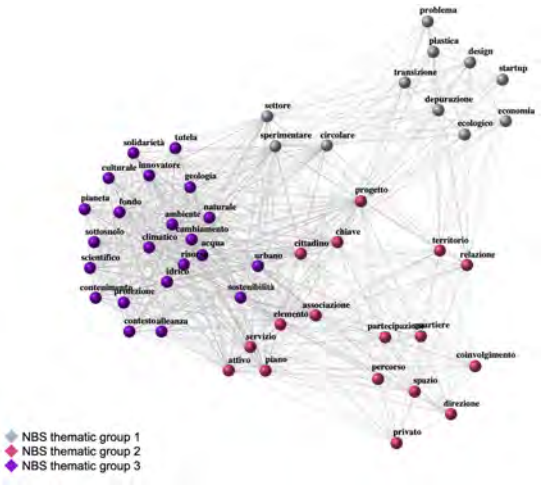

Figure 5: Thematic groups of female sub-corpora (RQ_2)

The Figure 5 shows the network of female sub-corpora and three communities detected on the most frequent 50 terms.

The first group (grey cluster) is a generalist view of the problem showing pollution, plastics and sewage systems. The second group (pink cluster) interprets the NBS as path of innovation of services, in contrast to the male perspective based on a transferring of the problem to the local authorities. The last group (purple cluster) is based on climate change, urban protection, science, culture and most of all highlights the gender difference.

5. Conclusion and future developments

In this paper, we combined text analytics and network analysis to detect thematic patters related to NBS on the water, by analysing the interviews of stakeholders which operates in the Milan city. At first, we studied the total perspective of interviewed, and at later we focused on gender-based sub-groups of interviews in order to detect potential gender differences in planning of strategies for urban systems development. The first investigation showed thematic groups based on: a) the simplification and digitalisation of systems; b) recycling-based economies; c) sewage treatment plants; (RQ1). However, by looking at the based-gender perceptions, it emerges that male stakeholders see NBS as a linear process

that moves from circular economy to the intermediation the territorial authorities as bridge. While, female stakeholders see NBS as a path of progressive transformation where the citizen take a key role and where are important welfare, solidarity, science and culture (RQ2).

Future developments might investigate additional demo-diversity features by means of techniques oriented to emotion and tone of voice recognition for better determining a diversification in defining of NBS on sustainability.

Abstract

In recent years, social media has become the main field for sourcing textual data. In particular, microblogging platforms such as Twitter make it possible to study users' online discussions by understanding and analysing the opinions, comments, and experiences that users share on different issues. One of the most debated issues in recent years is the voluntary termination of pregnancy. In particular, the United States Supreme Court's Roe v. Wade ruling has brought the abortion debate back to the forefront. Indeed, after the annulment of the ruling that restricted the right to abortion in the U.S., the response of online users has been crucial. Indeed, the aim of the paper is to understand what the major topics of discussion have been in the wake of the ruling. To do this, semantic clusters of terms were created through a symmetrical matrix reduction technique, Symmetric Non-Negative Matrix factorization.

Key words: Twitter, Symmetric non-negative matrix factorization, Lexical matrix decomposition

1. Introduction

On 24th June 2022, the U.S. Supreme Court overturned the sentence Roe v. Wade, which established the constitutional right to abortion in the United States in 1973. The Republican-appointed justices voted to strike down the federal right, while the other Democratic justices voted against it.

With the annulment of the ruling, individual U.S. states now have the power to establish their own laws regarding the right, or not, of a woman to have a termination of pregnancy, which Roe v. Wade allowed by the 24th week. In the absence of a law from Congress regulating abortion at the federal level, it will mean that each state can decide whether to allow abortions, whether to ban them always or under certain circumstances.

This event produced legal-normative consequences regarding whether or not voluntary termination could be accessed, but also social consequences in that it opened up a wide debate about the freedom to choose and to protect women's bodies. In addition, people seeking abortions will have to move from the city where they live and travel to more distant clinics or hospitals that allow the practice.

The outcome of the ruling has created a wide online debate among citizens who have expressed positions for or against the incident. This is because social networks and microblogging platforms are used as tools of political exchange: the debate on microblogging platforms has been studied before (Graells-Garrido et al. 2020; Sharma et al., 2017; Zang et al. 2016). Data from social media platforms such as Twitter offer new possibilities to study these dynamics because it provides a public arena for information gathering and opinion formation (Grassia et al. 2022).

So, the following work contributes to the study of the online debate on the issue of abortion through the analysis of tweets posted by users following the ruling. To understand the issues that users focused on in the online discussion, we used Symmetric Non-Negative matrix factorization (symNMF), which is a symmetric matrix reduction method used in clustering operations to create semantic clusters of terms.

2. Symmetric Non-Negative Matrix Factorization

Non-Negative Matrix Factorization (NMF) is an unsupervised matrix decomposition method that decomposes a matrix $\mathbf{X} \in R^{n \times m}$ by a product of two factor matrices $\mathbf{X} \approx \mathbf{WH}$, where $\mathbf{W} \in R^{n \times k}$ and $\mathbf{H} \in R^{k \times m}$, both with nonnegative elements. The product WH is an approximate factorization of rank at most k that it is assumed to satisfy the condition $k \ll min\ \{m,n\}$ (Gaujoux and Seoighe, 2010). The value of the parameter k shows the numbers of factors to be used to explain data (Casalino et al. 2016).

The NMF has the advantage that provides easily interpretable results because the extracted latent features are parts of the original data. Recently, NMF is widely used in text mining and document clustering but also for topic modeling in short texts. However, NMF is not a general clustering method that can be applied in every condition, as it is dependent on the linear or non-linear structure of clusters. (Kuang et al. 2015).

To solve the problem, it is used the symmetric version of NMF, the Symmetric Non-Negative Matrix Factorization (symNMF). This method factorizes a symmetric matrix input $\mathbf{A}$ by the product of two matrices $\mathbf{A} \approx \mathbf{HH^T}$, where $\mathbf{H}$ is the cluster assignment and its transpose $\mathbf{H^T}$ (Jia et al. 2021). Specifically, the matrix $\mathbf{H}$ is a nonnegative matrix of size $n \times k$, and k is the number of clusters requested.

Suppose the data points of the same group have high similarity values and the data points of the different groups have weak similarity values. So, a better approximation of $\mathbf{A}$ defines the cluster structure because the largest entry in the i-th row of $\mathbf{H}$ indicates the clustering assignment of the i-th data point, according to the nonnegativity of $\mathbf{H}$. The usual approach for approximating the input matrix $\mathbf{A}$ is to minimize the Frobenius norm $min_{H \geq 0} ||A \approx HH^T||^2_F$, and it can be related to a generalized form of many clustering objectives (Kuang et al. 2012).

SymNMF has been shown to be more effective for nonlinearly separable data than NMF (Kuang et al. 2015). It is important to know that symNMF is equal to spectral clustering, but Vangara et al. (2021) showed that it assumes better performance than k-means and spectral clustering. Kabir et al. (2020) stated that symNMF is more functional for clustering because it converts spectral clustering into an optimization problem with stationary point solutions. It has also been used as a graph clustering method (Luo et al.2021) and for topic extraction from a lexical matrix (Grassia et al. 2022; Yan et al., 2013)

3. Methodology

According to the open access academy API, we extracted English-language tweets using #RoeVsWade in the week following the outcome of the ruling (June 24-30, 2022). The volume of data extracted was very large: 943,696 tweets were extracted. In this regard, we eliminated retweets and identified 214,469 documents.

As part of an information mining process, it is necessary to process texts and obtain a set of structured data that can be elaborated using statistical techniques. So, several text pre-processing operations were carried out to transform the textual data (i.e., tweets) into structured data.

Documents are parsed and tokenized, resulting in a set of distinct strings (*tokens*) separated by blanks, punctuation marks, or other types of special characters (e.g., hashtags). These tokens correspond to the terms used in the vocabulary. The particular scheme achieved by tokenization is commonly known as bag-of-words (BoW), as it treats each document as a multiset of its tokens, without regard to grammatical and syntactic roles.

Once documents have been atomized into their basic components, pre-processing is necessary to reduce linguistic variability (Uysal and Gunal, 2014). First, all characters of the terms were changed to lowercase. To account for language variety, the following were carried out other *normalization* operations, such as correcting misspelled terms or removing numbers (Misuraca and Spano, 2018).

To reduce morphological variability, *lemmatization* was carried out, where each term was returned to its canonical form (verbs are returned to the present infinitive, nouns, and adjectives to the masculine singular). When texts have been pre-processed, it is possible to construct the so-called *vocabulary* by stacking identical terms and counting the number of occurrences of each vocabulary (type) in the document collection. To avoid uninformative terms, the vocabulary can be trimmed by removing so-called *stop-words*, i.e., the common terms used in the specific language and domain analysed (prepositions, conjunctions, etc.). For the same reason, rare terms with a low number of occurrences are usually removed from the vocabulary.

These phases returned a database composed of 2.819,642 tokens, 63,150 types and 214,469 documents. In the final stage of the pre-processing process, we applied the matrix vector space model of documents and words. Each document can be seen as a vector in *p*-dimensional vector space spanned by the terms belonging to the vocabulary. We created a term-document matrix, where *term frequency* is used to express the relative importance of each term in each document. Raw frequency weights are calculated as the number of occurrences of a term in a document and correspond to the absolute frequency. This system of weights results in the creation of a sparse matrix, which, in the case of NMF, leads to numerous problems with the interpretability of the result.

According to Yan et al. (2013), to reduce the sparsity of the term-document matrix, we transform it into a *co-occurrence* matrix, that represents the number of times two terms w_i and w_j co-occur together. For each pair of vectors, we define the *cosine* similarity measure that expresses the association of terms. Cosine similarity measures the similarity between two vectors of an inner product space. It is defined by the cosine of the angle between two vectors and determines whether two vectors are pointing in roughly the same direction. Thus, we created a similarity matrix, and we applied the symNMF to the similarity matrix for defining semantic clusters of terms.

4. Preliminary results

Specifically, we define four semantic clusters.

Table 1: Semantic clusters by SymNMF

Cluster 1	Cluster 2	Cluster 3	Cluster 4
Odd	Trample	Hypocrisy	Healthy
Prevent	Witness	Demand	Daughter
Process	Terrible	Duty	Disappoint
Progress	Upheld	Moral	Embarrassment
Miscarriage	Trash	Legalize	Disregard
Oppose	Violation	Fail	Harm
Overturn	Stripping	Democracy	Freedom
Practice	Norm	Jesus	Mother
Respect	Rights	Life	Children
Vote	Amendment	Church	Violence

From the analysis of the clusters extracted from the matrix, we noticed how there was a strong aversion to the outcome of the judgment. Table 1 shows the top ten terms associated with the clusters created.

We can see that the first cluster focuses on the narrative of the ruling and the reversal of the right to abortion. The Supreme Court overturned the ruling legalizing abortion, reaffirming that authority now reverts to the people and state representatives. All of this led to a strong outrage from Twitter users against the ruling, highlighting how the result will lead to negative consequences for the right to abortion. Through the overturning of the ruling numerous women's rights are going to be violated, primarily the freedom to choose one's own body and choose whether to continue the pregnancy. This is also interpreted in the second cluster, which highlights a number of terms such as 'trample', 'trash' and 'terrible' which indicate a strong aversion of online users to the decision taken.

Added to this are the users' criticism of the Catholic world and the church, pointing out how the church is hypocritical in not recognizing individuals who decide to have an abortion full legality. Abortion presents a profound moral issue, and the church and bishops have called the incident a "historic day" as defenders of the so-called "pro-life" movements. The rationale behind pro-life movements is to equate the gynaecological practice with the killing of an embryo, which acquires the status of a person at the moment of conception, and to consider abortion a highly damaging intervention for health.

The latest cluster created, however, shows parents' concern for their children's future. Users wonder what will happen after the ruling and hope that their children will be able to grow up in a state that

guarantees more rights than they had. And it is especially the issue of violence that creates discontent, as people are frightened and perplexed about the future of girls should they experience violence and have difficulty accessing abortion practices.

5. Conclusions

Nowadays, short texts have become an interesting form of text information, such as social media posts, question titles, and comments on posts. Short texts from the Internet are often extremely short, noisy, and ambiguous, imposing great challenges to clustering. The biggest difficulty is that each short text only holds very few word tokens.

This preliminary work aims to show how symNMF is an optimal technique for creating term clusters. About what has been analysed, it has been shown how Twitter users had a strong reaction to the overturning of the U.S. Roe v. Wade ruling by expressing strong criticism of the Supreme Court's choice.

For future developments, we are improving the level of efficiency in the construction of clusters by automatically defining the number of k clusters to be detected and adopting of specific metrics that effectively measure the quality of clusters.

Abstract

In observational studies, confounders may bias the estimates of the causal effects. Propensity score adjustment is commonly used to correct these estimates for such bias. The presence of missing data is another problem that often characterises the statistical analysis. The aim of our contribution is to discuss the performance of the four main methods for dealing with confounding based on the propensity score when combined with different techniques for imputing missing values according to the Multiple Imputation approach. The discussion will be based on the insight achieved from an extensive simulation study, which embraces multiple scenarios, on the estimation of the ATT.

Keywords: ATT, confounding, imputation, missing data, propensity score

1. Motivation and rationale

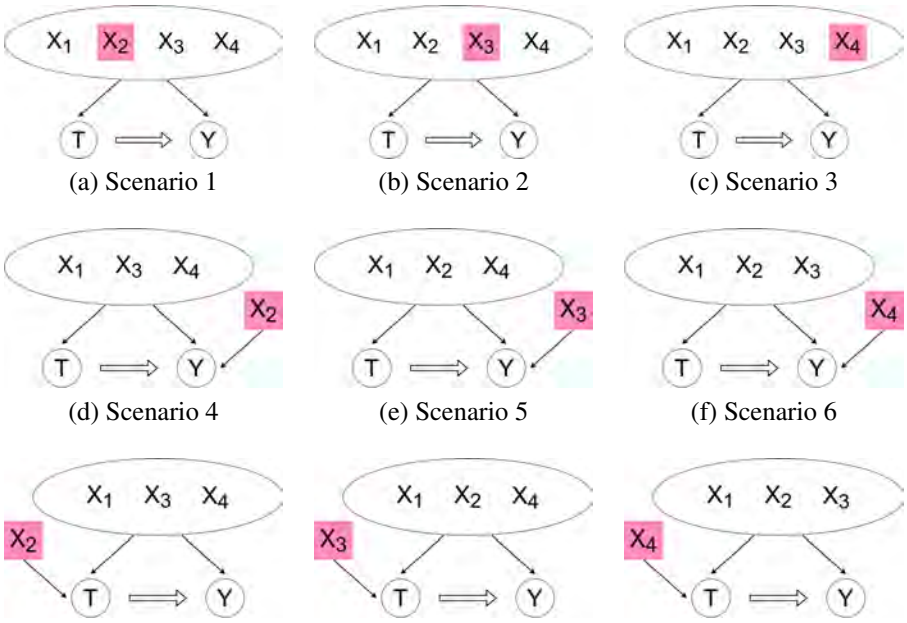
When observational or non randomised data are investigated, propensity score methods are powerful solutions to estimate causal treatment effects, as they minimise the influence of observed confounding variables (6). While this approach has been widely investigated in the literature, limited attention has been paid to the role of missing values in the covariates used to compute the propensity scores (3; 5).

By means of an extended and diversified simulation study, we aim at comparing the performance of the four main methods based on the propensity score to treat confounding, while taking different techniques of imputation of missing data into account. The motivation which inspired our work was suggested by an observational study on smokers who were discharged alive after being hospitalized with a diagnosis of acute myocardial infarction: the outcome variable is mortality within three years of hospital discharge, while the treatment was receipt of smoking cessation counseling prior to hospital discharge (1).

2. The simulation design

Nine different scenarios were investigated, summarised in Fig. 1. The following assumptions were made on the four covariates $X = (X_1; X_2; X_3; X_4)$:

- X_1 and X_2 are continuous, simulated from two independent normal distributions;
- X_3 is dichotomous, created from a Bernoulli distribution;
- X_4 is ordinal, assuming values $(1, 2, 3, 4)$ with probabilities $(0.3, 0.2, 0.4, 0.1)$, respectively.



(a) Scenario 1 (b) Scenario 2 (c) Scenario 3

(d) Scenario 4 (e) Scenario 5 (f) Scenario 6

(g) Scenario 7 (h) Scenario 8 (i) Scenario 9

Figure 1: Simulation scheme: Y binary response, T binary treatment, X_1 and X_2 continuous covariate, X_3 binary covariate, X_4 discrete covariate. In pink: covariate with missing values.

Treatment assignment

Let T be the dichotomous variable which assumes value 1 for those who received the treatment with probability π_T. Values of T were generated according to the following four different working assumptions:

Assumption A: Linear
$\text{logit}(\pi_T) = \alpha_1 X_1 + \alpha_2 X_2 + \alpha_3 X_3 + \alpha_4 X_4$
Assumption B: Quadratic with no interaction term
$\text{logit}(\pi_T) = \alpha_1 X_1 + \alpha_2 X_2 + \alpha_3 X_3 + \alpha_4 X_4 + \alpha_5 X_2^2 + \alpha_6 X_4^2$
Assumption C: Linear with interaction terms
$\text{logit}(\pi_T) = \alpha_1 X_1 + \alpha_2 X_2 + \alpha_3 X_3 + \alpha_4 X_4 + \alpha_7 X_1 X_3 + \alpha_8 X_2 X_4$
Assumption D: Quadratic with interaction terms
$\text{logit}(\pi_T) = \alpha_1 X_1 + \alpha_2 X_2 + \alpha_3 X_3 + \alpha_4 X_4 + \alpha_5 X_2^2 + \alpha_6 X_4^2 + \alpha_7 X_1 X_3 + \alpha_8 X_2 X_4$

with $(\alpha_1, \alpha_2, \alpha_3, \alpha_4, \alpha_5, \alpha_6, \alpha_7, \alpha_8) = (0.8, -0.25, 0.6, 0.4, 0.05, -0.25, 0.4, -0.15)$ in scenarios 1–3 and 7–9, while in scenarios 4–6 some parameters had to be assumed equal to 0:

- Scenario 4: $\alpha_2 = \alpha_5 = \alpha_8 = 0$
- Scenario 5: $\alpha_3 = \alpha_7 = 0$
- Scenario 6: $\alpha_4 = \alpha_6 = \alpha_8 = 0$.

Response variable

Let Y be a dichotomous outcome variable which assumes the value 1 for those who experience the event under investigation with probability π_Y. We simulated the outcomes according to

$$\text{logit}(\pi_Y) = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \beta_3 X_3 + \beta_4 X_4 + \gamma T,$$

where $(\beta_0, \beta_1, \beta_2, \beta_3, \beta_4) = (-1, 0.3, -0.25, 0.35, 0.5)$ and $\gamma = -0.7$ in scenarios 1–6. Similar to the simulation of treatment, the following assumptions had to be made to some parameters in the remaining scenarios:

- Scenario 7: $\beta 2 = 0$;
- Scenario 8: $\beta 3 = 0$;
- Scenario 9: $\beta 4 = 0$.

Missing values

We assume that only one explanatory variable at a time includes missing values, as illustrated by Fig. 1. For each condition, 50 fake datasets of sample size equal to 1,000 were generated.

3. Handling missing data

For each of the nine scenarios considered by our simulation study, the proportion of missing values was fixed at 40% of the sample size. Assuming a Missing-At-Random (MAR) mechanism, missing data were generated according to the amputation procedure proposed by (8). The amputation was repeated 10 times for each simulated dataset to take into account the variability inherent the procedure itself.

Following Rubin's (1987) methodology (7), Multiple Imputation (MI) was adopted. Each imputation was repeated 5 times for each simulated dataset, for a total of 500 fake datasets. Missing data were imputed following a MICE (Multiple Imputation by Chained Equations) approach by three different solutions: i) Predictive Mean Matching (PMM); ii) Weighted Predictive Mean Matching (WPMM); iii) regression imputation (REGRESS). According to the type of the variable with missing values, that is continuous, binary or discrete, a Bayesian linear model, a Bayesian logistic model or a proportional odds logistic model was adopted for the regression imputation solution, respectively. See (9) for further details on these procedures and their implementation in numerical computing environment R. All fully observed covariates were involved in each imputation model, while the outcome and treatment variables were excluded.

The single imputation approach, based on the unconditional mean imputation (MEAN) solution, was included in our analysis as a further comparison.

4. Propensity score methods

The individual propensity scores were estimated through a logistic regression model which includes all covariates. The Average Treatment Effect on Treated (ATT) was estimated using the four main different propensity score approaches (2): i) matching (to the nearest neighbour); ii) stratification (based on five strata obtained according to the quintiles of the estimated propensity scores); iii) covariate adjustment; iv) Inverse Probability of Treatment Weighting (IPTW) (according to Imbens' estimator (4)).

The propensity score methods were also benchmarked on the complete case analysis (CCA), that is by analysing the dataset where missing values are just deleted and not replaced.

5. Main results

Performance metrics

The performance of the different estimators were compared by means of their relative bias and mean squared error. For every combination of scenario, assumption, strategy used to handle missing data and propensity score adjustment method, let ATT_r be the true values of the ATT and $\widehat{\text{ATT}}_{r,i}$ be the estimates of the ATT for the $r = 1, \ldots, 50$ fake datasets and their $i = 1, \ldots, 10$ amputations. The average relative bias is defined as

$$\overline{\text{Bias}} = \frac{1}{50} \sum_{r=1}^{50} \left(\frac{\frac{1}{10} \sum_{i=1}^{10} \widehat{\text{ATT}}_{r,i} - \text{ATT}_r}{\text{ATT}_r} \right),$$

Table 1: Best and worst combinations of PS adjustment methods and missing data imputation techniques for Assumption A (linear relationship), by simulation scenario.

MI: Multiple Imputation (all methods). Imputation: all the multiple and single imputation methods

while the average mean squared error is

$$\overline{\text{EQM}} = \frac{1}{50}\sum_{r=1}^{50}\sqrt{\frac{1}{10}\sum_{i=1}^{10}\left(\widehat{\text{ATT}}_{r,i} - \text{ATT}_r\right)^2}.$$

Take-home messages

Generally, no specific combination worked markedly better or worse for all the nine investigated scenarios of Fig. 1. The largest differences were observed among the four propensity score adjustments rather than for the varying techniques to handle missing data. In terms of relative bias, it seems that stratification tends to produce the worst results, while covariate adjustment often outperforms the other three techniques. However, this cannot be generalised to all circumstances.

If we focus on the single simulation scenarios, lower performances in terms of bias are generally observed in the first three cases, that is when the missing data are present in a confounding variable. The effect of missing data in variables which are only predictors of treatment or of the response is null or minimal. Also the type of variable with missing values seems to have limited effects on the performance of the estimators. In particular, as far as the last six scenarios goes, that is, when the incomplete variable is either a predictor of treatment or of the response, there is almost no difference whether it is continuous, dichotomous or discrete.

Tables 1 and 2 highlight, for the two opposite Assumptions A ("additive and linear") and D ("quadratic with interaction terms"), the most efficient and the least performing combinations of propensity score adjustment and missing data imputation. In most cases, the best choice to treat confounding is covariate adjustment, while it is more difficult to provide general guidelines with respect to the treatment of missing data. According to relative bias, the best combination seems to be with complete case analysis when missing data are in confounding variables, and with multiple imputation in all other cases. However, if we focus on the mean squared error, multiple imputation shows better performances.

Table 2: Best and worst combinations of PS adjustment methods and missing data imputation techniques for Assumption D (quadratic with interaction terms' relationship), by simulation scenario.

Abstract

A new penalized estimator for sparse inference in Gaussian Graphical Models is proposed in this paper. It is based on the adaptive non-convex penalty function first presented in (4). In comparison to other estimators based on non-convex penalty functions, such as SCAD and MCP, the proposed estimator has a number of advantages because it allows controlling the degree of the non-convexity of the objective function through a second tuning parameter, which eliminates the inferential issues associated with the existence of multiple local minima. A simulation study is used to assess the proposed estimator's performance.

Keywords: Gaussian Graphical Models, high-dimensional data, non-convex penalty function, penalized inference, sparse inference

1. Introduction

Let X be a p-dimensional random variable with joint distribution $p(x)$ and let $\mathscr{V} = \{1,\ldots,p\}$ be the associated vertex-set. A *probabilistic graphical model* can be defined as the triplet $(X, p(x), \mathscr{G})$, where $\mathscr{G} = \{\mathscr{V}, \mathscr{E}\}$ is a graph whose edge-set $\mathscr{E}$ encodes the conditional dependence and independence structure among the p random variables, that is X_h and X_k are stochastically independent given the remaining random variables iff $(h,k) \notin \mathscr{E}$. For a comprehensive treatment of the probabilistic graphical models, the interested reader can refer, for example, to (9) and (11).

The Gaussian Graphical Models (GGM) are probabilistic graphical models based on the assumption that X follows a p-dimensional Gaussian distribution:

$$f(x;\mu,\Sigma) = (2\pi)^{-p/2}|\Sigma|^{-1/2}\exp\{-1/2(x-\mu)^\top\Sigma^{-1}(x-\mu)\}, \tag{1}$$

where μ is the vector of expected values of X, whereas Σ is the covariance matrix. The inverse of the covariance matrix, denoted by $\Theta = \Sigma^{-1}$, is called *precision matrix* and its off-diagonal elements, denoted as θ_{hk}, are the parametric tools by which density (1) factorizes according to the undirected graph $\mathscr{G}$, formally:

$$(h,k) \notin \mathscr{E} \Leftrightarrow X_h \perp\!\!\!\perp X_k \mid X_{\mathscr{V}\setminus\{h,k\}} \Leftrightarrow \theta_{hk} = 0.$$

The interested reader is referred to (9) for a proof. The problem of finding a parsimonious representation of the model (1) was originally studied in (5), and it is known in the literature as *covariance selection problem*.

2. Sparse inference via adaptive non-convex penalty function

Suppose that a set of n independent and identically distributed observations is drawn from the distribution (1) and denote the corresponding GGM by $\{X, f(x;\mu,\Theta),\mathscr{G}\}$, where $\mathscr{G}$ is the undirected graph whose edge set encodes the conditional independence structure among the p random variables. In principle, inference on the factorization of the density (1), and consequently on $\mathscr{G}$, can be carried out by maximizing the following profile log-likelihood function:

$$\ell(\Theta) = \log\det\Theta - \mathrm{tr}(S\Theta),$$

where S denotes the empirical covariance matrix. Then, the edge-set $\mathscr{E}$ the can be estimated by $\widehat{\mathscr{E}} = \{(h,k); \hat{\theta}_{hk} \text{ is significantly different from zero}\}$.

Although the procedure described above is theoretically well-founded, the application to real datasets is limited for two main reasons. Firstly, the number of measured variables is often larger than the sample size, implying the non-existence of the maximum likelihood estimator of the precision matrix. Secondly, the maximum likelihood estimator will exhibit very high variance even when the sample size is large enough. In terms of GGMs, this evidence translates into the assumption that Θ has a sparse structure; consequently, a number of authors have proposed a penalized approach to estimate Θ and $\mathscr{G}$ at the same time. We refer the interested reader to (1) for an extensive review of the more recent penalized methods proposed in the literature for GGMs.

Following the approach presented in (12), in this paper, we propose to estimate Θ and $\mathscr{G}$ using a penalized approach based on the usage of the non-convex penalty function introduced in (4). Formally, the proposed estimator is defined as follows:

$$\widehat{\Theta} = \arg\min_{\Theta\succ 0} -\ell(\Theta) + \rho \sum_{h,k=1}^{p} P(|\theta_{hk}|/\nu_{hk}), \tag{2}$$

where $\ell(\cdot)$ is the log-likelihood and $P(|\theta_{hk}|/\nu_{hk}) = \nu_{hk}\int_0^{|\theta_{hk}|/\nu_{hk}} \exp\{-x^2/2\}\mathrm{d}x$. In the proposed estimator, $\rho > 0$ is a tuning parameter aimed to control the amount of sparsity in $\widehat{\Theta}$ and, consequently, in the corresponding estimated graph $\widehat{\mathscr{G}} = \{\mathscr{V}, \widehat{\mathscr{E}}\}$, where $\widehat{\mathscr{E}} = \{(h,k) : \hat{\theta}_{hk} \neq 0\}$. When ρ is large enough, some $\hat{\theta}_{hk}$ are shrunken to zero resulting in the removal of the corresponding link in $\widehat{\mathscr{G}}$; on the other hand, when ρ is equal to zero, and the sample size is large enough, $\widehat{\Theta}$ coincides with the maximum likelihood estimator of the concentration matrix, which implies a fully connected estimated graph.

The additional parameter ν allows the penalty function to be flexible enough to mimic the widely popular penalty functions proposed in the literature, both convex (e.g. LASSO (10)) and non-convex ones (e.g. SCAD (6), MCP (13)). For example, noting that

$$\rho \lim_{\nu\to\infty} P'(|\theta_{hk}|/\nu_{hk}) = \rho,$$

we can conclude immediately that, for large enough ν-values, the results given by the proposed model are approximately equivalent to the one given by the graphical lasso (gLASSO) model (12).

Figure 1 shows the derivatives of the most well-known penalties and the proposed penalty in (4), for different values of ν. Graphically it is possible to notice how it is a trade-off between the L1 and L0 penalty, taking (in the middle) the form of a non-convex penalty.

As can be guessed from Figure 1, ν determines the degree of nonconvexity, thus affecting the presence of multiple local solutions, especially in contexts where the number of covariates is huge ((3; 7)). For sufficiently small values of ν and ρ, the uniqueness of the solution to the problem (2) is not guaranteed. As discussed in (4), it is possible (and easy) to find, for every value of ρ, the lowest value of $\nu_{min,\rho}$ such that the solution is unique having the highest degree of non-convexity. It is important to emphasize that the value ν_{min} is not to be understood as the best value to use (in terms of, e.g., minimizing the prediction error committed) but as the lower-bound of the search space for the optimal value of ν.

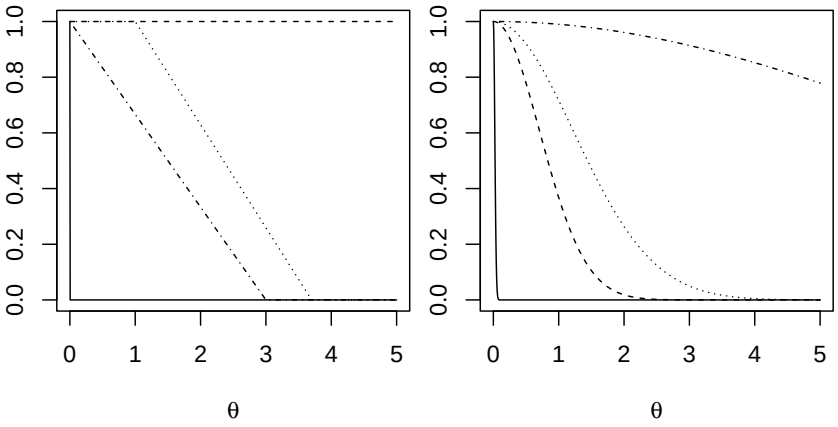

Figure 1: Plot of $P'(\cdot)$ functions over $\theta > 0$. Left panel: L0 (solid line), LASSO (dashed line), SCAD (dotted line, $\gamma = 3.7$) and MCP (dot-dashed line, $\gamma = 3$). Right panel ANP fixing ν at 0.001 (solid line), 1 (dashed line), 3 (dotted line) and 100 (dot-dashed line)

3. Computational Aspects: An efficient ADMM algorithm

In this section, we propose an efficient Alternating Direction Method of Multipliers (ADMM) methodologically grounded on the results given in (2). We begin redefining the solution of our minimization problem (2) as the solution of the following equality-constrained minimization problem, with matrix variables Θ and Z:

$$\begin{aligned} \min_{\Theta, Z \succ 0} \quad & -\ell(\Theta) + \rho \sum_{h,k=1}^{p} P\left(\frac{|Z_{hk}|}{\nu_{hk}}\right) \\ \text{s.t.} \quad & \Theta - Z = 0. \end{aligned}$$

According to the standard ADMM theory, the augmented scaled Lagrangian function takes the form:

$$\mathscr{L}(\Theta, Z, U) = -\ell(\Theta) + \rho \sum_{h,k=1}^{p} P\left(\frac{|Z_{hk}|}{\nu_{hk}}\right) + \frac{\tau}{2}\|\Omega - Z + U\|_F^2 - \frac{\tau}{2}\|U\|_F^2,$$

where $\tau > 0$ is a penalty parameter, $U \succ 0$ is the scaled dual matrix and $\|\cdot\|_F$ denotes the Frobenius norm, respectively. Using $\mathscr{L}(\Theta, Z, U)$, the solution of the initial minimization problem (2) can be computed through the following procedure:

1: **repeat**
2: $\quad \Theta^{k+1} = \arg\min_{\Theta \succ 0} -\ell(\Theta) + \frac{\tau}{2}\|\Theta - Z^k + U^k\|_F^2$,
3: $\quad Z^{k+1} = \arg\min_{Z \succ 0} \frac{\tau}{2}\|\Theta^{k+1} - Z + U^k\|_F^2 + \rho \sum_{h,k}^{p} P(|Z_{hk}|/\nu_{hk})$,
4: $\quad U^{k+1} = U^k + \Theta^{k+1} - Z^{k+1}$
5: **until** convergence criterion is met

As we shall show, the main advantage of the ADMM algorithm consists of the ability to split the initial complex problem into a series of simpler problems, each of which is easy to solve. In the remaining part of this section, we shall study in greater detail the minimization problems defined in Step 2 and 3.

Updating Θ. The problem in Step 2 has been studied in (2), where the authors show that the update of the precision matrix estimator admits the solution in closed form. To get more insight into the updating formula, consider the first-order optimality condition of the problem in Step 2, which can be rewritten in the following more convenient form:

$$\tau\Theta - \Theta^{-1} = \tau(Z^k - U^k) - S. \tag{3}$$

Let $Q\Lambda Q^\top$ be the spectral decomposition of $\tau(Z^k - U^k) - S$, then from the equation (3) we can immediately conclude that Θ^{k+1} can be written as $Q\widetilde{\Lambda}Q^\top$, where $\widetilde{\Lambda}$ is a diagonal matrix whose elements are the

solutions of the equation $\tau\widetilde{\Lambda} - \widetilde{\Lambda}^{-1} - \Lambda = 0$, that is:

$$\tilde{\lambda}_{ii} = \frac{\lambda_{ii} + \sqrt{\lambda_{ii}^2 + 4\tau}}{2\tau},$$

which are always positive since $\tau > 0$.

Updating Z. Before delving into the technical details related to the update of the matrix Z, we note that the objective function in Step 3 takes the following additive structure:

$$\frac{\tau}{2} \sum_{h,k=1}^{p} \left\{ (\theta_{hk}^{k+1} + U_{hk}^{k} - Z_{hk})^2 + \rho P\left(\frac{|Z_{hk}|}{\nu_{hk}}\right) \right\},$$

which implies that the minimization problem in Step 3 can be split into $p(p+1)/2$ univariate optimization problems that can be solved in parallel. Therefore, in the remaining part of this section, we shall focus on how to solve the subproblem:

$$Z_{hk}^{k+1} = \arg\min_{Z_{hk}} \frac{\tau}{2}(\theta_{hk}^{k+1} + U_{hk}^{k} - Z_{hk})^2 + \rho P\left(\frac{|Z_{hk}|}{\nu_{hk}}\right).$$

Following the approach presented in (4), we solve the problem above using the local linear approximation (LLA) method (14), that is, Z_{hk}^{k+1} is computed as solution of a sequence of new minimization problems involving a new objective function obtained replacing the penalty function with a suitable local approximation. Formally, Z_{hk}^{k+1} is obtained by the following iterative procedure:

1: Let $\widetilde{Z}_{hk}^{k}$ be a starting value
2: **repeat**
3: Let $w_{hk} = \exp\{-(\widetilde{Z}_{hk}^{k}/\nu_{hk})^2/2\}$
4: $\widetilde{Z}_{hk}^{k+1} = \arg\min_{\widetilde{Z}_{hk}} \frac{1}{2}(\theta_{hk}^{k+1} + U_{hk}^{k} - \widetilde{Z}_{hk})^2 + \frac{\rho}{\tau} w_{hk} |\widetilde{Z}_{hk}|$
5: **until** convergence criterion is met
6: Return $Z_{hk}^{k+1} = \widetilde{Z}_{hk}^{k+1}$

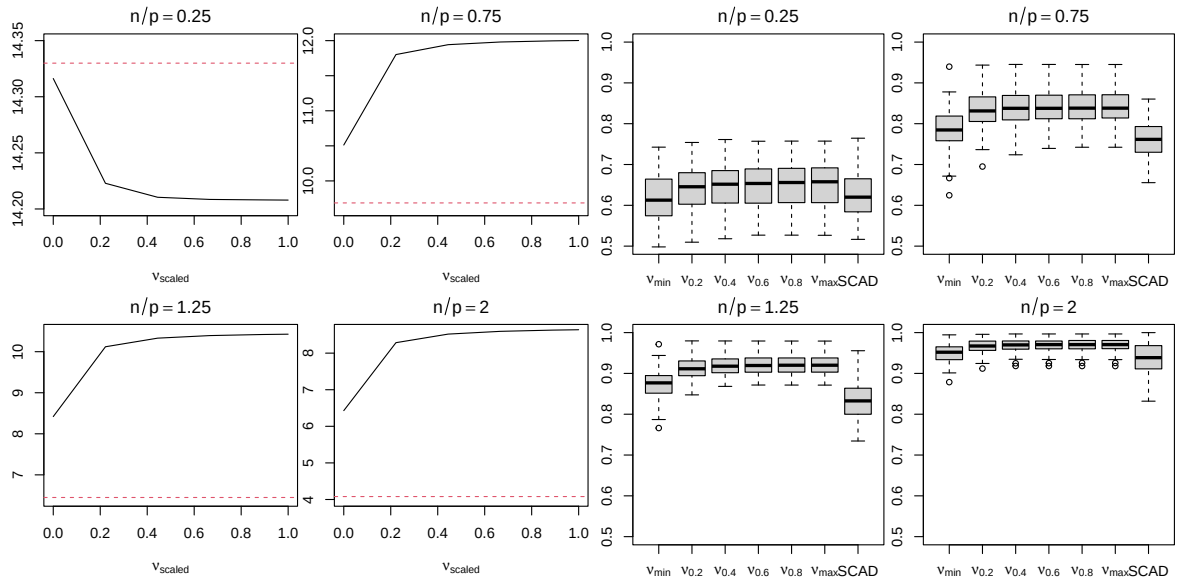
In Step 4, we immediately recognize a weighted lasso problem; therefore, using the results given in (8), we have that the updating step of $\widetilde{Z}_{hk}^{k+1}$ admits the following solution in closed form:

$$\widetilde{Z}_{hk}^{k+1} = S(\theta_{hk}^{k+1} + U_{hk}^{k}; \frac{\rho}{\tau} w_{hk}),$$

where $S(x;\lambda) = \text{sign}(x)(|x| - \lambda)_+$ is the soft-thresholding operator.

4. Simulation Study

We perform some simulation experiments to compare the behaviour of the estimator with that obtained using the SCAD penalty function. As discussed above, the gLASSO model is a limiting case of our proposal, i.e. as the tuning parameters ν go to infinity, the estimates given by the estimator (2) are asymptotically equivalent to those given by the gLASSO model. Therefore, in this study, we aimed to evaluate the effects of ν on the entire path of $\widehat{\Theta}$. Specifically, we used an evenly spaced sequence of six ν values, from ν_{min} to $\nu_{max} = 3$, where the largest ν value was chosen after a preliminary study to ensure that our estimates were approximately equal to those of GLASSO. To assess the effect of ν for different values of the ratio n/p, we set $p = 50$ and considered four different sample sizes, i.e. $n = (13, 38, 63, 100)$. To simulate a sparse precision matrix, we defined the edge set as a collection of J disjoint edge sets encoding star structures. Formally, $\mathscr{E} = \cup_{j=1}^{J} \mathscr{E}_j$, where $\mathscr{E}_j = \{(j,k) : k = (j+1), \ldots (j+k_j)\}$. In our setting, $k_j = 24$ and, consequently, $J = 2$. The corresponding off-diagonal entries of Θ are simulated using a uniform distribution on the interval $(0.65, 1)$. In contrast, diagonal entries are computed to make



(a) Frobenius distances (b) AUC

Figure 2: Frobenius distances (left panel) and AUC (right panel) for SCAD (red dotted line in the left panel) and our proposal varying ν.

the resulting precision matrix positively definite. For each possible combination of ν and n, we run 100 simulations.

The performance of the evaluated models is measured in terms of the accuracy of the graph structure recovery and the Frobenius distance between the estimated and the actual precision matrix. Regarding the first aspect, we summarise the coefficient paths using the AUC based on the ROC curves in each simulation run. Regarding the Frobenius distances, we take the minimum value of the total path of each estimator. We average the minima across replicates: in this way, we look at the best performance that all estimators can achieve.

Figure 2 (a) shows the curves of the Frobenius distances varying ν and the value obtained using the SCAD penalty. When the number of parameters is much larger than the number of observations, SCAD has the maximum average Frobenius distance. At the same time, it is observed that with our proposal, the distance decreases as ν increases (although the decrease is not large in absolute terms). As the ratio n/p increases, it is observed that the lowest value of the distance to the true matrix Θ is obtained with the smallest value of ν, i.e. ν_{min}. The advantage with respect to the opposite limit case (i.e. gLASSO) increases as the ratio n/p increases. Finally, by considering the capacity of the correct selection of non-zero coefficients (and thus the box plots of the AUCs), it is observed that our proposal always gives better results than SCAD. For different values of ν, the AUC tends to improve as the value of ν increases, but the differences decrease as the ratio n/p increases.

5. Conclusions

This paper presents a new penalized estimator for sparse inference in Gaussian Graphical Models. The estimator is based on an adaptive non-convex penalty function and can control the degree of non-convexity through a second tuning parameter ν, avoiding inferential issues associated with multiple local minima. The simulation study results show the proposed estimator's improved performance compared to non-convex penalty functions like SCAD. From the evaluations based on the simulations study, it can be seen that it may be crucial to propose a method for selecting the ν parameter, which certainly depends on the n/p ratio

Abstract

The notion of identifiability has a long history in the statistical literature, with econometrics providing the first theoretical contributions. On the one hand, within the frequentist paradigm, identifiability represents a critical issue to tackle, closely tied to the feasibility of the model estimation. On the other hand, identifiability issues in the Bayesian framework could be overcome by complementing the non-identifiable likelihood with additional prior beliefs summarized via an informative prior distribution. Unfortunately, since estimation is still feasible, unidentifiabily may remain unnoticed and silently hinder posterior consistency. This contribution provides a tool to inspect whether the model specification is weakly identified. Our procedure is based on estimating the intrinsic dimension of posterior samples. The methodology is illustrated with a simulated example.

Keywords: Identifiability, Intrinsic Dimension, Bayesian models, Monte Carlo Markov Chain.

1. Introduction

Identifiability plays a relevant role in the specification of statistical models. As the modeling complexity increases, identifiability issues are more likely to arise. Generally, a statistical model is identifiable in the standard parametric setting if the parameter values uniquely determine the data distribution and vice versa. In other words, given a model specification, it is possible to perform consistent inference on the parameters with the available data. Moreover, a model is *weakly identified* if the available data do not provide sufficient information to perform correct inferences, leading, for example, to very similar likelihood values in the maximum likelihood region, even if the one-to-one correspondence between likelihood and parameter values holds in that region.

Econometrics is an example of a research field in which identifiability plays a crucial role, originating a long research track on both its theoretical and applied sides. For example, the seminal paper [12] established a strong link between the information matrix and the identifiability of a statistical model under some regularity conditions on the data distribution. Moreover, the study introduced the notion of *local identifiability*, a form of identifiability restricted to open neighborhoods within the parameter space. Successively, [2] generalized this result to any distribution along with a very general criterion to study the identifiability of a specific parametric model based on the Kullback-Leibler divergence. Finally, the extension to non-parametric model specifications has been addressed in [11].

This branch of research has provided theoretically solid conditions for model identifiability. Unfortunately, checking these conditions on increasingly complex models is not immediate. Even worse, these

conditions are far from satisfied in modeling settings such as mixture, overparameterized, or spatial models. The problem of identifiability in mixture models is addressed in [5] and [10]. Other notable weakly identifiable models are latent variable models; see, for example, [9], and [1]. All these approaches are explicitly developed into a frequentist likelihood-based framework. The Bayesian approach could bypass the issue by the specification of informative priors. These priors can play the role of identifiability constraints, which are necessary to derive a well-defined posterior. However, the problem is not automatically solved but rather ignored. Because identifiability issues are not immediately apparent, there is the risk that, under the Bayesian framework, they are just overlooked.

Moreover, specifying informative priors to aid model estimation has consequences. Indeed, suppose we focus on frequentist properties of the Bayesian approach. In that case, if the prior is very informative, the posterior distribution of unidentified models could converge to a point mass that is not the true value. For this reason, highly informative priors would eventually lead to strongly biased inference.

In the Bayesian framework, weak identifiability could be present whenever the posterior distribution is "too" close to the prior according to some distributional. In particular, the marginal distributions of the non-identifiable parameters would not scale with the sample size and, consequently, will strongly impact the intrinsic dimension (id) of the posterior distribution support. We speculate that the id of the posterior distribution support could provide interesting insights into whether or not a specific set of parameters is identified, thus eventually representing an indication of some identifiability issues in the adopted model specification.

Although many definitions of id appeared in the literature, a fairly intuitive one is that the id is the dimension of the latent manifold on which the data-generating probability distribution has support. [3] is a comprehensive review of different approaches to id estimation. In this contribution, we focus on nearest-neighbor methods since they can effortlessly be embedded in a theoretically coherent modeling framework, allowing for uncertainty quantification of the estimates. As an example, [7] proposes a general and robust approach to id estimation based on ratios of distances between a unit and its nearest neighbors of arbitrary order. The intuition that motivates our proposal is based on the idea that weakly identified Bayesian models lack posterior consistency in the dimensions of the unidentified parameters.

The remainder of this contribution is organized as follows. In Section 2, we discuss the id estimation. Successively, in Section 3, we describe our methodology in more detail, providing some fundamental theoretical justifications and an example of application on a simulated scenario. We conclude the contribution with some final remarks in Section 4.

2. Intrinsic dimension estimation

Consider a dataset $\{\boldsymbol{x}_i\}_{i=1}^n$ with n observations and D observed features. Moreover, assume it is a realization from a Poisson process with a locally constant (or alternatively, locally homogeneous) intensity function. Define $r_{i,l}$ as the distance between unit i and its l-th nearest neighbor. Then, let n_1, n_2 be two integers with $n_2 > n_1$ and define the ratio $\mu_{i,n_1,n_2} = r_{i,n_2}/r_{i,n_1}$. In [7], the authors introduced the Gride model, proving that μ_{i,n_1,n_2} has density

$$f\mu_{i,n_1,n_2}(\mu) = \frac{d(\mu^d - 1)^{n_2-n_1-1}}{\mu^{d(n_2-1)+1}B(n_2-n_1, n_1)}, \quad \mu > 1 \tag{1}$$

where $B(\cdot,\cdot)$ is the Beta function and d is the id. This result elegantly generalizes the Two-NN estimator proposed in [8], since when $n_1 = 1$ and $n_2 = 2$, the density in (1) reduces to a $Pareto(1, d)$. These novel distributional results allow the derivation of efficient estimators for d in both the frequentist and Bayesian paradigms. In this contribution, we consider the unbiased maximum likelihood estimator of d, which has closed form when $n_1 = 1$ and $n_2 = 2$. Therefore, the Two-NN estimator is given by

$$\widehat{d} = \frac{n-1}{\sum_{i=1}^n \log(\mu_i)}, \tag{2}$$

with $1-\alpha$ confidence interval

$$\tau_{1-\alpha} = \left[\frac{\widehat{d}}{q_{IG_{n,n-1}}^{1-\alpha/2}}, \frac{\widehat{d}}{q_{IG_{n,n-1}}^{\alpha/2}} \right]$$

where $q_{IG}^{\alpha/2}$ denotes the $\alpha/2$-order quantile of the Inverse Gamma distribution. Alternatively, in the Bayesian framework, it suffices to set a prior $d \sim Gamma(a, b)$ and derive the posterior distribution

$$d|\mu_1, \ldots, \mu_n \sim Gamma\Big(a + n, b + \sum_{i=1}^{n} \log(\mu_i)\Big), \tag{3}$$

whose mean is asymptotically equivalent to (2). It must be pointed out that, if compared to the Gride estimator based on values of $n_2 > 2$, the Two-NN is more likely to satisfy the local homogeneity assumption of the Poisson process because it only uses information up to the scale of the second nearest neighbor of each statistical unit. On the other hand, it is potentially affected by the presence of noise in the data.

3. Identifiability and the intrinsic dimension of the posterior support

Let us introduce the following non-identifiable setting. To fix notation, let $\mathcal{Y}$ be a sample space and let $Y_1, \ldots, Y_N$, $Y_j \in \mathcal{Y}$ be a random sample whose generating process is described by some statistical model $\mathcal{M}_\theta$. Here, $\theta \in \Theta$ is a parameter vector which indexes the family $(\mathcal{M}_\theta)_{\theta \in \Theta}$. Suppose that the aim is to model $Y_1, \ldots, Y_N$ adopting a family of models $(\mathcal{G}_\lambda)_{\lambda \in \Lambda}$ with $\Theta \subset \Lambda$. Here, we assume $\dim(\Lambda) > \dim(\Theta)$. Since the function $f : \Lambda \times \mathcal{Y}^N \to \mathbb{R}^+$ is not injective once we condition on the sample $Y_1, \ldots, Y_N$, we can readily conclude that the model $\mathcal{G}_\lambda$ is not identified, since the likelihood $\ell(\lambda) := f(\lambda; Y_1, \ldots, Y_N)$ is flat on a set of Λ characterized by positive Lebesgue measure.

In the frequentist setting, this characteristic compromises the optimization procedure. On the Bayesian side, instead, one can always set a prior distribution over the parameter vector λ such that the posterior distribution is well-defined. This caveat allows posterior inference, being it exact or approximated using suitable sampling algorithms - such as Markov Chain Monte Carlo (MCMC) simulation. Since, under the Bayesian framework, unidentifiability does not have the same disruptive effects in the estimation as under the frequentist one, sometimes the model feasibility is taken for granted, leading to ignoring identifiability issues that may exist in the model specification.

To understand how a posterior is affected by the non-identifiability setting described above, let us split the parameter space into its identifiable and unidentifiable components: $\Lambda = \Lambda' \times \Lambda''$. Here, Λ'' is the non-identified component. If we let $\lambda|Y_1, \ldots, Y_N$ be the posterior random variable, it yields a marginal component $\lambda'|Y_1, \ldots, Y_N$ that degenerates to a constant as $N \to \infty$. This also implies that the id d of the support of $\lambda|Y_1, \ldots, Y_N$ converges to $\dim(\Lambda'') < \dim(\Lambda)$. In real settings, the posterior distribution is often not available in closed form, but it is possible to sample from it employing MCMC algorithms. In this case, the id d of the $n \times D$ matrix, where each row is a sample from the posterior, can be estimated using the methodologies previously presented in Section 2, bringing valuable insights on the identifiability of the model. Notice that here $D = \dim(\Lambda)$ and the id $d = \dim(\Lambda'')$.

Before proceeding to a simulated example, a cautionary note must be given. In well-identified models, when N is finite, we expect the id to be equal to $\dim(\Theta) = \dim(\Lambda)$. When $N \to \infty$, instead, the entire posterior converges to a point mass, resulting in a degenerate id equal to 0. This argument suggests that the id of the posterior distribution support is determined by the magnitude of variability each marginal component has w.r.t. each other. In an unidentifiable setting, we expect the variability to be much higher for the specific unidentified parameters set. Conversely, the well-identified model leads to a posterior distribution whose marginal components have variances of comparable scales for any N resulting in an id of $\dim(\Theta)$, although as $N \to \infty$ the variances vanish to 0 jointly with the id.

3.1 A simulated example

To provide a more concrete example, we consider the following simulated setting. Suppose we want to estimate a parameter vector $(\beta_0, \beta_1, \ldots, \beta_4)^\top \in \Lambda$ representing the coefficients of a regression line. According to the notation introduced above, $\mathcal{G}_\lambda$ is the linear model, while $\lambda = (\beta_0, \beta_1 \ldots, \beta_4)^\top$. We consider the following two data-generating processes:

$$Y_j = \beta_0 + \beta_1 + \beta_2 X_{2j} + \beta_3 X_{2j} + \beta_4 X_{4j} + \varepsilon_j, \quad j = 1, \ldots, N, \tag{4}$$

and

$$Y_j = \beta_0 + \beta_1 X_{1j} + \beta_2 X_{2j} + \beta_3 X_{3j} + \beta_4 X_{4j} + \varepsilon_j, \quad j = 1, \ldots, N. \tag{5}$$

We assume $X_{kj} \overset{ind.}{\sim} Unif\,[u_k, v_k]$ for $k = 1, \ldots, 4$, with $\boldsymbol{u} = (-2, -3, -4, 0)$ and $\boldsymbol{v} = (2, 3, 0, 6)$. Moreover, $\varepsilon_j \sim \mathcal{N}(0, 1)$ and, crucially, the priors are chosen to be highly non-informative $\beta_l \sim Cauchy(0, 10),\ l = 0, 1, \ldots, 4$.

Notice that model (4) is parametrized by a parameter vector whose dimension is smaller than $\dim(\Lambda)$ leading to the unidentifiability of some parameters. Thus, data generated from (4) do not allow the identification of $(\beta_0, \beta_1 \ldots, \beta_4)^\top$ and this makes the id of the support of the 5-dimensional posterior shrink to 2, which is the number of the unidentified parameters. On the other hand, we expect the id of the posterior distribution support obtained on data generated by (5) to be around 5 for finite sample sizes and 0 asymptotically in N. We must point out that the choice of non-informative priors allows a fast convergence of id to 2. Assuming informative priors could lead to incorrect conclusions about the id of the posterior and, consequently, on the identifiability of the model when the sample size is small.

To validate our hypothesis, posterior sampling is performed using efficient HMC algorithms available in the STAN software [4]. At the same time, the id estimation can be carried out via the routines in the R package `intRinsic` [6]. As a first step, we fit the model obtaining the Markov chains of the parameters. In detail, if we take an MCMC sample of $n = 1000$ and $N = 150$ statistical units, we obtain a Two-NN id estimate of 2.12 with 95% confidence interval $[1.99, 2.26]$ on model (4). On model (5), we obtain an estimated id of 4.87 with 95% confidence interval $[4.58, 5.18]$. If we instead use the Bayesian id estimator, setting a non-informative prior $d \sim Gamma(10^{-3}, 10^{-3})$ we get as posteriors a $Gamma(10^3 + 10^{-3}, 471.03 + +10^{-3})$ with mean 2.12 for model (4) and a $Gamma(10^3 + 10^{-3}, 205.22 + 10^{-3})$ with mean 4.87 for model (5). The posterior densities are reported in Figure 1. As expected, for finite sample sizes, the id of the support of the identifiable posterior is equal to the ambient dimension (i.e., 5) because all the marginal components are shrinking at the same rate to a point mass. The non-identifiable posterior scales with the sample size only in its identifiable marginals, while the non-identifiable ones do not scale with N and keep the variability induced by the prior distributions. This source of variability dominates the variability of the identified marginals. This last fact holds asymptotically and for finite sample sizes. Thus, the non-identifiable marginals determine an id of 2.

4. Conclusions

In this paper, we proposed an easy-to-use tool to detect identifiability issues in Bayesian models. The methodology is based on estimating the id of samples from the posterior distribution. The estimation of the id is carried out employing the Two-NN, a method that recently appeared in the literature. The simulated example shows that the id of the posterior sample is equal to the number of non-identified parameters. The presented results could be easily extended to other modeling settings, such as generalized linear models or mixture models.

Abstract

We investigate the problem of deriving highest density regions (HDRs) from multivariate data samples. We are interested in estimating minimum volume sets that contain a given probability. In the case of unknown distribution probabilities f, the problem involves their estimation, which may be challenging in multidimensional settings. Motivated by the ubiquitous role of copula modelling in modern statistics, we explore their use in the context of HDR estimation. Rather than directly estimating the multivariate f, we propose to estimate the marginals and their dependence structure, i.e., the copula structure, separately. We evaluate this new method, using both a parametric and a nonparametric approach, in a number of synthetic experiments and considering a real dataset.

Keywords: Highest density regions, Copula modelling, Kernel density estimation

1. Introduction

A ubiquitous problem in statistics is to derive statistical intervals or *regions* (in the multivariate setting) for population parameters or other unknown quantities. Given a random sample of data, they provide a way to quantify the uncertainty about a quantity of interest, or simply a way to summarize the information contained in a distribution. In this work, we are interested in statistical *regions* for summarizing probability distributions and we focus on one approach to addressing this problem: *highest density regions* (HDRs, 1). As the name suggests, an HDR specifies the set of points of highest density: the density for every point inside the region is greater than that for every point outside it. More specifically, as we will better discuss in Section 2, the concrete problem is to estimate minimum volume sets of the form $R(f_\alpha) = \{\mathbf{x}\colon f_{\mathbf{X}}(\mathbf{x}) \geq f_\alpha\}$, such that $P(\mathbf{X} \in R(f_\alpha)) \geq 1-\alpha$, where $f_{\mathbf{X}}$ is the probability distribution of the variable of interest $\mathbf{X} \in \mathbb{R}^d$ and $1-\alpha$, with $\alpha \in (0,1)$, a prespecified coverage probability. In principle, HDRs can be derived for any probability distribution and their scope can be widely different. The following are possible applications of HDRs.

Forecasting The goal is to obtain a "prediction region" for a set of observable variables in order to inform any required action (for illustrative examples, see e.g., 1; 2);

Anomaly detection The goal is to detect abnormal observations from a sample: if a data point does not belong to a region of normal or concentrated data, then it is regarded as anomalous (see e.g., 3);

Unsupervised or semi-supervised classification Identify areas or clusters with a relatively high concentration of a given phenomenon, e.g., areas with remarkably high coronavirus incidence (4).

Such regions are of interest in Bayesian analysis as well, in the formulation of *highest posterior density regions* and *credibility regions* (5; 6). In that context, they are based on a posterior distribution.

Because of their flexibility "to convey both multimodularity and asymmetry in the forecast density", HDRs are argued to be a "more effective summary of the forecast distribution than other common forecast regions" (1). However, to build an accurate HDR, one needs to know (or accurately estimate) the

underlying probability distribution. Methods for estimating f such as the kernel density estimator (KDE, 7) or the local likelihood approach (8) work very well for unidimensional problems, but they may be inefficient for multidimensional problems (9). For example, the bandwidth selection in KDE, recognized as the most crucial and difficult step (see e.g., Chapter 2 in 10), has no definite and unique solution. Further, high-dimensional data pose challenges also from the algorithmic/computational perspective. Altogether, these aspects hamper the ability to derive an appropriate HDR.

The scope of this work is to propose an alternative approach to build HDRs using *copulae* so as to overcome the direct estimation of the multivariate f. Specifically, copulae allow to relax the estimation of multivariate random vectors, by separately estimating the marginals and their dependence structure, i.e., the copula model (11). Motivated by the ubiquitous role of copula modelling in modern multivariate statistics, specifically multivariate density estimation, we explore its use the context of HDR estimation.

2. Problem Setting: Highest Density Regions

Assume we have access to a sample $\mathbf{s}_n = \{\mathbf{x}_1, \ldots, \mathbf{x}_n\}$ of independent and identically distributed (iid) observations, drawn from a probability measure $\mathbb{P}$. Each data point can be multidimensional, that is $\mathbf{x}_i \in \mathbb{R}^d$, with $d \geq 1$. We denote by $x_i^{(j)}$ the j-th coordinate of $\mathbf{x}_i$, for $j = 1, \ldots, d$ and $i = 1, \ldots, n$. For simplicity, we restrict our analysis to bivariate data points with $d = 2$, and we focus on continuous random variables $\mathbf{X} = (X^{(1)}, X^{(2)}) \in \mathbb{R}^2$. Let $f_{\mathbf{X}}$ denote the probability density function (PDF) of $\mathbf{X}$ and $F_{\mathbf{X}}$ its cumulative density function (CDF). Then, given a coverage probability $1-\alpha$, with $\alpha \in (0, 1)$, the $100(1-\alpha)\%$ HDR is defined as the subset $R(f_\alpha)$ of the sample space of $\mathbf{X}$ such that:

$$R(f_\alpha) \doteq \{\mathbf{x} \colon f_{\mathbf{X}}(\mathbf{x}) \geq f_\alpha\}, \tag{1}$$

where f_α is the largest constant such that $P(\mathbf{X} \in R(f_\alpha)) \geq 1 - \alpha$.

It follows from the definition that the boundary of an HDR consists of those values of the sample space with equal density. Hence a plot of a bivariate HDR is a form of contour plot. One of the most distinctive properties of HDRs is that, of all regions of probability coverage $100(1-\alpha)\%$, the HDR has the smallest region possible in the sample space. Clearly, an HDR always contains the global mode, and in the case of multimodal distributions, it often consists of several disjoint subregions, each containing a local mode. This provides useful information which is "masked" by other types of statistical regions.

To estimate an HDR for $\mathbf{X}$ according to Eq. (1), one needs to know the density function $f_{\mathbf{X}}$. If this is known, the typical way to compute HDRs is the density quantile approach (1), which is based on the following rationale. Let $\mathbf{Y} = f_{\mathbf{X}}(\mathbf{X})$ be the random variable obtained by transforming $\mathbf{X}$ by $f_{\mathbf{X}}$ (bounded and continuous in $\mathbf{x}$). Consider a set of independent observations from the distribution of $\mathbf{X}$, say $\mathbf{s}_m = \{\mathbf{x}_1, \ldots, \mathbf{x}_m\}$. It follows that independent observations from the distribution of $\mathbf{Y}$ can be obtained as $\{f_{\mathbf{X}}(\mathbf{x}_1), \ldots, f_{\mathbf{X}}(\mathbf{x}_m)\}$. Consider now the ordered sample $\{f_{(1)}, \ldots, f_{(m)}\}$ with $f_{(j)}$ the j-th largest of $f_{\mathbf{X}}(\mathbf{x}_i)$, $i = 1, \ldots, m$, so that $f_{(j)}$ is the (j/m) sample quantile of $\mathbf{Y}$. Then, given a constant $\alpha \in [0, 1]$, and denoted with $\lfloor \cdot \rfloor$ the floor operator, we have that:

$$\hat{f}_\alpha \doteq f_{\lfloor \alpha m \rfloor} \to f_\alpha, \quad \text{and} \quad R_m(\hat{f}_\alpha) \doteq \{\mathbf{x} \colon f_{\mathbf{X}}(\mathbf{x}) > \hat{f}_\alpha\} \to R(f_\alpha), \quad \text{as } m \to \infty.$$

Basically, the HDR can be derived based on the sample quantile of $\mathbf{Y} = f_{\mathbf{X}}(\mathbf{X})$.

However, in most real-world scenarios, the density function is unknown. If we have access to a sample of iid observations $\mathbf{s}_n = \{\mathbf{x}_1, \ldots, \mathbf{x}_n\}$, then we can estimate it, and subsequently obtain an estimate of the $100(1-\alpha)\%$ HDR by using the again the density quantile approach with

$$\hat{R}_n(\hat{f}_\alpha) \doteq \{\mathbf{x} \colon \hat{f}(\mathbf{x}) > f_{\lfloor \alpha n \rfloor}\}, \tag{2}$$

where $\hat{f}$ is a possibly consistent estimator of f.

Note that for small n it may not be possible to get a reasonable density estimate. Besides, with few observations and no prior knowledge of the underlying density function, there seems little point in attempting to summarize the sample space. In higher dimensions, the difficulty of selecting an appropriate region is even greater due to the density estimation challenges (see e.g., 9; 10).

3. Using Copulae for Deriving HDRs

A general d-dimensional copula $C\colon [0,1]^d \to [0,1]$ is a joint cumulative density function whose d marginals are uniform over $[0,1]$. Consider, without major loss of generality, the bivariate case $d=2$, with $F_{\mathbf{X}}$ the joint CDF of the random vector $\mathbf{X} = (X^{(1)}, X^{(2)})$, and $F_{X^{(1)}} = F_1$ and $F_{X^{(2)}} = F_2$ its marginals. Then, it follows from the *probability-integral transform* (12) that the joint distribution of (F_1, F_2) is a copula, say $C_{\mathbf{X}}$, and its expression can be derived by noting that

$$C_{\mathbf{X}}(u^{(1)}, u^{(2)}) = \mathbb{P}(F_1(X^{(1)}) \leq u^{(1)}, F_2(X^{(2)}) \leq u^{(2)}) = F_{\mathbf{X}}(F_1^{-1}(u^{(1)}), F_2^{-1}(u^{(2)})).$$

Letting $u^{(j)} \doteq F_j(x^{(j)})$, $j=1,2$, this yields the following result due to Sklar (13):

$$F_{\mathbf{X}}(x^{(1)}, x^{(2)}) = C_{\mathbf{X}}(F_1(x^{(1)}), F_2(x^{(2)})), \quad \forall \mathbf{x} = (x^{(1)}, x^{(2)}) \in \mathbb{R}^2.$$

In summary, we can decompose the bivariate CDF $F_{\mathbf{X}}$ into a composition of the two marginal distribution functions and a two-dimensional copula $C_{\mathbf{X}}$. $C_{\mathbf{X}}$ is the copula of $F_{\mathbf{X}}$ and describes the dependence structure of F_1 and F_2. We refer to (11) for book-length treatment of the foregoing ideas.

In case the bivariate distribution has density f, and if this is available, it holds further that

$$f_{\mathbf{X}}(x^{(1)}, x^{(2)}) = c_{\mathbf{X}}(F_1(x^{(1)}), F_2(x^{(2)}))f_1(x^{(1)})f_2(x^{(2)}),$$

with c being the copula density and f_1 and f_2 the marginal densities. The main advantage of this representation over the one involving the joint PDF is that an estimate of $f_{\mathbf{X}}$ can be obtained by estimating the marginals and the copula density separately, evading potential high-dimensional data challenges (see e.g., 14). Furthermore, copulae offer a flexible framework that can capture complex dependency structures.

If $\hat{c}$ is an estimate of the copula density, we propose to estimate the $100(1-\alpha)\%$ HDR as

$$\hat{R}_n(\hat{f}_\alpha) = \{\mathbf{x}\colon \hat{c}_{\mathbf{X}}(\hat{F}_1(x^{(1)}), \hat{F}_2(x^{(2)}))\hat{f}_1(x^{(1)})\hat{f}_2(x^{(2)}) > f_{\lfloor \alpha n \rfloor}\},$$

with $\hat{f}_j$ and $\hat{F}_j$ consistent estimators of the marginals f_j and F_j, $j=1,2$. While here, for the sake of space, we focus on the bivariate case, we emphasize that the approach can be easily extended to higher dimensions, as copulae naturally apply to multidimensional contexts (see e.g., *vine copula* methods; 14).

4. Empirical Evaluation

Simulation studies We start with simulation studies, considering the following four data-generation scenarios, with constant parameters fixed at $\mu_1 = 0, \mu_2 = 1, \sigma_1 = \sigma_2 = 2$, and $w_1 = 1 - w_2 = 0.7$ over an increasing number of sample sizes (from 50 to $10,000$). For copula specifications, we refer to (11).

SC1: Gaussian marginals $\mathcal{N}$ – Gaussian copula C^{Gauss}

$$f_1 = \mathcal{N}(\mu_1, \sigma_1), \quad f_2 = \mathcal{N}(\mu_2, \sigma_2), \quad C = C^{\text{Gauss}}_{\rho=0.7}$$

SC2: Gaussian $\mathcal{N}$ & Student t marginals – Clayton copula C^{Clay}

$$f_1 = \mathcal{N}(\mu_1, \sigma_1), \quad f_2 = t_{\nu=10}, \quad C = C^{\text{Clay}}_{\alpha=2}$$

SC3: Gaussian $\mathcal{N}$ & Gaussian mixture marginals – Student t copula C^{t}

$$f_1 = \mathcal{N}(\mu_1, \sigma_1), \quad f_2 = w_1\mathcal{N}(\mu_2, \sigma_2) + w_2\mathcal{N}(\mu_2 + 10, \sigma_2), \quad C = C^{\text{t}}_{\rho=0.4,\nu=6}$$

SC4: Gaussian $\mathcal{N}$ mixture marginals – Gaussian copula C^{Gauss}

$$f_1 = w_1\mathcal{N}(\mu_1, \sigma_1) + w_2\mathcal{N}(\mu_1 + 10, \sigma_1), \quad f_2 = w_1\mathcal{N}(\mu_2, \sigma_2) + w_3\mathcal{N}(\mu_2 + 10, \sigma_2), \quad C = C^{\text{Gauss}}_{\rho=0.7}.$$

For each scenario, we evaluate the following three methods.

Method1: Direct estimation of the bivariate density We use the nonparametric KDE (7), and consider the asympotically optimal solution proposed in (15) for the bandwidths selection.

Method2: Indirect fully-parametric copula-based estimation of the bivariate density For the estimation of the marginals, we consider the true data-generation processes models (with no misspecification) and maximum likelihood fitting. For the copula model, we perform both model selection (with the AIC criterion) and parameter estimation (with maximum likelihood estimation).

Method3: Indirect fully-nonparametric copula-based estimation of the bivariate density For the marginal densities, we use the standard KDE. For the copula model, we use a KDE approach with the *transformation local likelihood estimator* of (16). We use the R KDECOPULA package, adopting the method with quadratic polynomials and nearest-neighbor bandwidths (17).

To quantify the performance of the methods in the simulation study, we call *positive* those points which should be outside the region and *negative* the others. Let FP, TP, FN and TN be, respectively, the number of false positive, true positive, false negative, and true negative points. Well-established measures of inefficiency are the False Negative (Positive) Rates (FNR and FPR), and the Total Error Rate (ER):

$$\text{FNR} = \frac{FN}{FN+TP}; \quad \text{FPR} = \frac{FP}{FP+TN}; \quad \text{ER} = \frac{FN+FP}{FN+FP+TN+TP}.$$

All methods are evaluated based on $\alpha = 0.05$, that is a coverage probability of 95%.

Results As depicted in Figure 1, the three methods lead to slightly different results, with the two copula-based approaches outperforming the direct KDE (Method1). Compared to the nonparametric Method3, the parametric copula-based approach (Method2) shows the lowest ER across all different scenarios and sample sizes, with an exception for the largest sample sizes, where the difference is negligible.

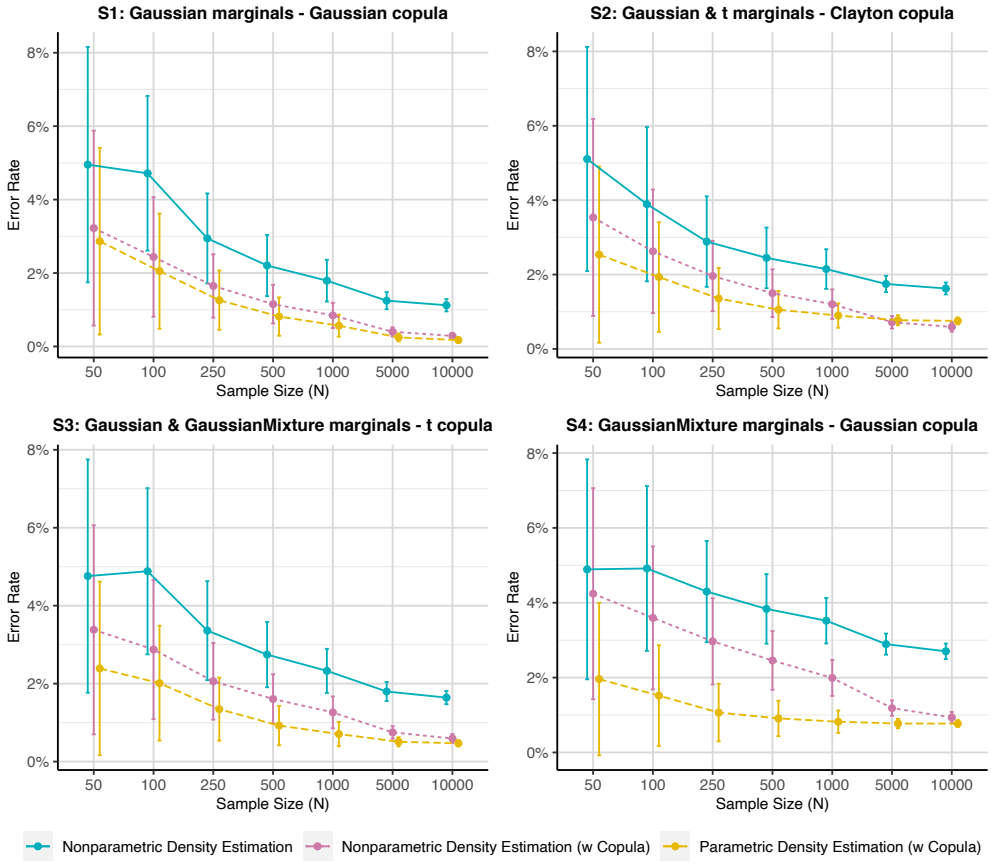

Figure 1: Total error rate (mean and error bars (mean $\pm$ SD), averaged across 10^4 MC samples) of the three compared methods across the different scenarios and for different sample sizes.

Looking at the FPR and FNR, results are very similar across different scenarios and we only discuss scenario S2. As displayed in Figure 2, Method1 has the best FPR performance, with a value close to 0. Rather than being a result of optimal performance, this is due to the fact almost or all data points were classified as highest density points, with no *positives* detected. This is also reflected in its FNR, highlighting a low ability to correctly place *positives* outside the HDR. The two copula-based approaches result in overall better performances, with a slight superiority of the parametric Method2. This was expected as simulation schemes consisted of only parametric copula families, and there is no misspecification.

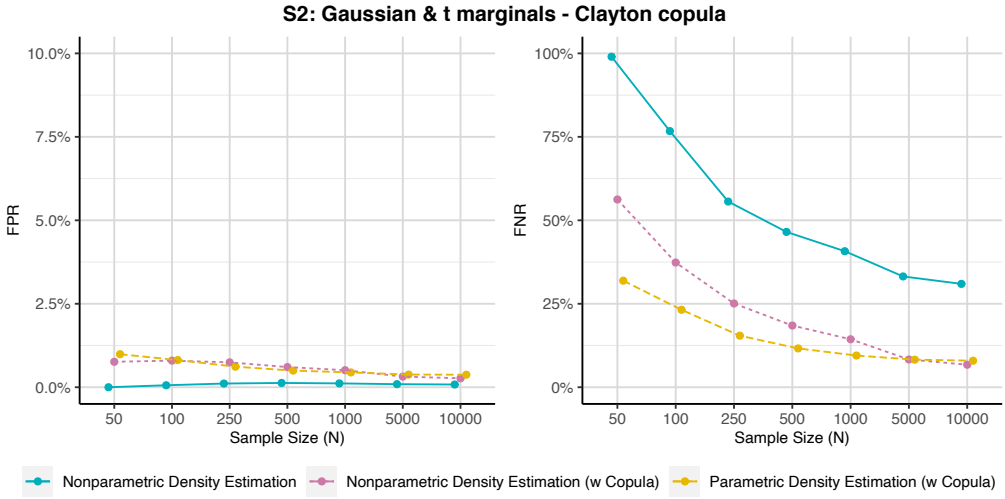

Figure 2: FPR and FNR (averaged across 10^4 MC samples) of the three compared methods for different sample sizes, relatively to scenario S2.

Application to MAGIC Data We apply the proposed methods for constructing a HDR for the joint distribution of two variables from the MAGIC dataset (https://archive.ics.uci.edu/ml/datasets/MAGIC+Gamma+Telescope). The data simulate the registration of high-energy gamma particles in a ground-based atmospheric Cherenkov gamma telescope. We focus on gamma observations (overall $n = 12,332$), and consider the two variables "fConc1" and "fM3Long". In such a case (as deduced from Figure 3), the parametric approach is inappropriate for both the estimation of the marginal distribution and, more importantly, the copula model. Thus, we illustrate the derived HDR using the nonparametric Method1 and Method3 only. While in absence of the underlying truth it is not possible to reliably evaluate the two methods, it seems that the copula-based approach (Method3; right plot), more sensibly excludes the tail data points (which may be expected to have a lower density) from the HDR.

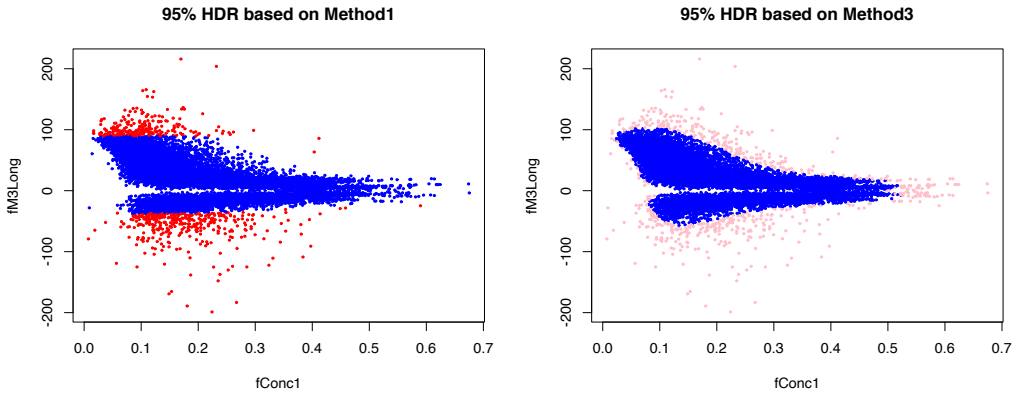

Figure 3: 95% HDR for two variables from the MAGIC dataset with Method1 and Method2.

5. Concluding Remarks

In this work, we proposed an alternative strategy for deriving HDRs in multivariate contexts using *copulae*, and evaluated both a parametric and a nonparametric approach. Compared to traditional kernel density estimation, the copula-based HDR resulted in lower missclasification errors in a number of simulation scenarios and possibly in real data. Although in this work we focused on the bivariate case ($d = 2$), we expect to see remarkable advantages over an increased number of variables $d > 2$. In fact, the extension of the common KDE to high dimensions has proven challenging in terms of both computational efficiency and statistical inference. We aim to pursue such a direction in future work, exploring, e.g., the use of vine copulae to construct flexible dependence models for an arbitrary number of variables using only bivariate building blocks.

Abstract

Multivariate circular observations, i.e. points on a p-dimensional torus, can be seen as random angular quantities. A way to model this kind of observation is using the multivariate wrapped normal distribution. In this paper, we tackle the problem of estimating the multivariate wrapped normal distribution parameters using a given set of samples. Here we focus on the parameters in the variance-covariance matrix that characterize the dependence among the variables of interest. For this purpose, we propose an Indirect Inference approach that relies on a Normal auxiliary model defined on the real space with the same dimension as the target model's parameter space. This approach provides an efficient and accurate estimation method for the parameters of the multivariate wrapped normal distribution.

Keywords: Indirect Inference; Multivariate directional data; Multivariate Wrapped Normal; Statistical computation and simulation.

1. Introduction

In a wide variety of fields, including natural and physical sciences, measurements involve directions and can be characterized as random angular quantities. Such data are commonly referred to as *directional data*, and their analysis and understanding rely on specific statistical models and procedures for non-Euclidean space; see e.g. Mardia and Jupp (2000) (12); Jona Lasinio and Gelfand (2012) (10). Several approaches have been proposed in the literature for defining distributions for directional data, including the embedding, intrinsic, and wrapping approaches, which are widely used and relevant for analyzing directional data. In the embedding approach, the sample space is obtained by radial projection of a distribution on the real space, onto the unit circle. In the intrinsic approach, the directions are represented as points on the circle, and probability distributions are defined on the circle directly. Instead, the wrapping approach constructs circular random variables as the modulo 2π version of real random variables. The circular distribution is obtained by wrapping the corresponding real distribution on the p-torus $\mathbb{T}^p$, the cartesian product of p circles. For each approach, several distributions have been proposed. In a multivariate setting, the most popular proposals are respectively the *Inverse Stereographic Gaussian* distribution (IS), see e.g. Selvitella (2019) (16), the *Von Mises* (VM) and the *Wrapped Normal* (WN).

In directional statistics, the VM and the WN distributions often play a similar role as the Normal distribution on the real space. The most used distribution, in the univariate framework, is the VM due to the analytical tractability of the maximum likelihood estimators. In the case of a high concentration

of the univariate distributions around the mean, both the VM and the WN can be approximated as Gaussian distributions, and they are a good approximation of each other. In the multivariate framework, both distributions present major problems with maximum likelihood estimation. The VM multivariate distribution has an unknown normalizing constant, and, as suggested by Mardia (2016) (13), inference can be achieved via the score-matching estimator, see e.g. Yu, Drton, and Shojaie (2022) (17). Conversely, likelihood-based inference for the WN distribution presents major difficulties as it involves infinite sums. In literature, among the main approximate inference methods for the parameters inference of a WN distribution, we can mention the iterative reweighted maximum likelihood estimating equation algorithm for univariate WN, also available in the R package `circular`, proposed by Agostinelli (2007) (1); the two steps Expectation-Maximization algorithm proposed by Fisher and Lee (1994) (8), recently generalized and improved by Nodehi et al., (2021) (14); the combination of maximum likelihood and moment matching proposed by Kurz and Hanebeck (2015) (11); the data augmentation approach in a Bayesian framework proposed by Coles (1998) (6) and Ravindran and Ghosh (2011) (15). This leads to the main goal of this paper: proposing an alternative parameter estimation approach for both univariate and multivariate WN distributions using Indirect Inference. Indirect Inference (II), see e.g. Gourieroux, Monfort, Renault (1993) (9), is a powerful simulation-based method for estimating parameters in complex statistical models whose likelihood is, for some reason, intractable. The method entails simulating data from an auxiliary model, whose likelihood is tractable, and then estimating parameters in the target model using an auxiliary criterion on the simulated data. Interesting use of the Indirect inference method for GARCH-type models can be found in Calzolari, Halbleib, and Parrini (2014) (4); Calzolari and Halbleib (2018) (5). Another application of this method can be found in Bee's (2022) (2) work on the wrapped stable distribution.

The remainder of this paper is organized as follows. Section 2. describes the multivariate WN model. Section 3. describes the II procedure in a general framework and introduces a possible application for inference on WN models. Section 4. gives final comments and remarks.

2. Wrapped Normal distribution

Given a discrete or continuous random variable $\boldsymbol{X}$ defined on $\mathbb{R}^p$ and its cumulative distribution function (CDF) G, the wrapped counterpart is defined as $\boldsymbol{Y} = \boldsymbol{X}\ (mod\ 2\pi)$, where the modulo is applied component-wise, and the corresponding wrapped CDF is

$$F(\boldsymbol{y}) = \sum_{\boldsymbol{j}\in\mathbb{Z}^p} \left[G(\boldsymbol{y} + 2\pi\boldsymbol{j}) - G(2\pi\boldsymbol{j})\right], \qquad \boldsymbol{y} \in [0, 2\pi)^p.$$

Similarly, for any r.v. X admitting a density function g, the wrapped version of the density function can be defined as

$$f(\boldsymbol{y}) = \sum_{\boldsymbol{j}\in\mathbb{Z}^p} g(\boldsymbol{y} + 2\pi\boldsymbol{j}), \qquad \boldsymbol{y} \in [0, 2\pi)^p.$$

The support of the resulting wrapped random variable is the p-torus $\mathbb{T}^p$ and its wrapped density function f is obtained from the density function g wrapping the $\mathbb{R}^p$ space on $\mathbb{T}^p$ and summing the densities of all identified points component-wise.
In this framework, a multivariate Wrapped Normal distribution is obtained by choosing $\boldsymbol{X} \sim N_p(\boldsymbol{\mu}, \boldsymbol{\Sigma})$. Consequently, the random variable $\boldsymbol{Y} = \boldsymbol{X}\ (mod\ 2\pi)$ has a multivariate Wrapped Normal distribution $WN_p(\boldsymbol{\mu}, \boldsymbol{\Sigma})$, with the exact same parameters as $\boldsymbol{X}$. Due to the model definition, the mean vector parameter is not identifiable: the parameter $\boldsymbol{\mu}$ is expressed as $\boldsymbol{\mu} = \boldsymbol{\mu}^* + 2\pi\boldsymbol{j}$, where $\boldsymbol{\mu}^*$ is the mean direction and a parameter on $[0, 2\pi)^p$ and, since the winding number j is not observed, it is impossible to identify $\boldsymbol{\mu}$. However, $\boldsymbol{\mu}^*$ is identifiable. In this paper, we focus on estimating the variance-covariance matrix, limiting to the case of a moderately large total variance. For very large variances, the WN distribution converges to a circular uniform distribution on the p-torus, and its parameters are not defined. The WN density distribution is defined as an infinite series and has no closed form, making it impossible to obtain

parameter estimates via direct maximization of the WN likelihood. Thus, different techniques must be used.

3. Indirect Inference for Wrapped Normal models

In this section, we first introduce the indirect inference estimating procedure for a general model and then concentrate on the case of the wrapped normal distribution.

Consider a multivariate random variable $\boldsymbol{Y}$ with values in $\mathcal{Y}$ and let $\mathcal{M}(\boldsymbol{\theta})$ be an adequate model for it, admitting a density function f, that depends on a vector of parameters $\boldsymbol{\theta} = (\boldsymbol{\theta}_1, \ldots, \boldsymbol{\theta}_K)$. Suppose that $\mathcal{M}(\boldsymbol{\theta})$ is associated with a complex or intractable likelihood, but such that drawing random samples from $\mathcal{M}(\boldsymbol{\theta})$ is feasible once given a set of values $\boldsymbol{\theta}$. Let $\widetilde{\mathcal{M}}_a(\boldsymbol{\beta})$ be an auxiliary model with density f_a and parameters $\boldsymbol{\beta} = (\boldsymbol{\beta}_1, \ldots, \boldsymbol{\beta}_K)$ that are easy to estimate.

To provide estimates for $\boldsymbol{\theta}$, the Indirect Inference method utilizes the auxiliary model $\widetilde{\mathcal{M}}_a(\boldsymbol{\beta})$, which is miss-specified and whose approximated maximum likelihood estimator can be inconsistent for $\boldsymbol{\theta}$. Using data simulated from the original model $\mathcal{M}(\boldsymbol{\theta})$, it is possible to correct the asymptotic bias under the hypothesis of the existence of an unknown bijective function between the two parameter spaces. Such a function is called *binding function* $b : \boldsymbol{\theta} \to \boldsymbol{\beta}(\boldsymbol{\theta})$. The choice of the auxiliary model impacts the functional form of the binding function and, thus, the properties of the estimators. The estimation of the auxiliary model parameters is conducted using both observed data and simulated samples generated from the original model $\mathcal{M}(\boldsymbol{\theta})$. The parameter estimates for $\mathcal{M}(\boldsymbol{\theta})$ are obtained via a calibration procedure that involves a comparison between the estimates obtained from the two aforementioned sources of auxiliary model information.

Now, consider the case of the wrapped normal distribution $\mathcal{M}(\boldsymbol{\theta}) = WN_p(\boldsymbol{\mu}^*, \boldsymbol{\Sigma})$. We propose to adopt precisely the Normal distribution as a suitable choice for the auxiliary model $\widetilde{\mathcal{M}}_a(\boldsymbol{\beta}) = N_p(\boldsymbol{\mu}^*, \boldsymbol{\beta})$, due to the intrinsic connection between the two models and the existence of closed-form, easy-to-compute, estimators for this auxiliary model. This is a case of so-called *exact identification*, with a one–to–one correspondence between the parameters $(\boldsymbol{\mu}^*, \boldsymbol{\Sigma})$ versus $(\boldsymbol{\mu}^*, \boldsymbol{\beta})$. The mean vector $\boldsymbol{\mu}^*$ can be estimated using the circular mean, as suggested by Mardia and Jupp (2000) (12). Thus, for sake of simplicity, we assume $\boldsymbol{\mu}^*$ known and we define $\boldsymbol{\theta}$ as the parameters vector of $\boldsymbol{\Sigma}$.

The II estimation procedure can be summed up in the following three steps.

(1) **PML**: Compute $\widehat{\boldsymbol{\beta}}$, the *Pseudo-Maximum-Likelihood* estimate of $\boldsymbol{\Sigma}$, using the variance-covariance matrix maximum likelihood estimator for the auxiliary model $\widetilde{\mathcal{M}}_a(\boldsymbol{\beta}) = N_p(\boldsymbol{\mu}^*, \boldsymbol{\beta})$ and using independent and identically distributed random sample $\mathbf{y} = (\mathbf{y}_1, \ldots, \mathbf{y}_n)$ from the model of interest $\mathcal{M}(\boldsymbol{\theta}) = WN_p(\boldsymbol{\mu}^*, \boldsymbol{\Sigma})$:

$$\widehat{\boldsymbol{\beta}} = \frac{\sum_{i=1}^{n} (\mathbf{y}_i - \boldsymbol{\mu}^*)^T (\mathbf{y}_i - \boldsymbol{\mu}^*)}{n},$$

The simple estimation of the auxiliary model parameters leads to biased (inconsistent) estimates, called *naive estimates*. Nevertheless, since all the random vectors $\mathbf{y}_i$ are sampled from $WN_p(\boldsymbol{\mu}^*, \boldsymbol{\Sigma})$, they hold large information content about $\boldsymbol{\Sigma}$, thus the equation above gives an implicit relation between $\boldsymbol{\Sigma}$ and $\boldsymbol{\beta}$, pseudo-true value, and the unknown binding function $\boldsymbol{\beta}(\boldsymbol{\Sigma})$ is necessarily related to the equation above.

(2) **Simulation**: Simulate R samples $\mathbf{y}^{(1)}, \ldots, \mathbf{y}^{(R)}$ of size n from the *true* model $WN_p(\boldsymbol{\mu}, \boldsymbol{\Sigma})$ and compute $\widetilde{\boldsymbol{\beta}}^{(1)}, \ldots, \widetilde{\boldsymbol{\beta}}^{(R)}$, R naive estimates. Regarding the size of the simulated samples, one may adopt a number n^* equal to the observed sample size n. Larger n^*, such as, for instance, $n^* = H \cdot n$, with a certain integer $H \geq 1$, can be adopted to improve estimates precision. In most available applications of II, the value of H has usually been chosen between 10 and 100, and the main reason is that for larger H, the estimator variance of the indirect estimator is smaller. Whether a much larger value of H is used (between 500 and 1000), it is possible to obtain a smoother function $\widetilde{\boldsymbol{\beta}}(\boldsymbol{\Sigma})$, numerically closer to a continuous function.

(3) **Estimation**: Estimate of $\widehat{\boldsymbol{\Sigma}} := \widehat{\boldsymbol{\Sigma}}(\boldsymbol{\beta}(\boldsymbol{\Sigma}))$ is obtained as solution of the optimization problem

$$\min_{\boldsymbol{\Sigma}} ||(\widehat{\boldsymbol{\beta}} - \widetilde{\boldsymbol{\beta}}^{(r)}(\boldsymbol{\Sigma}))||.$$

It is worth noting that the arbitrary choice of the Euclidean norm is possible because the parameter vectors of the true and auxiliary models have the same dimension. Whenever the number of parameters of the auxiliary model is greater than the one of the true model, the estimation is dependent on the choice of the norm induced by a positive definite matrix. The tentative values for the true model parameters $\boldsymbol{\Sigma}$ are chosen iteratively until the equality $\widehat{\boldsymbol{\beta}} = \widetilde{\boldsymbol{\beta}}^{(r)}(\boldsymbol{\Sigma}))$ is fulfilled. This iterative procedure for choosing tentative values of $\boldsymbol{\Sigma}$ is called *calibration*.

Generally, an analytic solution for the optimization problem in the Estimation step does not exist and the II estimator cannot be written in closed form. However, as proposed by Calzolari et al., 1999 (3), the problem can be solved numerically, by adopting as updating equation at the i-th step

$$\widehat{\boldsymbol{\Sigma}}_i = \widehat{\boldsymbol{\Sigma}}_{i-1} - \delta * \left(Jac(\boldsymbol{\beta}(\boldsymbol{\Sigma}))|_{\widehat{\boldsymbol{\Sigma}}_{i-1}} \right)^{-1} (\widehat{\boldsymbol{\beta}} - \widetilde{\boldsymbol{\beta}}(\widehat{\boldsymbol{\Sigma}}_{i-1})).$$

where

- $\widehat{\boldsymbol{\Sigma}}_i$ is the value of the calibrated parameters after i iterations;
- δ is a scale constant in $[0, 1]$, which reduces the step size in the given direction;
- $\left(Jac(\boldsymbol{\beta}(\boldsymbol{\Sigma}))|_{\widehat{\boldsymbol{\Sigma}}_{i-1}} \right)^{-1}$ is the inverse of the Jacobian matrix, evaluated in the $(i-1)$-th parameter estimate and it determine the direction of the i-th step.
  The derivatives are computed numerically by finite difference method.

For a better understanding of the iterative implementation, the numerical procedure is summarized in Figure 1.

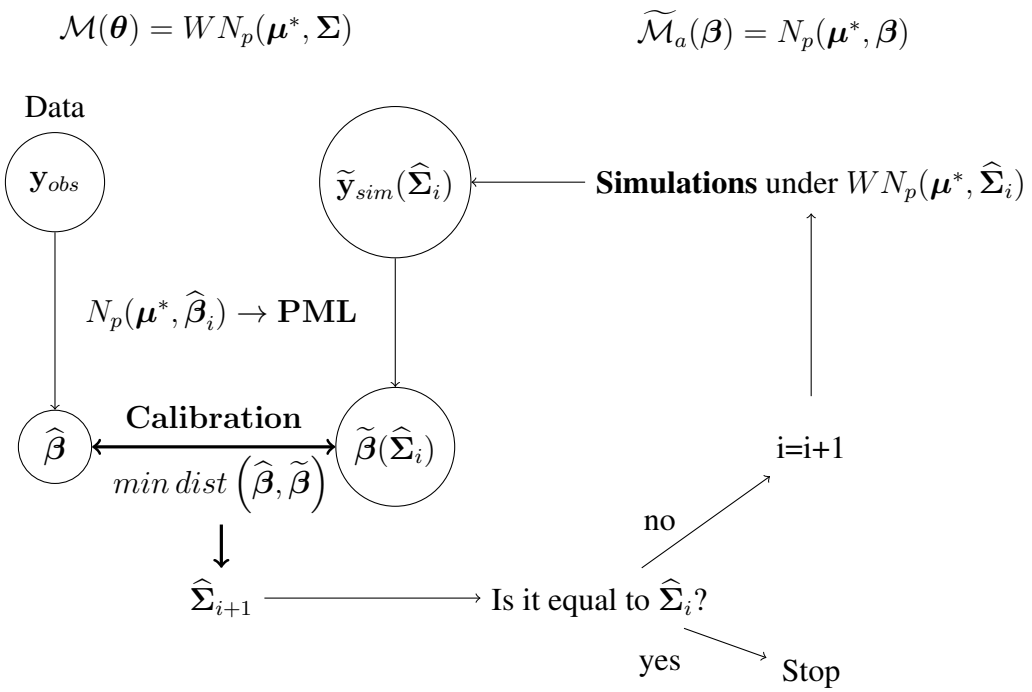

Figure 1: Diagram of the Indirect Inference estimation procedure for the variance-covariance matrix of a p-variate Wrapped Normal distribution, when using the standard p-variate Normal distribution as auxiliary model

4. Final remarks

We propose a novel approach to estimate the parameters of univariate and multivariate Wrapped Normal models via Indirect Inference with a Normal distribution as the auxiliary model. The II procedure explained in Section 3.is well-defined for all sample space dimensions, and has a low computational cost. Consequently, it can be used in a general context when the model of interest is a generic multivariate Wrapped Normal. The II estimators are similar to the auxiliary model estimators for very small variances and small p. Thus the convergence is sure. However, a direct approximation of the WN distribution based on truncated infinite series is sufficient. Nevertheless, computation becomes fastly infeasible when the dimension of the truncated sum increases. In such situations, the II estimators are a good and fast alternative to the estimator based on the approximate likelihood. For large variances, it is not guaranteed that the II calibration procedure is coming to convergence. This issue is also related to a structural problem implied by the construction of the WN distribution: the distribution is not distinguishable from a uniform distribution on the hypertorus, and its parameters tend to be undefined.

Sequential marginal likelihood selection for the estimation of sparse correlation matrices

Claudia Di Caterina[a] and Davide Ferrari[b]

[a]Università di Verona; claudia.dicaterina@univr.it
[b]Libera Università di Bolzano; davide.ferrari2@unibz.it

Abstract

Estimation of high-dimensional sparse correlation matrices is performed by selecting relevant marginal likelihoods from a large set of candidates. Selection occurs by minimizing the distance between maximum likelihood and marginal composite likelihood score, plus a weighted L_1-penalty which discourages the inclusion of noisy marginal likelihoods. The resulting parameter estimator involves a sequential thresholding mechanism, whereby the marginal estimates are set to zero based on the absolute value of their adjusted z-score. Inferential properties of the proposed procedure are illustrated via simulation experiments and the analysis of cell signaling data.

Keywords: adaptive penalty, composite likelihood, LASSO, model selection.

1. Introduction

Composite likelihood methods form valid objective functions for inference through the combination of a number of low-dimensional likelihood objects (11; 18). A popular type of composite likelihood is the composite marginal likelihood (CML), which is formed by combining partial likelihood objects based on marginal densities.

Let Y be a $d \times 1$ random vector with probability mass or density function $f(y;\theta)$ indexed by the parameter $\theta \in \Theta \subseteq \mathbb{R}^p$, which is sparse in the sense that a relatively large fraction of its elements are exactly zero. Suppose that the full d-dimensional distribution of Y is difficult to specify or compute, but we can identify p probability mass or density functions $f_j(y;\theta_j)$ $(j = 1,\dots,p)$ defined on low-dimensional subsets of Y, such as marginals Y_j, pairs (Y_{j_1}, Y_{j_2}), etc. For simplicity, it is assumed here that each f_j depends on a scalar marginal parameter component θ_j. Given independent observations $Y^{(1)},\dots,Y^{(n)}$ on Y, we compute the CML estimator $\tilde{\theta}$ by maximizing the CML function

$$L(\theta; Y^{(1)},\dots,Y^{(n)}) = \prod_{j=1}^{p} L_j(\theta_j; Y^{(1)},\dots,Y^{(n)})^{w_j}\,, \tag{1}$$

where $L_j(\theta_j; Y^{(1)},\dots,Y^{(n)}) = \prod_{i=1}^{n} f_j(Y^{(i)};\theta_j)$ denotes the sub-likelihood associated with the jth data subset and $w = (w_1,\dots,w_p)^\top$ is the design vector, namely a vector of weights that determines which margins are included in the CML function. Specifically, when $w_j = 0$ the sub-likelihood L_j does not contribute to estimation of θ. Then choosing w corresponds to selecting a model with reduced complexity, whenever w contains at least one zero element.

Model selection for composite likelihood has often been carried out using classic information criteria (8; 13) or sparsity-inducing penalties which focus on shrinking to zero the elements of θ (3; 21; 7; 10).

The composite likelihood design is instead crucial to determine both statistical properties and computing cost of the resulting estimator (20; 12). In the past years, criteria balancing the trade-off between the statistical and the computational efficiencies have been proposed to select the design vector (17; 6).

Building on the approach of Huang and Ferrari (9), we develop a methodology for the situation where the parameter θ is sparse and potentially high-dimensional. Our strategy aims to discourage the inclusion of entire marginal likelihood objects in (1) rather than just elements of θ. This is done by introducing an adaptive sparsity-inducing penalty for the design vector w, which allows to retain unbiasedness of the estimating equations and consistency of the final sparse CML estimator.

2. Parameter thresholding by marginal likelihood selection

Here the parameter vector $\theta = (\theta_1, \ldots, \theta_p)^\top$ is sparse with only $p^* \ll p$ nonzero elements, and p grows with the sample size n, but at a slower rate. Let $\ell_j(\theta) = \log L(\theta_j; Y^{(1)}, \ldots, Y^{(n)})$ be the jth marginal log-likelihood based on observations $Y^{(1)}, \ldots, Y^{(n)}$.

2.1 Method

The CML estimator $\tilde{\theta} = (\tilde{\theta}_1, \ldots, \tilde{\theta}_p)^\top$ is found by maximizing the log-CML function

$$\ell(\theta; Y^{(1)}, \ldots, Y^{(n)}) = \sum_{j=1}^{p} w_j \ell_j(\theta_j; Y^{(1)}, \ldots, Y^{(n)}),$$

with design vector $w = (w_1, \ldots, w_p)^\top$. Since each marginal likelihood depends on separate parameters, we have

$$\tilde{\theta}_j = \left\{ \theta_j : \sum_{i=1}^{n} u_j(\theta_j; Y^{(i)}) = 0 \right\} \quad (j = 1, \ldots, p)\,,$$

where $u_j(\theta_j; y) = u_j = \partial \ell_j(\theta_j; y)/\partial \theta_j$ denotes the jth marginal score and $u(\theta; y) = (u_1, \ldots, u_p)^\top$. We propose to induce sparsity in the final estimator $\hat{\theta}$ by applying the thresholding mechanism

$$\hat{\theta}_j = \begin{cases} \tilde{\theta}_j & \text{if} \quad \hat{w}_j \neq 0 \\ 0 & \text{if} \quad \hat{w}_j = 0 \end{cases} \quad (j = 1, \ldots, p)\,, \tag{2}$$

where $\hat{w} = (\hat{w}_1, \ldots, \hat{w}_p)^\top$ is a sparse design vector to be appropriately chosen. We suggest to select w, and hence the marginal likelihoods, by minimizing for some pre-specified $\lambda > 0$ the convex criterion:

$$\hat{d}_\lambda(w) = \frac{1}{2} w^\top \hat{C} w - w^\top \mathrm{diag}(\hat{C}) + \frac{\lambda}{n} \sum_{j=1}^{p} \frac{|w_j|}{\tilde{\theta}_j^2}, \tag{3}$$

where $\hat{C} = \sum_{i=1}^{n} u(\tilde{\theta}; Y^{(i)}) u(\tilde{\theta}; Y^{(i)})^\top / n$ is the sample covariance matrix of the marginal scores.

The intuition is that the optimal design vector $\hat{w}$ maximizes the resemblance between the maximum likelihood and the CML scores, for a given level of sparsity. The adaptive sparsity-inducing penalty in the last term of (3) serves to discourage the inclusion of noisy marginal likelihoods and is inspired by (22). Yet here, for the first time, it focuses on the coefficients w_j associated with entire sub-likelihoods rather than on parameter elements θ_j. This strategy preserves the consistency of the final sparse CML estimator $\hat{\theta}$.

2.2 Connections with adaptive thresholding

Traditional thresholding approaches set a parameter estimate to zero if the absolute value of the z-score $\tilde{\theta}_j / SE_j$ is sufficiently small. Examples include adaptive thresholding methods for sparse covariance

matrix estimation (1; 5; 15; 4). In the current notation, the standard error is $SE_j = \{n\widehat{\text{var}}(u_j)\}^{-1/2}$ and $\widehat{\text{var}}(u_j) = n^{-1}\sum_{i=1}^{n} u_j^2(\tilde{\theta}; Y^{(i)})$ is the empirical Fisher information based on the the jth sub-likelihood. While this approach is widely used for its extreme simplicity in large multivariate problems, the standard error SE_j fails to take into account the joint variability contributed by other marginal parameter estimates when assessing the significance of θ_j.

Close scrutiny of the Karush-Kuhn-Tucker (KKT) conditions for (3) reveals that $\hat{\theta}$ in (2) is a type of adaptive thresholding estimator where standard errors in the z-score are adjusted sequentially, based on the information available from the nonzero estimates selected along the λ path. Particularly, the final sparse CML estimator obeys the adaptive thresholding mechanism

$$\hat{\theta}_j = \begin{cases} \tilde{\theta}_j & \text{if} \quad |\tilde{\theta}_j|/SE_j^{\text{adj}} > \sqrt{\lambda} \\ 0 & \text{if} \quad |\tilde{\theta}_j|/SE_j^{\text{adj}} \leq \sqrt{\lambda} \end{cases},$$

where $SE_j^{\text{adj}} = SE_j/\sqrt{|\hat{\beta}_j|}$ is the adjusted standard error with positive rescaling factor

$$|\hat{\beta}_j| = \left| \frac{\sum_{i=1}^{n} u_j(\tilde{\theta}_j; Y^{(i)}) \times \text{res}_j^{(i)}}{\sum_{i=1}^{n} u_j^2(\tilde{\theta}_j; Y^{(i)})} \right|, \qquad \text{with} \;\; \text{res}_j^{(i)} = u_j(\tilde{\theta}_j; Y^{(i)}) - \sum_{k \neq j} u_k(\tilde{\theta}_k; Y^{(i)})\hat{w}_k.$$

Note that $\hat{\beta}_j$ equals the estimated slope in the regression of the pseudo-residual res_j on the score u_j. Thus, SE_j^{adj} is larger whenever there is not much information carried by the jth sub-likelihood term in addition to that provided by the sub-likelihoods already included in the CML. The adjusted z-score $|\tilde{\theta}_j|/SE_j^{\text{adj}}$ will then be closer to zero than its unadjusted version, making it less likely for θ_j to be selected.

3. Estimation of sparse correlation matrices

Sparse covariance and correlation matrix estimation is a fundamental problem in statistics. A variety of strategies have been proposed for reducing the number of parameters in large matrices. Among those are penalized likelihood methods (2; 14; 19) and thresholding methods (1; 5; 15; 4).

Let $Y \sim N_d(0, SRS)$, where S is the diagonal matrix with d standard deviations and $R = R(\theta)$ is a sparse correlation matrix with (j_1, j_2)th entry denoted by $\{R\}_{j_1 j_2}$; thus for $j = 1, \ldots, p$ we have that $\theta_j = \{R\}_{j_1 j_2}$ with $1 \leq j_1 < j_2 \leq d$. Since marginal univariate sub-likelihoods do not contain information on θ, we consider unit pairwise sub-likelihoods obtained by taking $p = d(d-1)/2$ bivariate normal log-densities for the pairs (Y_{j_1}, Y_{j_2}). Each corresponding jth score equals then

$$u_j(\theta_j; y_{j_1}, y_{j_2}) = (1 + \theta_j^2) y_{j_1} y_{j_2} - \theta_j(y_{j_1}^2 + y_{j_2}^2) + \theta_j(1 - \theta_j^2)\,, \tag{4}$$

and the method described in Section 2.1 can be applied using $u_j(\theta_j; y) = u_j(\theta_j; y_{j_1}, y_{j_2})$.

3.1 Monte Carlo simulations

The model-selection and estimation properties of the proposed method in the context of sparse correlation matrix estimation are illustrated through two Monte Carlo experiments. Monte Carlo samples of size $n = 100$ are generated from the d-variate normal model $Y \sim N_d(0, R)$ with $d \in \{30, 50\}$. The $p = d(d-1)/2 \in \{435, 725\}$ parameters in the correlation matrix $R = R(\theta)$ correspond to entries $\theta_j = \{R\}_{j_1 j_2}$ ($j = 1, \ldots, p$; $1 \leq j_1 < j_2 \leq d$), where a proportion s is set different from zero (a) randomly, with $s = 2\%$, or (b) in hubs, with $s = 5.74\%$ for $d = 30$ and $s = 3.67\%$ for $d = 50$. The score sample covariance matrix $\hat{C}$ in the objective (3) is obtained based on the pairwise scores described in (4). The proposed sparse CML estimator $\hat{\theta}$ is compared with four procedures designed for sparse correlation matrix estimation: soft- and hard-thresholding methods (Soft and Hard, (1)), the L_1-penalized ML approach (L_1-ML, (2)) and the penalized log-barrier method (Log bar, (14)). The

Table 1: Estimation of sparse correlation matrix with structure (a): Random 2% of the entries is nonzero ($d = 30$: $p^* = 7$; $d = 50$: $p^* = 16$). The sparse CML estimator $\hat{\theta}$ is compared to four competitors. Results are based on 50 Monte Carlo samples of size $n = 100$.

50		0.046	0.043	0.047	0.054	0.046

comparison between different methods is carried out in terms of estimates for the true positive probability (TPP) and false discovery probability (FDP), given by

$$\text{TPP} = \frac{\#\{j : \hat{\theta}_j \neq 0, \theta_j \neq 0\}}{p^*}, \quad \text{and} \quad \text{FDP} = \frac{\#\{j : \hat{\theta}_j \neq 0, \theta_j = 0\}}{p^*},$$

average number of selected parameters $\hat{p}^*$ and root mean squared error $\text{RMSE} = \sqrt{\sum_{j=1}^{p} (\hat{\theta}_j - \theta_j)^2}$.

Tables 1 and 2 show results obtained when the tuning constants of all competitors are selected by five-fold cross validation, as in (19). Despite having a much more general applicability, the proposed strategy proves to be accurate for estimating sparse correlation matrices, even with respect to methods specifically tailored for this setting. In terms of selection, it provides a good compromise between the tendency of the hard-thresholding to underestimate the true number of nonzero entries, and the opposite behavior of the other competing methods. We remark that our method is not intended for ultra-high dimensional scenarios with $p \gg n$, yet the increase of dimensionality from $d = 30$ to $d = 50$ does not imply a critic deterioration of the model-selection performance with respect to other procedures. Taking into account the unreported simulation standard errors, the overall estimation ability measured by the RMSE is in line with the competitors and particularly accurate in the first configuration with few random nonzero correlations.

3.2 Analysis of cell signaling data

A further illustration is given using a cell signaling data set. The data consist of flow cytometry measurements of the concentration of $d = 11$ proteins in $n = 7466$ cells (16). The sample size is much larger

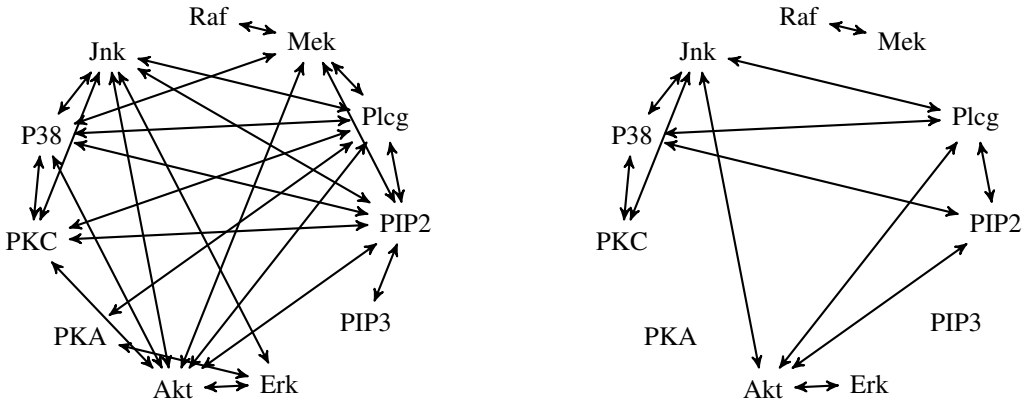

Figure 1: Covariance graphs resulting by sequential marginal likelihood selection. The two underlying values of λ correspond to $\hat{p}^* = 25$ (left) and $\hat{p}^* = 12$ (right).

Table 3: Edges ranked according to the significance of the maximum likelihood z-statistic for the corresponding correlation coefficient, from highest to lowest. The ticks indicate the edges selected by each method when $\hat{p}^* = 6$.

Ranking	Edge	$\hat{\theta}$	L_1-ML	Soft
1	(Raf, Mek)		✓	✓
2	(PKC, P38)	✓		
3	(Plcg, PIP2)	✓	✓	✓
4	(PKC, Jnk)	✓		
5	(P38, Jnk)	✓	✓	✓
6	(Erk, Akt)	✓		

than the total number of correlation parameters $p = d(d-1)/2 = 55$, which means we can compare the accuracy of our method with the maximum likelihood benchmark. After standardizing the data, we perform the analysis using bivariate normal sub-likelihoods for each protein pair with pairwise scores as in (4). For values of λ corresponding to $\hat{p}^* = 25$ and $\hat{p}^* = 12$, Figure 1 shows the covariance graphs where edges represent nonzero correlations between protein pairs.

Table 3 reports the protein pairs corresponding to the six most significant z-scores for testing $H_0 : \text{cor}(Y_{j_1}, Y_{j_2}) = 0$ $(j_1 < j_2)$ and the selection made for $\hat{p}^* = 6$ by our sparse CML estimator $\hat{\theta}$, and by methods L_1-penalized ML (L_1-ML) and soft-thresholding (Soft). The pairs resulting from sparse CML selection are clearly the ones that agree the most with the maximum likelihood ranking, with the main exception being the pair (Raf, Mek), which is however included when we set λ such that $\hat{p}^* = 12$ (see Figure 1).

A Comparison of Distribution-Free Control Charts

Michele Scagliarini[a]

[a] Department of Statistical Sciences, University of Bologna; michele.scagliarini@unibo.it

Abstract

In this study the statistical properties of several non-parametric control charts are investigated and compared. It is considered the problem of monitoring data streams when the distributional form of the monitored data is the generalized inverse Gaussian distribution. Two simulation studies are performed to assess the performance of the monitoring algorithms in various scenarios. The aim is to identify the most suitable monitoring algorithm considering jointly the ability in detecting shifts in location and/or scale and the percentage of missed alarms.

Keywords: change detection, control charts, non-parametric tests; simulation experiments

1. Introduction

Distribution-free control charts have received increasing attention in non-manufacturing fields because they can be used without any assumption on the distribution of the data to be monitored. This feature makes them particularly suitable for monitoring environmental phenomena often characterized by highly skewed distribution. In this work, we compare using Monte Carlo simulations, the performance of several non-parametric change point control charts for monitoring data distributed according the Generalised Inverse Gaussian (GIG) distribution. The choice of the GIG distribution is motivated by the fact that on the one hand it is often used to describe environmental radioactivity data, but on the other hand it has never been considered in connection with non-parametric control charts. For our purposes, aware of being non-exhaustive, we consider: the non-parametric change-point control chart proposed by [2] which is based on the Mann-Whitney (MW) statistic; the distribution-free control chart, based on Recursive Segmentation and Permutation (RS/P) proposed by [1]; the two non-parametric control charts based on the Kolmogorov-Smirnov (KS) and Cramer-von-Mises (CvM) statistics proposed by [4].

2. Methodology

In the Change Point Model (CPM) framework, it is assumed that the time ordered observations x_1, x_2,... are generated by the random variables X_1, X_2,... with unknown distribution functions F_1, F_2,... , respectively. A change point occurs at instant τ when $F_\tau \neq F_{\tau+1}$ and it is usually assumed that the observations are independent and identically distributed between every pair of change points. Therefore, the distribution of the sequence can be described by the following model: $X_i \sim F_0$ if $0 < i \leq \tau_1$, $X_i \sim F_1$ if $\tau_1 < i \leq \tau_2, \ldots,$ $X_i \sim F_k$ if $\tau_k < i \leq m$, where $0 < i < \tau_1 < \tau_2 < \cdots < \tau_k < m$ denote k unknown change points. Within this framework, it is of interest to test H_0: k=0, versus H_1: $k \neq 0$, to estimate the number of change points, k, and to estimate their locations $\hat{\tau}_1, \hat{\tau}_2, ..., \hat{\tau}_k$.

For testing the above described hypothesis system [4] proposed two change point control charts designed to detect arbitrary changes in the process distribution. The first is based on the Cramer-von-

Mises test and the second uses the Kolmogorov-Smirnov statistic. Both the control charts test for a change point immediately following any observation x_k by partitioning the observations into two samples, $S_1=(x_1,\ldots,x_k)$ and $S_2=(x_{k+1},\ldots,x_t)$, and comparing the corresponding empirical distribution functions $\hat{F}_{S_1}(x)$ and $\hat{F}_{S_2}(x)$. The CvM test uses a statistic based on the square of the average distance between the empirical distributions $W_{k,t}=\int_{-\infty}^{\infty}\left|\hat{F}_{S_1}(x_i)-\hat{F}_{S_2}(x_i)\right|^2 dF_t(x)$, while the KS test uses a statistic defined as the maximum difference between the empirical distributions $D_{k,t}=\sup_x\left|\hat{F}_{S_1}(x_i)-\hat{F}_{S_2}(x_i)\right|$. Further details can be found in [4].

To detect location (mean) shifts [2] proposed a control chart based on the Mann-Whitney U-statistic: $U_{k,n}=\sum_{i=1}^{k}\sum_{j=k+1}^{n}D_{ij}$ for $1\le k\le n-1$, where $D_{ij}=\operatorname{sgn}\left(X_i-X_j\right)=\left\{1 \text{ if } X_i>X_j;0 \text{ if } X_i=X_j;-1 \text{ if } X_i<X_j\right\}$. The variance of $U_{k,n}$ depends on the split point k, so for this reason it is suitably standardized, thus obtaining the statistic $T_{k,n}$ [2]. Therefore, the test for the presence of a change point and the estimate of its time of occurrence are given by maximizing $T_{k,n}$ over k: $T_{\max,n}=\max_{1\le k\le n-1}\left|T_{k,n}\right|$. For further details see [2].

The RS/P control chart [1] allows to detect location and scale (variability) shifts. Initially, a set of elementary test statistics, T_k, designed to detect the possible shifts are calculated. For detecting changes in the process location, the statistics T_k and the possible change points are computed using a forward recursive-segmentation approach. The algorithm starts with k=0 and proceeds in K successive stages. At the beginning of stage k, the interval [1, m] is partitioned into k subintervals, each having a length greater or equal to l_{MIN}. The quantities K and l_{MIN} can be appropriately chosen by the researcher [1]. At stage k, one of these subintervals is split, adding a new potential change point. The new change point is selected maximizing the function $f_k=\sum_{i=1}^{k+1}\left(\hat{\tau}_i-\hat{\tau}_{i-1}\right)\left(\bar{x}\left(\hat{\tau}_{i-1},\hat{\tau}_i\right)-\bar{\bar{x}}\right)^2$, conditionally on the results of the previous stages, and the control statistic T_k is equal to the attained maximum value of function f_k. Here $0=\hat{\tau}_0<\hat{\tau}_1<\ldots<\hat{\tau}_k<\tau_{k+1}=m$ are the boundaries of the new partition and $\bar{x}(a,b)=\sum_{i=a+1}^{b}\bar{x}_i\Big/(b-a)$. Then, these statistics are standardized and aggregated to obtain an overall statistic and the p-value is computed using a permutation approach. For detecting changes in scale, the steps are the same as for the process location, but the function f_k, used for the recursive segmentation, is different. Complete details can be found in [1].

3. Simulation Studies and Discussion

Environmental radioactivity data are usually positive and their distribution is often right skewed [5]. To analytically model these data good results have been obtained with the generalized inverse Gaussian distribution. The generalized inverse Gaussian distribution [3] has density function given by $f(x)=\frac{(\psi/\chi)^{\frac{\lambda}{2}}}{2K_\lambda\left(\sqrt{\psi\chi}\right)}x^{\lambda-1}e^{-\frac{1}{2}\left(\chi x^{-1}+\psi x\right)}$ for $x>0$, where $K_\lambda()$ is the modified Bessel function of the third kind with order λ. It is denoted with $N^{-1}(\lambda,\chi,\psi)$ and the domain of variation of the parameters is given by $\lambda\in R$, $(\chi,\psi)\in\Theta_\lambda$ where: $\Theta_\lambda=\left\{(\chi,\psi):\chi\ge 0,\psi>0\right\}$ if $\lambda>0$; $\Theta_\lambda=\left\{(\chi,\psi):\chi>0,\psi>0\right\}$ if $\lambda=0$; $\Theta_\lambda=\left\{(\chi,\psi):\chi>0,\psi\ge 0\right\}$ if $\lambda<0$.

As far as the control charts is concerned, there are several measures for assessing their statistical properties. The most commonly used measure is the Average Run Length (ARL). The Run Length (RL) of a control chart is a discrete random variable that is defined as the number of plotted statistics before an out-of-control point is observed on the chart. The ARL is the expected value of this random variable. The control charts introduced in the previous Section can be designed to achieve the same in-control

average run length, ARL_0 [1,2, 4]. Thus, to allow a fair comparison, we set ARL_0=200 for all the monitoring algorithms and focus our attention on their out-of-control performance.

Without loss of any generality, we consider as an initial benchmark the situation where the data come from a GIG distribution with parameters equal to: $\chi_0 = 0.596400$, $\psi_0 = 0.048177$ and $\lambda_0 = -0.738610$. In the first simulation study, for each run of the k=5·10^4 replications, we generate n observations: the first m observations are generated from $X_0 \sim N^{-1}(\lambda_0, \chi_0, \psi_0)$ while the observations from m+1 to n are generated as $X_1 \sim N^{-1}(\lambda_0, \chi_0, \psi_0) + \delta$ (location shift) and $X_1 \sim \varepsilon \cdot N^{-1}(\lambda_0, \chi_0, \psi_0)$ (scale shift), with δ=1, 1.5, 2.5 and ε=1.5, 2, 2.5, respectively. In our case, without loss of any generality we set m=50 and n=400. The first observation >m for which the control chart signals an alarm is the out-of-control run length (RL_1). The average of the k run lengths is our estimate of the out-of-control average run length (ARL_1). In each run, if at the end of the n observations the control chart did not detect any alarm, we defined this event as a missed alarm. Therefore, we compute for each control chart the percentage of missed alarms obtained in the k replications. The results are summarised in Tables 1 and 2, where for each control chart and each simulated scenario the following quantities are reported: %missAL, the percentage of missed alarms; ARL_1, the estimated average length; SDRL, the standard deviation of the RL_1.

In the second simulation study the observations from m+1 to n are generated with specific changes in the parameters. More specifically, as far as the parameter χ is concerned, we considered cases where the "in-control" parameter χ_0 had been increased by 50%, 100% and 150%, while the other parameters remain unchanged. Therefore, the data from observations m+1 to n are generated from $X_1 \sim N^{-1}(\lambda_0, \chi_1, \psi_0)$ with χ_1 equal to $1.5\chi_0$, $2\chi_0$ and $2.5\chi_0$. For the parameter ψ we considered cases where the "in-control" parameter ψ_0 had been decreased by 25%, 50%, 75%, while the other parameters remain unchanged. Therefore, the data from observations m+1 to n are generated from $X_1 \sim N^{-1}(\lambda_0, \chi_0, \psi_1)$ with ψ_1 equal to $0.75\psi_0$, $0.5\psi_0$ and $0.25\psi_0$. For the parameter λ we considered cases where the "in-control" parameter λ_0 had been increased by 25%, 50% and 75%, while the other parameters remain unchanged. Therefore, the data from observations m+1 to n are generated from $X_1 \sim N^{-1}(\lambda_1, \chi_0, \psi_0)$ with λ_1 equal to $0.75\lambda_0$, $0.5\lambda_0$ and $0.25\lambda_0$. The results are summarised in Tables 3-5.

Table 1: Simulation results for $X_1 \sim N^{-1}(\lambda_0, \chi_0, \psi_0) + \delta$

SD	2.3	97.4	0.8	0.7	0.5

Before commenting on the results, it is important to mention that we are aware that the scenarios examined in the simulations, although quite extensive, do not include all possible cases.

With these reservations in mind, the results of the first simulation study reveal that the RS/P control chart has good performance in terms of ARL_1 for detecting location shifts (see the values with a shaded background in Table 1). However, for δ=1 it has a relatively high percentage of missed alarms (8.3%) if compared with the MW, CvM and KS control charts. For scale changes (Table 2) the results show that for all the shift magnitudes considered (ε=1.5, ε=2 and 2.5) the KS monitoring algorithm has the best performance both in terms of ARL_1 and missed alarms (values with a shaded background in Table

2). Furthermore, the MW control chart gives slightly better performance when compared with the CvM counterpart. It can also be noted that for small shifts (ε=1.5), both MW and CvM have relatively high percentages of missed alarms (9.1% and 9.8%) if compared with the KS control chart (2.4%). Surprisingly, the RS/P monitoring algorithm, even if it has been specifically designed to detect scale changes, gives the worst performance.

In the second simulation study (Tables 3-5), where specific changes in the distribution parameters have been imposed, the KS change point model control chart has the best statistical properties both in terms of ARL_1 and percentage of missed alarms (values with a shaded background in Tables 3-5). Furthermore, the performance of the MW and CvM control charts is very similar across all change magnitudes. As an example, for the case where the parameter ψ had been decreased by 75% (Table 4 for $\psi_1 = 0.25\psi_0$) the estimated ARL_1 for the KS monitoring algorithm is 98.2 (%missAL=5.7), whereas the ARL_1 for the CvM, MW, RS/P (scale) and RSP/location are 118.5 (%missAL=14.5), 117.4 (%missAL=14.3), 107.7 (%missAL=94.1) and 208.1 (%missAL=95.7), respectively. It can be noted that detecting changes in the distribution parameters seems a very difficult task for the RS/P control chart since for all the considered scenarios it has a very high percentage of missed alarms.

Summarising, the monitoring algorithm based on recursive segmentation and permutation has the best performance for detecting moderate shifts (δ=1.5, 2.5) in the location. However, its statistical properties are not as good for the other scenarios examined. On the whole the Kolmogorov-Smirnov control chart provides the best results both in terms of out-of-control ARL and missed alarms.

Characterizing Heterogeneity of Causal Effects in Air Pollution in Florida

Dafne Zorzetto[a]

[a]Department of Statistics, University of Padova, Italy; dafne.zorzetto@phd.unipd.it

Abstract

A main actual interest, in epidemiological studies, is environmental justice –i.e. to identify vulnerability/resilience to air pollution, taking into account the unfair difference among people with different races, national origin, and/or social-economic status [3]. In several studies, the causal link between long-term exposure to fine particulate and mortality risk is been studied and this work wants to identify how this causal effect changes among different population subgroups. This work analyses data on air quality in Florida with the goal of estimating the causal effects of fine particulate matter on mortality rates, leveraging the flexibility of a recently proposed Bayesian nonparametric mixture model specification. Five population subgroups, with different levels of vulnerability/resilience, are discovered and characterized by socio-economic status and ethnicity composition.

Keywords: Air Pollution Epidemiology, Bayesian Nonparametrics, Causal Inference, Cluster-Specific Characteristics, Heterogeneous Causal Effects.

1. Introduction

Several epidemiological studies have provided significant evidence that long-term exposure to fine particulate matter ($PM_{2.5}$) increases mortality risk [see, e.g., 2; 5; 13; 16; 17]. However, it is now in the spotlight the importance of achieve the environmental justice, as the the Environmental Protection Agency (EPA) has declared [3]. This is mean, that health regulations and policies take into account the unfair difference in air pollution vulnerability among people with different race/ethnicity, national origin, and/or social-economic status.

Indeed, variable as race (e.g. white, black, hispanic, etc), national origin, age, sex, and/or social-economic status seem to play an explanatory role on identification of population subgroups, characterized by different level of vulnerability/resilience to air pollution [see, e.g., 4; 6]

In causal inference, the estimation of different causal effects, conditional to values of covariates or specific subgroups, is unified in the heterogeneous causal effect literature [see the reviws 1; 15]. In particular, the focus is on the estimation of the Conditional Average Treatment Effect (CATE), i.e. the expectation of the causal effect (defined as a function of the individual potential outcomes) for the units allocated in pre-specified groups of the population.

While, most of the approaches for estimating the CATE require defining covariates values *a priori*, with consequent limitations due to the subjective choices, [18] recently proposed a fully Bayesian model enabling us to identify heterogeneous and mutually exclusive population subgroups defined by shared CATEs, and discover the group-specific characteristics. The approach presented in [18] leverages on the flexibility of Bayesian Nonparametric approach, specifically using a Dependent Dirichlet Mixture Model [7; 9] specification.

In this work, we adopt the approach presented in [18] and analyse the causal effect of $PM_{2.5}$ on mortality in Florida.

2. Assumptions and model specification

The potential outcome framework [11] assumes that each observed subjects can potentially be assigned to a treatment T. Notably, in case of binary variable $T_i \in \{0, 1\}$, $T_i = 1$ if the unit i is assigned to the treatment group, otherwise $T_i = 0$ when the unit i is assigned to the control group. The potential outcome for unit i is defined as $\{Y_i(0), Y_i(1)\} \in \mathbb{R}^2$, for $i = 1, \ldots, n$. The vector $\{Y_i(0), Y_i(1)\}$ represents the collection of the two potential outcomes, specifically $Y_i(0)$ is the outcome when the unit i is assigned to the control group while $Y_i(1)$ is the outcome when it is assigned to the treatment group. In practice, however, for $i = 1, \ldots, n$, we observe only y_i, that is the realization of the random variable Y_i defined as

$$Y_i := (1 - T_i) \cdot Y_i(0) + T_i \cdot Y_i(1).$$

Conversely, we can not observe the realization y_i^{mis} of the random variable $Y_i^{mis} := T_i \cdot Y_i(0) + (1 - T_i) \cdot Y_i(1)$. Additionally, we define x_i the p-dimensional vector of subject-specific background characteristics.

Some assumptions are necessary to identify and estimate the causal effect, according with the potential outcome literature [12]. Specifically, Stable Unit Treatment Value Assumption (SUTVA)—i.e. there are no different versions of the treatment levels assigned to each unit and no interference among the units—and strong ignorability—i.e all units, in each group conditional on some covariates values, have a positive chance of receiving the treatment.

We leverages the flexibility of the probit stick-breaking process [10] and adopt an infinite mixture specification for the probability density distribution of the outcomes. Details are reported in [18].

In the subsequent analysis we focus on estimating the Conditional Average Risk Ratio (CARR), defined as

$$\tau(x) := \frac{\mathbb{E}[Y_i(1) \mid X_i = x]}{\mathbb{E}[Y_i(0) \mid X_i = x]}, \tag{1}$$

where the value of x are identified by the discovered groups.

3. Causal Effects of Air Pollution in Florida

The analysis used the ZIP codes level data recorded in Florida (USA). In particular, for each ZIP code (i.e. a statistical unit) the following variables are available: average of $PM_{2.5}$ levels during the years 2010, mortality rate in the 5 follow-up years, census variables such as the percentage of residents for different races/ethnicities (in particular, categorized as Hispanics, blacks, whites, and other races), percentage of men/women, age average among the Medicaid enrolees (people older than 65), population densities, and percentage of people who are eligible for Medicaid (this variable is a proxy of low social-economic status, abbreviate in S.E.S.).

The population density, in Florida during 2010, is represented in the first left map in Fig. 1 and it is clear how the population is concentrate around the main cities, as Jacksonville, Miami, Tampa, and Orlando. Consequently, we consider the ZIP codes with a population density significantly different to zero, and for them we reported in the second and third map in Fig. 1 the $PM_{2.5}$ level, recorded during 2010, and the mortality rate in the 5 follow-up years. The distribution of $PM_{2.5}$ among the state, seem to increase in the north particularly, due to the morphology of this peninsula, and close to the main cities, but with less intensively. While the mortality rate doesn't show any particular pattern.

3.1 Results

We define the exposure variable as $T = 1$ if the average $PM_{2.5}$ in 2010 is above the threshold $10\mu g/m^3$ and $T = 0$ otherwise. The choice of $10\mu g/m^3$ as a threshold aligns with the trend of National Ambient Air Quality Standard (NAAQS) established by the EPA [3].

The model estimation identifies 5 different subgroups: 3 with a negative effect of the exposure to $PM_{2.5}$ on the mortality rate, i.e. a high exposure to $PM_{2.5}$ increases the mortality rate, and 2 groups with a positive effect, i.e. a high exposure to $PM_{2.5}$ decrease the mortality rate.

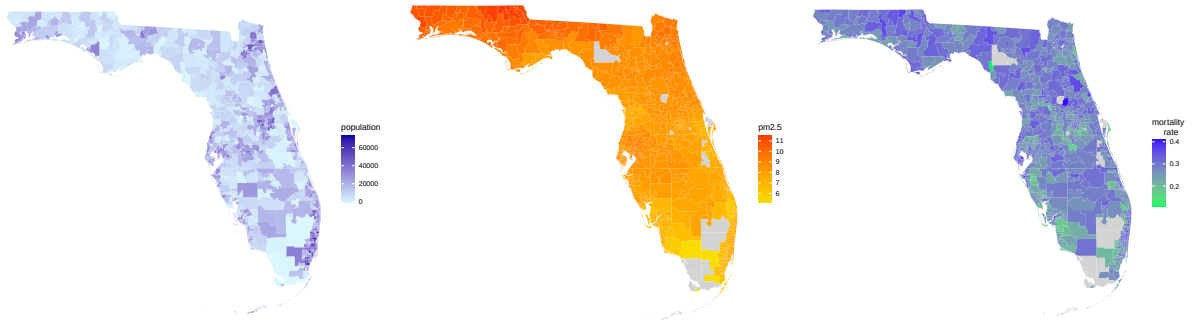

Figure 1: Florida information by ZIP code level: (i) Population in 2010; (ii) Recorded $PM_{2.5}$ during the years 2010; (iii) Mortality rate in the 5 follow-up years.

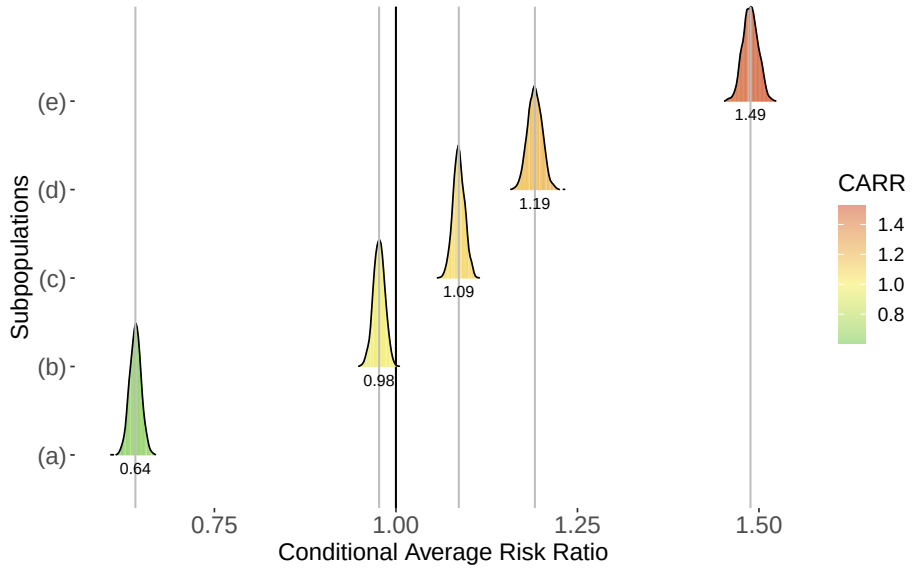

Figure 2: Posterior Conditional Average Risk Ratio (CARR) for the identified subgroups. The black line identifies the CARR = 1, i.e. the null causal effect. The gray lines are the mean of each posterior distribution.

Figure 2 presents the posterior distribution of the CARR for each identified subgroup. The vertical black line in the figure represents the null causal effect, which is indicated by a CARR equal to 1. The first three subgroups, which exhibit negative effects, have CARR values greater than 1 (in order from highest to lowest: (e) 1.49, (d) 1.19, (c) 1.09), while the two subgroups with positive effects have CARR values less than 1 (in order from lowest to highest: (a) 0.64, (b) 0.98).

By the definition of CARR—in (1)—, the causal effect of the $PM_{2.5}$ exposure varies among the groups, with a increment of up to 49% of the mortality rate when the sub-population in (e) is exposed to high level of $PM_{2.5}$ instead of a lower level, and a decrement of 36% of the mortality rate when the sub-population in (a) is exposed to high level of $PM_{2.5}$ instead of a lower level. However, these more extreme subgroups include both 1% of the ZIP codes, while the majority of the population is included in the groups with less powerful effects: the group (d) includes the 37% of the ZIP codes, where the mortality rate of the population increases by 19% under high level of $PM_{2.5}$, the main group (c), with 52% of the ZIP codes, has an increment of 9%, and the group (b) includes the 9% of the ZIP codes, where the mortality rate of the population decrease by 2% under high level of $PM_{2.5}$.

The different vulnerability/resilience to $PM_{2.5}$ across the identify subgroups, can be understood analysing the various compositions of the population among the ZIP codes. Indeed, the Fig. 3 shows

Figure 3: Group-specific covariates. Each spider plot reports in the colored area the group-specific characteristics (the mean of the analyses covariates) and in the gray area the collective characteristics (the mean of the covariates among the analyzed Californian ZIP codes).

that each group has different means of the analysed characteristics (reported with colours in the spider-plots) from the means of the same characteristics among all the consider ZIP codes (reported in gray in each spider-plot). Specifically, the spider-plots compare the following variables: sex (close to the center indicates a bigger percentage of women in the population of the ZIP codes, far to the center a bigger percentage of men), percentage of white, hispanic, black and other races (where smaller percentages are closer to the center), age (where the ZIP codes with the age mean close to 65 years for Medicaid enrollees are close to the center, and older population far from the center), and S.E.S. (close the center the population with high income and far from the center lower income the opposite).

Starting from the most vulnerable group, we can recognize that the group (e) is characterized by hispanic and black poor women, identify in literature as one of the most vulnerable population [4]. Additionally, the group (d) is distinguished by minorities as black and other races women. Actually, minorities, as hispanics, lack, or other no white races, are structurally exposed, over time, to higher levels of air pollution, becoming subjects more vulnerable and with more risk of mortality [4]. Moreover, the vulnerable group (c) is characterize by old men with a income lower than the average mean.

In juxtaposition, the groups characterized by positive effects, i.e. high exposure to $PM_{2.5}$ decrease the mortality rate, are mainly composed by rich young whites. In particular, the two groups differ in the sex: women in the group (a) and men in the group (b). This behavior is particular interesting, and it could be clarified by the potential survival bias [see, e.g., 8; 14], usually linked to younger people. Basically, cohort studies that start later leading to vulnerable individuals in certain subgroups dying before entering the cohort, therefore the individuals entering the cohort are the most resilient ones and might depict a decreasing mortality effect even when exposed to higher levels of pollutant.

[c]University of Naples-L'Orientale, Naples, Italy; mgallo@unior.it, ntrendafilov@unior.it

Abstract

CANDECOMP/PARAFAC aims to identify the true components underlying data with a trilinear configuration. The search for a unique solution is not always an easy task, as degeneracies may occur. The presence of outlier contamination further complicates the matter by requiring the implementation of robust procedures. The most used robust approach R-ALS is based on the iterative repetition of the standard alternating least squares algorithm, which is known to be slow and vulnerable to over-factoring, collinearity, and bad initial values. Here the faster and stable robust alternative R-INT1, based on the SWATLD-ALS integrated scheme INT-1, is implemented. Its performance is tested against ALS, R-ALS, and R-INT2 (built on INT-2, an ATLD-ALS procedure already proposed in the literature). Performance is assessed in a simulation study with varied levels of outlier contamination.

Keywords: ALS, ATLD-ALS, SWATLD-ALS, outliers, computational efficiency

1. Introduction

Three-way data sets collect observations on a set of variables measured over several occasions (locations, times, conditions) and are represented as three-dimensional arrays rather than data matrices, as it is usual in the multivariate data analysis. Different techniques exist to analyze such three-way data but CANDECOMP/PARAFAC (CP), which can be seen as a generalization of principal component analysis (PCA) to higher-order tensors is one of the most popular. The idea of CP is to find a given number of components that jointly represent the data well.

The usual way of parameter estimation in CP is an alternating least squares (ALS) procedure which yields least-squares solutions and provides consistent outcomes. It is well-known that algorithms which rely on least squares easily break down in the presence of outliers. This is well recognized for PCA and a number of robust alternatives were proposed in the literature. In the multivariate case where two-way data are analyzed, the outliers are assumed to be rows (observations, objects, subjects, etc.) in the data set which lie significantly far from the other observations. Similarly, in the three-way case, we can assume that outliers are matrices (slices) that have a profile strongly deviating from the rest. (3) have demonstrated the influence of outlying samples on the classical ALS. They split the observations into four groups: regular observations, good leverage points, bad leverage points and residual outliers constructing a plot, the outlier map, similar to the one in robust regression or in robust PCA on two-way

data. To cope with the presence of outlying samples they have also proposed a robust version of the ALS algorithm, R-ALS, which relies on the robust PCA method ROBPCA (5).

Apart from its proneness to outlying samples, the standard ALS-PARAFAC procedure suffers several major flaws which might be particularly problematic for large-scale problems: slow convergence and sensitiveness to degeneracy conditions such as over-factoring, collinearity, bad initialization and local minima. A lot of research was invested to find a solution to these problems and a number of improved versions of ALS were created. Several alternatives to ALS were developed, like the alternating trilinear decomposition (ATLD) (10), self-weighted trilinear decomposition (SWATLD) (2) and their properties and comparative performances have been studied in several works, e.g. (9). These alternative procedures resist temporary degeneracies and over-factoring problems while ensuring a much speedier estimation process than ALS, thanks to a steeper convergence curve. These advantages are obtained at the cost of losing the stability of results and obtaining non-least-squares solutions. As a possible fix, an algorithm integration strategy was introduced in (6; 7) to combine the benefits of faster procedures with ALS stability.

The robust version of ALS proposed by (3) also shares these issues. In this approach, standard ALS is iteratively executed; thus, the effect of these disadvantages will be multiplied causing the whole procedure to become very slow, especially in the case of large data sets. The ATLD-based procedure INT2 (7) was extended to a robust version R-INT2 by (8) and its superior performance was demonstrated in an extensive simulation study and experimental data. Following these lines, in this paper we propose to robustify also the INT1 procedure based on SWATLD and call it R-INT1. We study its performance in the case of data without contamination or with increasing levels of contamination and compare to the other two known robust procedures.

2. The CP model, the ALS algorithm and its integrated versions

The CP model (1; 4) decomposes the 3-way data array $\underline{\boldsymbol{X}}(I \times J \times K)$ with a generic element x_{ijk} into the three loading matrices $\boldsymbol{A}$ $(I \times R)$, $\boldsymbol{B}$ $(J \times R)$, $\boldsymbol{C}$ $(K \times R)$ with R components (using the same number for each mode). The CP model can be written formally as

$$\boldsymbol{X}_A = \boldsymbol{A}(\boldsymbol{C} \otimes \boldsymbol{B})^\top + \boldsymbol{E}_A, \tag{1}$$

where $\boldsymbol{X}_A$ and $\boldsymbol{E}_A$ are the original array and the error array unfolded with respect to mode A and the symbol $\otimes$ represents the *Kronecker product* between two matrices. To estimate the optimal component matrices the residual sum of squares

$$||\boldsymbol{E}_A||^2 = \sum_{i=1}^{I}\sum_{j=1}^{J}\sum_{k=1}^{K}(x_{ijk} - \hat{x}_{ijk})^2 = \sum_{i=1}^{I}||\boldsymbol{x}_i - \hat{\boldsymbol{x}}_i||^2 = \sum_{i=1}^{I} RD_i^2 \tag{2}$$

is minimized. The residual distance (RD) for observation i is thus given by

$$RD_i = ||\boldsymbol{x}_i - \hat{\boldsymbol{x}}_i|| = \sqrt{\sum_{j=1}^{J}\sum_{k=1}^{K}(x_{ijk} - \hat{x}_{ijk})^2} \tag{3}$$

and the estimation is equivalent to the minimization of the sum of the squared distances. With ALS the component matrices are estimated one at a time, keeping the estimates of the other component matrices fixed, i.e. we start with initial estimates of $\boldsymbol{B}$ and $\boldsymbol{C}$ and find an estimate for $\boldsymbol{A}$ conditional on $\boldsymbol{B}$ and $\boldsymbol{C}$ by minimizing the objective function. Estimates for $\boldsymbol{B}$ and $\boldsymbol{C}$ are found analogously. The iteration continues until the relative change in the model fit is smaller than a predefined constant.

As already mentioned in the introduction, while ALS is still the algorithm of choice because of its many desirable characteristics, its use can be problematic especially in cases of large data sets due to slow convergence and sensitiveness to degeneracy conditions such as over-factoring, collinearity, bad initialization and local minima. The alternating trilinear decomposition (ATLD) proposed by (10) seems

to be the most efficient method among the proposed alternatives to ALS and it is claimed to be less sensitive than ALS to over-factoring. It is based on the use of three loss functions with different response surfaces. SWATLD (2) does not attempt to find the minimum of (2), instead, it alternates between minimizing three different (non-least squares) loss functions, one per each of the loading matrices. It is important that the three matrices $\boldsymbol{A}$, $\boldsymbol{B}$ and $\boldsymbol{C}$ must have full column rank in order for the algorithm to resolve uniquely the components of interest. SWATLD seems to be the best algorithm in terms of recovery capability (factor congruence) (9).

However, these advantages of ATLD and SWATLD are obtained at the cost of unstable results and non-least squares solutions. To cope with these disadvantages a recent research development demonstrated that an integrated approach, combining algorithms with complementary points of strength, could provide a suitable solution. Two integrated algorithms INT-1 (6) and INT-2 (7) were proposed which combine SWATLD and ATLD steps with ALS, respectively, to ensure faster convergence, stability, and insensitivity to wrong model specification. For both integrated procedures the authors demonstrated the gain in performance in terms of computational efficiency and resistance to different undesirable effects. However, it is not known which of them is to be preferred in different situations since no comparison between them was conducted.

3. The robust alternatives to ALS

The idea of a robust version of CP proposed by (3) is to identify enough "good" observations and to perform the classical ALS on these observations. This is repeated until no significant change is observed. Finally, a reweighting step is carried out to improve the efficiency of the estimators. To identify the "good" observations a robust version of PCA, e.g. ROBPCA (5), is used on the unfolded array. We will call this procedure R-ALS in the rest of the paper. It is obvious that the robust procedure will be much more time-consuming than the classical one, repeating many times the ALS optimization. Therefore, any improvement of the parameter estimation procedure will contribute to the improvement of the performance of the complete robust procedure. R-ALS is entirely based on ALS and thus suffers the slow convergence and other disadvantages of this algorithm. (8) proposed to replace ALS by INT2 thus obtaining a new robust estimation procedure which they called R-INT2. As in R-ALS, it starts with robust principal components to identify any outlying points and then iterates using the INT2 algorithm until no significant change is observed. After convergence, a reweighting step with INT2 is conducted which produces the final solution.

Since the integrated procedure (6) based on SWATLD was demonstrated to have also very good performance as an alternative to ALS, we suggest extending it to a robust version in the same way as it was done for R-INT2 in (8). To verify that it can cope with outlying samples in the data and outperform R-ALS we conduct a simulation survey which is presented in Section 4. The purpose of this simulation study is also to find out which of the two integrated robust procedures performs better.

4. Simulation study

We will study the performance of the newly proposed procedure R-INT1 for robust estimation of trilinear CP models and will compare it to the classical ALS and the other two known robust procedures R-ALS and R-INT2 on a detailed simulation platform. Similarly as with the other integrated procedures the performance of the two-stage procedure R-INT1 will depend significantly on the transition parameters for switching from the initialization stage to the refinement stage. For this reason, the preliminary part of this simulation study is dedicated to the empirical estimation of these parameters, but due to the space limitation we will only state the final result - the values 10^{-2} and 10^{-3} seem to be most favorable and 10^{-2} will be used in all further computations. Successively we will compare the classical CP, the robust version based on ALS as proposed by Engelen and Hubert (3) R-ALS, the integrated robust version proposed by Todorov et al (8) R-INT2 and the newly proposed integrated procedure based on SWATLD R-INT1. First of all, we want to verify that R-INT1 and R-INT2 work well on data sets with

and without contamination by identifying the outliers at least as well as R-ALS, retrieving solutions with good statistical quality. At the same time, we want to verify that the convergence of these two procedures is improved significantly and thus the computational time is reduced. And finally, we want to compare the computational performance of R-INT1 and R-INT2 in different scenarios.

These aspects will be illustrated on three-way data generated as in (7), (9), (3) and (8). The three-way arrays have $I = 50$ observations, $J = 100$ variables and $K = 10$ occasions and the number of factors is $R = 3$ or $R = 5$. For each data set random matrices $\boldsymbol{A} \in \mathbb{R}^{I \times R}$, $\boldsymbol{B} \in \mathbb{R}^{J \times R}$ and $\boldsymbol{C} \in \mathbb{R}^{K \times R}$ are generated from a uniform distribution. With the so defined loadings matrices a three-way data set can be constructed according to Equation 1 with different levels of homoscedastic (HO) and heteroscedastic (HE) noise $\boldsymbol{E}_A^{HO}$ and $\boldsymbol{E}_A^{HE}$ respectively defined as in (9).

Different types of outliers were then added following the scheme proposed by (3) and used by (8). First of all, we want to study the behavior of the four procedures on clean data and thus, the first setup is created by not including any outliers. In the other configurations 10% and 20% of the observations are modified to contain *bad leverage points*. For each setup, in order to account for minor statistical fluctuations 100 replicates were conducted. For evaluating efficiency performance CPU time, iterations, and incidence of temporary degeneracies (swamps) are considered. For accuracy, the computed diagnostics include the value of the objective function (FIT), the occurrence of fault recoveries (FR), the mean square error (MSE), and the angle between the estimated and original subspaces of the second and third mode. See (9) and (8) for a full description.

Overall, at 20% contamination with bad leverage points, the difference between R-ALS FIT and R-INT1 FIT is higher than $1e^{-4}$ in less than 1% of the cases. In more than half of the cases (55.9%) the fit of R-INT1 is better than that of R-ALS which demonstrates that R-INT1 is capable of identifying the best low rank approximation as well as R-ALS. The results for R-INT2 are similar, as shown in (8).

It is important to verify that the known instabilities of ATLD and SWATLD are not passed to the integrated procedures. We can check this by looking at the percentage of fault recoveries reported for all three algorithms for different levels of contamination and different ranks in Table 1. For $R = 3$, both in the correct rank estimation case and when over-factoring, the percentage of fault recoveries for all robust methods is not higher than 1%. Only for the classical estimates on data with 10% and 20% contamination the percentage increases drastically, coming close to 100%. For R = 5 all percentages are slightly higher (not shown here).

		$F = R = 3$				$F = R + 1 = 4$			
		C	RALS	RINT1	RINT2	C	RALS	RINT1	RINT2
FR	0%	0.0	0.0	0.0	0.1	1.2	1.1	0.0	0.0
	10%	98.9	0.0	0.0	0.1	0.0	1.0	0.0	0.0
	20%	99.4	0.0	0.2	0.1	0.0	0.9	0.0	0.0
SWAMPS	0%	0	0	0	0	22	18	0	0
	10%	0	0	0	0	1	25	0	1
	20%	0	0	0	0	2	15	0	0

Table 1: Total percentages of FR and number of swamps (out of 4500 repetitions) by rank and number of factors for different levels of contamination with bad leverage points.

The next measure of accuracy to look at is the MSE. The results for the four estimators and three types of data (no outliers, 10% bad leverage points and 20% bad leverage points) are presented in the box plots in the left panel of Figure 1. The right panel of the same figure presents the angles of the B-loadings for the four methods and the three contamination types.

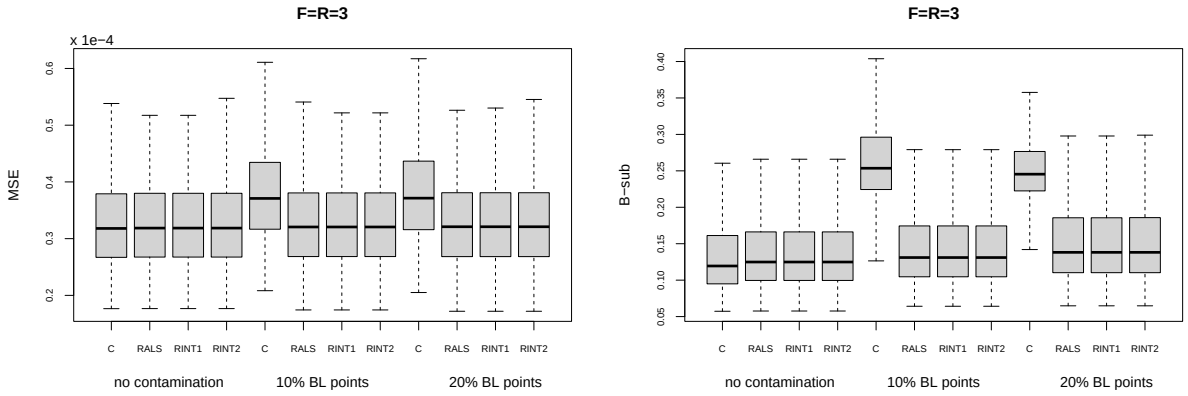

Figure 1: MSE values and angle of B-loadings of classical CP (C), robust CP with ALS (R-ALS), robust CP with INT1 (R-INT1) and robust CP with INT2 (R-INT2) on data sets without contamination, and with 10% and 20% bad leverage points respectively.

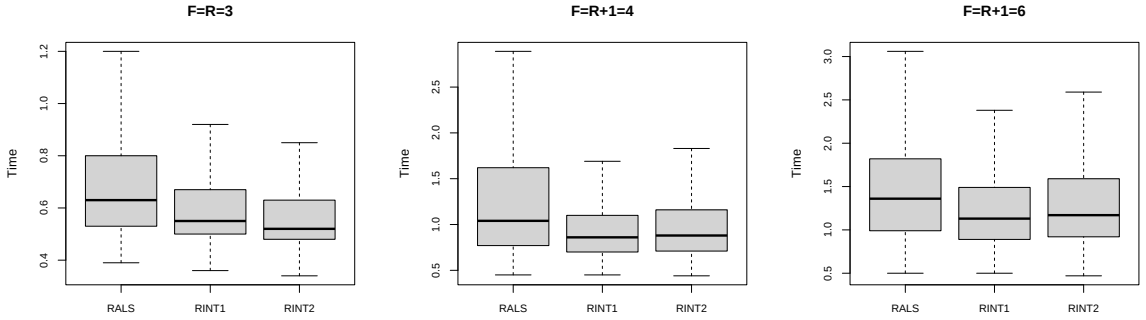

Figure 2: CPU time in seconds, robust CP with ALS (R-ALS), robust CP with INT1 (R-INT1) and robust CP with INT2 (R-INT2) on data sets 20% bad leverage points for different number of factors.

All four estimators perform equally well on clean data both in terms of MSE and maxsub, however, when outliers are added to the data (10% and 20%) the classical CP is influenced - the MSE increases and the quality of the fit of the loadings decreases. There is non much difference in the performance of the three robust methods in terms of MSE and maxsub. However, if we look at Fig. 2 which presents their performance in terms of computational time the gain in performance in the two integrated procedures is obvious. The integrated procedures R-INT1 and R-INT2 perform better than R-ALS both in terms of median time and variance, with R-INT2 being slightly better in the case of correct factor decomposition ($F = R = 3$, left panel). In over-factoring ($F = R + 1 = 4$ and $F = R + 1 = 6$, middle and right panels) the roles change and R-INT1 becomes better.

The computational efficiency can also be judged by counting the number of swamps, i.e. the temporary degeneracies which continue for more than 10 iterations and thus slowdown the procedure. This problem was not significantly manifested in our simulation. As seen in the lower part of Table 1, no swamp cases are observed when estimating the correct rank and when $R = 3$, for none of the estimators and for none of the contamination levels. Only several cases were observed when over-factoring, for the classical ALS and the robust R-ALS, however the number of these cases is insignificant when compared to the total number of 4500 repetitions.

5. Summary and conclusions

The simulation study shows that R-INT1 is a viable alternative to R-ALS for dealing with outliers in a three-way setting. Throughout scenarios, it is stable in converging to the correct parameters and does not appear to model excessive noise, reaching least squares solutions. The integrated strategy ensures higher efficiency and also proves useful in terms of accuracy when over-factoring. As far as the differences between R-INT1 and R-INT2 go, they are both solid procedures. R-INT2 is slightly more efficient in terms of median values, however, in presence of over-factoring, R-INT1 is the top performer. A thorough presentation of the resulting diagnostics, as well as an analysis carried out on an application will be provided to further strengthen the comparison and complete this work. Future work should also study the possibilities for combination with other computational algorithms. The behavior of the algorithms if collinearity is present will be of great interest as well as their extension with additional constraints.

Abstract

Procedures with true discovery guarantee, i.e., methods for simultaneous inference on the True Discovery Proportion (TDP), have become widely popular in many applications. They permit addressing the multiplicity problem while at the same time solving the spatial specificity paradox. Here we propose a comparative analysis of some of the most widely used permutation-based procedures: *sumSome*, *pARI*, *sansSouci* and *Notip*. We compare their performance on differential gene expression data analysis, where the interest lies in quantifying levels of activation in different pathways.

Keywords: true discovery proportion, permutation testing, differential gene expression

1. Introduction

In recent years, simultaneous inference on the True Discovery Proportion (TDP) has become a popular inferential method. Its wide use is substantial since several application fields, including neuroscience and genetics, have to cope with the problem of multiple testing and the spatial specificity paradox. Indeed, in most analyses the inference is made not at the level of individual features but of groups of features (e.g., biological pathways in genetics and brain regions in neuroimaging) to have a less conservative correction for multiplicity. However, this leads to the so-called spatial specificity paradox: a significant p-value for a group only denotes that there is at least one significant feature, but does not give any information on the number of significant features nor their localization. Therefore, as the size of the group becomes larger, the finding becomes weaker (9).

Simultaneous inference on the TDP addresses the multiplicity problem while overcoming this paradox. The main idea is to define procedures with true discovery guarantee, i.e., methods that give lower confidence bounds for the TDP simultaneously over all possible groups. Simultaneity guarantees that the confidence bounds remain valid when the group of interest is chosen post-hoc and when doing follow-up inference inside a group (6). Several methods have been proposed in the literature; here we focus on the permutation framework, as it relies on minimal assumptions and often offers an improvement over the parametric approach (7).

This paper follows the idea presented in (12), where two permutation-based procedures with true discovery guarantee, *sumSome* (13) and *pARI* (2), are compared on brain imaging data. Here we provide a more comprehensive comparison, studying the performance of the above-mentioned methods, as well as other recent proposals: *sansSouci* (4) and *Notip* (3). We analyze the differential gene expression dataset studied in the supplementary material of (13). This type of data contains expression levels for different genes; interest lies in assessing differences between two sub-populations at the level of pathways, collections of genes associated with a specific biological process that interact with each other.

The manuscript is organized as follows. In Sect. 2, we formalize the concept of true discovery guarantee and briefly review the methods that will be used in the analysis. Then we discuss the dataset in Sect. 3. and present results in Sect. 4.

2. Permutation-based true discovery guarantee

Suppose that we are interested in studying m univariate hypotheses H_i with $i \in M = \{1, \dots, m\}$, with significance level $\alpha \in [0, 1)$. Denote with $T \subseteq M$ the subset of false hypotheses. Subsequently, for any non-empty subset $S \subseteq M$ define its TDP as $\pi(S) = |S \cap T|/|S|$, where $|\cdot|$ denotes the size of a set. Hence $\pi(S)$ represents the proportion of false hypotheses (true discoveries) in S. The set T is unknown, and so is $\pi(S)$. In the case of differential gene expression data, M represents the whole set of genes. A hypothesis H_i is false when gene i is active, i.e., differentially expressed between two populations. Finally, each subset S represents a biological pathway, and $\pi(S)$ is the proportion of truly active genes inside.

To make inference on $\pi(S)$, we consider procedures with true discovery guarantee. They are defined as random functions $\bar{\pi} : 2^M \to \mathbb{R}$, where 2^M is the power set of M, such that

$$P\left(\pi(S) \geq \bar{\pi}(S) \text{ for each } S \subseteq M\right) \geq 1 - \alpha.$$

Hence $\bar{\pi}(S)$ is a lower $(1 - \alpha)$-confidence bound for $\pi(S)$, simultaneously over all possible subsets S; simultaneity ensures the validity of the confidence bounds even under post-hoc selection (6).

As argued in Sect. 1, in this paper we focus on the permutation framework. In this context, recent proposals for methods with true discovery guarantee are the following. *sumSome* (13) is an iterative method that relies on sum-based global tests, such as most p-value combinations, and converges to an admissible procedure after a finite, but possibly exponential in m, number of iterations. *pARI* (2) and *sansSouci* (4) both use critical vectors of ordered p-values, e.g., based on higher criticism (5) or Simes inequality (10). *pARI* is presented in two ways: a fast single-step version, similar to *sansSouci*, and an iterative version that uniformly improves both the single-step version and *sansSouci*. Since the gain in power is generally small, here we will consider the single-step version. Finally, *Notip* (3) further improves *pARI* and *sansSouci* through a modification of the critical vector that is data-dependent. The default version of the method requires to divide the data into two subsets, employing the first (training set) to define a family of data-dependent critical vectors, and the second (inference set) to select a suitable critical vector within the family and use it for inference. The Authors show through simulations that the method remains valid and is even more powerful if the same data is used for training and inference, provided that two independent rounds of randomization are performed; here we will focus on this second version.

With the exception of *Notip*, all the above-mentioned procedures are not single methods but families of methods, allowing for different choices of the setting: the sum test in *sumSome* and the family of critical vectors in the others. Different choices have different power properties, depending on many aspects of the problem, such as intensity of the signal, density, homogeneity, structure, etc. In the next sections, we will apply the methods to differential gene expression data. For each method, we choose the setting that we expect to be more powerful according to simulation results from the corresponding original paper.

Finally, we underline that each particular choice for the method/setting gives statements for all possible subsets of genes; so it may be more powerful than other choices for some pathways and less powerful for others. Depending on which pathways we are interested in, different choices may result to be preferable. Here we will comment on the overall behavior on all pathways.

3. Analysis of the breast invasive carcinoma data

In this section, we analyze the breast invasive carcinoma dataset from The Cancer Genome Atlas (TCGA) research network (https://www.cancer.gov/tcga). It contains gene expression data,

i.e., levels of each gene's product, for patients with different types of breast tumor. The analysis aims to assess differences between two histological types of primary solid tumor: infiltrating lobular carcinoma and infiltrating ductal carcinoma. After selecting patients in the two sub-populations of interest, we filter out the 10% of genes with the lowest mean expression among subjects, obtaining expression values for 985 subjects and $15{,}678$ genes. We study the whole set of genes as well as the 352 pathways contained in the Kyoto Encyclopedia of Genes and Genomes (KEGG) database (8). The database contains a large pathway including $1{,}339$ genes, while the size of the others ranges from 3 to 501.

The analysis is carried out as following. For each gene, we consider the null hypothesis that the mean expression is the same in the two sub-populations, and we compute a p-value through a two-sided two-sample t-test. Then we use the p-values as input for the different procedures with true discovery guarantee, taking $\alpha = 0.05$ as significance level. Hence each procedure will return lower 0.95-confidence bounds for the TDP of the considered gene sets.

For each method, the analysis is performed using the code provided by the Authors: the R packages (11) and (1) for *sumSome* and *pARI*, respectively, and the Python code available at `https://github.com/sanssouci-org/sanssouci.python` for the remaining methods. Each setting is chosen considering that gene expression data is generally characterized by dense signal and medium-high correlation between genes. Therefore in *sumSome* we use the harmonic mean p-value, with truncation of all p-values greater than α to 0.5; the algorithm is run for at most 50 iterations. In *pARI* and *sansSouci* we use critical vectors based on higher criticism (5) and Simes (10), respectively. The different choice is due to the fact that higher criticism is not implemented for *sansSouci*. Finally, the methods that rely on critical vectors require choosing the vector size (parameter K in (4), and $k_{\max}$ in (3)). As there is no choice that is optimal in all scenarios and there are no guidelines for the particular case of gene expression data, we opt for the most intuitive alternative and take the size as the number of all genes. However, smaller sizes could lead to more powerful procedures.

Regarding the number B of permutations, *Notip* requires a high number to obtain a suitable resolution when computing the data-driven critical vector. Therefore we take $B = 1000$ for the main analysis. For the other methods, however, we run additional analyses with $B = 200$ permutations to evaluate to which extent results are robust to this choice.

4. Results

First, we consider the main analysis, carried out with 1000 permutations. All methods find activation, i.e., non-null TDPs, in the whole set of genes and in the same 344 pathways out of 352. Table 1 contains results for all genes and for some of the most active pathways. In particular, for each method we report the ten pathways having the highest TDP. Notice that there is a substantial, but not complete, overlap between the pathways that result to be most active in different methods; as a consequence, the table shows thirteen pathways in total.

Now we can compare the results given by different methods. For each pair of methods, Fig. 1 displays the relationship with an highlight on the size of the pathways, while Fig. 2 shows the boxplot of the differences in results. Results are generally homogeneous, with differences most likely dominated by the variability due to the random permutations. The greatest differences, with a maximum of 9.94%, tend to correspond to the smallest pathways, but there is not a clear pattern regarding size.

Finally, we examine results for *sumSome*, *pARI*, and *sansSouci* from the additional analyses that make use of $B = 200$ permutations instead of 1000. In general, the only requirement on B to have non-zero power in permutation-based tests is that $B \geq 1/\alpha$. However, low values of B give lower mean power and more variable results due to the randomness of the permutations (7). The role of the choice of B has been investigated for *sumSome* (13), for which the Authors suggest that $B = 200$ is generally sufficient to have suitable power. The outcome of this analysis seems to point in the same direction for all considered methods, as the TDP does not change significantly for the two choices of B (Fig. 3).

To summarize, we have compared four permutation-based procedures with true discovery guarantee in the analysis of a gene expression dataset. The methods under study exhibit comparable powers, with differences primarily concentrated in the smallest pathways. We underline that we considered only one

Abstract

The Non Parametric Combination (NPC) methodology is a permutation-based solution which can be successfully applied in many statistical analysis. It has many advantages including the fact that it does not require any distributional assumptions, it has few requirements (e.g. exchangeability), it can deal with different types of variables both for repeated measures and paired data, it is flexible in terms of choice of test statistic, and it implicitly takes into account dependency among variables. All these features make it suitable for application in many challenging contexts. The aim of this paper is to prove a literature review on recent developments on this topic since 2010.

Keywords: Non Parametric combination methodology, literature review, applications, developments

1. Introduction

The Non Parametric Combination (NPC) methodology is a permutation-based technique. Being permutation-based, it does not require any distributional assumptions. This feature makes it quite competitive when compared to the parametric methodologies presented in the literature, i.e. it can be considered a good alternative to the parametric F-test or t-test which require an assumption of normality. In fact, in real applications data do not follow a known distribution and in the multivariate framework the assumption of normality is particularly hard to justify. This is true in many application fields, such as medicine, psychology and biology, both for survey data and observational studies. Additionally, NPC has multiple advantages that make it particularly exploitable in multivariate business contexts: it has few requirements, such as the exchangeability property, it can handle different types of data, such as continuous, categorical or mixed variables, both for repeated measures and paired data, it can be successfully applied in situations characterized by small sample size or high dimensional data, it can handle restricted alternative hypotheses or datasets characterized by missing values. NPC shows low type II error and good power performances even with small sample sizes (2). Furthermore, thanks to a permutation approach, the NPC methodology implicitly takes dependency among variables into account, both for dependent and independent samples. Finally, it is flexible: the most suitable system of hypotheses can be chosen depending on the nature of the problem. For more detail on technical aspects of the methodology, see Pesarin and Salmaso (30). Given all these promising characteristics, the NPC methodology appears to be an instrument of interest not only from a statistical point of view but also for practitioners. The main aim of this short paper, therefore, is to understand what developmental trends have been introduced for the NPC methodology since 2010. In particular, we want to understand: the main directions of development reported in the literature; the main content of the developments introduced; the methodology's main

fields of application; and what suggestions have been made for interesting future directions of study. To address the aforementioned points, we perform a systematic literature review of the Non Parametric Combination methodology with specific focus on most recent developments since 2010.

The paper is set out as follows: the next section explains the methodology used to conduct the literature review (Section 2); Section 3. presents the results; conclusions and final remarks are provided in Section 4.

2. Methodology

The review was carried out on two databases, namely Scopus and Web of Science, using a query made up of three main blocks: the first concerned the NPC methodology or variations of the term; the second concerned permutation tests; the third concerned a multivariate setting. All keywords were searched for in titles, abstracts and keywords. Filters were then used to select the papers: only papers in English, only papers published in the period 2010-2023 (for methodology prior to 2010, see Pesarin and Salmaso (2010) (30)) and only articles were considered. Papers from the two databases were merged and duplicates removed. We then read the abstracts and made an initial selection based on the information reported there. The resulting 27 papers were read in full and analysed.

3. Main findings

Of the 27 papers considered, 18 focus on theoretical developments (67%) and 9 focus on the application of the methodology in real contexts (33%). With regard to the papers on application of the methodology, the majority are linked to the field of medicine, confirming the assertion of Racioppi et al. (2015) that NPC is particularly suited to the biomedical field (33). The importance of NPC's applicability is further confirmed by the structure of the papers focused on the development of knowledge from a theoretical point of view. Of the 18 theoretical papers, 15 (which is approximately 83%) contain one or more case studies from datasets presented in the literature or from datasets collected by the authors. The presence of a case study in almost all the publications highlights the importance of the applicability of the methodology in real contexts. As such, the methodology is not only appealing from a theoretical and statistical perspective, but is also appealing to practitioners. The NPC methodology also appears to be particularly suited to analyzing survey data. Indeed, 4 of the 9 application papers deal with this scenario.

As stated before, the NPC methodology appears to be particularly suited to many application fields, such as biomedical, or in general to both observational and experimental studies (33) as well as to survey data (11). In all these scenarios the number of observational units is commonly lower than the number of considered variables. Two considerations of particular interest arise from this field. Firstly, in Pesarin et. al (2010) (31), the authors described a particular property of the NPC methodology, namely finite sample consistency. According to this property, by adding a variable while the sample size remains the same (preferably small), the power of the NPC methodology can monotonically increase. As a result, NPC is seen to be particularly suited to application in datasets characterized by a number of variables higher than the number of observational units: this type of configuration is known as thick data and is challenging to deal with. Langthaler et al. (2022) (24) further investigate the analysis of thick data by considering the most popular methods used to analyze this type of dataset, including the NPC methodology, and compare them by running a simulation study. Secondly, medical datasets are very frequently characterized by a high number of zero values and this can represent a challenge when it comes to performing a statistical analysis. The reason for this high presence of zero data is the fact that the field often includes censored data or data with measurements below the limit of the instruments used for the measurement. Arboretti et al. (2020) (8) focused on the application of NPC in this particular circumstance taking into consideration three different test statistics (Anderson-Darling, Mann-Whitney and difference of means) in a two-sample multivariate setting.

The property of finite sample consistency leads to another property, namely equipower, introduced

by Salmaso (2015) (34). This property states that, by adding informative variables while the sample size remains fixed, the power of the NPC-based test increases. This is also a very important feature of the NPC methodology from a computational point of view: it allows us to apply NPC in situations characterized by high dimensional datasets, which are typical in, for example, healthcare or genetic studies. Neuroimage data is a concrete example of a high dimensional dataset, particularly if we consider the high-resolution imaging of today. Winkler et al. (2016) (36) introduce a modified NPC solution to deal with this type of data with the aim of obtaining an improvement in power performances compared to traditional tools. Another feature of the NPC methodology is the impact of the presence of dependency structures in a dataset, in other words the presence of correlated variables. Salmaso (2015) (34) used a simulation study to analyze the impact of correlation in terms of power performances of NPC: the results reveal that the presence of correlation causes a loss in power performance. Similarly, Arboretti Giancristofaro et. al (2016) (4) investigated this aspect specifically for ordered categorical outcomes with the same results. The power performance of the NPC methodology is also influenced by the choice of combining function as studied in Arboretti Giancristofaro et. al (2016) (4). On a similar theme, Langthaler et al. (2022) (24) provide some recommendations for choosing the most suitable combining function. Alfieri et al. (2012) (1) proposed an NPC-based methodology to perform an iterated procedure on the choice of most appropriate combining function.

As said at the beginning, the NPC methodology appears to be particularly suitable for many application fields. Specifically, it seems to be regularly adopted in all statistical problems related to comparisons among $C > 2$ populations, from different points of view. Some examples of its application to compare $C > 2$ groups or populations are presented in Lanfranchi et al. (2020) (23), Barisan et al. (2015) (11), Fasolato et al. (2010) (20) and Alibrandi et al. (2022) (2). Corain et. al (2019) (19) applied NPC as a ranking procedure as did Montelli et. al (2016) (28). This represents a common problem in statistics which deal with the ability to rank C populations according to $p > 2$ variables of interest. Arboretti et al. (2014) (5) and Corain et al. (2014) (17) focused on ordered categorical response variables and provided a solution within the NPC approach. Although the problem is widely studied in the literature, the solution provided by Arboretti et al. (2014) (5) is essentially different to all the other solutions, particularly in relation to its purpose, methodology and inference. This NPC-based ranking solution can be applied to different mixes of response variables as well as to thick data. Another way to study the ordering of C is to use the stochastic ordering problem, which is slightly different. In this case the aim is to test the equality of distributions against a one-sided ordered alternative with at least one strict inequality. An example of the application of the NPC methodology to this problem is presented in Brombin et. al (2016) (13). For a theoretical application of the NPC methodology to the stochastic ordering problem, we refer the readers to contributions by Bazyari et al. (2013) (12) and Arboretti et al. (2021) (9), the latter in particular for the goodness-of-fit problem. The problem of comparing populations can also be approached from different angles. Comparing populations also means dealing with location, scale or symmetry testing in a multivariate scenario. For example, Antonucci et al. (2019) (3) applied the NPC methodology to test the mean difference and this is particularly true if the symmetry of distribution is around zero. Many authors have contributed to the development of methodologies to address these issues. The most popular multivariate parametric test in the literature for the location problem is Hotelling's T^2 test. Some authors also provided non-parametric solutions based on ranks (see for example Oja et al. (2004) (29)). In a multivariate non-parametric setting, other solutions were provided based on the notion of data depth - see for example Liu et al. (1993) (27), the T-based and M-based test by Li et al. (2004) (25), Chanvan et al. (2016) (14), Chenouri et al. (2012) (16), and Li et al. (2016) (26). However, even solutions within the NPC methodology framework are developed and presented in the literature. Chanvan et al. (2019) (15) presented a solution to simultaneously deal with location and scale by considering an NPC-based solution based on the notion of data depth. This is not the only development introduced in the last decade. Corain et al. (2015) (18) proposed some improvements to NPC to test the equality of mean vectors with a linear additive model by exploiting a multi-aspect strategy, an adding-variable strategy, and an iterated combination technique. Arboretti et al. (2017) (6) faced another peculiar problem: testing location shift among populations, which is useful for comparing, for example, two treatments. To do so they exploited an NPC-based methodology and extended the solution provided by Pesarin et al. (2016) (32) for a multivariate setting taking the union-intersection (UI) solution into account. A natural extension of

the multivariate location problem is the MANOVA problem; see, for example, Racioppi et al. 2015 (33). NPC methodology developments are also proposed in the literature to deal with this task; see Giancristofaro et al. (2012) (21) and Arboretti et al. (2018) (7). In the first, an extension was introduced to compare two or more treatments in a randomized complete block (RCB) design dealing with categorical response variables. In the second, the authors suggested an NPC-based methodology for a two-way design for the specific scenario of small sample size and high number of variables. In the literature there are also solutions to test specific symmetries among populations (e.g. bivariate, angular, spherical and central). Kalina (2021) (22) presents a test for general symmetry. The paper considered the NPC methodology for testing symmetry among multivariate populations after providing a list of robust multivariate estimators.

By exploiting the multi-aspect strategy mentioned above, the NPC methodology can be successfully applied in all situations which require the testing of a multidimensional hypothesis. Again this could be useful to resolve the issue of comparing $C > 2$ populations under different aspects of interest. To this end, Arboretti et al. (2022) (10) exploited the approach to resolve the goodness-of-fit problems in Arboretti et al. (2021) (9) and exploited multi-aspect testing to provide an NPC-based solution to test three population aspects: location, variability and cumulative distribution function.

In summary, from the literature review we have identified three main strands of development: insights into NPC properties; particular types of data dealt with by NPC; and comparisons among populations using NPC. If we consider the percentage of papers for each principle direction, we observe that development of knowledge in support of comparisons among populations is the one with the highest percentage (61.1%), i.e. this is the topic on which authors have concentrated efforts to propose solutions in the NPC field, either to solve some challenging tasks or to propose a better alternative to the solutions already present in the literature. The importance of this field is also confirmed by papers on the practical applications of the NPC methodology; all of them focus on the problem of comparing populations in a multivariate permutation framework. This is found to be quite a common problem in many different application fields (medical, sport, agricultural, biological, food, psychological, and so on). Therefore, we recommend further investigation of the application of the NPC methodology to solve the task of comparing multivariate populations and implementing appropriate changes. Another important aspect of interest is the fact this methodology can handle not only numerical variables, but also categorical or mixed variables. As mentioned above, some authors have focused their attention over the past decade on these types of variables in order to provide some solutions. Furthermore, the NPC methodology can be successfully applied in situations characterized by small sample size or high dimensional dataset. Given the development of information technologies in recent years which allow the collection of huge amounts of data, and given the higher quality and complexity of, for example, imaging data, the application of NPC may be a suitable solution which needs more attention in future years. Particular attention should be paid to thick data as they become more and more popular in many industrial contexts and the need grows for the right instruments to carry out their statistical analysis. Langthaler et al. (2022) (24) suggest an in-depth investigation of the ratio between informative and uninformative variables within the framework of thick data in order to investigate NPC's power performance. Additionally, the multi-aspect strategy which is possibly applicable in NPC methodology can be further exploited in common application contexts. For example, Arboretti et al. (2020) (8) suggested providing a multi-aspect solution within the NPC-based framework in situations characterized by zero-inflated data. Finally, with regard to properties of the NPC methodology, some aspects were investigated, such as finite sample consistency, equipower, and the impact of correlation and combining functions, however further aspects could be investigated especially in cases where exchangeability might not be fully assumed (e.g. second order exchangeability (35)).

4. Conclusion

This short paper looks at the Non Parametric Combination (NPC) methodology and in particular recent developments in the multivariate framework, the main directions of development since 2010, and its main applications to real contexts. To the best of our knowledge, a comprehensive literature review which explains and summarizes the most important recent developments and possible future developments of the methodology has not been carried out therefore the review presented in this short paper fills

this gap. The analysis highlighted three main directions of development, namely development of NPC properties, development to treat non-traditional types of data, and development to conduct statistical comparisons among populations. The large number of case studies in papers devoted to the theoretical development of NPC methodology together with analysis of the NPC application in real contexts emphasize its suitability to deal with real case studies. NPC appears to be particularly suitable for performing statistical analysis both in observational studies and on survey data, particularly in the biomedical field. Our literature review highlights also emerging fields of application as well as some possible directions of development.

Abstract

The efficiency of the judicial system should be one of the main objectives of every democratic state, mainly to prevent the continuation of uncertainty, from a legal and procedural point of view, which can cause prejudice and harm to those who are subjected to a trial. Among the institutions that have the greatest impact on economic performance, the legal and judicial system plays a prominent role. Understanding how laws and regulations affect economic behaviour is fundamental in modern economies in order to verify the distributive impact of the different legal and judicial systems and what features they should have to encourage economic growth. Our analysis, using data disaggregated at district level, has the goal of measuring the efficiency of the Italian judicial offices, empirically estimating a quantile regression model to evaluate the performance of the courts. Data referred to 2021 about judges, pending cases on, incoming cases, as well as resolved cases are extracted from the annual reports of the Italian Ministry of Justice.

Key words: quantile regression, judicial system, efficiency evaluation

1. Introduction

Efficiency in the general context of modern society is the ability to achieve a predetermined goal, which takes the form of keeping the level of resource productivity. The objective is relevant both in the private sector and in the public one and is achieved through the definition of defined cost standards ex-ante. In the private sector, the issue is based on available resources and therefore often not related to ethical constraints, although these are operational both in the public and in the private. In several countries, economic development has boosted the mobility of population, changing the distribution of litigation. Hence, the increasing difference between the new demand of legal services and the old judicial maps has increased processing time and backlog, therefore, badly affecting judiciary efficiency. According to the Organization for Economic Co-operation and Development [11], the European Union [1], as well as the International Monetary Fund [3], the Italian judicial system is one of the less efficient in Europe, and its inefficiency differs within Italy also respect to judgment Court grade [2] and geographical areas [10].

In the current debate we often discuss of the public sector, being widely believed that an administration that has high levels of spending is inefficient. In fact, the concept of efficiency applied to the functions performed by government institutions should take on a meaning of productivity in relative terms, similarly to the activities of companies: an institution can be defined more or less efficient on the basis of a benchmarking analysis with other units involved in the same production process, and it is correct to speak of greater efficiency only when this comparison shows that a unit is able to achieve the same final results in terms of goods and services delivered (output) using a smaller amount of resources (input), or higher results on a parity of resources used. Identifying efficient performance cannot therefore

result from the mere observation of lower levels of expenditure but must result from an assessment of the institution's ability to allocate to the better resources than the objectives pursued.

2. Statistical methodologies for efficiency assessment

The purpose of our paper is to provide new information in judicial context. The performance of frontier estimation methods using data from Italian Courts is analysed in the paper. Quantile Regression (QR) is also suggested as solution to frontier production function estimation [6]. The choice of estimation methods among conventional techniques significantly affects the juridical evaluation. Consequently, QR furnishes valuable new information by estimating different levels of production functions corresponding to different efficiency scores. In addition, the method analyses the performance of the conventional methods.

For the median regression line, we consider initially the case in which it is required that the straight line passes through a point and, subsequently, the case without restrictions. The presentation of the methodology for the determination of the parameters of the straight-line results, especially in the constrained case, in this case the determination of the regression coefficients is obtained by leading, through an appropriate decomposition of the regression residues, bringing the minimum problem back to a linear programming problem.

This methodology, originally introduced and appreciated for its characteristics of robustness, has found great interest in the literature and success in various application areas for the greater completeness of analysis that it is able to offer compared to the classical linear model of regression. Linear quantile regression modelling is introduced using loss functions: in this case it is illustrated how the use of several loss functions lead to least squares regression, absolute minimums and, for the asymmetric absolute loss function, QR. In the application on judicial efficiency, we show some characterizations and properties of the estimators obtained by applying QR. Modelling for economic phenomena, typically not negative, such as income and consumption or for efficiency in a general sense, makes us understand the importance of this technique [14].

Since the Seventies, QR has gained considerable popularity in different fields of research. In the economic field it has been applied, for example, for the study of changes in incomes and wages, in the study of market strategies and in market analysis real estate [6]. QR can be seen as an extension of the linear regression model as it characterizes the entire distribution of a response variable, conditioned on a set of covariates through the estimation of its quantiles. In other words, the estimate of the conditional average is replaced from estimates of conditioned quantiles (e.g., the median), which allow to define more completely and exhaustive the relationships between the variables. Unlike regression on the mean, for QR it is not no assumption is needed about the distributional form of errors, and this makes this method robust [5].

A possible application is based on estimating the efficiency frontier through QR [8]. Moutinho et al. [9] proposed a Data Envelopment Analysis (DEA) and QR approach to evaluate the economic and environmental efficiency assessment in EU country. Tsionas [12] proposed a novel quantile Stochastic Frontier Model (SFM) and develop Markov Chain Monte Carlo techniques for numerical Bayesian inference. In an empirical application to US large banks, he documents important differences between the QR and the traditional SFM, in terms of several aspects of the data and considerable heterogeneity among different quantiles in terms of returns to scale, technical change, efficiency as well as productivity growth.

Economic analysis of productive system is fundamentally based on production function specification and estimation. The production function is a frontier function since it describes the maximum output attainable by the firms that implements efficient production processes. In particular if we denote with y_n^{δ} the maximum output given the input vector $\boldsymbol{x}_n$ for the n.th firm, in this case the theoretical frontier production is represented by the equation

$$y_n^{\delta} = f(\boldsymbol{x}_n) \tag{1}$$

which correspond to the technology upper limiting the production possibility set. At the same time, the observable production process could be at most equal to its maximum, that is

$$y_n \leq y_n^{\delta} \tag{2}$$

In this context, the frontier estimation can be made in parametric and non-parametric way.

Following the parametric approach, the frontier is represented by a probabilistic relation $f(\mathrm{x}, \theta)$ deriving by means of econometric techniques. This approach is better suited for frontier estimation than standard techniques since it explicitly attempts to estimate the parameters of production function on the frontier. To this purpose the function error term is supposed to consist of a Gaussian random component $\boldsymbol{v}_n$ and of a negative random component which explains the inefficiency $\boldsymbol{u}_n$

$$y_n^{\delta} = f(\boldsymbol{x}_n) + \boldsymbol{v}_n - \boldsymbol{u}_n \tag{3}$$

Empirical implementation of the data provides estimates of economic parameters and efficiency scores for each firm by mean of distance measured obtained separating the (in)efficiency component from the overall error term. In order to improve the implicit neutrality of efficiency distribution it is possible to reformulate the stochastic frontier model substituiting the unconditional mean with a conditional mean dependent on a set of explanatory factors. The quantile function $Q_y(\tau|\mathbf{x})$ is defined as $\mathrm{F}^{-1}(\tau) = inf\ \{y: F(y|x) \geq \tau\}$ where $F(y|x)$is the conditional distribution of y given x. The conditional quantile can be determined through

$$\rho_\tau(\epsilon) = \epsilon(\tau - 1) \tag{4}$$

with $\epsilon < 0$ and where the loss function $\rho_\tau(\epsilon)$ is known as the check function.

For a traditional linear model $Q_y(\tau|\mathbf{x}) = x_i'\beta(\tau)$ and the quantile estimators can be obtained solving

$$\min_{\beta} \sum_{i=1}^{n} \rho_\tau(y_i - x_i'\beta(\tau)) \tag{5}$$

for a given τ.

3. Analysis results

During the last two decades, greater attention was paid to improved performance in the public sector. In this context, the importance of a good judicial system is acknowledged, since it allows to maintain a peaceful coexistence among the citizens of a nation and, above all, the rights and duties that are necessary for each of them [13]. This is even more relevant if we consider the Italian judicial system, which is considered one of the most inefficient in Europe according to the Organization for Economic Co-operation and Development [11] and the European Union [1], as well as the International Monetary Fund [3]. Moreover, inefficiency differs within Italy also respect to the diverse geographical areas [4].

Data referred to 2021 about judges, pending cases on, incoming cases, as well as resolved cases are extracted from the annual reports of the Italian Ministry of Justice.

A Cobb-Douglas frontier function, for which factors returns are equal to parameters is specified.

The number *J* of judges, the incoming cases *I*, and the average duration (in days) *D* are considered as input. The output is represented by the resolved cases. The analysis is conducted on 140 Italian courts. Therefore, the general production function equation is:

$$lny_n = \beta_0 + \beta_1 lnJ + \beta_2 lnI + \beta_3 lnD + \boldsymbol{v}_n - \boldsymbol{u}_n \tag{6}$$

with $\boldsymbol{v}_n \sim N(0, \sigma_v^2)$

In the model all the Courts are assumed to operate efficiently. (In)Efficiency among Courts is admitted by subtracting a truncated normal stochastic component from the error component of the classical regression model.

Table 1: Stochastic Frontier parameters

	Estimate	Std. error	Z-value	Pr(>|z|)
(Intercept)	-0.1734	0.6341	-0.2735	0.7845
log(Judges)	0.0299	0.0535	0.5598	0.5756
log(Incoming)	0.8876	0.0418	212.3380	< 2.2e-16
log(the average duration in days)	0.1552	0.0961	16.1530	0.1063
sigmaSq	0.6238	0.1042	59.8670	< 2.2e-6
Gamma	0.8793	0.0496	177.3070	< 2.2e-16

An alternative approach can be obtained using QR which provides a description of a response variable as a conditional function of a set of covariates broader than the methods based on conditional means. The interesting feature consists of extending the analysis from mean or median values to the full range of other conditional quantile functions, providing an analytical description of an ordered set of technological relationships corresponding to different level of efficiency.

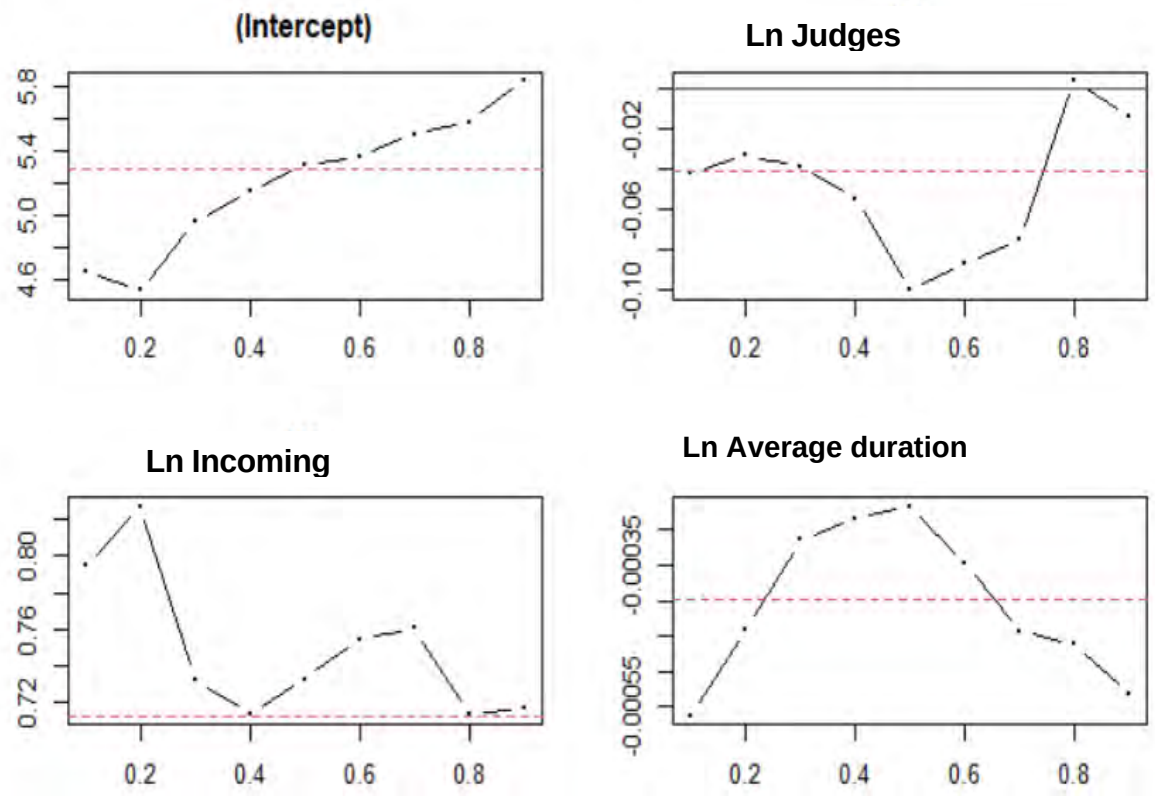

Figure 1: Estimate quantile regression

On Fig. 1 we can observe a strong variation in estimated coefficient along the percentile axis, and an increasing intercept along the quantiles. The change of coefficient is more noticeable for the incoming cases but also considered for the Judges.

The dotted line in each figure shows the least squares estimate of the conditional mean effect. A considerable dispersion is observed for the coefficient of explicative variables at different quantiles. The estimated value of $\beta_{1\tau}$ varied between -0,10 to -0,02. The estimated value of $\beta_{2\tau}$ varied 0,72 to 0,80 while $\beta_{3\tau}$varied from -0,00055 to -0,00035 and it reached it's the maximum at 50th quantile.

4. Final remarks

The purpose of the present paper is to provide new information in Judicial context. The performance of frontier estimation methods using data from Italian Courts is analysed in the application. QR is also suggested as solution to frontier production function estimation [6]. The choice of estimation methods among conventional techniques significantly affects the juridical evaluation. Consequently, QR furnishes valuable new information by estimating different levels of production functions corresponding to different efficiency scores. In addition, the method analyses the performance of the conventional methods.

Civil justice has been the subject of numerous legislative interventions over the recent years, also because of growing attention that the institutions European countries have attributed to this area reform. Since 2012 the improvement of quality, independence and efficiency of judicial systems has become, in fact, a priority of the European system. An inefficient judicial system harms the fundamental rights of citizens and penalizes businesses and investors. The European Commission, in the country-specific recommendations it presents each year, has for long been asking Italy for a reform of justice that eliminates delays and inefficiencies.

From the analyses we carried out concerning performance of the ordinary courts, the existence of territorial differences emerges significantly, between the Northern and Southern regions of the country. There are also evident greater difficulties of the smaller courts, respect to those of larger dimensions. Small courts seem, in fact, to suffer of critical issues such as the impact on the ability to cope with the annual flow of new practices, resulting increased gradients, both on duration of the proceedings.

Abstract

The contribution is meant as a pilot exercise on the development of a variable selection technique that combines fitting and prediction performance. The simplest step towards this goal involves a forward selection algorithm for binary classification achieved via logistic regression. At each step, the algorithm selects the predictor, among the covariates that are significantly associated with the outcome, that entails the significantly largest AUC increment with respect to the previous model. For the sake of illustration, we present some examples relative to the search of the most predictive factors of the propensity to pension planning, health insurance subscription, and the use of Financial Technology services like home banking, taken from the Survey on Household Income and Wealth 2020 run by Bank of Italy. Concluding remarks are provided on further developments.

Keywords: Logistic regression, Forward variable selection, AUC index

1. The framework

The paper investigates the performance of a forward variable selection for (possibly weighted) logistic regression based on the area under the ROC[1] curve (AUC) (1; 5) with the aim of determining a parsimonious model with both good fitting and predictive abilities. This goal is strategic for diagnostic procedures in the medical field, but also for socio-economic studies, as several indicators of consumers' behavior are difficult to predict. The background idea is not new, as the challenge of combining explanatory and predictive goals in regression models has solicited several works in the literature (13). For instance, (11) provided an estimation procedure based on the optimization of the empirical area under the ROC curve, which has been improved in (14). When approaching this challenge, one of the first issues one has to wonder is related to methods of testing the statistical significance of the AUC difference of correlated ROC curves, as those corresponding to nested models on the same data. The so-called DeLong test (3) for comparing the AUC difference between correlated ROC curves may raise some critical issues, as it can be conservative if based on in-sample analysis and it is based on multivariate normal data (a setting that is very common in the biomedical framework). For these reasons, the Authors in (4) advice against its direct application and suggest evaluations based on the corresponding confidence intevals instead. Issues due to the asymptotic distribution of the AUC under the null are discussed also in (9), and motivate the introduction of a test procedure based on AUC for logistic regression but only for two binary predictors and solely for testing the first-stage null $H_0 : AUC = \frac{1}{2}$.

[1]Receiving operating characteristic

Hereafter, in order to obtain an automatic procedure and embed a test on AUC differences within a variable selection algorithm, we resort to the (stratified) bootstrap procedure implemented in the `R` package `pROC` (12) to test that the prediction improvement between subsequent steps is statistically significant.

1.1 AUC-based forward variable selection for logistic regression

Several measures can be chosen to assess the predictive performance of a binary classification, as the classical Brier Score (2) and the (empirical) AUC index of the receiving operating characteristic curve constructed on out-of-sample observations. Here we will rely on the AUC since it is the most popular choice and also since it is a normalized indicator.

Since the selection depends on prediction performances, K-fold cross validation will be exploited and at each step (with $K = 10$), model estimation will be carried out in-sample on a training set, whereas its discrimination ability will be assessed on out-of-sample observations. The algorithm can be summarized as follows:

- Let $\mathcal{M}^{(h-1)}$ be the model estimated and validated at step $h-1$, with $h-1$ covariates $\mathbf{Z}^{(h-1)}$.
- The goal of the h-th step of the forward procedure is to identify the covariate X in the available predictor space $\mathbf{X}(\mathcal{M})$ that optimizes both fitting and prediction with respect to the previous step. With some more details:
  1. for each $k = 1, \ldots, K$, the dataset is divided into K folds, say $\mathcal{D}_1, \ldots, \mathcal{D}_K$;
  2. for each $k = 1, \ldots, K$, consider $\mathcal{F}_k = \bigcup_{i \neq k} \mathcal{D}_i$ as training set and $\mathcal{D}_k$ as test set;
  3. for each k, estimate the Model $Y \sim (X, \mathbf{Z}^{(h-1)})$ for each available covariate X, say $\mathcal{M}_X^{(k,h)}$: let $BIC_X^{(k,h)}$ be its BIC on $\mathcal{F}_k$, $AUC_X^{(k,h)}$ be the corresponding AUC on the test set $\mathcal{D}_k$ and $\beta_X^{(k,h)}$ its estimated regression effect;
  4. for each covariate X entailing significant effects over all the folds, consider the average BIC, AUC and regression coefficients over the folds:

$$\widehat{BIC}_X^{(h)} = \frac{1}{K}\sum_{k=1}^{K} BIC_X^{(k,h)}, \qquad \widehat{AUC}_X^{(h)} = \frac{1}{K}\sum_{k=1}^{K} AUC_X^{(k,h)}, \qquad \widehat{\beta}_X^{(h)} = \frac{1}{K}\sum_{k=1}^{K} \beta_X^{(k,h)} \tag{1}$$

- the h-th variable selected to enter the model is then given by $X^\star$ if:

$$\widehat{AUC}_{X^\star}^{(h)} = \max_{X \in \mathbf{X}(\mathcal{M})} \{\widehat{AUC}_X^{(h)}\}$$

  and if the difference with respect to $\widehat{AUC}_{X^\star}^{(h-1)}$ is statistically significant, at given α level, so that $\mathbf{Z}^{(h)} = (\mathbf{Z}^{(h-1)}, X^\star)$ is the new predictor vector. If $h = 1$, the procedure will resort to testing the null $H_0 : AUC = \frac{1}{2}$ against the alternative $H_1 : AUC > \frac{1}{2}$ for each significant covariate, choosing in the end the one entailing the largest significant difference with respect to the null.
- Then step $h+1$ is initiated and the procedure is re-iterated until either there is no covariate entailing significant effects or if there is no significant covariate that implies a significant increment in the AUC with respect to the previous step.

2. Some examples

In recent decades, the growing diffusion of financial technology (FinTech) and the progressive ageing of the population have profoundly changed the behavior of individuals. In particular, the longer lifespan requires individuals to make greater efforts in planning their retirement deciding how and how

much to save in order to ensure an adequate level of well-being and adequate health care in old age. Similarly FinTech is revolutionizing the financial services sector with a strong impact both in terms of financial planning and financial well-being (10). In this context we chose to test our proposal to the identification of the most predictive factors of some indicators of the propensity to pension planning and to use FinTech services. We refer to the 2020 edition of the Survey on Household Income and Wealth (SHIW) run by the bank of Italy (6), one of the most comprehensive studies carried out by the Bank of Italy to collect information on economic and financial status of Italian households. We consider the usage of home banking as an indicator of the propensity to use the FinTech services, and health insurance and pension plan subscription as indicators of pension planning. Indeed, these indicators are deemed to reveal important aspects of the respondent economic and financial behaviour, thus their prediction can be of interest to stakeholders.

The set example used hereafter consists of $n = 4044$ responses from household's head, after omission of missing values. The predictor space consists of all socio-economic and demographic variables collected within the survey: gender[2], having or nor a university education, work condition[3], household composition and its economic and living conditions, and the age generation of the household head. For the sake of simplicity, the procedure will consider only binary indicators as predictors.

Table 1 reports the most influential predictive factors of the indicator of usage of home banking service, listed in the ordering determined by the procedure. Specifically, for each row, we report the corresponding average AUC and BIC referring to the model including the covariates up to that row, where, at each step, we have averaged the AUC measures referring to the out-of sample ROC curves constructed on the left-out fold, for varying folds. We also report the average p-value for the test of significant differences in AUC between subsequent steps and the average regression coefficient since our ultimate goal is to identify both explanatory and predictive properties of available predictors. Tables 2-3 report the analogous results for the analysis on the indicators of health insurance and pension plan subscription, respectively.

It is worth to notice that the ordering in average AUC across folds does not match the corresponding one relative to BIC chosen as fitting indicator. A graphical display of the results with the plot of (empirical) ROC curves computed stepwisely is provided in Figure 1.

Table 1: Results from AUC-based forward variable selection applied to the logistic regression of the binary indicator of usage of home banking services in 2020

Comparison of binary regressions with asymmetric link function for imbalanced data

Michele La Rocca[a], Marcella Niglio[a], and Marialuisa Restaino[a]

[a]Di.S.E.S., University of Salerno, Via Giovanni Paolo II, 132 - Fisciano (SA) - Italy ,
[larocca, mniglio, mlrestaino]@unisa.it

Abstract

Logit and Probit link functions are largely used in the regression domain to model binary response data. In the presence of an imbalanced dependent variable their use can lead to obtaining biased estimates of the regression model parameters and then the selection of asymmetric links may be more appropriate in this case. We here compare two asymmetric link functions for regression models, the Generalized Extreme Values and the Generalized Logistic links, presenting some results related to their maximum likelihood estimators. Using different rates of imbalance in the response data, the comparison of the empirical distribution and the accuracy of the estimates of the models' parameters based on the two link functions are evaluated through a simulation study.

Keywords: Asymmetric link, GEV, Generalized Logistic, likelihood

1. Introduction

Estimating binary response variable is an important statistical task in many areas, including social sciences, biology, and economics. In binary regression, the two commonly used symmetric link functions are the Logit and Probit [10]. Several studies have investigated their limitations. In particular, statistical models based on the symmetric link functions lie on the assumption of equal class distribution for data [8, 14] and they might produce biased estimates [10]. However, these functions might be improper in the presence of imbalanced data, which occurs when one of the classes is much smaller than the other. If the degree of imbalance is extreme, the events become rare [8, 14]. The main reason for this inadequacy is that the probability of a binary response, as a function of covariates, approaches zero and one at different rates [3, 7], and consequently the probability of imbalanced events should be underestimated [8, 14].

To deal with these problems, some proposals have been suggested such as i) the bias correction method [8], ii) the penalized methods [6], and iii) the use of asymmetric link functions [9, 11, 12, 14].

Given this framework, our attention is on the last point, i.e. on the use of asymmetric link functions, and we investigate the effect of the finite sample size on the choice of the link functions. In more detail, the aim is to evaluate and compare the performance of two classes of asymmetric link functions, Generalized Extreme Values (GEV) distribution [14], and Generalized Logistic distribution [5], in the presence of different rates of imbalance in the binary response variable, according to the finite sample sizes.

In Sect. 2, the regression models for unbalanced binary data are introduced. In Sect. 3, through a simulation study, the empirical distribution of the estimates and their accuracy are shown for the two classes of asymmetric link functions is done.

2. Regression models for imbalanced binary data

Consider a response variable Y whose distribution belongs to the exponential family and a vector of p covariates $\mathbf{X} = (X_1, X_2, \ldots, X_p)$. Further, $E[Y_i] = \mu_i$ is the expectation of Y_i, for $i = 1, 2, \ldots, n$, with n the sample size and where $g(\cdot)$ is a monotone and differentiable function such that:

$$g(\mu_i) = \mathbf{x}_i'\boldsymbol{\beta}, \tag{1}$$

where $\boldsymbol{\beta} = (\beta_0, \beta_1, \beta_2, \ldots, \beta_p)$ is the $[(p+1) \times 1]$ vector of parameters and $\boldsymbol{\beta} \in \mathbb{R}^{p+1}$, $\mathbf{x}_i' = (1, x_{i1}, x_{i2}, \ldots, x_{ip})'$ is the vector of explanatory variables of unit i. The function $g(\cdot)$, called *link function*, relates $\mathbf{x}_i'\boldsymbol{\beta}$ to μ_i and has to be chosen to properly deal with the set of values assumed by μ_i, for $i = 1, 2, \ldots, n$. The equation (1) defines the generalized linear model (GLM) characterized by a link function that is an increasing or decreasing function of μ_i (among the others see [10]).

When Y is a binary response variable which assumes values $y = \{0, 1\}$, the probability associated to $Y_i = y_i$ is π_i if $y_i = 1$ and $1 - \pi_i$ if $y_i = 0$. Therefore, Y_i can be modeled by using a Bernoulli random variable with probability density function $P(Y_i = y_i) = \pi_i^{y_i}(1 - \pi_i)^{1-y_i}$, for $y_i = \{0, 1\}$ and $i = 1, 2, \ldots, n$.

Furthermore,

$$E[Y_i] = \pi_i = P(Y_i = 1) = F(\mathbf{x}_i'\boldsymbol{\beta}), \tag{2}$$

where $F(\cdot)$ is the cumulative distribution function and using the GLM notation (1):

$$\pi_i = g^{-1}(\mathbf{x}_i'\boldsymbol{\beta}) = F(\mathbf{x}_i'\boldsymbol{\beta}).$$

The selection of the link function $F(\cdot)$ is strictly related to the nature of the dependent variable Y and its misspecification may affect the estimated regression coefficients (for small and large-sample effects in the binary response case see [4]).

As underlined in Section 1, the symmetric links function (logit and probit) are mostly used even if they might produce biased estimates in the presence of imbalanced data. Therefore, asymmetric link functions should be preferable.

In this manuscript, we will focus on two classes of asymmetric link functions:

1. *Generalized Extreme Value* (GEV) *distribution* [14]:

$$\pi_i = \exp\{-[1 + \xi\mathbf{x}_i'\boldsymbol{\beta}]^{-\frac{1}{\xi}}\}, \tag{3}$$

   where $(1 + \xi\mathbf{x}_i'\boldsymbol{\beta}) > 0$ and $\xi \in \mathbb{R}$ is the shape parameter.
2. *Generalized Logistic distribution* [5]:

$$\pi_i = \frac{1}{(1 + \exp\{-(\mathbf{x}_i'\boldsymbol{\beta})\})^{\alpha}}, \tag{4}$$

   where $\alpha > 0$ is the parameter that controls the asymmetry. If $\alpha = 1$, the symmetric logistic distribution is obtained whereas as $\alpha \to \infty$ the (4) becomes a Gumbel distribution [13].

The corresponding log-likelihood function associated with the binary regression model is given by:

$$\ell(\boldsymbol{\beta}, \gamma; \mathbf{X}, \mathbf{y}) = \sum_{i=1}^{n} \{y_i \log(\pi_i) + (1 - y_i) \log(1 - \pi_i)\}, \tag{5}$$

where π_i is given by (3) and (4), according to which distribution is chosen, γ is the shape parameter, and therefore $\gamma = \xi$ in the GEV case and $\gamma = \alpha$ with the Generalized Logistic distribution.

In Fig. 1 Generalized Logistic and GEV cumulative distributions are plotted for different shape parameters and for the sake of comparison Logistic distribution is also shown. It can be clearly appreciated the asymmetry of the Generalized Logistic and of the GEV distribution and their different behaviors as the probability approaches 0 or 1.

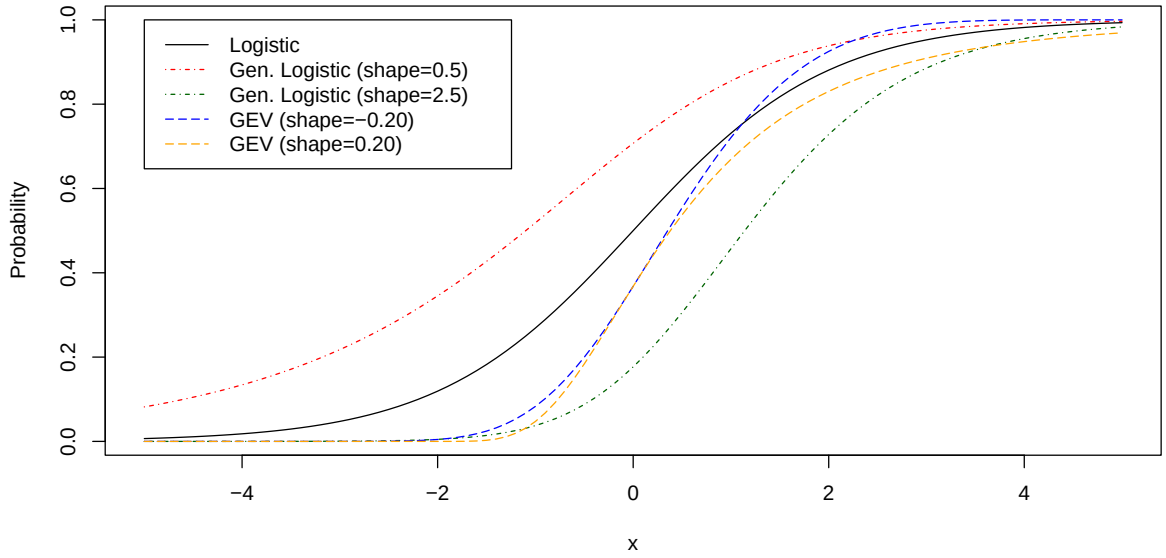

Figure 1: GEV and Generalized Logistic cumulative distributions for different values of the shape parameters.

The estimation of the parameters of the GEV regression model based on the maximum likelihood method has been largely investigated in [1] whereas different approaches have been considered for the estimation of the parameters when the link function is given by (4).

In both cases, the score functions do not have closed form and then the maximum-likelihood estimators can be obtained by maximizing the log-likelihood by numerical algorithms. In this case, the knowledge of the score vector can be of help to reduce the computational time and simplify the search of the maximum (mainly in this case where the function to be maximized is not linear).

The score vector of the GEV regression model has been presented in [1] but, in our knowledge, any corresponding results are given for the Generalized Logistic regression. For this reason, we present here the score function of the Generalized Logistic regression model, given by:

$$\frac{\partial \ell(\boldsymbol{\beta}, \alpha; \mathbf{X}, \mathbf{y})}{\partial \beta_j} = \sum_{i=1}^{n} \alpha \frac{\pi_i^{1/\alpha}}{(1-\pi_i)} x_{ij} \exp[-\mathbf{x}_i'\boldsymbol{\beta}](y_i - \pi_i), \quad j = 0, 1, \ldots, p \tag{6}$$

$$\frac{\partial \ell(\boldsymbol{\beta}, \alpha; \mathbf{X}, \mathbf{y})}{\partial \alpha} = \sum_{i=1}^{n} \alpha^{-1} \left[(y_i - \pi_i) \frac{\log(\pi_i)}{1-\pi_i} \right]. \tag{7}$$

where π_i is given in (4), for $i = 1, 2, \ldots, n$.

What associates the two distributions (3) and (4) is not only the asymmetric behavior but also the difficulties that can arise to estimate the shape parameter (ξ and α respectively). These difficulties are mainly due to the complexity of the function to be maximized and the behavior of the log-likelihood that can be empirically appreciated in Fig. 2.

This problem is overtaken in the GEV case, defining for ξ a grid of values over which the $\boldsymbol{\beta}$ vector is estimated, as in [2] among the others. Bayesian approaches are instead used for the Generalized Logistic case.

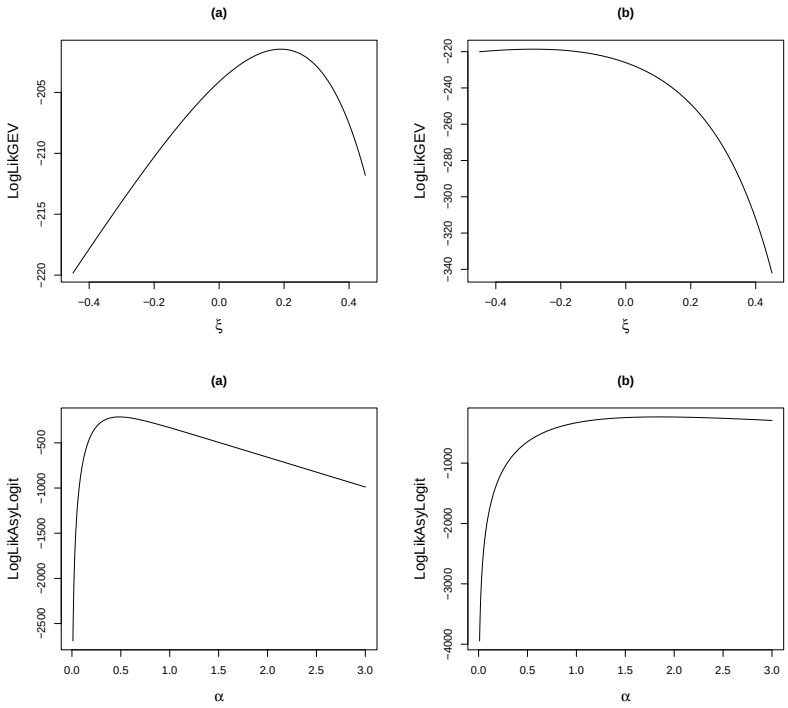

Figure 2: Top: Profile log-likelihood of the GEV regression when $\xi = 0.20$ frame (a) and $\xi = -0.20$ frame (b); Low: Profile log-likelihood of the Generalized Logistic regression when $\alpha = 0.5$ frame (a) and $\alpha = 2$ frame (b).

3. Simulation study

The choice of the asymmetric link function in the presence of imbalanced binary response data cannot be an easy task when the selection is made in large classes of functions. We have presented in Sect. 2. two asymmetric links and we have discussed some problems that can arise when the log-likelihood has to be maximized. Another problem that needs to be faced is how to choose between them. We here consider this point evaluating how the imbalance of the dependent variable affects the estimate of the vector $\boldsymbol{\beta}$, and consequently its variability, with finite samples.

To evaluate how the imbalance of the Bernoulli dependent variable (Y) affects the maximum likelihood estimates when n is finite, we have implemented a simulation study to compare the estimate of the vector $\boldsymbol{\beta}$ in the presence of GEV and Generalized Logistic regression models, when Y is characterized by different proportions of imbalance.

For this aim, we have generated the data from both regression models using four sample sizes $n = \{100, 250, 500, 1000\}$, three different proportions of imbalance $Pr(Y = 1) = \{0.05, 0.10, 0.20\}$, with $Pr(Y = 1)$ the proportion of one's of the dependent variable Y. The covariates X_j, for $j = 1, 2, 3, 4$ have been generated from independent standard Normal random variables, the true value of $\beta_j = 0$, for $j = 1, 2, 3, 4$, whereas the true value of β_0 is selected to guarantee the proportion of imbalance fixed in each case examined in the simulation design.

For all 24 scenarios of the simulation design we have generated 1000 datasets and for each of them, we have estimated the parameters of the vector $\boldsymbol{\beta}$, fixing the shape parameter ($\xi = -0.20$ in the GEV model and $\alpha = 2$ in the Generalized Logistic model).

In Fig. 3 the empirical distributions of $(\hat{\beta}_j - \beta_j)$, for $j = 0, 1$ are presented for all values of $Pr(Y = 1)$ and n (the remaining β_j parameters, $j = 2, 3, 4$, are not included in the figure because, as expected, their behavior is similar to β_1).

The corresponding empirical distributions of the Generalized Logistic distribution are instead given in Fig. 4 where the main difference with the GEV case, can be appreciated only for small n and small

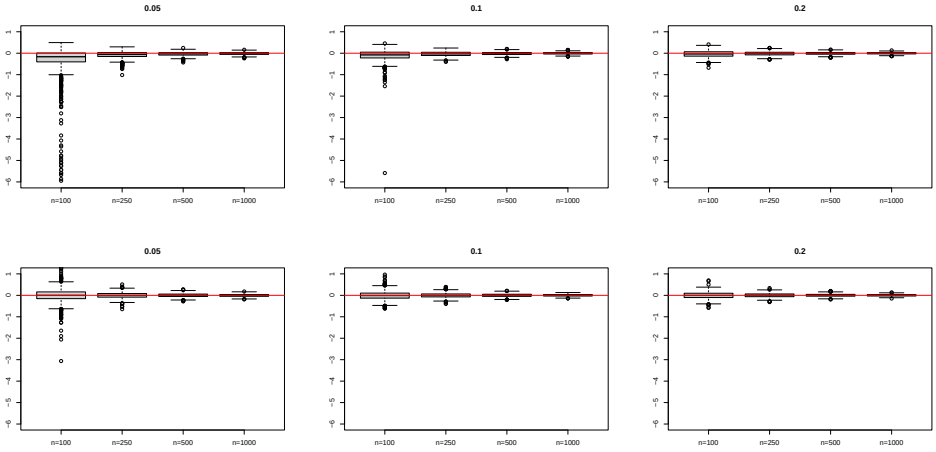

Figure 3: Empirical distribution of $(\hat{\beta}_0 - \beta_0)$ (first row) and $(\hat{\beta}_1 - \beta_1)$ (second row) for the GEV regression model, with $Pr(Y = 1) = 0.05$ (left), $Pr(Y = 1) = 0.10$ (center) and $Pr(Y = 1) = 0.20$ (right).

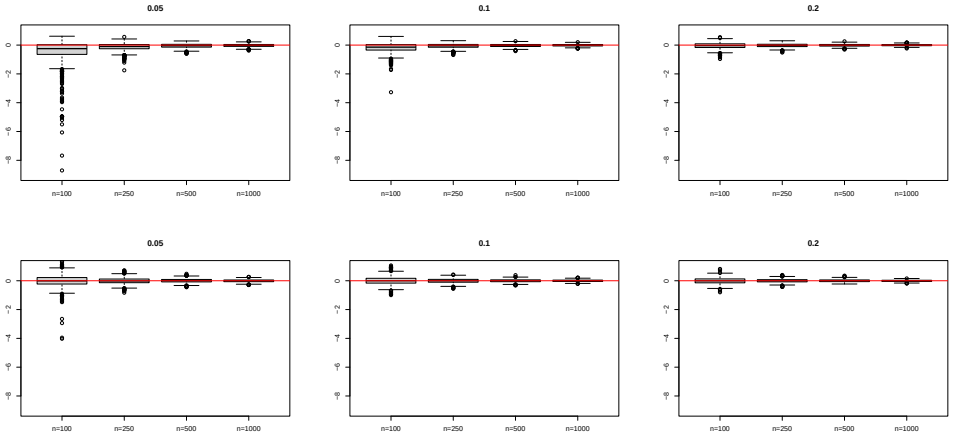

Figure 4: Empirical distribution of $(\hat{\beta}_0 - \beta_0)$ (first row) and $(\hat{\beta}_1 - \beta_1)$ (second row) for the Generalized Logistic regression model, with $Pr(Y = 1) = 0.05$ (left), $Pr(Y = 1) = 0.10$ (center) and $Pr(Y = 1) = 0.20$ (right).

$Pr(Y = 1)$.

To further evaluate the estimates obtained for $\boldsymbol{\beta}$ by using both models, in Table 1 the MSE ratios of the $\hat{\beta}_j$, $j = 0, 1$, estimated from the GEV and the Generalized Logistic regression are presented. In all cases, the MSE of the parameters estimated from the GEV regression is lower than the Generalized Logistic case and this difference is more marked when n is small and the imbalance of data is quite high ($Pr(Y = 1) = 0.05$).

As expected, the choice of the link function in binary regression with imbalanced data becomes crucial in finite sample sizes, especially when n is small.

This is the first step of the comparison that needs to be further explored considering a larger class of asymmetric link functions that is left for future research.

Table 1: MSE ratios of the $\hat{\beta}_j$, $j = 0, 1$ estimated from the GEV and the Generalized Logistic regression.

	n=100			n=250			n=500			n=1000		
$Pr(Y=1)$	0.05	0.10	0.20	0.05	0.10	0.20	0.05	0.10	0.20	0.05	0.10	0.20
$\hat{\beta}_0$	0.016	0.618	0.536	0.391	0.481	0.560	0.396	0.478	0.537	0.353	0.455	0.522

Abstract

In this paper we propose a new Mixed-Effects Quantile Regression Forest by generalizing the Quantile Regression Forest approach to longitudinal data. The inferential procedure is based on the Nonparametric Maximum Likelihood exploiting the Asymmetric Laplace distribution tool. The performance of the ME-QRF is tested in a simulation study and compared with the results of standard quantile regression models. Finally, the ME-QRF is applied to a data set for analysing the effect of the tratment on lead-exposed children.

Keywords: Quantile Regression, Random Forests, mixed-effects, longitudinal data

1. Introduction

Mixed-effects quantile regression models are used in longitudinal studies to obtain a more complete picture of the response variable distribution with respect to standard linear regression while accounting for serial correlation among observations of the same statistical unit [5; 4; 2; 7]. This paper proposes a novel machine learning algorithm, denoted Mixed- Effects Quantile Regression Forest (ME-QRF) to estimate quantiles of longitudinal data generalizing the Quantile Regression Forest (QRF) algorithm of [9]. The inferential approach is based on the Asymmetric Laplace distribution tool by applying the Non Parametric Maximum Likelihood approach (NPML) of [6] already introduced in a quantile regression framework by [1; 10] to the Quantile Regression Forest contest. In particular, we develop an EM algorithm to estimate quantiles by decoupling the fixed-effects estimation part from the random-effects one without making any parametric assumption. The ME-QRF performance is tested by means of a simulation study and by comparing its performance with standard quantile regression models. The ME-QRF is also applied empirically using a dataset from the study of [13] conducted to assess whether the succimer treatment of children with Blood Lead Levels (BLL) $< 45\mu$g/dL is beneficial and safe.

2. Methodology

Let $y_{it}, i = 1, \ldots, N, t = 1, \ldots, T_i$ be the response variable for the i-th statistical unit observed at time t, and $\mathbf{x}_{it} \in \mathbb{R}^p$ be the vector of explanatory variables where $x_{it,1} \equiv 1$.

By indicating with $\tau \in (0, 1)$ the quantile probability level, the standard quantile regression linear mixed-model (LQMM) is:

$$y_{it} = \mathbf{x}'_{it}\boldsymbol{\beta}_\tau + b_{i,\tau} + \varepsilon_{it} \quad \text{where} \quad Q_\tau(\varepsilon_{ij}|\mathbf{x}_{it}, \boldsymbol{\beta}_\tau, b_{i,\tau}) = 0, \quad \forall\tau \in (0, 1) \tag{1}$$

where $\boldsymbol{\beta}_\tau$ is a vector of τ- dependent regression coefficients common to all statistical units, the term $\mathbf{x}'_{it}\boldsymbol{\beta}_\tau$ is the "fixed-effects" part of the model, whereas the term $b_{i,\tau}$ is the "random-effects" part, represented by a time-constant parameter that varies across statistical units according to a distribution $f_b(\cdot)$ with support $\mathcal{B}$.

Here we avoid making a parametric assumption concerning the fixed-effects part as in (1) and formulate the quantile mixed model as follows:

$$y_{it} = g_\tau(\mathbf{x}_{it}) + b_{i,\tau} + \varepsilon_{it} \quad \text{where} \quad Q_\tau(\varepsilon_{it}|\mathbf{x}_{it}, b_{i,\tau}) = 0, \quad \forall\tau \in (0,1) \tag{2}$$

where $g_\tau : \mathbb{R}^p \to \mathbb{R}$ is a non-parametric unknown function. The terms $g_\tau(\mathbf{x}_{it})$ and $b_{i,\tau}$ are estimated via Maximum Likelihood by means of an EM algorithm based on QRF. We exploit the Asymmetric Laplace (AL) distribution as suitable tool [14], where $y_{it} \sim AL(\mu_{it}, \sigma_\tau, \tau)$:

$$f(y_{it}|\mu_{it,\tau}, \sigma_\tau, \tau) = \frac{\tau(1-\tau)}{\sigma_\tau} \exp\left\{ -\rho_\tau\left(\frac{y_{it} - \mu_{it,\tau}}{\sigma_\tau}\right)\right\}, \tag{3}$$

where $\sigma_\tau > 0$ is the scale parameter, the function $\rho_\tau(u) = u(\tau - \mathbf{1}_{\{u<0\}})$ is the quantile loss function of [5] and the location parameter $\mu_{it,\tau} = g_\tau(\mathbf{x}_{it}) + b_{i,\tau}$ represents the quantile at level τ.

The observed data likelihood is:

$$L(\boldsymbol{\Phi}_\tau) = \prod_{i=1}^{N}\left\{ \int_{\mathcal{B}} \prod_{t=1}^{T_i} f(y_{it}|\mu_{it,\tau}, \sigma_\tau, \tau) f_b(b_{i,\tau})\, \mathrm{d}b_{i,\tau}\right\} \tag{4}$$

where $\boldsymbol{\Phi}_\tau = \{\sigma, b_1, \ldots, b_N\}$. The main issue concerning the likelihood in (4) is that it involves a multidimensional integral that does not have a closed form solution and that it requires to specify the functional form of $f_b(\cdot)$. Thus, an EM algorithm is developed to estimate $g_\tau(\mathbf{x}_{it})$ with a QRF and to estimate $b_{i,\tau}$ by maximising (4) without making any parametric assumptions about the form of $f_b(\cdot)$.

In line with previous contributions [8; 11; 1], we approximate $f_b(\cdot)$ with a discrete distribution by exploiting the NPML approach of [6]. In particular, we consider a discrete distribution on $K < N$ locations $b_{k,\tau}$ such that $b_{i,\tau} \sim \sum_{k=1}^{K} \pi_{k,\tau}\delta_{b_{k,\tau}}$, where the probability $\pi_{k,\tau}$ is defined as $\pi_{k,\tau} = \mathbb{P}(b_{i,\tau} = b_{k,\tau})$ with $i = 1, \ldots, N$ and $k = 1, \ldots, K$ where $\delta_{b_{k,\tau}}$ is a one-point distribution putting a unit mass at $b_{k,\tau}$. The likelihood (4)is reformulated as:

$$L(\Phi_\tau) = \prod_{i=1}^{N}\left\{ \sum_{k=1}^{K} \prod_{t=1}^{T_i} f(y_{itk}|\mu_{itk,\tau}, \sigma_\tau, \tau)\pi_{k,\tau}\right\}, \tag{5}$$

where $\boldsymbol{\Phi}_\tau = \{\sigma, b_1, \ldots, b_K, \pi_1, \ldots, \pi_K\}$ is the parameter vector.

The next section described the EM algorithm based on (5) and QRF used to obtained $\hat{\Phi}_\tau$.

2.1 The EM algorithm

Given that each observation i in (5) can be considered as drawn from one of the K locations of the discrete distribution used to approximate $f_b(\cdot)$, we denote with w_{ik} the indicator variable equal to 1 if the i-th unit belongs to the k-th component of the finite mixture, and 0 otherwise. The component membership w_{ik} is considered as missing data and, from (5), the complete data log-likelihood is:

$$\ell_c(\boldsymbol{\Phi}_\tau) = \sum_{i=1}^{N}\sum_{k=1}^{K} w_{ik,\tau}\Big\{ \sum_{t=1}^{T_i} \log(f(y_{it}|\mu_{itk,\tau}, \sigma_\tau)) + \log(\pi_{k,\tau})\Big\} \tag{6}$$

Estimates $\widehat{g}_\tau(\mathbf{x}_{it})$ and $\widehat{b}_{i,\tau}$ in (2) are obtained from (6) in a EM algorithm by decoupling the fixed-effects estimation, obtained with a QRF, from the random-effects one as follows.

Initialization By indicating with r the generic iteration of the algorithm, in the first step $r = 0$, $\widehat{b}^{(0)}_{i,\tau}, \hat{\sigma}^{(0)}_\tau, \hat{\pi}^{(0)}_{k,\tau}, \widehat{g}_\tau(\mathbf{x}_{it})^{(0)}$ are initialised. In particular, the initial value $\widehat{g}_\tau(\mathbf{x}_{it})^{(0)}$ is computed as the τ-th quantile estimated with a QRF fitted with the training set $\mathcal{T}^{(0)} = \{(y_{it}, \mathbf{x}_{it})\}_{\substack{i=1,\ldots,N \\ t=1,\ldots,T_i}}$.

E-step The E-step consists in updating $\hat{w}_{ik,\tau}^{(r+1)}$ and $\widehat{g}_\tau(\mathbf{x}_{it})^{(r+1)}$. In particular, $\hat{w}_{ik,\tau}^{(r+1)}$ is updated as:

$$\hat{w}_{ik,\tau}^{(r+1)} = \mathbb{E}[w_{ik,\tau}|y_{it}, \mathbf{x}_{it}, \hat{\Phi}_\tau^{(r)}] = \frac{\prod_{t=1}^{T_i} f_{itk,\tau}^{(r)} \hat{\pi}_{k,\tau}^{(r)}}{\sum_{l=1}^{K} \prod_{i=1}^{T_i} f_{itl,\tau}^{(r)} \hat{\pi}_{l,\tau}^{(r)}}, \tag{7}$$

where $f_{itk,\tau}^{(r)}$ is the response variable distribution when considering the k -th component of the finite mixture.

The estimate $\widehat{g}_\tau(\mathbf{x}_{it})^{(r+1)}$ is updated by decoupling the random-effects from the fixed-effects. To this end, $\widehat{g}_\tau(\mathbf{x}_{it})^{(r+1)}$ is estimated with the QRF fitted using the training set $\mathcal{T}^{(r+1)} = \left\{ \left(y_{it}^{*(r+1)}, \mathbf{x}_{it} \right) \right\}_{\substack{i=1,\dots,N \\ t=1,\dots,T_i}}$, in which $y_{it}^{*(r+1)} = y_{it} - \widehat{b}_{i,\tau}^{(r)}$.

M-step In the M-step, numerical optimisation techniques are applied to maximise $\mathbb{E}[\ell_c(\mathbf{\Phi}_\tau)|y_{it}, \mathbf{x}_{it}, \hat{\mathbf{\Phi}}_\tau^{(r)}]$ with respect to $\hat{\sigma}_\tau$ and $\widehat{b}_{k,\tau}$.

The E- and M-steps are alternated iteratively until convergence.

3. Simulation study

This section reports the results of a simulation study carried out to assess the performance of the ME-QRF in a non-linear setting. To this end, the ME-QRF is used to predict quantiles at levels $\tau \in \{0.1, 0.5, 0.9\}$ of an outcome variable simulated under the following non-linear data generating process (DGP) [3]:

$$y_{it} = g(\mathbf{x}_{it}) + b_i + \varepsilon_{it} \quad \text{where} \quad g(\mathbf{x}_{it}) = 2x_{it,1} + x_{it,1}^2 + 4 \cdot \mathbf{1}_{\{x_{it,3}>0\}} + 2x_{it,3} \log|x_{it,1}|$$

The covariates are generated as $x_{it,1},\ x_{it,2},\ x_{it,3} \sim \mathcal{N}(0,1)$. The random-effects parameters and the error terms are generated independently according to two DGPs:

$$\textbf{(NN)}\ b_i \sim N(0,1),\ \ \varepsilon_{it} \sim N(0,1) \qquad \textbf{(TT)}\ b_i \sim t(3),\ \ \varepsilon_{it} \sim t(3)$$

As in [3], for each scenario we consider a training set of 500 observation for $N = 100$ statistical units and $T_i = 5$ measurements each, and an unbalanced test set with $T_i \in \{9, 27, 45, 63, 81\}$ for a total of 4500 observations. Each scenario has been replicated $S = 100$ times.

The average performance of the ME-QRF across the 100 replications is assessed in terms of Average Mean Absolute Error (MAE) and average Mean Squared Error (MSE) with respect to the theoretical quantile of the DGP, computed as in [12]:

$$MAE_\tau = \frac{1}{S}\sum_{s=1}^{S}\frac{1}{N}\sum_{i=1}^{N}\frac{1}{T_i}\sum_{t=1}^{T_i}|Q_{it,\tau}^s - \hat{Q}_{it,\tau}^s| \qquad MSE_\tau = \frac{1}{S}\sum_{s=1}^{S}\frac{1}{N}\sum_{i=1}^{N}\frac{1}{T_i}\sum_{t=1}^{T_i}(Q_{it,\tau}^s - \hat{Q}_{it,\tau}^s)^2$$

where $Q_{it,\tau}^s = Q_\tau^s(y_{it}|\mathbf{x}_{it})$ and $\hat{Q}_{it,\tau}^s = \hat{Q}_\tau^s(y_{it}|\mathbf{x}_{it})$ are respectively the theoretical and estimated conditional quantiles of variable y_{it} at level τ of the s-th simulated dataset.

The ME-QRF is compared with three benchmark models: LQMM, Quantile Random Forest (QRF) and the Quantile Mixed Model (QMM) of [10]. The latter model exploits the same methodological approach of the ME-QRF in a linear setting. Results are reported in Table 1.

		$\tau = 0.1$				$\tau = 0.5$				$\tau = 0.9$			
		ME-QRF	**LQMM**	**RF**	**QMM**	**ME-QRF**	**LQMM**	**RF**	**QMM**	**ME-QRF**	**LQMM**	**RF**	**QMM**
NN	**MAE**	**1.83**	1.86	2.64	4.67	**1.65**	1.72	2.11	2.80	1.67	**1.57**	2.20	5.16
	MSE	**5.87**	5.89	10.98	40.62	**4.62**	5.27	7.15	14.61	4.86	**4.34**	7.93	61.12
TT	**MAE**	**1.80**	1.94	2.02	4.11	**1.43**	1.57	1.44	2.01	**1.87**	2.06	2.06	5.13
	MSE	6.66	**6.42**	7.88	33.16	**4.32**	4.48	4.51	7.82	7.10	**6.81**	8.02	50.79

Table 1: Loss values for each scenario computed on the test set of the four fitted models. Values in bold indicate the smallest loss.

The results highlight that the ME-QRF outperforms the benchmark models at almost all quantile levels in each scenario, especially when the data violate the Gaussianity assumptions. The only exception is represented by the quantile at $\tau = 0.9$ for the NN scenario. In this case, the LQMM outperforms the ME-QRF since the Gaussianity assumptions of the LQMM model hold. The ME-QRF and the LQMM perform similarly in terms of MSE and represent the two models with the lowest MAE and MSE values.

4. Empirical Application

In this section, the ME-QRF is applied to a dataset from a placebo-controlled, double-blind, randomised trial to study whether the succimer treatment of children with Blood Lead Levels (BLL) $<$ 45μg/dL is beneficial and safe. Following [1], three quantile levels are considered $\tau \in \{0.25, 0.5, 0.75\}$.

The dataset includes $T_i = 4$ weekly measurements of BLL for $N = 100$ children with BLL of 20–44 μg/dL. The covariates are the dummy variable Treatment (R_i) taking value 1 for children that have been treated and 0 otherwise, and Time $W_{it} \in \{0, 1, 4, 6\}$ representing week 0 -baseline-, week 1, week 4 and week 6. Given the results of the simulation study, the ME-QRF has been compared in terms of quantile loss with the LQMM with the following formulation:

$$BLL_{it} = \beta_{i1}R_i + \beta_{i2}W_{it}^2 + \beta_{i3}(R_i * W_{it}^2) + \beta_{i4}(R_i * W_{it}) + b_i \tag{8}$$

The quantile loss of [5] is computed as follows and the related results are presented in Table 2:

$$QLOSS_\tau = \frac{1}{N}\sum_{i=1}^{N}\frac{1}{T_i}\sum_{t=1}^{T_i} u_{it}(\tau - \mathbf{1}_{\{u_{it}<0\}}) \quad \text{where} \quad u_{it} = y_{it} - \hat{Q}_{it,\tau}. \tag{9}$$

τ	**0.25**	**0.5**	**0.75**
QLOSS$^{\text{ME-QRF}}$	**1.22**	**1.55**	**1.31**
QLOSS$^{\text{LQMM}}$	1.61	1.82	1.59

Table 2: Results in terms of QLOSS for the treatment of lead-exposed children dataset.

Results show that our model outperforms the LQMM at each quantile level. Figure 1 depicts the treatment and control group quantile trajectories estimated with the ME-QRF for each mixture component at level $\tau \in (0.25, 0.5, 0.75)$. Each trajectory is colour-coded according to the mixture component and the treatment and control group of each component are identified with the solid and dashed lines, respectively. The legend reports the number of statistical units in the control and treatment group of each mixture component. The trajectories estimated with our model are coherent with the findings of [1].

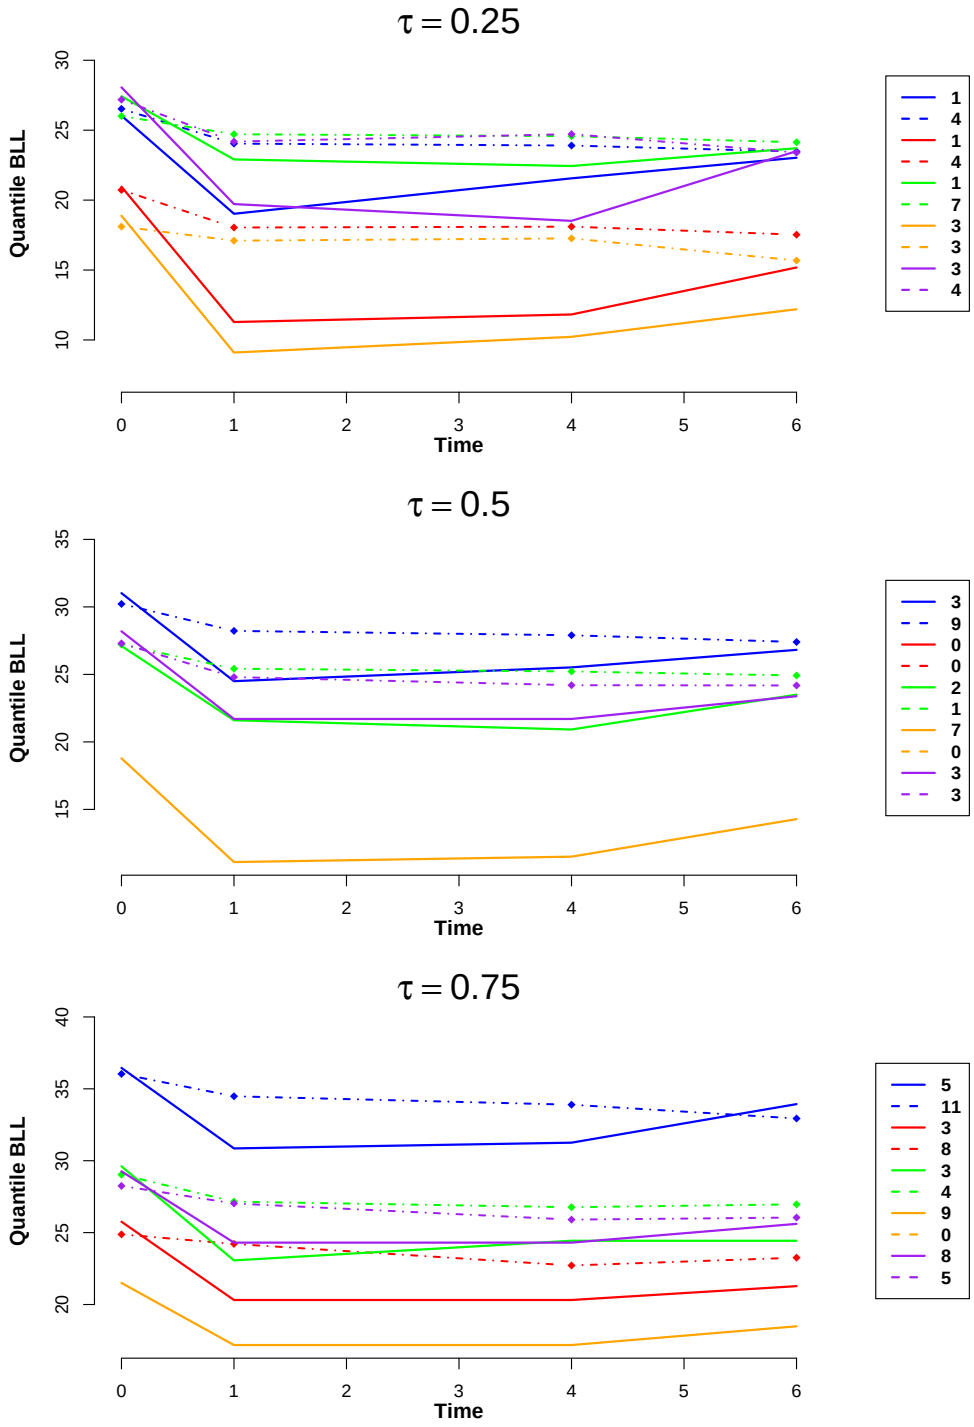

Figure 1: Estimated trajectories for ME-QRF for the first five mixture components. Each component is indicated with one colour, and the treatment (solid curves) and control (dashed lines) groups are represented separately. The legend reports the number of statistical units belonging to each mixture component.

5. Conclusions

This paper introduces the Mixed-Effects Quantile Regression Forest (ME-QRF) model, which combines QRF and mixed-models to estimate quantiles of longitudinal data wotjoud any parameteric as-

sumption on the fixed-effects and the random-effects distribution. Simulation results highlight that the ME-QRF outperforms benchmark models in non-linear settings, especially when Gaussianity assumptions are violated. The ME-QRF is applied empirically using data from the study of [13] in order to assess the effectiveness of the succimer treatment on lead-esposed children. Results show that the ME-QRF outperforms the LQMM model in terms of quantile loss and that findings are coherent with the ones presented in the previous literature.

Abstract

In high-dimensionality regression modelling, the number of candidate covariates to be included in the predictor is quite large, and variable selection is critical. In this paper, we study in detail the CDF penalty, an adaptive non-convex penalty function that ensures consistent variable selection, along with unbiasedness and uniqueness of the solution. We evaluate the effect of the scale parameter in the CDF penalty on the estimates by stressing the role of the ratio between the number of observations and the number of variables.

Keywords: Variable selection, non-convex penalty function, CDF penalty

1. Introduction

Model selection is a critical step in building statistical models when the number of covariates is large, as the choice of the model can greatly impact the quality of predictions and inference. Penalized models, such as lasso [7], SCAD [4] and MCP [8], have gained popularity as methods able to perform, via regularization, both variable selection and estimation. In addition to the aforementioned penalties, the new CDF penalty has recently been proposed [2]. It is a non-convex penalty function capable of adapting the degree of non-convexity such that it enjoys its good properties (e.g., quasi-unbiasedness of non-null coefficients), ensuring the uniqueness of the solution. In addition to the usual tuning parameter λ, the definition of the CDF penalty includes an additional scale parameter ν, which controls the amount of non-convexity. This paper aims to investigate the possible relationship between the n/p ratio (number of observations and number of parameters) and the additional parameter ν.

The work is organised as follows: in Section 2, we will discuss the method and our proposal; in Section 3, a numerical study will be presented; then, the conclusions will follow in Section 4.

2. Penalized GLM framework and our proposal

The penalized Generalized Linear Models (GLM) involve adding a penalty term to the traditional GLM log-likelihood to account for overfitting and improve the stability and interpretability of the model. The penalty term is often in the form of a regularization term, such as the L1 norm of the coefficients (lasso, [7]), which penalizes the magnitude of the coefficients.

Let's assume that the data are (y_i, x_i), $i = 1, ..., n$, where $x_i = (x_{i1}, ..., x_{ip})^T$ are the covariates and y_i is the response. We assume that a random sample of size n is drawn from the distribution (X, Y),

where the conditional distribution of $(Y|X = x)$ density comes from a one-parameter exponential family distribution. The goal of regression analysis is to estimate β, which expresses how the covariates affect μ, i.e. the expected value of Y. Estimation is done by maximizing the likelihood; when the number of covariates is large or $p > n$, a penalty on the parameters can add to shrink the parameter estimates. Following [4], the penalized log-likelihood is defined as usual

$$\ell_\lambda(\beta) = \ell(\beta) - \sum_{j=1}^{p} p_\lambda\left(|\beta_j|\right), \tag{1}$$

where $\ell(\beta)$ is the classical log-likelihood. The tuning parameter λ is the parameter that affects the model's complexity. The penalty function, denoted by $p_\lambda\left(|\beta_j|\right)$, enables simultaneous coefficient selection and estimation. There is an unbounded body of literature on penalty functions; for a broad perspective on high-dimensional statistical issues, see, for instance, [5]. The CDF penalty [2] is defined as

$$p_{\text{CDF}}(|\beta_j|) = \lambda\sqrt{2\pi}\nu\Phi\left(\frac{|\beta_j|}{\nu}\right), \tag{2}$$

where $\Phi\left(\cdot\right)$ is the cumulative distribution function of the standard normal distribution. It is important to emphasize that the choice of the standard Normal distribution is solely based on the penalty shape and not on any assumption regarding the distribution of coefficients. The absolute value of the parameter ensures the singularity at the origin which, in turn, guarantees that the fitted model can include a sparse solution. Our proposal enjoys all three properties enunciated by Fan et al. (2001), i.e.:

1. the estimator $\hat{\beta}$ can reduce the number of parameters, thus setting to 0 the noise-source coefficients (sparsity);
2. the estimator $\hat{\beta}$ is continuous in the data: a slight change in the data should not result in a significant change in the estimates (continuity);
3. the estimator $\hat{\beta}$ is nearly unbiased for large coefficients (unbiasedness).

The correct specification of ν is essential because it affects computational and inferential aspects. The parameter ν determines the "degree of non-convexity" of the penalty and the bias of the non-null estimates, beyond the solution's non-uniqueness. More specifically, a large ν guarantees the uniqueness of the solution, but estimates will be biased. In contrast, using a small ν the non-zero coefficients will be nearly unbiased, but it can result in severe non-convexity, which could result in local optimum conditions for the objective function that is being optimized. Non-uniqueness of the solution is common with non-convex penalties like SCAD or MCP. It is crucial to determine the minimum value of ν that ensures uniqueness. It can be demonstrated (the specifics are omitted here) that the smallest value of ν for any value of λ can be found easily and that the solution is unique. This value is denoted by the symbol ν_{min_λ}. Additional considerations should be made, however. The ν_{min_λ} value found should not be regarded as the best value to use in estimating the penalized model: it should be understood as the lower bound of a range of possible values for finding the best ν value to use.

It is also possible to see the influence of ν on the shape of the penalty from a graphical point of view. Figure 1 shows the CDF penalty at three different values of ν: it is evident how it affects the "degree of non-convexity" of the penalty; the larger ν, the more negligible the non-convexity.

Considering the limiting case, for ν tending to infinity, we have that $\lim_{\nu\longrightarrow\infty} p'_{CDF}(|\beta_j|) = \lambda\,\text{sgn}(\beta_j)$, which is exactly the lasso. In this way it is easy to see how our proposal moves between two limiting cases, namely lasso and a non-convex penalty.

The usual tuning parameter, $\lambda \geq 0$, can be chosen using (generalized) CV or AIC/BIC, and for a fixed λ we propose to use the Alternating Direction Multiplier Method (ADMM) to estimate the coefficients, an algorithm that resolves challenging optimization issues by splitting them up into a number of manageable, smaller issues (for more details, refer to [1]).

As sketched above, the additional parameter ν influences the results, specifically the convergence speed of non-null coefficients to maximum likelihood estimates. The smaller the value, the faster the convergence speed. However, it turns out the smallest allowable value of ν (i.e. ν_{min}) is not always the

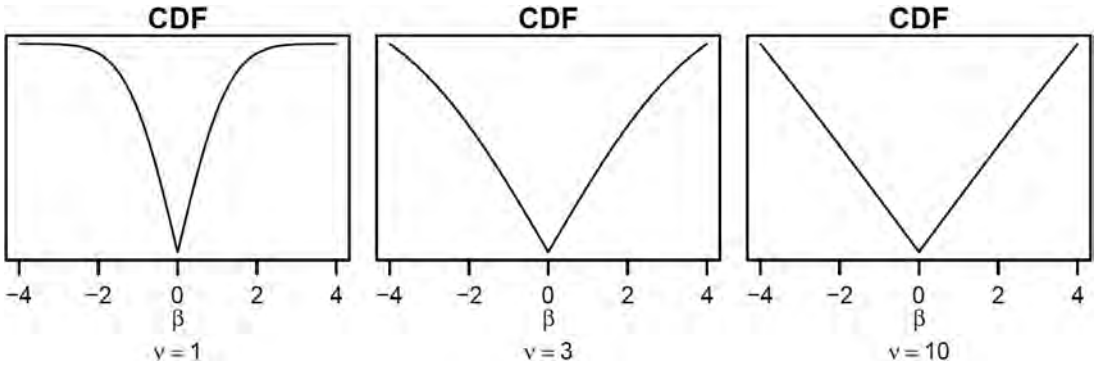

Figure 1: The shape of CDF penalty for different values of ν.

best value to use. In fact, the maximum likelihood theory requires that n is "sufficiently larger than p" (see, for example, [6]). If $n < p$, ML theory does not apply: estimates far from the ML ones are expected to perform better in these contexts. If ν_{min} does not guarantee to have the best solution when $n < p$, the natural question is about the optimal ν, i.e. ν_{opt}.

In the next section, we study the estimator performance as a function of ν and the ratio n/p.

3. Numerical study

To evaluate the evolution of the estimator's performance as ν and the n/p ratio change, a simulation study was undertaken. We simulated data from

$$y_i = \beta_0 + \sum_{j=1}^{p} x_{ij}\beta_j + \epsilon_i.$$

The number of coefficients is fixed to $p = 100$ (only $p_{\mathcal{A}}$ = 10 are non-null); to study the influence of ν at different sample sizes, we consider different n. Based on some preliminary studies, what most influences the differences for different values of ν is not the n/p ratio (i.e. the ratio of the sample size to the number of coefficients, both null and non-null), but the $n/p_{\mathcal{A}}$ ratio (i.e. the ratio to the cardinality of the non-null coefficients). Then, we will consider 21 different sample-size n: the first 20 are fixed to have $n/p_{\mathcal{A}}$ ratios in [0.2, 3] and equally-spaced, the last is fixed to have $n/p_{\mathcal{A}}$ = 4. The covariates are defined as $x_i \sim \mathcal{N}(0, \Sigma)$ with the Toeplitz correlation matrix $\Sigma_{jk} = 0.5^{|j-k|}$ and $\epsilon_i \sim \mathcal{N}(0, 1)$. The locations of non-null coefficients are randomly chosen, and their values are drawn randomly from a $Unif(1, 2)$. Three measures are considered to compare the simulation results, namely

$$\text{MSE} = \sqrt{\frac{1}{B}\frac{1}{p}\sum_{j=1}^{p}\sum_{b=1}^{B}\left(\hat{\beta}_{b,j} - \beta_j\right)^2} \quad \text{FPR} = \frac{\#(\hat{\beta}_{bj} \neq 0 | \beta_j = 0)}{\#(\beta_j = 0)} \quad \text{TPR} = \frac{\#(\hat{\beta}_{bj} \neq 0 | \beta_j \neq 0)}{\#(\beta_j \neq 0)},$$

where b is the index related to the replicates and $\hat{\beta}$ are the estimated coefficients. The TPR and the FPR are used to compute the AUC. We ran 100 replicates for each scenario, and for each replicate, we fitted 40 different penalized models using k = 40 different ν-values, i.e.

$$\nu_k = k \times \nu_{min}.$$

The 40 different values of ν proved are composed of an "expansion factor" k always greater than 1 and ν_{min}: in this way, different values of increasing ν are used, which guarantee the uniqueness of the solution. The different values of k are 40 equispaced values in [1, 100]: the first value we use, therefore corresponds to ν_{min}; on the other hand, as the "expansion factor" increases, the estimated model becomes more and more similar to lasso.

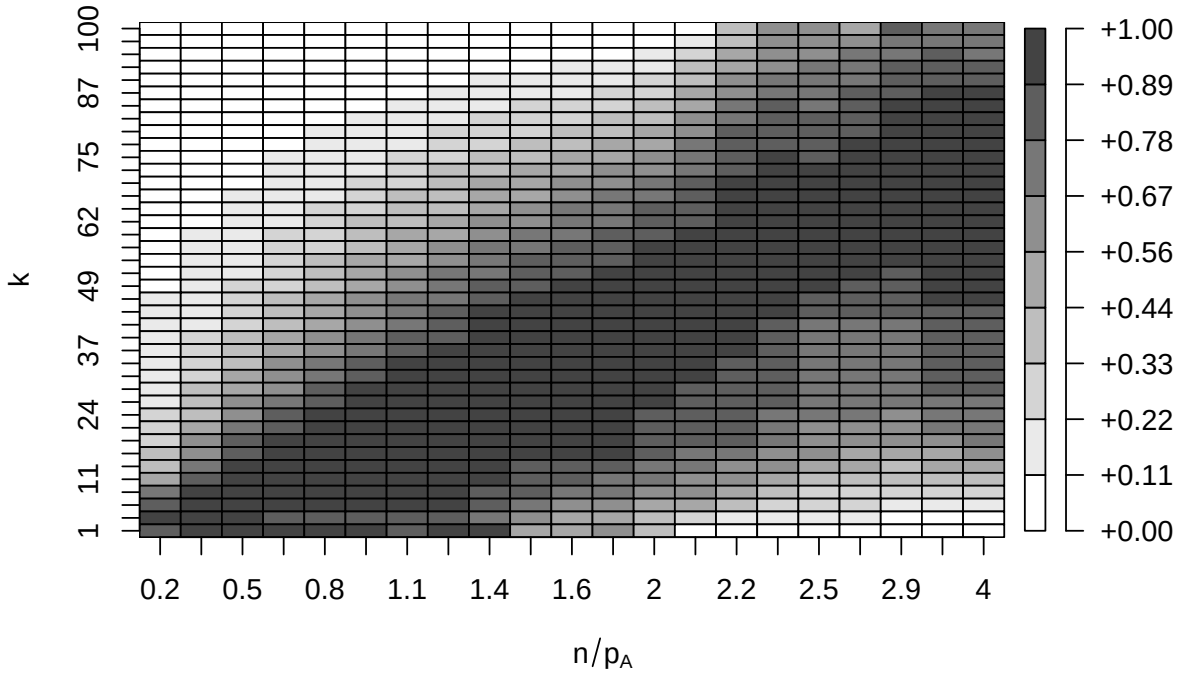

Figure 2: Scaled MSE (by $n/p_{\mathcal{A}}$), varying k and $n/p_{\mathcal{A}}$. Lighter squares correspond to lower MSE (better).

Figure 2 shows the values of the MSE varying the coefficient of expansion (i.e. ν) and the ratio $n/p_{\mathcal{A}}$. The MSEs have been standardised in [0,1] by row, to make it easier to read the result when the ratio $n/p_{\mathcal{A}}$ varies: a standardisation carried out on all values would not have made the interpretation of the result easier, since the variations in the results due to the effect of k would have been covered by the influence of the ratio $n/p_{\mathcal{A}}$. Values close to 0 indicate better performance (as they correspond to the best values for a given $n/p_{\mathcal{A}}$), while values close to 1 indicate poor performance (as they are close to the maximum MSE calculated for a given $n/p_{\mathcal{A}}$).

It can be seen from the graph that in the presence of a low sample size with respect to a high number of non-null parameters, the best performance is obtained using a high value of $n/p_{\mathcal{A}}$. The interpretation of this result is quite simple: by using small values of ν, the estimates of the model quickly converge to the maximum likelihood estimates. Since the maximum likelihood estimator requires the sample size to be larger than the number of parameters to be estimated, the penalised estimator with small ν therefore "inherits" the same difficulties as the maximum likelihood estimator. In this context, using a lasso-like form of the penalty (which introduces bias into the estimated parameters at the cost of reduced variance) gives better results. Conversely, as the ratio $n/p_{\mathcal{A}}$ increases, the performance obtained with a reduced value of ν tends to improve; for values of the ratio $n/p_{\mathcal{A}}$ greater than 2, the MSEs calculated with the smallest value of ν are always the best. This is because the maximum likelihood estimator performs better with more information available, and so does the penalised model.

In the simulation study, we tried the same setting with much higher values of $n/p_{\mathcal{A}}$ (up to 20), and the pattern remained the same. However, for reasons of readability, we decided to report values up to $n/p_{\mathcal{A}}$ equal to 4.

Figure 3 shows the results based on the AUC. The values have been standardised with respect to the different $n/p_{\mathcal{A}}$ values for the same reasons as above. In this context, however, the best results are obtained for the $n/p_{\mathcal{A}}$ values that have a value of 1, since they correspond to the combination that obtained the highest AUC value (and therefore the best identification of the correct subset of non-zero coefficients).

Again, it can be observed that for larger values of $n/p_{\mathcal{A}}$, the use of large ν gives better results: as $n/p_{\mathcal{A}}$ increases, it is more convenient to use smaller ν. Although the logic is the same as that observed in Figure 2, in the case of the AUC it is observed that the reversal of the trend occurs much earlier (already

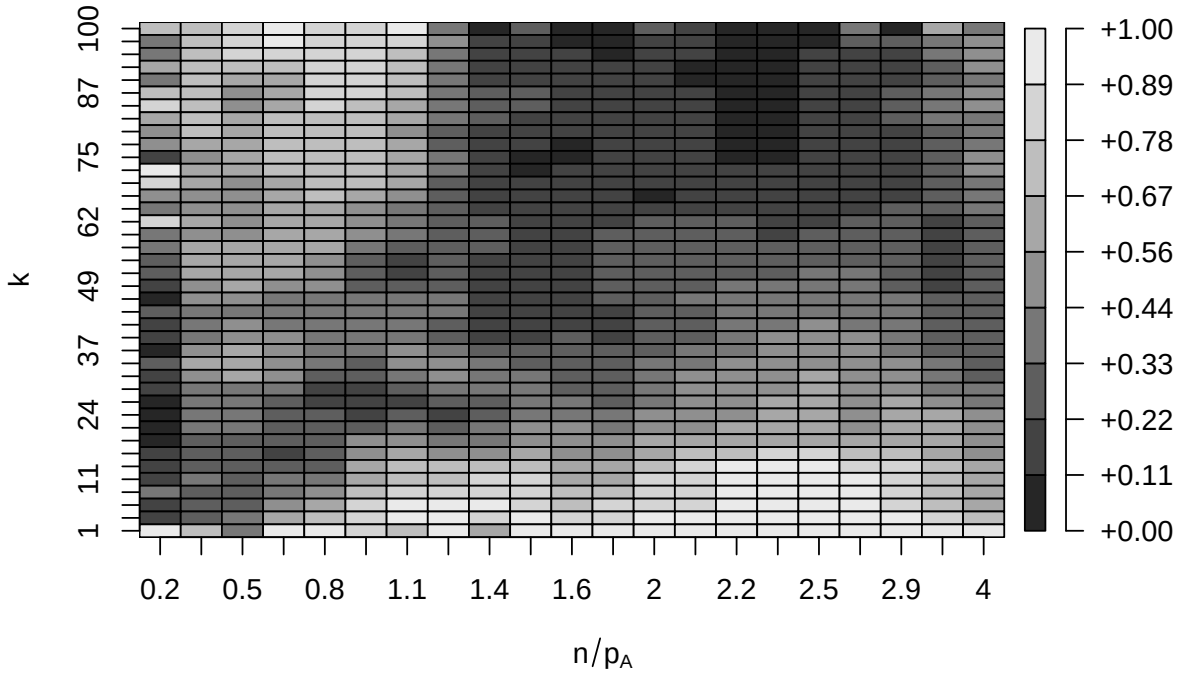

Figure 3: Scaled AUC (by $n/p_{\mathcal{A}}$), varying k and $n/p_{\mathcal{A}}$. Lighter squares correspond to higher AUC (better).

for $n/p_{\mathcal{A}}$ equal to 1.1, the use of the smaller ν is better).

4. Conclusion

In this paper we have provided an in-depth analysis of the methodology presented in [3], which utilizes an adaptive non-convex penalty function for variable selection in high-dimensionality regression modelling. Through a simulation study, we have evaluated the effect of the parameter ν on the estimates as the ratio of the number of observations to the number of variables $n/p_{\mathcal{A}}$ changes. Our findings contribute to the understanding of the behaviour of this method in different scenarios and can aid practitioners in selecting appropriate values for the parameter ν in their own applications, highlighting in this case how it is better, both in terms of estimation error and in terms of identifying the non-zero coefficients, to use a high ν if $n/p_{\mathcal{A}}$ is very small; conversely, if $n/p_{\mathcal{A}}$ is large, it is better to use a very small value of ν.

Abstract

In this paper we introduce a linear expectile hidden Markov model with the goal of modeling the entire conditional distribution of asset returns and, at the same time, to grasp unobserved serial heterogeneity and rapid volatility jumps typical of financial time series. The temporal evolution of asset returns is captured by introducing time-dependent coefficients evolving according to a latent discrete homogeneous Markov chain. To implement the procedure, we consider the Asymmetric Normal distribution as a working likelihood for the estimation of model parameters and the estimation procedure is carried out using an efficient EM algorithm. The empirical application investigates the relationship between daily Bitcoin returns and major world market indices.

Keywords: Bitcoin, financial time series, hidden Markov models, tail risk

1. Introduction

The recent exploit of the cryptocurrency market have attracted investors and risk managers as never before. The enormous price jumps and levels of high volatility of these digital assets, and Bitcoin in particular, caused by speculative behaviors have threatened the stability of financial markets (19), and research and practitioners have recently started to investigate the peculiar characteristics of cryptocurrencies, as well as their relationship with tradition financial markets. Many contributions to this strand of literature rely on well-known econometric techniques such as GARCH models (9), variance decomposition (6; 21) and Granger causality test (4). Rather than investigating measures of conditional central tendencies, fewer works have focused on the tails of returns distribution. For instance, (15) focused on the tail connectedness among major cryptocurrencies in extreme downward and upward market conditions using LASSO penalized quantile regressions, while (22) apply a risk spillover approach based on generalized quantiles, showing the existence of a downside risk spillover between Bitcoin and traditional assets. From a risk management perspective, it is of extreme importance to be able to investigate the dynamics of extreme occurrences. Since the seminal work of (10), quantile regression has represented one of the most used approaches for modeling the entire distribution of returns while accounting for the well-known stylized facts, i.e., high kurtosis, skewness and serial correlation, that typically characterize financial assets. Since then, several generalizations of the concept of quantiles have been presented, among which we find expectile regression (14), which, similar to quantile regression, allows to describe the entire conditional distribution of a response variable based on an asymmetric squared loss function. Despite having a more difficult interpretation, expectiles possess several advantages, both from an informative and a computational point of view. In particular, the asymmetric squared loss is continuously

differentiable, which makes the estimators and their covariance matrix easier to compute using fast and efficient algorithms. In the context of risk management, expectiles have gained an important role as potential competitors to the Value at Risk (VaR) and the Expected Shortfall measures, and indeed possess several interesting properties in terms of risk measures, being the only risk measure that is both coherent and elicitable (11; 23). However, homogeneous regression models are not able to capture the volatility clustering behavior that often financial time series exhibit. In this context, hidden Markov models (HMMs) have been intensively employed to characterize temporal evolution of returns distribution, modeling volatility regime shifting trough a latent Markov chain. Since (8), different works have combined the quantile framework with HMMs by introducing in the model parameters that vary according to the outcome of a latent Markov process (20; 12; 13). To the best of our knowledge, however, an expectile hidden Markov regression model has not been explored yet. In this paper we introduce an expectile regression model to analyze the entire conditional distribution of Bitcoin returns where the dynamics of returns over time is described by state-specific regression coefficients which follow a latent discrete homogeneous Markov chain. The proposed model contributes to the existing literature regarding the relations between cryptocurrencies and traditional asset class to control for potential inherent risks related to the participation in crypto exchanges. As usual for latent variable models, inference is carried out in a Maximum Likelihood (ML) approach using an Expectation-Maximization (EM) algorithm based on the asymmetric normal distribution of (17) as working likelihood. In the empirical analysis, we model daily Bitcoin log-returns as a function of major stock and global market indices, including Crude Oil, Standard & Poor's 500 (S&P500), Gold COMEX daily closing prices and the Volatility Index (VIX) from September 2014 until October 2022.

The rest of the paper is organized as follows. In Sect. 2. we specify the proposed model with the EM algorithm for estimating the model parameters and the computational aspects. Sect. 3. discusses the results obtained and concludes.

2. Model Specification and Inference

In this section we describe the proposed expectile hidden Markov regression model. Formally, let $\{S_t\}_{t=1}^T$ be a latent, homogeneous, first-order Markov chain defined on the discrete state space $\{1,\dots,K\}$. Let $\pi_k = Pr(S_1 = k)$ be the initial probability of state k, $k = 1,\dots,K$, and $\pi_{k|j} = Pr(S_{t+1} = k|S_t = j)$, with $\sum_{k=1}^K \pi_{k|j} = 1$ and $\pi_{k|j} \geq 0$, denote the transition probability between states j and k, that is, the probability to visit state k at time $t+1$ from state j at time t, $j,k = 1,\dots,K$ and $t = 1,\dots,T$. More concisely, we collect the initial and transition probabilities in the K-dimensional vector $\boldsymbol{\pi}$ and in the $K \times K$ matrix $\boldsymbol{\Pi}$, respectively. To build the proposed model, let Y_t denote a continuous observable response variable and $\boldsymbol{X}_t = (1, X_{t2},\dots,X_{tP})'$ be a vector of P exogenous covariates, with the first element being the intercept, at time $t = 1,\dots,T$.

For a given expectile level $\tau \in (0,1)$, the proposed linear expectile hidden Markov model is defined as follows:

$$Y_t = \boldsymbol{X}_t'\boldsymbol{\beta}_k(\tau) + \epsilon_{tk}(\tau), \tag{1}$$

where $\mu_{tk} = \boldsymbol{X}_t'\boldsymbol{\beta}_k(\tau)$ defines the linear expectile model, $\boldsymbol{\beta}_k(\tau) = (\beta_{1k}(\tau),\dots,\beta_{Pk}(\tau))' \in \mathbb{R}^P$ is the state-specific coefficient vector that assumes one of the values $\{\boldsymbol{\beta}_1(\tau),\dots,\boldsymbol{\beta}_K(\tau)\}$ depending on the outcome of the unobservable Markov chain S_t and $\epsilon_{tk}(\tau)$ is the error term whose conditional τ-th expectile is assumed to be zero. When $\tau = \frac{1}{2}$, expectile regression reduces to the standard mean regression while, when $\tau \neq \frac{1}{2}$, the regression targets the entire conditional distribution of the response given the covariates. The estimation of the model parameters is carried on through a Maximum Likelihood approach. We employ the Asymmetric Normal (AN) distribution, originally introduced by (16), to describe the conditional distribution of the response given covariates and the state occupied by the latent process at time t, whose probability density function is given by

$$f_Y(y_t|\boldsymbol{X}_t = \boldsymbol{x}_t, S_t = k) = \frac{2\sqrt{\tau(1-\tau)}}{\sqrt{\pi\sigma_k^2}(\sqrt{\tau}+\sqrt{1-\tau})} \exp\left[-\omega_\tau\left(\frac{y_t - \mu_{tk}}{\sigma_k}\right)\right], \tag{2}$$

where $\omega_\tau(\cdot)$ is the expectile loss function defined as $\omega_\tau(u) = u^2|\tau - \mathbb{I}(u < 0)|$, which assigns weights τ and $1-\tau$ to positive and negative deviations, respectively, and $\mathbb{I}(\cdot)$ denotes the indicator function. The location parameter μ_{tk} is defined by the linear model $\mu_{tk} = \boldsymbol{x}_t'\boldsymbol{\beta}_k(\tau)$ and corresponds to the τ-th expectile, $\sigma_k > 0$ is a scale parameter and $\tau \in (0,1)$ determines the asymmetry of the distribution. Particularly, when $\tau = \frac{1}{2}$ the density in eq. (2) reduces to the well-known normal distribution, and μ_{tk} and σ_k coincide with its mean and standard deviation, respectively. The use of this distribution is deemed to be as a likelihood inferential tool for estimating the model parameters in a regression framework rather a parametric assumption. As common for latent variable models, and HMMs in particular, inference on model parameters is made through the development of an EM algorithm (1). To ease the notation, unless specified otherwise, hereinafter we omit the expectile level τ, yet all model parameters are allowed to depend on it. The complete log-likelihood of the proposed model is defined as follows for a given number of hidden states K:

$$\begin{aligned}\ell_c(\boldsymbol{\theta}_\tau) = \sum_{k=1}^{K}\gamma_1(k)\log\pi_k + \sum_{t=1}^{T}\sum_{k=1}^{K}\sum_{j=1}^{K}\xi_t(j,k)\log\pi_{k|j} \\ + \sum_{t=1}^{T}\sum_{k=1}^{K}\gamma_t(k)\log f_Y(y_t|\boldsymbol{x}_t, S_t = k),\end{aligned} \tag{3}$$

where $\boldsymbol{\theta}_\tau = (\boldsymbol{\beta}_1, \ldots, \boldsymbol{\beta}_K, \sigma_1, \ldots, \sigma_K, \boldsymbol{\pi}, \boldsymbol{\Pi})$ represents the vector of all model parameters, $\gamma_t(k)$ denotes a dummy variable equal to 1 if the latent process is in state k at occasion t and 0 otherwise, and $\xi_t(j,k)$ is a dummy variable equal to 1 if the process is in state j in $t-1$ and in state k at time t and 0 otherwise.

To estimate $\boldsymbol{\theta}_\tau$, the algorithm iterates between the E- and M-steps until convergence, as briefly showed in what follows. In the E-step, at the generic $(h+1)$-th iteration, the unobservable indicator variables $\gamma_t(k)$ and $\xi_t(j,k)$ in eq. (3) are replaced by their conditional expectations given the observed data and the current parameter estimates $\boldsymbol{\theta}_\tau^{(h)}$. To compute such quantities one can use the Forward-Backward algorithm of (18). Then, we use these to calculate the conditional expectation of the complete log-likelihood function in eq. (3) given the observed data and the current estimates. In particular, in the M-step update of the regression coefficients is obtained by using Iteratively Reweighted Least Squares for cross-sectional data with appropriate weights.

The EM algorithm is initialized by assigning the initial states partition, $\{S_t^{(0)}\}_{t=1}^T$, to a Multinomial distribution with probabilities $1/K$. From the generated partition, the elements of $\boldsymbol{\Pi}^{(0)}$ are computed as proportions of transition, while we obtain $\boldsymbol{\beta}_k^{(0)}$ and $\sigma_k^{(0)}$ by fitting mean regressions on the observations within state k. A multiple random starts strategy is adapted to deal with the possibility of multiple roots. Once we computed the ML estimate of the model parameters, to estimate the standard errors we employ a parametric bootstrap scheme, refitting the model to R bootstrap samples and approximating the standard error of each model parameter with the corresponding standard deviation of the bootstrap estimates.

3. Main Results and Conclusions

The empirical analysis is based on the log-returns of Bitcoin, Crude Oil, S&P500, Gold COMEX daily closing prices and the VIX from September 2014 to October 2022. We consider the following model with the idea of providing insights into the temporal evolution of Bitcoin returns and its relationship with traditional global financial assets

$$\mu_{tk}^{Bitcoin} = \beta_{1k}(\tau) + \beta_{2k}(\tau)r_t^{Crude\ Oil} + \beta_{3k}(\tau)r_t^{S\&P500} + \beta_{4k}(\tau)r_t^{Gold} + \beta_{5k}(\tau)r_t^{VIX}, \tag{4}$$

with $\mu_{tk}^{Bitcoin}$ corresponding to the τ-th conditional expectile of Bitcoin return at time t in state k, while $r_t^{Crude\ Oil}$ denotes the return of the same date for Crude Oil, and similarly for the other indices. We fit the proposed model for two values of K, representing high and low volatility market conditions, at three expectile levels $\tau = \{0.10, 0.50, 0.90\}$, which allow us to focus on both downside and upside

risks. For the selected models, we report the clustering results in Figure 1 at $\tau = 0.50$ expectile level. The plot shows the time series of Bitcoin daily returns colored according to the estimated posterior probability of class membership, $\max_k \gamma_t(k)$, with the vertical dashed lines representing globally relevant events such as the Chinese stock market crash in 2015, the cryptocurrencies crash at the beginning of 2018, the COVID-19 market crash in March 2020, Biden's election at the USA presidency in November 2020 and the Russian invasion of Ukraine at the beginning of 2022. Here we clearly see that the latent components can be associated to specific market regimes characterized by low and high volatility periods. Specifically, light-blue points (State 1) tend to identify low returns, while dark-blue ones (State 2) correspond to periods of extreme positive and negative returns. Table 1 shows the parameter estimates along with the standard errors (in brackets) computed by using the parametric bootstrap technique over $R = 1000$ resamples, as illustrated in Sec. 2. As it happens in the quantile regression framework, the state-specific intercepts are increasing somewhat with τ, with State 1 having lower values than State 2 for all τ's. Moving forward with the analysis, at $\tau = 0.50$ we observe none or few interactions among Bitcoin and financial assets, during low and high volatility states, respectively. In particular, S&P500 and Gold significantly influence the mean of Bitcoin only in the second state, highlighting a weak hedge behavior of the crypto-asset during tranquil periods and confirming results founded in (2; 5). If we move to the tails of return distributions, in the not-at-risk state (State 1) at the extreme left-tail ($\tau = 0.10$) the S&P500, Gold and the VIX index positively influence Bitcoin returns, while only S&P500 and Gold significantly influence the right-tail ($\tau = 0.90$) expectiles of the cryptocurrency, exposing a connection during high volatility periods between traditional financial markets and Bitcoin both for negative and positive returns. In the at-risk state (State 2) we observe a positive influence of the S&P500 and Gold across the conditional distribution of returns. Also, one can see that Crude Oil is negatively associated with the crypto returns at the 10-th expectile. This finding is in line with (3) but it is contrary to the works of (7) and (6), which may be due to the events and crises occurred in the last years.

In conclusion, we developed a linear expectile hidden Markov model for the analysis of time series where temporal behaviors of the data are captured via time-dependent coefficients following an unobservable discrete homogeneous Markov chain. The proposed method enables us to model the entire conditional distribution of asset returns and, at the same time, to grasp unobserved serial heterogeneity and rapid volatility jumps that would otherwise go undetected. With this model we strengthen the existing literature in this field, contributing towards a deeper understanding of the interrelations between Bitcoin and traditional financial markets.

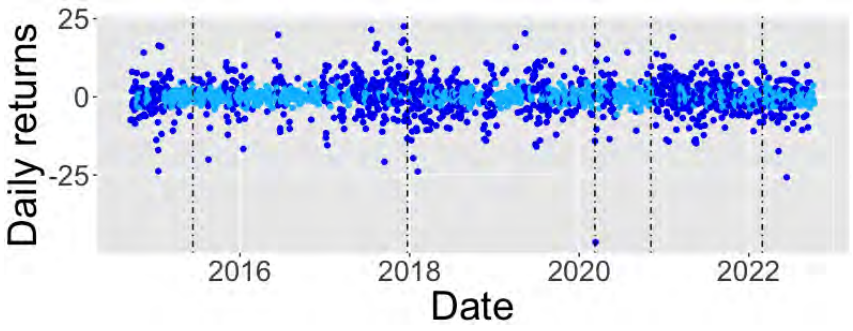

Figure 1: Bitcoin returns series classified according to the estimated posterior probability of class membership at $\tau = 0.50$. Vertical dashed lines indicate globally relevant events in the financial markets that occurred in 2015,06; 2017,12; 2020,03; 2020,11; and 2022,02.

4 Program

SIS 2023 - Statistical Learning, Sustainability and Impact Evaluation

(Italy)
June 21, 2023 - June 23, 2023

Conference programme

20-06-2023

18:30

Welcome Address

Room: A
Floor: ground

19:00

Round table "STATISTICA E COMUNICAZIONE"

Speakers: **Gian Carlo Blangiardo**, già Presidente ISTAT - **Gian Luca Gregori**, Rettore Università Politecnica delle Marche - **Lella Mazzoli**, Direttore scuola comunicazione Urbino
Chair: **Guido Maurino**, TGR Marche
Room: A
Floor: ground

20:30

Welcome Cocktail

21-06-2023

08:30 - 09:00

Registration

09:00 - 10:00

Plenary session

Speaker: **Maria-Pia Victoria-Feser**, Research Center for Statistics Geneva School of Economics and Management - University of Geneva
Chair: Angela Montanari (Dipartimento di Scienze Statistiche Università di Bologna)
Discussant: Silvia Cagnone (Dipartimento di Scienze Statistiche Università di Bologna)
Room: A
Floor: ground

Papers

Inequality Indices: Accurate Simulation-Based Inference
Author(s) Maria-Pia Victoria-Feser

10:05 - 11:15

"SIS-DIAS" group meeting

Organizer: Filomena Maggino
Room: A1
Floor: ground

Contributed Session

Bayesian nonparametric methods

Chair: Federico Castelletti (Università Cattolica del Sacro Cuore)
Discussant: Raffaele Argiento (Università degli studi di Bergamo)
Room: T32
Floor: ground

Invited Session

Machine learning in the design, analysis and integration of sample surveys

Organizer: Daniela Marella (Sapienza Università di Roma)
Chair: Chiara Bocci (Università degli Studi Firenze)
Discussant: Fulvia Mecatti (Università degli Studi Milano Bicocca)
Room: T31
Floor: ground
Short summary: Machine learning methods are beginning to be used in various aspects of sample surveys such as weighting, nonresponse and data integration. In this session three main aspects are examined. First of all, the use of Bayesian Networks to deal with the statistical matching problem in a multivariate context is discussed. Next, machine learning techniques incorporating the sampling weights in the imputation process are considered. Finally, a modified version of the PC algorithm for structural learning is proposed to take into account complex sample designs.

Invited Session

Machine learning: different uses and perspectives

Organizer: Matteo Mazziotta (ISTAT)
Chairs: Salvatore Strozza (Università di Napoli Federico II)
Discussant: Annamaria Bianchi (Università di Bergamo)
Room: T32
Floor: ground
Short summary: The use of machine learning techniques is increasing and it can play a crucial role in Official Statistics improving the quality of the outputs or increasing the efficiency of the production processes. In the last few years, several projects were launched for testing its use and applicability in different contexts. The aim of the session is to show the various applications in order to understand their usefulness in a critical perspective in which pros and cons are at the center of scientific debate

Invited Session

Statistical Machine Learning for environmental applications

Organizer/Chair: Michela Cameletti (Università di Bergamo)
Discussant: Francesco Finazzi (Università di Bergamo)
Room: T30
Floor: ground
Short summary: This session is about the use of machine learning and deep learning methods as an alternative to (or integrated with) standard approaches for environmental data, such as for example kriging and spatial point pattern models. These new approaches are appreciated thanks to their flexibility and can be useful for modeling complex spatial or spatio-temporal data. However, some concerns remain with respect to interpretability and uncertainty quantification.

Invited Session

Statistical Process Monitoring for Complex Data in Industry 4.0

Organizer/Chair: Christian Capezza (Università di Napoli Federico II)
Discussant: Alessandro Fassò, (Università degli studi di Bergamo)
Room: T36
Floor: ground
Short summary: The session addresses the challenges of monitoring and improving industrial processes in the context of Industry 4.0, where data are increasingly complex and high-dimensional. Talks cover advanced statistical techniques for anomaly detection, which are crucial for maintaining quality control and optimizing production processes. Attendees will gain insights into practical applications of statistical process monitoring and learn how to deal with complex data in Industry 4.0.

Population Dynamics, Climate Change and Sustainability

Organizer/Chair: Raya Muttarak (Università di Bologna)
Discussant: Raya Muttarak (Università di Bologna)
Room: T31

Floor: ground

Short summary: Understanding the relevance of population dynamics on sustainability is fundamental because human activities are, by now, undoubtedly responsible for anthropogenic climate change. The already visible impact of climate change, meanwhile, can influence demographic behaviour and population dynamics. This session explores the reciprocal relationship between climate change, population dynamics and sustainability by presenting novel empirical findings based on various untapped data sources. The first and second papers focus on the impact of climate change on demographic outcomes, that is fertility and mortality. Based on harmonisation of Demographic and Health Surveys for >60 low- and middle-income countries, the first paper investigates whether and to what extent exposure to extreme climate events affect monthly and quarterly fertility rates measured at a refined spatial scale. Considering exposure to both climatic events and air pollution, the second paper explores to what extent these environmental hazards interact and increase mortality risks of children age under five in India. The third paper considers the outcome related to well-being. Using Twitter data, this paper investigates how experiencing extreme climate events influence underlying positive or negative sentiments with a focus on demographic heterogeneity. Social media data allow real-time measurement of climate-related sentiments which are not possible in a survey setting. All three studies will contribute new insights into the fields of population influence on sustainability and climate impact on population dynamics.

Papers

Climate change impacts on fertility in low- and middle-income countries
Author(s) Côme Cheritel

Environmental and socio-demographic determinants of under-5 mortality in India: A survival analysis based on Indian DHS data

Advances in statistical methods for complex problems

Organizers: Luigi Augugliaro (Università degli Studi di Palermo), Guido Consonni (Università Cattolica del Sacro Cuore)
Chair: Guido Consonni (Università Cattolica del Sacro Cuore)
Discussant: Luca La Rocca (Università degli studi di Modena e Reggio Emilia)
Room: T36
Floor: ground
Short summary: Inferring treatment effects on responses in complex systems is a major challenge. This can be tackled by structuring variables into a network and using techniques of causal inference and path analysis; also the role of confounders can be assessed using feature selection in large regression models. The session addresses computational issues and includes applications to salary gap discrimination and cyber-security risk.

Inequalities in higher education outcomes: learning from data

Organizers: Isabella Sulis (Università di Cagliari), Maria Gabriella Campolo (Università di Messina)
Chair: Isabella Sulis (Università di Cagliari)
Discussant: Maria Gabriella Campolo (Università di Messina)
Room: T30
Floor: ground
Short summary: The contributions explore, using innovative or advanced methodological approaches (propensity score analysis based on generalized boosted models, weighted networks, and static models of strategic interactions), the effect of territorial, socioeconomic conditions and peers in determining inequalities in higher education outcomes, focusing on gender differences and preferences for stem and non-stem disciplines. Different aspects related to educational outcome indicators are investigated: the transition from high school to university, students mobility choices in university selection, participation in international mobility programs.

Challenges towards Fairness and Transparency for Data Processes, Algorithms and Decision-Support Models

Organizer/Chair: Claudia Tarantola (Università di Pavia)
Discussant: Gloria Polinesi (Università Politecnica delle Marche)
Room: T30
Floor: ground
Short summary: In this session, we will explore various aspects of the ethics of data science. Nowadays, many decisions are made by taking predictive models based on observed data as suggestions. Despite being created through a fair and well-intentioned learning process, these models can still unintentionally discriminate against certain groups of people, leading to unfair outcomes. Algorithmic bias is a pressing problem in this regard, as machine learning models can perpetuate existing discrimination by taking into account factors such as race, gender, or age. In addition, the use of sensitive data to train and validate these models raises issues of privacy and data security.

Short summary:
"Demographic change and sustainability: novel approaches from digital and computational demography"

Sustainability is a multidimensional concept that encompasses the natural, economic and social environments. This talk highlights recent advances in digital and computational demography with respect to (i) leveraging digital trace data to measure the impact of natural disasters on demographic outcomes; (ii) repurposing large-scale bibliometric data to assess the sustainability of the global system of mobility of scientists; (iii) exploiting simulation approaches to assess the impact of demographic change on the sustainability of care needs and family structures.

Bayesian contributions to Statistical Learning

Organizer/Chair: Federico Camerlenghi (Università di Milano-Bicocca)
Discussant: Alessandra Guglielmi (Politecnico di Milano)
Room: T32
Floor: ground
Short summary: Bayesian statistical methods include a large variety of effective tools to face prediction, statistical learning and estimation via a principled approach. The session is focused on some recent hierarchical Bayesian models, which are designed for different applied problems arising, e.g., in precision medicine and cancer detection. Both Bayesian parametric and nonparametric methods will be discussed.

Invited Session

Data Visualization for Smart Insights and Advanced Predictive Analytics

Organizer/Chair: Roberta Varriale (Sapienza Università di Roma)
Discussant: Ilaria Prosdocimi (Università Ca' Foscari Venezia)
Room: T30
Floor: ground
Short summary: Data visualization can be defined as the representation of data through the use of common graphs, such as charts, graphs, infographics, etc. These information visualizations communicate complex data relationships and data-driven insights in a way that is easy to understand. The science of data visualiza-tion comes from understanding how humans collect and process information: we process visual infor-mation much faster than text. In addition, the human brain decodes information through patterns and models. Effective data visualization is the final step in data analysis: without it, important information and messages can be lost and incorrect data visualization leads the audience to misunderstand the actual data and make wrong decisions. The session will examine three examples of data visualization from different fields of research: of-ficial statistics, private companies, and universities. The session will be an opportunity to exchange ideas and perspectives on a topic that is becoming fundamental to the communication of statistical infor-mation in a world of big and fast data.

Migrants and Refugees in Europe: social, economic and health-related issues

Organizers: Manuela Stranges (Università della Calabria) - Livia Elisa Ortensi (Università di Bologna)
Chair: Anna Paterno (Università di Bari)
Discussant: Livia Elisa Ortensi (Università di Bologna)
Room: T7
Floor: ground
Short summary: This session is devoted to exploring social, economic, and health-related issues of migrants and refugees in different European contexts. The paper from Haodong et al. looks at the combination of human capital accumulation and investment at destination on future economic performance of refugees in Sweden. The authors find that, overall, refugees income increases with total hours devoted to human capital investments (except for men who attained secondary education) suggesting a positive labor market return. However, the magnitude of the return varies depending on refugee s initial level of education, it is the greatest for those who attained university education. This educational difference suggests that human capital investments help refugees restore the value of their original educational credentials. The income effects of human capital investment vary depending on the type of training. Refugee women tend to benefit more from learning language, compared to training in introduction programme (EPA). In contrast, refugee men tend to benefit from EPA (except those who attained secondary education), but not from Swedish language training (SFI). The paper from Piccitto concentrates on the role of legal environment on the asylum applications, focusing on Italy. In 2020, the Italian government approved the so-called Immigration and security decree. Among its intentions, regarding a wide range of matters (contrast to mafia and terrorism, urban security), the decree remarkably changed the regulation of asylum, immigration and citizenship. The decree has abolished the Humanitarian protection, which has traditionally been used as the main source of legal protection for migrants (the other two being the refugee status and the subsidiary protection in Italy). The paper focuses on the impact of the introduction of this restrictive law on immigration on the number of asylum application in the country, by leveraging Eurostat data and performing a range of statistical analyses. The paper from Amati et al. focuses on loneliness among older migrants in Italy, analyzing the impact of different types of support networks, namely the instrumental/support and emotional networks, while controlling for standard socio-economic variables. The authors identified seven different network typologies have been identified, ranging from the complete ego network, where all the alters are present, to the almost empty network comprising only children and friends. The results of their study indicate that there is a significant association between loneliness and network typologies. However, loneliness might also affect the embeddedness in a network since it might lead to isolation from others.

Modelling and Forecasting High-dimensional time series

Organizer/Chair: Edoardo Otranto (Università di Messina)
Discussant: Giovanni De Luca (Università Parthenope di Napoli)
Room: T36
Floor: ground
Short summary: High dimensional time series, both univariate and multivariate, are pandemic in several scientific fields; the interest in their modelling is often associated to the possibility of obtaining reliable forecasts and monitoring many social phenomena. The three contributions of this invited session are examples of managing these data in the fields of economics, finance and climatology.
